Classic symptoms of FTC include vaginal bleeding or discharge or lower abdominal pain. In many cases, these symptoms are vague and nonspecific. Vaginal bleeding is the most commonly reported symptom of FTC and is present in approximately 50% of the patients. Vaginal bleeding is caused by blood that accumulates from the lesion in the fallopian tube, which subsequently passes into the uterine cavity and finally exits into the vagina. Because FTC occurs most frequently after menopause, postmenopausal bleeding is common. Although carcinoma of the endometrium is the first consideration, FTC should be considered if the results of dilation and curettage are negative and symptoms persist.

Pain, often colicky, is frequently a symptom in tubal carcinoma and often accompanies vaginal bleeding. The pain is caused by distension of the tubal wall and stimulation of peristaltic activity. This pain, in many cases, is relieved with the passage of blood or watery discharge. Vaginal discharge, which is usually clear, occurs in approximately 25% of patients with tubal carcinoma. The triad of pain, metrorrhagia, and leukorrhea is considered pathognomonic for tubal carcinoma, but it occurs infrequently. Pain combined with a profuse, watery vaginal discharge, referred to as hydrops tubae profluens, is reported to be present in fewer than 5% of cases. If a patient is examined during the time that hydrops tubae profluens is present, a palpable pelvic mass may be found. The mass can decrease during the examination while the watery discharge continues. With the cessation of watery discharge and decrease in pelvic mass, the pain also decreases. Hydrops tubae profluens is caused by the effusion produced by the tumor that accumulates within the tube and causes the distension, which in turn produces the colicky pain.

Delay of diagnosis appears to be common due to nonspecific findings and overlap with ovarian cancer features. In a study by Eddy and associates, symptoms had been present for as long as 48 months. Half of the patients had symptoms for 2 months or longer. Semrad and colleagues noted a delay from the onset of symptoms to the diagnosis of an average of 4 months in about half of their patients. Peters and colleagues reported that 14% of patients were asymptomatic in their series of 115 patients.

Malignant cells are found in 11% to 23% of cervical cytologic preparations in patients with tubal cancer. In patients with hydrops tubae profluens, the chance of obtaining malignant cells should be relatively high. The identification of psammoma bodies in cervical cytology of postmenopausal women is often a sign of uterine or clear cell carcinoma, with serous fallopian tube or ovarian cancer occasionally being identified as the source.

EMERGING PARADIGMS

As noted previously, until relatively recently, the prevailing view of extrauterine HGSC was that FTC was relatively rare and the majority of these cancers formed in the ovary, perhaps in cortical inclusion cysts. The major challenge to this theory was the lack of an identifiable precursor lesion despite decades of interrogation of the ovarian surface epithelium.

Fallopian Tube Cancer and *BRCA* Mutations

In the late 1990s, a number of reports emerged of FTCs associated with germline mutations in *BRCA*. Piek and colleagues, responding to these reports of FTC associated with *BRCA1* and *BRCA2* mutations and their own molecular evidence that FTC was part of the cancer spectrum in *BRCA* mutation carriers, began screening serial sections of fallopian tubes removed during risk-reducing surgeries of women determined to be at high genetic risk of ovarian cancer. In 2001, they published their findings of the presence of dysplasia in the fallopian tubes of six of 12 cases and hyperplastic changes in an additional five with no corresponding abnormalities in 13 control cases. The provocative findings provided evidence for hyperplastic or dysplastic changes occurring in the carcinogenesis sequence of FTC and recommendations that risk-reducing surgery include both the ovaries and fallopian tubes and furthermore that both should be examined in all such cases to "attain more insight into *BRCA1*-related oncogenesis."

Occult or Intraepithelial Fallopian Tube Cancer Found During Risk-Reducing Surgery

Accumulating evidence and Piek et al.'s initial report prompted increased pathologic scrutiny of the fallopian tubes at the time of risk-reducing surgeries. Investigators at Brigham and Women's Hospital and Dana Farber Cancer Institute developed the Sectioning and Extensively Examining the FIMbria (SEE-FIM) protocol in which the fallopian tubes are sectioned at 2- to 3-mm intervals and examined histologically with lengthwise sectioning of the fimbriated portion to maximize exposure of tubal plicae. When reviewing their series of 122 *BRCA*-positive patients undergoing risk-reducing surgery, these investigators found seven (5.7%) patients with occult malignancy, all of which originated in the distal fallopian tube. Additionally, six of the cancers were accompanied by a noninvasive component.

A number of other reports during this same decade corroborated the experience, although reported rates of occult malignancy varied because of differences in study populations, pathology processing, and diagnosis. The majority of occult lesions identified were invasive and noninvasive cancers in the fallopian tubes. The best estimate to date of invasive or intraepithelial ovarian, tubal, or peritoneal neoplasms in the genetically

high-risk population is from the surgical intervention arm of Gynecologic Oncology Group (GOG) Protocol 0199 (GOG 0199), also known as the National Ovarian Cancer Prevention and Early Detection Study. This prospective trial found a 4.6% risk in *BRCA1* and 3.5% risk in *BRCA2* mutation carriers. The primary sites were assigned based on distribution and extent of tumor unless an intraepithelial lesion of the fallopian tube was identified, in which case it was designated as tubal cancer. Of the 25 (of 966) lesions identified, 10 were designated ovarian, 10 were designated tubal, and five were designated primary peritoneal. The authors acknowledge that the use of more sensitive sectioning protocols, combined with growing diagnostic acumen, may prove their estimates of tubal neoplasia low.

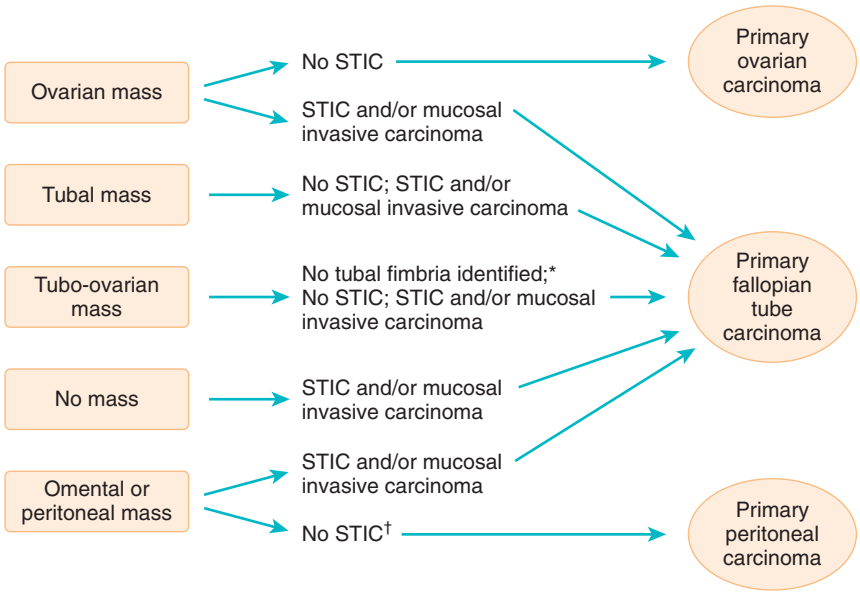
Serous Tubal Intraepithelial Carcinoma

The dysplastic tubal cells initially identified are now more commonly referred to as tubal intraepithelial carcinoma (TIC) or serous tubal intraepithelial carcinoma (STIC). TICs are distinguished from normal mucosa by variably stratified epithelium with nuclear enlargement and atypia, high nuclear-to-cytoplasmic ratio, prominent nucleoli, variable loss of cell polarity, and mitotic activity. Hyperchromasia, irregular nuclear membranes and chromatin distribution, and absence of cilia also characterize TICs.

Immunohistochemistry (IHC) may be useful adjuncts in diagnosis. An elevated Ki-67 labeling index (>10%) and either intense or absent p53 staining (both correlate closely with mutation) support the diagnosis of TIC. Somatic mutations of p53 are the most common mutations in HGSC and are detected in more than 90% of TICs. Whereas the majority are missense mutations that correlate with intense and diffuse p53 immunoreactivity, frameshift, nonsense, and splicing junction mutations are associated with complete loss of p53 staining.

Strongly p53-positive, benign-appearing epithelium, described by Lee and colleagues as "p53 signatures" may be an even earlier event in serous carcinogenesis than TICs. These investigators demonstrated that these signatures were equally common in nonneoplastic tubes from women with and without *BRCA* mutations but more frequently present and multifocal in fallopian tubes with STIC. These signatures were much more common in the secretory cells of the fimbriae similar to TICs and often represented reproducible p53 mutations. In laser-capture microdissected (LCM) specimens, they also demonstrated that TICs and their associated ovarian cancers shared identical mutations and in one case demonstrated an identical mutation between the p53 signature and a contiguous TIC.

Despite the characteristics of STICs noted, the recognition of these lesions remains challenging, and the spectrum of changes within the fallopian tube can be difficult to interpret. In an effort to establish a reproducible classification for STIC, Visvanathan led a group of six gynecologic pathologists from four academic institutions through serial independent reviews to establish a reproducible algorithm. Intraobserver reliability was only fair for STIC versus not STIC when classification was based on morphologic criteria alone. An algorithm incorporating morphology and IHC for p53 and Ki-67 resulted in substantial agreement and provided the basis for a standardized, and later validated, classification of STIC for clinical diagnosis and future investigations.



Fallopian Tube Cancer and Serous Tubal Intraepithelial Carcinoma Beyond *BRCA*

Building on the findings from high-risk populations, in 2007, Kindelberger and colleagues published the first study extensively examining the fallopian tubes (SEE-FIM protocol) in a consecutive series of pelvic serous carcinoma from patient not necessarily known to be at high risk. Of 55 evaluable cases, 75% had endosalpingeal involvement, and of these, 71% (29 of 41) had a coexisting STIC. Tumors classified as HGSOC by conventional criteria based on disease distribution often involved the endosalpinx and contained TICs (71% and 48%, respectively, of 42 cases). Five of five cases of ovarian cancer with concurrent TICs contained identical p53 mutations, supporting their clonality.

Przybycin and colleagues similarly examined a series of 52 pelvic (nonuterine) gynecologic cancers in which fallopian tube tissue was available for extensive examination. TIC was identified in 28 (60%) of 47 HGSCs, and because TIC was associated exclusively with this histology, they suggested the more specific term *serous TIC* or *STIC*. STICs in the absence of invasive carcinoma in the same tube was identified in seven (30%) of cases. By including STIC as supplemental criteria for extrauterine HGSC, the rate of FTC increased from 13% by conventional criteria to 64%. More extensive LCM examinations of STICs by this same group confirmed the clonal relationships of p53 mutations in STICS and concurrent HGSOCs. Additionally, they demonstrated telomere shortening, an early change in carcinogenesis, in STICs compared with their concurrent ovarian cancers, further supporting the primary role of the fallopian tube in high-grade serous carcinogenesis.

In 2014, Singh and colleagues proposed new guidelines for assigning the primary site of HGSC intended as an evolutionary change based on current understanding of the state of the science. Their intent was to build on the 2014 FIGO staging revision, which unified staging but did not unify nomenclature under an umbrella term (eg, *pelvic serous carcinoma*) or provide specific guidance for primary site assignment. Indeed, there were numerous examples in which, depending on philosophy, different pathologists might assign the same clinical case as tubal, ovarian, primary peritoneal, tubo-ovarian, or undesignated in the new system. To avoid giving different diagnostic labels to the same disease in different centers, Singh et al. made a number of recommendations, offering a standard and systematic approach based on current knowledge. Among the most important recommendations was that the fallopian tubes should be sampled by a SEE-FIM–like protocol in all cases of HGSC and that any cases with STIC should be classified as tubal carcinoma.

The following year, this same group published an assessment of their system for primary site assignment in HGSC of the fallopian tube, ovary, and peritoneum. They retrospectively assessed 151 HGSC (both chemonaive and postneoadjuvant chemotherapy) of which 68% of cases were previously considered ovarian primaries. Using the new guidelines, they rendered

*Failure to detect the tubal fimbria implies overgrowth by tumor.
†Apply criteria as specified in the **Required Data Elements** (section iv: Tumour site) of the ICCR.

FIGURE 13.1 Flow chart for assigning the site of origin of extrauterine high-grade serous carcinoma from the International Collaboration on Cancer Reporting (ICCR). *STIC,* Serous tubal intraepithelial carcinoma. (Adapted from McCluggage WG, Judge MJ, Clarke BA, et al. Data set for reporting of ovary, fallopian tube and primary peritoneal carcinoma: recommendations from the International Collaboration on Cancer Reporting (ICCR). *Mod Pathol* 2015;28:1105.)

a revised diagnosis of fallopian tube primary in 74% of cases. In a prospective cohort of 111 HGSC cases, a majority of which were advanced stage, they classified 79% as fallopian tube primaries and only 14% as ovarian primaries. There were fewer cases of primary FTCs diagnosed after neoadjuvant chemotherapy and more diagnosed as primary peritoneal or undetermined potentially resulting from regression of small lesions in the fallopian tube. In chemonaive cases, ovarian involvement was bilateral in 62% of cases, but fallopian tube involvement was bilateral in only 16%, lending further evidence that ovarian disease is metastatic instead of primary. The proposed system combined with the revised FIGO staging system provided uniform and reproducible site assignment while classifying most HGSC as fallopian tube primaries.

Building on the above work, in 2015, the International Collaboration on Cancer Report (ICCR) published recommendations on the classification of peritoneal, ovarian, and fallopian tube carcinomas (Fig. 13.1). In this algorithm, any case with STIC and associated cancer involving the ovary, fallopian tube, or peritoneum should be classified as fallopian tube primary with classification using conventional criteria only if they lack STIC. The recommendations also conveyed that failure to identify fallopian tube fimbriae implied overgrowth by a fallopian tube carcinoma, and therefore careful attention to identify a fallopian tube in cases of an adnexal mass is important for accurate classification. Aberrant staining of p53 and Mindbomb E3 Ubiquitin Protein Ligase 1 (MIB1) is often found in association with STIC and therefore may prove helpful in confirming the diagnostic presence of the preinvasive lesion in questionable cases.

CLINICAL IMPLICATIONS

Changes in classification of tumor origin will result in changes to the annual incidence of ovarian and FTCs. Because extrauterine HGSC are currently treated using the same platinum and taxane backbone, the immediate clinical implications reflective of this paradigm shift are limited in the setting of advanced disease. The management of STIC in the absence of other disease requires further study before evidence-based recommendations can be provided. Similar to precursors of serous uterine cancer, STIC, although intraepithelial, is capable of exfoliation and metastasis. The ICCR classifies such cases as stage IA tubal carcinoma with an annotation that there is no invasive carcinoma while also acknowledging that these lesions have a favorable prognosis based on limited data. Two series of isolated STIC with a total of 23 patients have recorded one recurrence to date. Although extremely limited, this initial signal calls into question whether isolated STIC warrants categorization as FIGO stage IA of the tube equivalent to other stage IA cancers. These data do provide hope that perhaps salpingectomy alone is sufficient for treatment, although further study is warranted before any utility of prophylactic cytotoxic therapy is ruled out.

The shifting paradigm of a fallopian tube origin for a substantial portion of HGSC has the potential to impact screening

for HGSC. Preliminary investigations report that early genetic mutations, potentially of tubal origin, can be detected in cervical cytology specimens. Similarly, with a tubal precursor lesion for HGSC now identified, biomarkers, perhaps from proximal biofluids, may reveal early tubal pathogenesis.

For women at high risk for HGSC because of hereditary predisposition, risk-reducing bilateral salpingo-oophorectomy has proven effective. Given the impact on quality of life due to surgically induced menopause in addition to the potential risks of cardiovascular disease, osteoporosis, and cognitive impairment, the option of salpingectomy alone has become clinically relevant. This has been advocated by some as an alternative in women who are not prepared or who are unwilling to undergo oophorectomy. Similarly, it may be clinically prudent to recommend early salpingectomy with delayed oophorectomy in *BRCA* patients. The TUBA (TUbectomy in BRCA1/2 mutation carriers) study by Harmsen and colleagues is a prospective nonrandomized study evaluating early salpingectomy with delayed oophorectomy versus risk-reducing salpingo-oophorectomy for *BRCA1* and *BRCA2* mutation carriers. If patients elect to proceed with early salpingectomy, the completion oophorectomy will be postponed for 5 years compared with standard treatment for their *BRCA* status. The primary outcome is menopause-related quality of life with secondary measures including ovarian and breast cancer incidence, surgery-related morbidity, histopathology, cardiovascular risk factors and diseases, and cost effectiveness. This multicenter study, when completed, hopes to offer additional guidance for delayed oophorectomy in this high-risk population.

An American College of Obstetricians and Gynecologist (ACOG) Committee Opinion addresses salpingectomy for cancer prevention in women at population risk of extrauterine HGSC undergoing routine pelvic surgery. Highlighted in the opinion is that salpingectomy at the time of hysterectomy or as sterilization does not appear to increase complication rates (over hysterectomy or tubal ligation alone) nor does it impact ovarian function based on surrogate serum markers or in vitro fertilization response. The ACOG recommends that the surgeon and patient discuss the potential benefits of the removal of the fallopian tubes at the time of hysterectomy or as an option for sterilization and that prophylactic salpingectomy may offer clinicians the opportunity to prevent ovarian cancer in their patients.

CONCLUSION

Although the epidemiology of FTC is unclear, except a few idiosyncratic presentations, signs and symptoms largely mirror

TABLE 13.1 2014 International Federation of Gynecology and Obstetrics (FIGO) Staging Classification for Cancer of the Ovary, Fallopian Tube, and Peritoneum

I	Tumor confined to ovaries or fallopian tube(s)	T1
IA	Tumor limited to one ovary (capsule intact) or fallopian tube No tumor on ovarian or fallopian tube surface No malignant cells in the ascites or peritoneal washings	T1a
IB	Tumor limited to both ovaries (capsules intact) or fallopian tubes No tumor on ovarian or fallopian tube surface No malignant cells in the ascites or peritoneal washings	T1b
IC	Tumor limited to one or both ovaries or fallopian tubes, with any of the following: IC1 Surgical spill intraoperatively IC2 Capsule ruptured before surgery or tumor on ovarian or fallopian tube surface IC3 Malignant cells present in the ascites or peritoneal washings	T1c
II	Tumor involves one or both ovaries or fallopian tubes with pelvic extension (below pelvic brim) or peritoneal cancer (Tp)	T2
IIA	Extension and/or implants on the uterus and/or fallopian tubes and/or ovaries	T2a
IIB	Extension to other pelvic intraoperative tissues	T2b
III	Tumor involves one or both ovaries or fallopian tubes or primary peritoneal cancer, with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes	T3
IIIA	Metastasis to the retroperitoneal lymph nodes with or without microscopic peritoneal involvement beyond the pelvis	T1, T2, T3aN1
IIIA1	Positive retroperitoneal lymph nodes only (cytologically or histologically proven)	
IIIA1(i)	Metastasis ≤10 mm in greatest dimension (note: this is tumor dimension and not lymph node dimension)	T3a/T3aN1
IIIA1(ii)	Metastasis > 10 mm in greatest dimension	
IIIA2	Microscopic extrapelvic (above the pelvic brim) peritoneal involvement with or without positive retroperitoneal lymph nodes	T3a/T3aN1
IIIB	Macroscopic peritoneal metastases beyond the pelvic brim ≤2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes	T3b/T3bN1
IIIC	Macroscopic peritoneal metastases beyond the pelvic brim >2 cm in greatest dimension, with or without metastases to the retroperitoneal nodes*	T3c/T3cN1
IV	Distant metastasis excluding peritoneal metastases Stage IV A: Pleural effusion with positive cytology Stage IV B: Metastases to extraabdominal organs (including inguinal lymph nodes and lymph nodes outside of abdominal cavity)†	Any T, any N, M1

*Includes extension of tumor to capsule of liver and spleen without parenchymal involvement of either organ.
†Parenchymal metastases are stage IV B.

other HGSC. Similarly, the staging and treatment of FTC are identical to those of high-grade serous ovarian and primary peritoneal cancers (Table 13.1). The transition from FTC's relative rarity to the increasing number of cases diagnosed in high-risk women and discovery of a precursor lesion that is present in a majority of HGSCs has evolved dramatically over the past 2 decades (Fig. 13.2). It is likely that many HGSCs thought to be of ovarian origin will now be categorized as fallopian tube primary. Ongoing research will reveal whether salpingectomy is an effective risk-reducing strategy, especially in those at highest risk.

Conclusions

KEY POINTS

1. Appropriate investigation of symptomatic patients with a breast mass consists of triple assessment and is crucial to rule out an underlying breast malignancy. Triple assessment involves physical examination, breast imaging with mammography and ultrasonography, and pathologic or cytologic evaluation. Nonconcordant results should prompt further investigation or careful follow-up.
2. All women should undergo regular breast screening at the appropriate age, and high-risk patients should be identified

for elevated screening pathways dependent on individual risk assessment.
3. Surgical planning needs to be individualized to the patient with regards to suitability for breast conservation versus mastectomy. Adjuvant radiation is an essential treatment component after breast conservation. Reconstructive options should be offered and discussed with all patients undergoing mastectomy.
4. Clinically node-negative patients with invasive cancer should have SLNB for axillary staging. Having two or less positive sentinel nodes in the setting of breast conservation does not require completion axillary dissection. Axillary dissection is required with more extensive nodal positivity or in the setting of any positive sentinel node in patients having mastectomy.
5. *BRCA* genetic counseling and testing should be offered to women who meet testing criteria. Surveillance programs should include regular breast examination and imaging with mammography and magnetic resonance imaging for those who test positive. Risk-reduction options such as chemoprevention and surgery such as bilateral mastectomies and bilateral salpingo-oophorectomies should be discussed.

INTRODUCTION

Breast cancer remains the most common cancer in women and is second only to lung cancer as the leading cause of cancer-related death in the United States. In 2015, an estimated 231,840 new cases of invasive breast cancer were expected to be diagnosed in women in the United States along with 60,290 new cases of noninvasive (in situ) breast cancer. The lifetime risk among women of developing breast cancer is 12.5% (1 in 8); the lifetime risk of dying from breast cancer is 3.6% (1 in 28). About 40,290 women in the United States are expected to die in 2015 from breast cancer, though death rates have been decreasing since 1989. This decline is thought to be secondary to the increased use of mammographic screening with early detection of breast cancer and the use of effective adjuvant therapies. This chapter presents an overview of breast cancer screening, diagnosis, and treatment of benign and malignant conditions of the breast.

ANATOMY OF THE BREAST

The adult breast lies between the second and sixth ribs in the vertical plane and between the sternal edge (medially) and midaxillary line (laterally). The average breast measures 10 to 12 cm in diameter and 5 to 7 cm in thickness. It is concentric, with a lateral projection into the axilla named the axillary tail of Spence (Figs. 14.1 and 14.2).

The breast consists of three major structures: skin, subcutaneous fatty tissue, and breast tissue (parenchyma and stroma). The skin contains hair follicles, sebaceous glands, and eccrine sweat glands. The glandular breast is divided into 15 to 20 segments (lobes) that are separated by connective tissue and converge at the nipple in a radial arrangement. These lobes are made up of 20 to 40 lobules, which in turn consist of 10 to 100 alveoli (tubulosaccular secretory units). Five to 10 major milk-collecting ducts drain each segment and open at the nipple into subareolar lactiferous sinuses.

A superficial pectoral fascia envelops the breast; the undersurface of the breast lies on the deep pectoral fascia. The superficial pectoral fascia is continuous with the superficial abdominal fascia of Camper. Between these two fascial layers are fibrous bands called Cooper suspensory ligaments that provide support for the breast. The space between the deep layers of the superficial fascia of the breast and the deep investing fascia of the pectoralis is the retromammary bursa.

The epidermis of the nipple (mammary papilla) and areola is pigmented and wrinkled and consists of keratinized, stratified squamous epithelium that contains smooth muscle fibers in dense connective tissue. These fibers are responsible for the erection of the nipple. Two receptor-type nerve endings (Ruffini-like bodies and end bulb of Krause) are present on the nipple and associated with the tactile reception of stretch and pressure.

The areola has no hair follicles; it has sebaceous glands (at its margin), apocrine sweat glands, and accessory areolar glands (Montgomery glands) that open on the surface of the areola as small elevations called Morgagni tubercles. Montgomery glands are large sebaceous glands capable of secreting milk; they represent an intermediate stage between the sweat and the mammary glands.

The blood supply of the breast is mostly from superficial vessels. The principal blood supply is derived from the internal thoracic (mammary) and lateral thoracic artery and their tributaries. The posterior intercostal arteries of the second to fourth intercostal spaces also give off tributaries called the mammary branches. Approximately 60% of the breast, mainly the medial and central parts, is supplied by the anterior perforating branches of the internal mammary artery. About 30% of the breast, mainly the upper outer quadrant, is supplied by the lateral thoracic artery.

The superficial veins follow the arteries and drain through perforating branches of the internal thoracic vein, tributaries of the axillary vein, and perforating branches of posterior intercostal veins. The veins anastomose circumferentially around the nipple, which is called the circulus venosus.

Subepithelial or a papillary plexus of lymphatics of the breast are confluent with the subepithelial lymphatics over the surface of the body. These valveless lymphatic vessels communicate with subdermal lymphatic vessels and merge with Sappey's subareolar plexus. The subareolar plexus receives lymphatic vessels from the nipple and the areola and communicates by way of the vertical lymphatic vessels that are equivalent to those connecting the subepithelial and subdermal plexus elsewhere in the body. Lymph flows unidirectionally from the superficial to

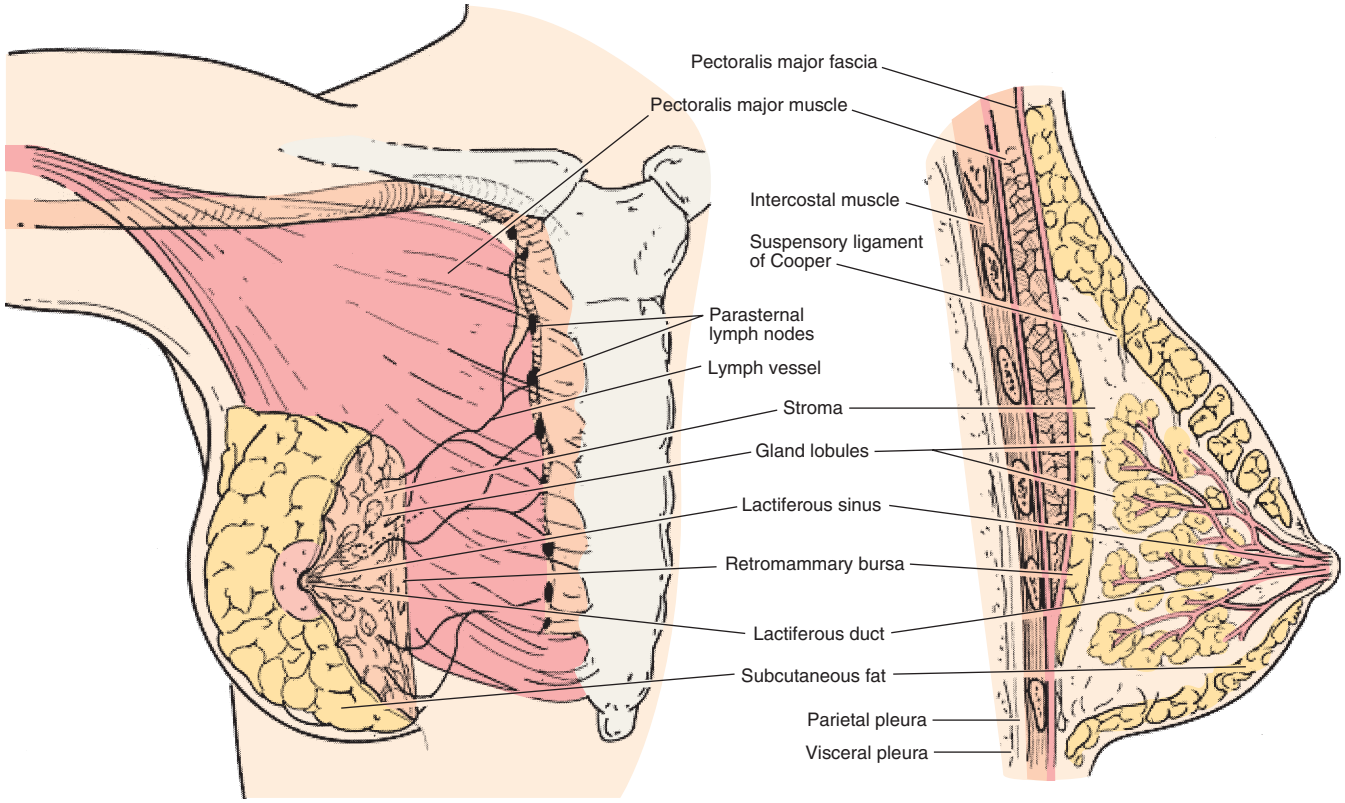

FIGURE 14.1 Anatomy of the female breast.

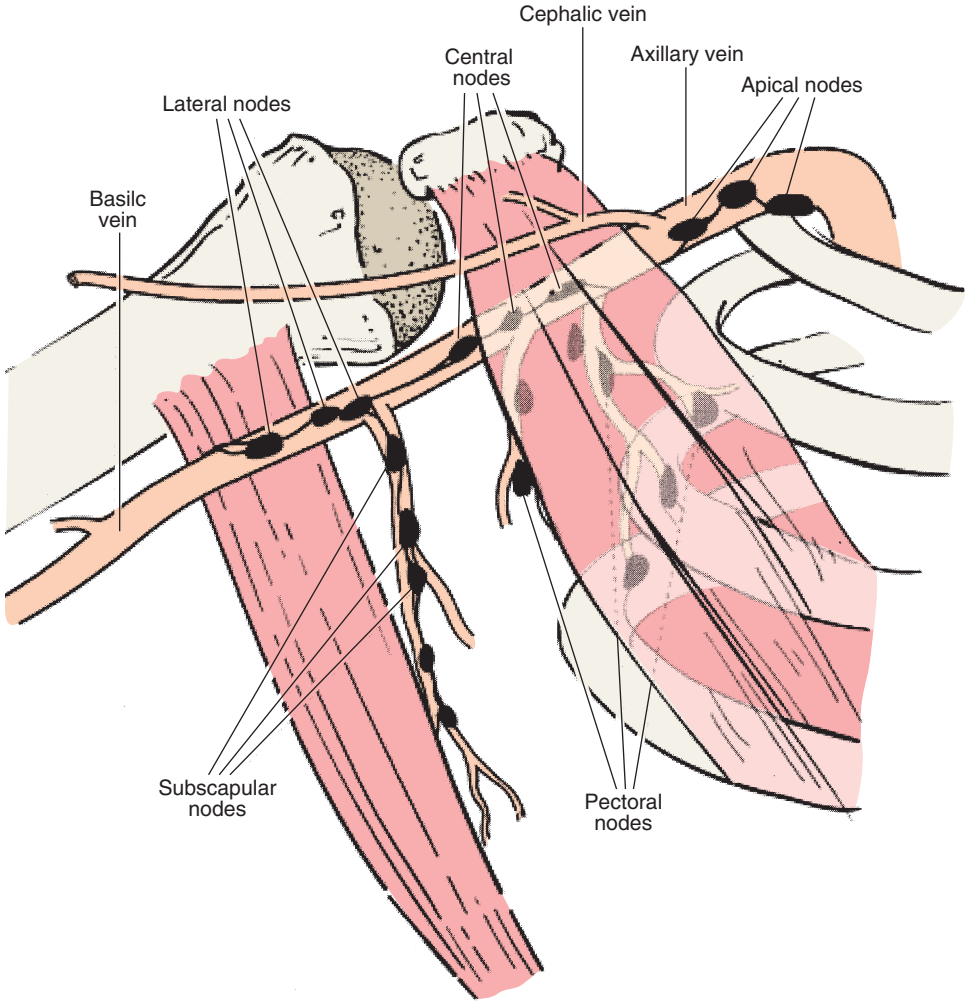

FIGURE 14.2 Axillary nodes.

the deep plexus and from the subareolar plexus through the lymphatic vessels of the lactiferous duct to the perilobular and deep subcutaneous plexus. Lymph flow from the deep subcutaneous and intramammary lymphatic vessels moves centrifugally toward the axillary and internal mammary lymph nodes. It is estimated that about 97% of the lymph flows to the axillary nodes and 3% to the internal mammary chain.

Axillary lymph nodes may be divided into three anatomic levels defined in reference to the pectoralis minor muscle. Level I nodes are the axillary vein lymph nodes that lie along the axillary vein from the lateral extent of the pectoralis minor muscle to the latissimus dorsi muscle. In this area, deep to the floor of the axilla, subscapular nodes that lie on the subscapularis muscle are identified.

Level II nodes are designated by their location underneath the pectoralis minor muscle. Medial to the pectoralis minor are level III nodes, which include apical or subclavicular nodes and are adjacent to Halstead's ligament.

Interpectoral nodes are called Rotter's nodes. They lie between the pectoralis major and minor muscle.

EMBRYOLOGY AND DEVELOPMENT OF THE BREAST

The mammary glands are highly specialized skin derivatives of ectodermal origin. The epithelial ridge that develops into breast tissue undergoes a series of proliferations to form the lactiferous ducts. Primitive breast tissue is under the gonadal control of fetal androgen production, which causes a suppression of breast growth during the period of gestation when the tissue is under the simultaneous influence of increasing levels of growth-promoting estrogen and progesterone. After birth, breast tissue remains dormant until adolescence, when estrogen produces a proliferation of ductal epithelium and progesterone produces rapid growth of the acini. However, breast growth and development are not totally dependent on estrogen and progesterone levels. Insulin, cortisol, thyroxine, growth hormone, and prolactin are also required for complete functional development. Minor deficiencies in any one of these hormones can be compensated for by an excess of prolactin.

PREGNANCY AND BREASTFEEDING

Increasing amounts of estrogen, progesterone, and human placental lactogen produce active growth of functional breast tissue during the course of pregnancy. Estrogen production is under the control of the fetus. Estrogen influences progesterone production, uteroplacental blood flow, mammary gland development, and fetal adrenal gland function. By the 20th week of pregnancy, most of the estrogen excreted in maternal urine comes from fetal androgens. About 90% of maternal estriol is derived from fetal precursors. Serum prolactin rises from nonpregnant levels of 10 ng/mL to term levels of 200 ng/mL. Amniotic fluid prolactin levels are more than 100 times greater than the levels in maternal or fetal blood early in pregnancy. It is not known whether the fetal pituitary gland or the trophoblast secretes the hormone into the amniotic fluid. Elevated levels of estradiol parallel those of prolactin and indicate that estriol may be responsible for increases in prolactin. Although estrogen may initiate prolactin secretion, high levels block its physiologic effects. Prolactin secretion is also controlled by the prolactin-inhibiting factor. A decrease in estrogen level after delivery and suppression of the prolactin-inhibiting factor by suckling increases prolactin levels. If breastfeeding does not occur, serum prolactin levels decrease to nonpregnant levels in about 1 week.

The release of oxytocin from the posterior pituitary gland affects contraction of the duct system, stimulating the delivery of milk to the nipples. However, after 3 to 4 months of breastfeeding, suckling appears to be the only stimulus required for lactation.

BENIGN BREAST CONDITIONS

Fibrocystic Changes

Fibrocystic change is the most common benign breast condition in women. It consists of no single entity and encompasses a histologic spectrum of changes in the breast, some of which are normal and some of which are abnormal. It is a result of fluctuating hormone levels and is most common in premenopausal women between the ages of 20 and 50 years. It is often associated with pain and tenderness (mastodynia) and tends to be bilateral. Most women report symptoms during the premenstrual phase of the cycle, which suggests that progesterone may play a role in the development and symptoms of cystic alterations in breast tissue. However, the proportional effect of both estrogen and progesterone on the cause of benign breast conditions is unclear.

Fibrocystic change is not a risk factor for cancer. In 1985, the Cancer Committee of the College of American Pathologists published a consensus statement and discouraged the use of the term *fibrocystic disease*; they prefer the terms *fibrocystic changes* or *fibrocystic condition.*

Mastodynia results from breast stromal edema, ductal dilation, and associated inflammatory response. An increase in breast size is also frequently reported. The differential diagnosis for breast pain includes other conditions affecting the anterior chest wall, such as intercostal neuralgia, myalgia, and chronic costochondritis. Women with large, pendulous breasts will have associated stretching of Cooper ligaments and associated breast pain.

The management of fibrocystic change in any patient presenting symptomatically first consists of ruling out any underlying breast cancer with appropriate imaging and workup. After that, advice can be given with respect to the patient's breast pain and tenderness. Symptomatic women may benefit from counseling regarding proper selection and fitting of a brassiere because improved mechanical support may relieve breast pain. The effectiveness of dietary interventions to reduce breast pain remains to be established. A low-fat diet was associated with a substantial improvement in mastalgia symptoms when 21 patients with severe mastopathy were randomized to a diet containing 15% fat intake or a general diet containing 36%

fat intake. Although many women report that a reduction in caffeine intake alleviates their breast pain, clinical studies have not shown consistent findings. In an uncontrolled study, 61% of women with breast pain who substantially decreased caffeine intake for 1 year had decreased pain or complete relief. Studies with small numbers of patients suggested a potential beneficial effect of vitamin E in fibrocystic change. Evening primrose oil (gammalinolenic acid) has been widely advocated as an option. Two small randomized, double-blind, placebo-controlled studies of evening primrose oil have shown efficacy in the treatment of breast pain. But this result has not been duplicated in other studies.

Hormonal manipulation may alleviate mastodynia but is associated with other side effects. There is no consensus with regards which of these is superior. Danazol is the only medication approved by the US Food and Drug Administration (FDA) for treatment of mastodynia. Overall, 59% to 92% of women treated with danazol experience relief of breast pain. Unfortunately, adverse effects occur in 30% of patients and result in discontinuation of treatment in 15% of patients, even when breast pain is improved. Adverse effects are dose related and are primarily androgenic, including acne, hair loss, decrease in voice pitch, weight gain, headache, nausea, rash, anxiety, and depression.

The selective estrogen receptor modulator (SERM) tamoxifen, which is commonly used to prevent and treat breast cancer, is effective in reducing pain in 71% to 96% of women with cyclic mastalgia and 56% of women with noncyclical mastalgia in controlled trials. In studies comparing tamoxifen dosages and duration for breast pain, the 10 mg/d dosage of tamoxifen was as effective as the 20 mg/d dosage with fewer adverse effects. Tamoxifen has a risk of potentially serious adverse effects, such increased risk of deep vein thrombosis and endometrial cancer. Menopausal symptoms such as hot flashes, nausea, menstrual irregularity, vaginal dryness or discharge, and weight gain have been associated with tamoxifen treatment and often lead to discontinuation.

Proliferative Changes

Proliferative changes include hyperplasia and adenosis. Hyperplasia is proliferation of ductal epithelium, which results in layering of the cells. Atypia may be associated with this proliferation. There are two types of atypical hyperplasia based on microscopic appearance: atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH). Both are associated with an increased relative risk (RR) of approximately 4 for development of a later invasive breast cancer. Because there is an approximate 25% chance of finding a concurrent cancer with ADH found on core biopsy, surgical excision is recommended. In the case of ALH, recent studies have suggested the invasive cancer "upgrade" rate is lower (0%–6%) after surgical excision of ALH. Therefore, if radiologic findings are concordant or the findings are incidental, excision may not be warranted. All patients with atypical hyperplasia warrant careful clinical and radiologic follow-up.

Adenosis is also a proliferative lesion caused by changes in the acini in the distal mammary lobule. Sclerosing adenosis refers to the dense, fibrotic tissue surrounding these small ducts. These lesions may present as a palpable mass in women in their 30s and 40s.

A papilloma can result from this ductal proliferation. Papillomas are papillary lesions with a branching fibrovascular core surrounded by epithelium. These lesions are associated with serosanguineous nipple discharge in 25% to 50% of presentations. Ninety percent of the time, there is a small palpable mass adjacent to the areola. Intraductal papillomas are rarely associated with carcinoma but require surgical excision to rule out the possibility of misdiagnosis of a malignancy.

Sclerosing Lesions

Sclerosing lesions have been described by a variety of names, including *sclerosing papillary proliferation, nonencapsulated sclerosing lesion, indurative mastopathy,* and *radial scar*. They are important because they may simulate carcinoma on mammographic, gross, and microscopic examinations. These lesions are typically less than 1 cm in diameter. On gross examination, they are irregular, gray or white, indurated with central retraction, and have an appearance identical to scirrhous carcinoma. On microscopic examination, the lesion has a stellate configuration and consists of a central, fibrotic core containing entrapped glandular elements. The surrounding breast tissue typically shows varying degrees of intraductal hyperplasia and adenosis. The significance of this lesion relative to subsequent development of carcinoma is controversial. Available evidence suggests that these lesions are part of the fibrocystic complex. It is likely that their premalignant potential is the same as that of the constituent parts. Local excision of these lesions is the treatment of choice.

Fibroadenoma

Fibroadenomas are benign fibroepithelial tumors and are the second most common benign lesion of the breast. They are the most common lesion found in women younger than age 25 years. They persist during the menstrual years of a woman's life, but regression after menopause has been reported. Patients typically present with a mobile, smooth, painless, palpable mass. Ultrasound examination along with physical examination can help in making the diagnosis.

Mammographically, fibroadenomas may appear as round, oval, or lobulated masses with circumscribed margins. In older women, they can have a rim of coarse calcifications. Fine-needle aspiration (FNA) will reveal benign ductal epithelial cells and elongated dense stromal cells. Microscopically, fibrous tissue comprises most of the fibroadenoma. Carcinoma arising in fibroadenomas is rare.

Fibroadenomas can be followed without the need for complete surgical excision. This can be achieved with physical examination or ultrasound examination if they are not palpable. However, surgical excision should be performed in the following situations:

- The mass continues to enlarge.
- The results of FNA or core biopsy are inconclusive or yield atypia.
- The patient desires surgical excision.

TABLE 14.1 Proliferative Breast Disease and Breast Cancer Risk

Characteristic	Relative Risk (Confidence Interval)
Proliferative disease, no atypia	1.3 (0.69–11.9)
Complex fibroadenoma*	1.46 (0.53–14.0)
Atypical hyperplasia	2.53 (1.01–6.3)
Neither proliferative disease nor complex fibroadenoma	1.27 (0.89–11.8)

*Contains cysts, sclerosing adenosis, epithelial calcification, or papillary apocrine changes.
Modified from Dupont WD, Page DL, Parl FF, et al. Estrogen replacement therapy in women with a history of proliferative breast disease. Cancer 1999;85:1277.

TABLE 14.2 Breast Diagnosis Grouped by Cancer Risk

Cancer Risk	Diagnosis
No increased risk	Adenosis, sclerosing or florid
	Apocrine metaplasia
	Cysts, macro or micro
	Duct ectasia
	Fibroadenoma
	Fibrosis
	Hyperplasia (mild)
	Mastitis
	Periductal mastitis
	Squamous metaplasia
Slightly increased	Hyperplasia, moderate or florid
	Papilloma, solid or papillary, with fibrovascular core
Moderately increased	Atypical hyperplasia
	Ductal
	Lobular

Table 14.1 lists proliferative breast disease and breast cancer risk. Table 14.2 shows breast diagnoses grouped by cancer risk.

Phyllodes Tumor

Phyllodes tumors are uncommon, slow-growing fibroepithelial tumors. Previously referred to as cystosarcoma phyllodes, this name contributed to confusion in understanding this entity. Although very similar to a fibroadenoma, the stromal component is hypercellular with increased pleomorphism and mitotic activity. Phyllodes tumors can occur in women of any age but more commonly occur in premenopausal women.

Malignant behavior in phyllodes tumors is rare in premenopausal women. Malignant phyllodes tumors are noted when there is a combination of increased mitotic activity, invasive borders, or marked pleomorphism. Incomplete excision is a major determinant for local recurrence. Treatment is total surgical excision with a wide margin of healthy tissue.

Adenoma

Adenoma of the breast is a well-circumscribed tumor composed of benign epithelial elements with sparse, inconspicuous stroma, a feature that differentiates this lesion from fibroadenoma, in which the stroma is an integral part of the tumor. For practical purposes, adenomas may be divided into two major groups: tubular adenomas and lactating adenomas. Tubular adenomas in young women are well-defined, freely movable nodules that clinically resemble fibroadenomas. Lactating adenomas manifest as one or more freely movable masses during pregnancy or the postpartum period. They are grossly well circumscribed and lobulated; on cut section, they appear tan and softer than tubular adenomas. On microscopic examination, these lesions have lobulated borders and are composed of glands lined by cuboid cells with secretory activity identical to the lactational changes normally observed in the breast tissue during pregnancy and the puerperium.

It should be noted that breast biopsy in a pregnant or lactating woman calls for meticulous hemostasis because of the increased vascularity and risk of postoperative hematoma formation. The lactating breast is predisposed to postoperative infection because milk is a good culture medium. Anesthesia by local injection may be difficult in the enlarged breast but is the method of choice. Incisional biopsy under local anesthesia is an option when excisional biopsy is a problem. Because of the significant risk of infection and milk fistula, the patient who is lactating should cease lactating before biopsy is performed.

Superficial Thrombophlebitis

Superficial thrombophlebitis is also known as Mondor disease of the breast. It is an uncommon benign inflammatory process. It can occur spontaneously but usually is associated with breast trauma, breast surgery, or pregnancy. It is a thrombophlebitis of the thoracoepigastric vein, which drains the upper-outer quadrant of the breast. Patients present with acute pain and a linear, tender fibrotic band with skin retraction over the distribution of the thoracoepigastric vein.

Treatment is conservative, with analgesics and application of heat. The condition resolves in 1 to 3 weeks. Skin retraction superficial to the area of inflammation can remain if the inflammation is extensive. Biopsy is not necessary.

Mastitis

Mastitis usually occurs in relation to lactation. It can occur in nonpuerperal periods in association with galactorrhea. Skin organisms, *Staphylococcus aureus,* and *Streptococcus* spp. may cause infection of the nipple and breast ducts. The presence of milk in the ducts can provide an excellent medium for infection.

Women with mastitis may continue to breastfeed. Antibiotic therapy with dicloxacillin sodium (250 mg qid) or penicillin G is indicated. If there is no response, an abscess that may require surgical drainage must be excluded. Inflammatory carcinomas can mimic mastitis, and if no resolution of infection is noted despite continued antibiotics, a skin biopsy may be indicated.

Galactoceles are milk-filled cysts. They are usually tender and present after the abrupt termination of breastfeeding. Aspiration of the cyst is often necessary for symptomatic relief. If reaccumulation occurs, however, surgical excision may be required to avoid infection.

Duct Ectasia

Duct ectasia is a condition that usually occurs in perimenopausal or postmenopausal women. Patients present with a tender, hard, erythematous mass adjacent to the areola in association with burning, itching, or a pulling sensation in the nipple area. A thick, greenish-black discharge may be present. The pathogenesis of this condition has not been fully established. Available evidence suggests, however, that the primary event is periductal inflammation and that ductal ectasia is the ultimate outcome of this disorder. The postulated sequence of events in the evolution of this disease is periductal inflammation leading to periductal fibrosis that subsequently results in ductal dilation. However, the etiology of the initial inflammatory response remains obscure. Histologic evaluation of the area shows dilated, distended terminal-collecting ducts obstructed with inspissated lipid-containing epithelial cells and phagocytic histiocytes. This process tends to occur in a segmental fashion extending from the involved nipple area to adjacent ducts. Occasionally, a small abscess forms at the base of the nipple. Treatment is excisional biopsy.

Younger women can present with inflammation of the ducts in the region of the nipple, which may produce fissures and fistulae with connection from the nipple ducts to the skin at the edges of the areola. Prior periductal mastitis leads to the squamous epithelium of the terminal dilated portion of the collecting ducts to undergo squamous metaplasia. Keratin is formed in the duct, accumulates, and can cause an abscess at the base of the nipple. Excision of the area usually is necessary.

Fat Necrosis

Fat necrosis is a relatively uncommon benign condition occurring as a response to breast trauma or surgery. Patients present with a hard mass that can mimic a carcinoma. The irregular mass is palpable and may involve skin retraction. Multiple calcifications can be seen on mammography.

The histology is active chronic inflammatory cells, with lymphocytes and histiocytes predominating. In the later stages, a collagenous scar is noted, with "oil cysts" or free lipid material released by lipocyte necrosis. Fat necrosis does not increase the risk of carcinoma, and its clinical importance is in the differential diagnosis of a carcinoma.

Nipple Discharge

Nipple discharge has been reported in 10.0% to 15.0% of women with benign breast disease and in 2.5% to 3.0% of those with carcinoma. Galactorrhea presents as bilateral milky nipple discharge consisting of lipid droplets; the condition is usually idiopathic but can be found after discontinuation of oral contraceptives or as a persistent discharge after pregnancy. Plasma prolactin levels should be determined because of the possibility of a prolactin-producing pituitary adenoma.

The discharge is classified according to its appearance as milky, green, bloody, serous, cloudy, or purulent. The drainage should be classified according to whether it is unilateral, bilateral, spontaneous, or recurrent. This information is obtained at the time of a thorough history and physical examination. For example, if the drainage first appeared in the patient's bra or nightgown on awakening, this finding is significant. The presence of a mass should also be investigated. The risk of cancer is increased when the discharge is unilateral from a single duct, when it occurs in a postmenopausal patient, or when a mass is present.

Unilateral, Spontaneous Nipple Discharge

In cases of unilateral, spontaneous nipple discharge, several causes are included in the differential diagnosis. The most common cause of nipple discharge is mammary-duct ectasia, which produces a multicolored (green, yellow, white, brown, gray, or reddish-brown) nipple discharge. The reddish-brown discharge is often mistaken for a blood discharge. It is thought to result from an increase in glandular secretions, with the production of an irritating lipid fluid that can produce a nipple discharge.

The next most common cause of a multicolored, sticky nipple discharge is nonpuerperal mastitis. The persistent type involves inflammation in deeper portions of the breast; the transient types are associated with periareolar inflammation. If the inflammation develops into an inflammatory mass, surgical excision and drainage are necessary. Medical management with local care, avoidance of all nipple manipulation, and administration of nonsteroidal antiinflammatory agents and an antistaphylococcal antibiotic are often successful when infection is suspected.

Bloody nipple discharge warrants surgical evaluation. Intraductal papillomas are the most common cause of bloody nipple discharge. During the breast examination, physicians should look for an associated periareolar mass. The examination consists of gently and carefully palpating the subareolar region to identify the pressure point that produces the discharge. It is important to reproduce the discharge and demonstrate the breast quadrant from which it emanates. All significant nipple discharges warrant referral for tissue biopsy. Although a mass is usually present when the discharge is a result of cancer, there is no palpable mass in 13% of cancers with nipple secretions. Bloody discharge occurring in the third trimester of pregnancy may be regarded as physiologic, however, and does not require intervention unless persistent for several months after delivery. There are no contraindications to breastfeeding in these patients. Cytology of the discharge is not routinely recommended because of a reported low sensitivity for detection of cancer (≈27%). Galactography (injecting radiopaque contrast into the discharging duct and then performing mammography) offers better visualization of small intraductal papillomas but cannot differentiate between benign and malignant lesions. A surgical procedure is still necessary. Mammography has a 9.5% false-negative rate and a 1.6% false-positive rate for detecting cancer in patients with a nipple discharge. Table 14.3 reveals characteristics of nipple discharge.

HISTORY AND PHYSICAL EXAMINATION

Obtaining a thorough history, including a family history and information on menstrual status, pregnancies and lactation,

TABLE 14.3 Characteristics of Nipple Discharge

Color	Likely Cause	Percentage Caused by Cancer
Milky (galactorrhea)	Pituitary adenoma, pregnancy, oral contraceptives	Rare
Green, yellow, sticky	Ductal ectasia	Rare
Clear, watery	Ductal carcinoma	30–50
Bloody, sanguineous	Fibrocystic changes, ductal papillomas	25
Pink, serosanguineous	Fibrocystic changes, ductal papillomas	10
Yellow, serous	Fibrocystic changes, ductal papillomas	5
Purulent	Bacterial infection	Rare

hormone use, and prior breast surgeries and trauma, is essential. In addition, ascertaining whether the patient performs breast self-examinations (BSEs) and determining the presence and characterization of nipple discharge or a breast mass are important.

Bilateral breast examination is best performed after menstruation and before ovulation. At this time, breast engorgement and tenderness are less likely to be present.

A multipositional breast examination should be performed, including examination in the upright and supine positions. Breast retraction and subtle changes in the skin and nipple may be missed if the patient is examined in only one position.

The patient should be in the sitting position during the inception of the physical breast examination. In this position, asymmetry, skin or nipple retraction, and nipple ulceration should be most apparent (Fig. 14.3, *A*). When the patient's arms are raised (Fig. 14.3, *B*), skin changes in the lower half of the breast or in the inframammary fold become accentuated. Contraction of the pectoralis major muscle, affected by the patient pushing her hands against her hips (Fig. 14.3, *C*), may demonstrate an otherwise undetected skin retraction. Next, palpation of the breast with the patient still upright may allow detection of subtle lesions that would be more difficult to palpate if she were supine (Fig. 14.3, *D*). Examination of the supraclavicular areas and both sides of the neck for the purpose of detecting suspicious lymphadenopathy is also best done when the patient is in the upright position.

The axilla should be examined with the patient in the upright position. The patient's right arm should be fixed at the elbow and held there by the physician's right hand. This allows relaxation of the chest wall musculature (Fig. 14.3, *E*). Palpation with the left hand permits assessment of the lower axilla, and with extension higher toward the clavicle, the middle and upper portions of the axilla can be assessed. The left axilla is examined with the right hand after relaxation of the patient's left arm in the physician's left hand. If lymph nodes are palpable, the clinician must assess their level and size and whether they are suspicious, single or multiple, and mobile or fixed to underlying structures.

The second phase of the breast examination is conducted with the patient in the supine position and with the patient's arm raised above the head (Fig. 14.3, *F*). Digital palpation is carried out using the index and middle fingers and by applying varying amounts of pressure with the flats or pads of the fingers. A thorough examination systemically covers the entire breast and chest wall. The examination can be done in a clockwise direction or by rows (stripwise). It is important to carefully examine beneath the nipple–areolar complex and within the axilla.

An inflammatory appearance of the breast should raise suspicion of an inflammatory carcinoma. The classic appearance of inflammatory breast cancer includes a red, swollen breast with skin edema ("peau d'orange"). The breast is generally not tender. If the inflammation persists after a short course of antibiotics to rule out cellulitis, biopsy of the breast and skin is warranted. Inflammatory breast cancer is often a clinical diagnosis, and a benign skin biopsy should not dissuade the clinician from undertaking further evaluation and treatment. Any asymmetric skin changes or changes of the nipple–areolar complex should arouse suspicion. Paget disease of the nipple suggests the presence of intraductal or invasive cancer involving the nipple, and cancer should be excluded by a nipple biopsy of the abnormal area after a mammogram.

It is important to instruct patients in the technique of BSE. Physician-directed discussion on BSE is the most effective approach. Physicians have the opportunity to reinforce what is normal versus abnormal to patients during the examination. If no abnormal findings are noted on examination, it is critical to document negative findings. The date of the last mammogram, discussion of cancer screening, and plans for follow-up should also be recorded.

Hormones (hormone replacement therapy [HRT] or oral contraceptive pills [OCPs]) should not be renewed without a documented annual breast examination or mammography if indicated. A great deal of litigation results from failure to diagnose breast cancer. The Physician Insurers Association of America's breast cancer claims study, conducted in 1988, determined that 75% of successful malpractice lawsuits involved primary care physicians with practices in family medicine, internal medicine, or obstetrics and gynecology. It is important that the medical chart include careful documentation because approximately one-third of the cases reported in the Physician Insurers Association of America's study resulted from inadequate documentation.

Clinical breast examination (CBE) and BSE as methods for screening for breast cancer mainly aim at detection of palpable breast lesions. However, there are no published reports demonstrating these methods as being effective in breast cancer mortality risk reduction.

A Cochrane systematic review published in 2003 included two large population-based studies from Russia and Shanghai, China that compared BSE with no intervention. In both trials, almost twice as many biopsies with benign results were performed in the screening group compared with the control group (RR, 1.89; 95% confidence interval [CI] 1.79–2.00).

Three trials were designed to determine mortality outcomes by using CBE as the primary screening approach in countries

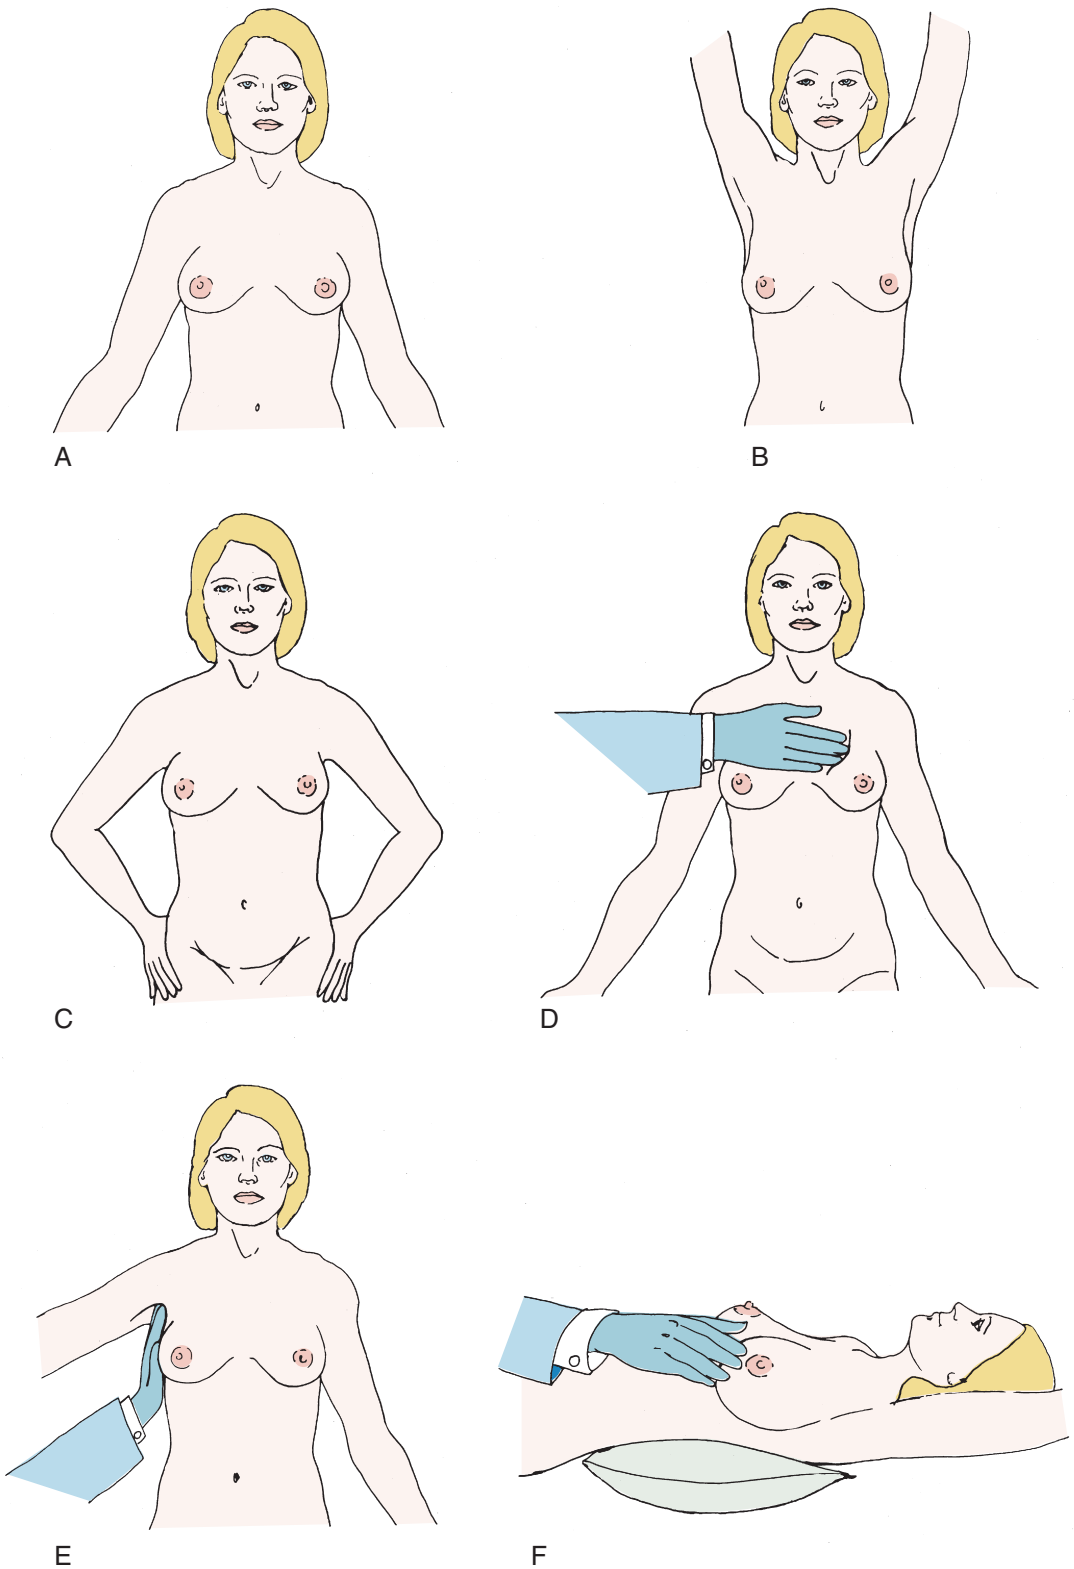

FIGURE 14.3 Physical examination of the breast. **A,** Upright position. **B,** Arms raised. **C,** Pushing hands against hips. **D,** Palpation in an upright position. **E,** Palpation of the axilla. **F,** Palpation in a supine position.

with limited health care resources and without mammography screening programs. The applicability of these trials to the United States is limited. One trial in the Philippines was discontinued because of poor acceptance, and the others are ongoing in India and Egypt.

In its most recent update, the United States Preventive Services Task Force (USPSTF) recommended against BSE based on a systematic review of published reports.

For breast cancer screening, the American Cancer Society (ACS) recommends CBE every 3 years for women aged 20 to 39 years and annually beginning at age 40 years.

TABLE 14.4 Randomized Population-Based Mammography Trials

Trial	Relative Risk (95% Confidence Interval)
Malmö	0.96 (0.68–1.35)
Canada	1.08 (0.84–1.40)
Göteborg	0.55 (0.31–0.95)
Stockholm	0.73 (0.50–1.06)
Kopparberg	0.58 (0.45–0.76)
Östergötland	0.76 (0.61–0.95)
New York	0.79 (0.64–0.98)
Edinburgh	0.87 (0.70–1.08)

MAMMOGRAPHY

The primary goal of mammography is to screen asymptomatic women to help detect breast cancer at an early stage. The goal of screening mammography is to find cancers before they are clinically palpable, more likely to be small, and less likely to have nodal involvement. Most studies of mammography use mortality as the endpoint, and the value of screening is often limited to mortality rates. Few studies factor the effects of early detection on quality of life or the fact that treatment at earlier stages carries less morbidity and has more treatment options.

In general, a routine screening mammogram consists of a mediolateral oblique (MLO) view and a craniocaudal (CC) view of each breast. With modern low-dose screening, the dose is less than 0.1 rad per study (for comparison, a chest radiograph delivers 0.025 rad per study). The effectiveness of screening depends on the density of the breast: The greater the breast density, the lower the sensitivity of the mammogram.

Breast composition may be one of four patterns of increasing density:

1. Almost entirely fat
2. Scattered fibroglandular densities
3. Heterogeneously dense
4. Extremely dense

It is important to note that the false-negative rate for mammograms is 10% to 15% and that a normal mammogram does not eliminate the need for further evaluation of a dominant mass in the breast. If the clinical examination is suspicious, a negative mammogram result should not delay further investigation. Breast density should be documented in the mammogram report, and many states require notification of the patients of their breast density in their results letter.

Mammographic screening in women 40 years or older has reduced mortality rates by 20% to 30%. The efficacy of screening mammography in decreasing breast cancer mortality rates has been demonstrated in numerous studies. In the 1960s, the Health Insurance Plan of Greater New York performed a study of physical examination and mammography in a study group of 30,756 women and a control group of 30,239 women between the ages of 40 and 64 years. At 10 years of follow-up, the study group had a 30% decrease in the breast cancer mortality rate compared with the control group.

A total of eight large randomized trials on mammographic screening have been conducted. Six of the eight trials revealed a statistically significant reduction in mortality with mammographic screening. The reduction in mortality rate was not as evident among women between the ages of 40 and 49 years compared with women older than 50 years of age. The relative mortality rate reduction appears later in women between the ages of 40 and 49 at randomization compared with women 50 years or older. It is also likely that the small numbers of women between 40 and 49 years of age in the existing randomized trials may have contributed to this difference.

In a meta-analysis of eight randomized controlled trials (RCTs) of mammographic screening, a statistically significant 18% reduction in mortality in women aged 40 to 49 years was noted. Combined data from five Swedish trials yielded a statistically significant mortality decrease of 29% (Table 14.4).

The updated Cochrane systematic review was published in 2013. Because of the inclusion criteria chosen for the review, they reported on six randomized trials. They concluded that screening is likely to reduce breast cancer mortality. The effect was lowest in the adequately randomized trials, and a reasonable estimate is an overall 15% reduction in mortality from breast cancer (RR, 0.81; 95% CI 0.74–0.87) after 13 years. However, it should be noted that there is a false-positive rate associated with screening.

Screening Interval

For several years, there has been a significant debate about the appropriate age at which to commence mammographic screening. Whereas the 2003 ACS guidelines for mammographic screening recommended a yearly mammogram starting at age 40 tears, the National Cancer Institute (NCI) recommended a mammogram every 1 or 2 years. The American College of Obstetricians and Gynecologists (ACOG) currently recommends annual mammography from 40 years of age. In October 2015, the ACS revised its guidelines with regards to screening mammography in average-risk women. The guidelines now advocate the commencement of annual mammography at age 45 years until age 54 years. Thereafter, from age 55 years onward, biennial mammograms are recommended while the patient's overall health is good or she has a life expectancy of 10 years or longer. The ACS falls short of recommending mammography from age 40 to 44 years but state that women should have the

TABLE 14.5 Recommendations for Mammographic Screening for Breast Cancer

Age (Years)	American College of Obstetricians and Gynecologists	American Cancer Society	National Cancer Institute	US Preventive Services Task Force
40–45	Annually	Not recommended but should have opportunity to begin	1–2 years	Individual decision
45–50	Annually	Annually	1–2 years	Individual decision
50–55	Annually	Annually	1–2 years	2 years
55–74	Annually	2 years	1–2 years	2 years

opportunity to commence screening. Table 14.5 lists recommendations by society.

Data from the Breast Cancer Surveillance Consortium, also recently published in October 2015, somewhat support this strategy. They reviewed screening mammography from 15,440 patients from ages 40 to 85 years who had either annual or biennial imaging. Premenopausal women diagnosed at the longer interval screening time point had more tumors with less favorable prognostic characteristics—that is, stage IIB or higher—than those screened annually. In those who were postmenopausal and not taking HRT, there was no difference in the proportions of stage IIB or higher tumors whether they were screened at 1 or 2 years. This would suggest that menopausal status rather than age may be a better factor to consider when determining mammographic screening interval. Biologically, this is plausible with the possibility that estrogen-exposed tumors may grow faster and thus have a decreased detectable preclinical phase combined with increased breast density premenopausally decreasing mammographic sensitivity.

The USPSTF published its screening recommendations in 2009 and currently has draft recommendations due for publication in 2015. After reviewing the evidence regarding the efficacy of BSE, CBE, and mammography in reducing breast cancer mortality, it recommends starting mammography at age 50 years and performing biennial screening. It does not recommend routine mammography in women younger than age 50 years but recommends that the decision is an individual one. They advise that, although there may be an improvement in the risk of dying from breast cancer with screening before age 50 years, that the advantage is not as big as in older women. They also note that it is associated with a higher false-positive rate in those younger than age 50 years; therefore, an individual can decide on her personal acceptability of the risk-to-benefit ratio. The task force cites the risk of false-positive mammography results (≤56%) as a potential harm and considers pain, anxiety, distress, and other psychologic responses as potential harms. However, the task force states that these harms are transient and thus do not represent a substantial deterrent to the continued use of mammography for screening. These recommendations have caused much controversy and debate in the medical community and lay press since they were announced in 2009. The majority of clinical societies did not change their recommendations after these guidelines were issued. Annual screening mammography may commence earlier than age 40 in a few special circumstances (Table 14.6).

TABLE 14.6 Screening Guidelines for Women Younger Than Age 40 Years

Condition	Timing of Annual Mammography
Lobular cancer in situ or breast cancer diagnosis	At time of diagnosis
First-degree relative with premenopausal breast cancer	10 years earlier than relative's age at diagnosis but not younger than 25 years
Mantle irradiation for Hodgkin disease	8 years after completion of radiation therapy
BRCA1 or *BRCA2* mutation	Age 25–35 years; specific age chosen based on adequacy of mammography imaging in the first study and patient choice

Data from American College of Obstetricians and Gynecologists. *Primary and preventive care: periodic assessments.* ACOG Committee Opinion 246. Washington, DC, 2000, Author.

Breast Imaging Reporting and Data System

In the past, a lack of uniformity in mammography terminology and reporting often led to confusion as to the malignant nature of a lesion. In 1994, the Mammography Quality Standards Act was passed by Congress and is administered by the FDA. It requires that mammography facilities monitor the results of their breast cancer detection programs, including the number of recommended biopsies and the size, number, and stage of cancers detected. The American College of Radiology (ACR) uses a terminology and lexicon system called the Breast Imaging Reporting and Data System (BI-RADS) for reporting abnormalities seen on mammography (Table 14.7). This standardized reporting system was developed in 1995. Each category leads to a fixed assessment and specific management recommendations. In addition, associated findings, such as skin or nipple retraction, skin thickening, skin lesions, axillary adenopathy, and the presence of architectural distortion, should also be reported.

The predictors of malignancy for the BI-RADS categories are 0% to 2% for category 3 and approximately 98% or greater for category 5. Category 4 is less predictable. Liberman and colleagues and Orel and colleagues have placed the risk of malignancy for this category at around 30%.

The ACR Task Force has published a fifth edition of the BI-RADS classification system in the form of a *BI-RADS Atlas* that includes second edition BI-RADS classifications for ultrasonography and MRI. The new edition of BI-RADS

TABLE 14.7 American College of Radiology BI-RADS Assessment Categories

BI-RADS Category	Assessment
	ASSESSMENT IS INCOMPLETE
0	Need additional imaging evaluation and/or prior mammograms for comparison
	ASSESSMENT IS COMPLETE: FINAL CATEGORIES
1	Negative
2	Benign finding(s)
3	Probably benign finding; initial short-interval follow-up suggested
4*	Suspicious abnormality; biopsy should be considered Optional subdivisions: 4A: Low suspicion for malignancy 4B: Moderate suspicion of malignancy 4C: High suspicion for malignancy
5	Highly suggestive of malignancy; appropriate action should be taken
6	Known biopsy; proven malignancy; appropriate action should be taken

BI-RADS, Breast Imaging Reporting and Data System.
*By subdividing category 4 into 4A, 4B, and 4C, it is encouraged that relevant probabilities for malignancy be indicated within this category so the patient and her physician can make an informed decision on the ultimate course of action.

includes the previously mentioned classification of patterns of breast density for uniform reporting in mammogram reports. Category 4 is divided into three parts based on the prebiopsy risk for malignancy of the lesion—4A (low suspicion), 4B (moderate), and 4C (high)—in an effort to better guide clinicians and to collect meaningful data about this category. By subdividing the category, the ACR hopes to provide better communication to the referring physician about the prebiopsy risk of malignancy. One recent retrospective study evaluated interobserver variability and positive predictive value of BI-RADS categories 4A, 4B, and 4C. The risk of malignancy was found to be 6%, 15%, and 53%, respectively. Table 14.7 shows BI-RADS reporting.

Diagnostic Mammography

Abnormalities found on mammographic screening may need further evaluation with additional mammography views or other imaging modalities, such as ultrasonography or magnetic resonance imaging (MRI). In some screening programs, the mammograms are reviewed by the radiologist as they are performed, and if additional views are needed, they are performed on the same day. In other programs, if additional studies are required, the patient is called back for them at a later date. In several studies, the frequency of "call-backs" has ranged from 5% to 11%.

TABLE 14.8 Morphology of Microcalcifications and Associated Lesions

Morphology	Description and Associated Lesion
Typically benign	Includes skin (lucent centered) Vascular (parallel tracks) Coarse "popcorn-like" (fibroadenomas) Large rodlike (secretory disease) Eggshell or rim (fat necrosis) Milk of calcium (within tiny cysts) Dystrophic (after trauma or irradiation)
Suspicious	Amorphous Coarse heterogenous Fine pleomorphic Fine linear or fine linear branching
Distribution	Diffuse Regional Grouped Linear Segmental

Mammographic Lesions

A "mass" is defined as a space-occupying lesion seen in two different projections. If a possible mass is seen on only one view, it is called a "density" until its three dimensionality is confirmed. A description of the shape and the margins of the lesion are also necessary. The highest frequency of carcinoma is noted in masses that have an irregular shape or spiculated borders. These lesions are associated with pleomorphic calcifications that appear discontinuous and linear in distribution. This discontinuous linear pattern suggests irregular filling of a duct with abnormal cells.

Microcalcifications

The BI-RADS lexicon describes calcification morphology (shape) and distribution. Calcifications may be scattered or clustered, coarse or fine, and old or new. Comparison with prior mammograms is often necessary (Table 14.8).

Digital Mammography

The benefits of digital mammography over traditional film mammography concern image acquisition and facilitation of storage. In addition, digital-image processing allows manipulation of image contrast and may enhance subtle contrast differences. In January 2000, the General Electric Senographe 2000D was approved by the FDA. Since its introduction, population-based screening trials comparing screen-film and full-field digital mammography have been conducted. In the Oslo I Study conducted in Norway, full-field digital and screen-film mammography were performed in 3683 women aged 50 to 69 years. The investigators found no statistically significant difference in cancer detection rates between the two modalities. The Oslo II Study yielded similar results in cancer detection rates. Full-field digital mammography did yield higher cancer detection rates, but this difference between film and digital mammography was not statistically significant. In Canada and the United States,

49,528 women were enrolled in the Digital Mammographic Imaging Screening Trial (DMIST). All participants underwent both digital and film mammography in random order. The investigators noted that, although the diagnostic accuracy of digital and film mammography was similar, the accuracy of digital mammography was better in women younger than age 50 years, women with radiographically dense breasts, and premenopausal or perimenopausal women. Thus, in women who met those criteria, the investigators recommended digital mammography. Digital mammography is now available in most screening centers. It can be also combined with computer-aided detection (CAD), which is a process designed to analyze mammographic images for suspicious areas; it is in effect a "second pair of eyes" for the radiologist. The ACR believes that CAD, when used for screening or diagnostic film screen mammography, can be a valuable procedure to aid in the early detection of breast cancer.

Digital tomosynthesis, or three-dimensional mammography, is approved by the FDA but is not yet considered the standard of care for breast cancer screening. Other experimental methods of breast imaging are being investigated but are not in routine use such as contrast-enhanced digital mammography, which is a recent development of digital mammography using the intravenous injection of an iodinated contrast agent in conjunction with a mammography examination.

BREAST ULTRASONOGRAPHY AND MAGNETIC RESONANCE IMAGING

Breast ultrasonography can be used to distinguish between solid and cystic masses in the breast. It can be used to evaluate a focal mass identified on a mammogram or a palpable mass. It is also used as an adjuvant for biopsy. Because of its low specificity, it is not thought to be a good modality for screening. It cannot replace mammography because it has no ability to detect microcalcifications. Ultrasonography can complement mammography in young women with dense breasts because dense breasts limit the accuracy of the mammogram.

Magnetic resonance imaging has a high sensitivity for the detection of breast cancer, and it is not affected by breast density. Screening studies to date have been done in high-risk patients, primarily those at risk because of known or suspected *BRCA* mutations or a family history of breast cancer. A systematic review by Warner and colleagues in 2008 identified 11 prospective studies of MRI screening. In the systematic review, MRI's sensitivity was 75%. Combining mammography and MRI increased the sensitivity to 84%. The specificity of MRI (96·1%) was comparable but marginally lower than the specificity of mammography (98·5%). These studies on the use of MRI for surveillance of women at high risk for hereditary breast cancer have demonstrated a substantial benefit for breast cancer detection.

The ACS has issued guidelines about the use of annual MRI for screening in high-risk women. A guideline panel was assembled to review evidence and develop new recommendations for women at different levels of risk. Based on this panel screening, MRI is recommended for women with an approximately 20% to 25% or greater lifetime risk of developing breast cancer. This includes women with strong family history of breast or ovarian cancer, untested first-degree relatives of *BRCA* mutation carriers, and women with a history of mantle radiation between ages 10 to 30 years. Screening MRI is also recommended for patients with Li-Fraumeni or Cowden syndrome and their first-degree relatives.

The optimal point in time to perform the MRI in relation to mammography has not currently been determined.

MRI can be useful in treatment selection for newly diagnosed breast cancers, particularly in evaluating tumor multifocality in women wanting to pursue breast conservation. However, it has not been shown to increase the likelihood of negative margins or the need to convert from lumpectomy to mastectomy. It is used to assess for residual disease after neoadjuvant chemotherapy. It is also a useful tool to assess for an occult primary breast tumor in patients presenting with axillary nodal metastases. There is insufficient evidence to recommend for or against screening with MRI for women with a personal history of breast cancer, atypical hyperplasia, or extremely dense breasts on mammography.

DIAGNOSTIC EVALUATION

Palpable Mass

The workup of a patient with a dominant mass should include bilateral mammography. In addition to gaining valuable information about the characteristics of the mass, a secondary purpose in this setting is to screen the normal surrounding breast and the contralateral breast for nonpalpable mammographic abnormalities (densities or calcifications). Evaluation of a palpable mass is important to determine whether the mass is cancerous even if the mammogram result is negative.

Fine-Needle Aspiration or Biopsy

Fine-needle aspiration can be extremely useful in providing a cytologic analysis of a palpable breast mass. Many palpable thickenings and all dominant masses should be considered for FNA because it can differentiate between solid and cystic masses. In addition, FNA can diagnose and treat simple cysts and provide cellular material for cytologic analysis. The FNA should be performed after radiologic examination because the resultant hematoma could mask an underlying abnormality.

The breast is prepped with alcohol; with the physician facing the patient, the lesion is stabilized with the physician's opposite hand. Usually, a 21- or 25-gauge needle on a 10-cc syringe is used. Approximately 3 cc of air is aspirated into the syringe to facilitate expulsion of the contents onto the slide after the procedure. The needle is introduced into the lesion, and suction is applied on the syringe. If the mass is cystic, the fluid is completely evacuated, and the lesion should completely disappear. The syringe is withdrawn, and the fluid is discarded if it is serous and nonbloody. The patient should return in 4 to 6 weeks for reexamination.

If the lesion encountered is not cystic or suspected to be solid, an FNA biopsy can be performed in the same manner.

After insertion into the lesion, multiple passes (10–15) through the lesion with changes in direction allow extensive sampling and create a "feel" for the mass (carcinomas are usually hard and gritty). The goal of sampling is to obtain material in the hub of the needle, not to fill the syringe. Care should be taken to release the suction before withdrawing the needle to prevent aspiration into the syringe. The sample is then ejected onto a glass slide, gently smeared with another slide, and placed in sterile jars containing 95% ethanol for transport to the cytology laboratory. Alternatively, it can be placed in a specimen jar containing cytofixative. The needle should be removed from the syringe, the medium aspirated into the syringe, the needle replaced, and the medium then ejected into the jar.

An FNA requires a cytopathologist experienced in breast pathology. The false-negative rate can range from 3% to 35% depending on the expertise of the aspirator and cytopathologist, the size of the lesion, the location within the breast, and the cellular composition of the lesion. Negative findings of an FNA sample in the presence of a suspicious mass should not preclude further diagnostic evaluation. A diagnosis of atypical cells after an FNA warrants a surgical biopsy. Any mass remaining after aspiration of a cyst should be excised. Similarly, a cyst that recurs in the same location after one or two aspirations should be excised.

The false-positive rate of an FNA sample is less than 1%, but in the United States most surgeons do not perform definitive surgery such as a mastectomy without a prior surgical biopsy, core-needle biopsy, or frozen-section diagnosis at the time of surgery. An FNA sample that is positive for adenocarcinoma could, however, provides a preliminary diagnosis and guides subsequent management.

Patients with palpable solid masses can have a biopsy of the mass in the office with use of a Tru-Cut 14.gauge biopsy device. The breast is prepped sterilely, and a local anesthetic is used to infiltrate the skin. A small nick is made in the skin with a scalpel to accommodate the biopsy instrument. A core biopsy of the solid mass is obtained. The instrument has a "firing range" and therefore should be kept parallel to the chest wall to avoid penetrating trauma. The specimen is placed in formalin and sent for pathologic examination. It is believed that if the specimen "floats" in the solution, it is likely nondiagnostic fat. Tumor specimens have a grayish appearance and typically "sink" in the solution.

Needle Localization and Excision

Needle localization is a technique that allows surgical excision of a lesion that is nonpalpable. The technique uses a hook and wire system to target the lesion, and image guidance can be provided by mammography; ultrasonography; and, in some cases, MRI. In mammography-guided needle localization, coordinates of the lesion are obtained by placing the breast in an alphanumeric grid. The needle is inserted and, when adequate placement is noted, the hook wire is deployed and the needle removed. Two mammographic views are then obtained.

The mammography films are available intraoperatively and show the relationship between the lesion and localizing hook. Excision with needle localization allows the surgeon to minimize the amount of breast tissue removed by following the needle to the targeted lesion. After removal, a specimen radiograph is obtained to ensure that successful removal of the lesion has been performed. Radiologists and surgeons experienced in needle localization and excisions report only 0.2% to 0.3% of lesions missed with this approach. The specimen radiograph helps to ascertain the lesion was not missed.

Another variation of this approach to excising nonpalpable lesions is the use of a radioactive seed, which involves a small titanium seed (4×0.8 mm) that is labeled with iodine-125 and placed in a similar fashion to the needle localization. Use of an intraoperative handheld gamma probe allows for accurate excision on the lesion, which is similarly radiographed to ensure retrieval of the lesion and the radioactive seed. It has advantages over needle localization because the placement of the radioactive can be performed several days before the procedure, which can improve flexibility with regards to scheduling.

Image-guided Percutaneous Breast Biopsy

With the current advancements available in breast imaging, percutaneous image-guided breast biopsy is increasingly being used as an alternative to surgical biopsy. Percutaneous biopsy methods differ with respect to the method of imaging guidance and the tissue-acquisition device used. The use of image-guided percutaneous biopsy has advantages over surgical excision for the diagnosis of breast lesions. It is less invasive, and because less tissue is removed, it will result in less scarring on subsequent mammograms. Regardless of whether the diagnosis is benign or malignant, the patients who have percutaneous biopsies will undergo fewer operations. In addition, in cases of malignancy, the discussion and surgical treatment plan can be streamlined. The choice of which image-guided modality to use depends on the lesion. Stereotactic biopsy is best for calcifications. If a lesion is seen on ultrasonography, it is best to use that modality because it is easier to use and has been reported to be less costly.

Stereotactic Biopsy

Stereotactic-guided core needle biopsy uses specialized mammography equipment to calculate the location of a lesion in three dimensions. Stereotactic biopsy can be performed with the patient prone on a dedicated table or with the patient sitting in an upright unit. Some patients may not be candidates for this approach. A patient may be too large to be accommodated by the system. The thickness of the breast must be adequate to accommodate to the automated biopsy device. Abnormalities just under the skin may also pose technical problems. A vague asymmetric density or diffuse group of widely separated calcifications may present difficulties. Patients who cannot remain prone or are unable to cooperate for the 20- to 40-minute duration of the procedure may not be candidates.

An automated core needle or directional vacuum-assisted biopsy probe is used to obtain the tissue specimens. Multiple tissue specimens are obtained for pathologic analysis. Many reports in the medical literature state the procedure has a sensitivity of 70% to 100% and a specificity of 85% to 100%. Studies have shown 99% accuracy with a 14-gauge needle obtaining five specimens. Radiography should be performed

routinely on women with specimens of breast microcalcifications to determine whether calcifications were obtained.

Ultrasound-guided Biopsy

The use of ultrasound imaging for percutaneous biopsy of lesions seen on ultrasonography has certain advantages. For example, it requires no specialized equipment, requires no radiation exposure, and has the ability to sample areas that may be inaccessible with stereotactic biopsy (eg, the axilla). A 14-gauge automated needle is used, and real-time imaging allows accurate positioning. Multiple tissue core samples are sent for pathologic analysis. Consideration to placement of a clip to demarcate the area of biopsy is necessary, particularly in cases in which neoadjuvant chemotherapy will be considered.

Tissue-acquisition Devices

Available tissue-acquisition devices include fine needles, automated core needles, directional vacuum-assisted probes, and biopsy cannulas. Excellent results have been obtained using the 14-gauge automated needle for biopsy of masses under ultrasound or stereotactic guidance. Most centers use larger tissue-acquisition devices instead of fine needles because of accuracy of tissue diagnosis when a larger volume of tissue is obtained. Compared with the automated needle, the vacuum device acquires larger samples of tissue, has a higher frequency of retrieval of calcifications, and may provide more accurate lesion characterization. Accurate placement of a localizing clip through the biopsy probe is necessary to facilitate subsequent localization if needed.

Surgical Excision and Breast Biopsy

A biopsy can be performed on an outpatient basis under local anesthesia in the majority of patients. It is important to choose the appropriate incision and location. Unless the lesion is close to the nipple or suspected to be a fibroadenoma, the incision should be made in close proximity to the mass and not circumareolar. The surgeon should keep in mind the possibility of subsequent mastectomy when placing the incision. Many times, the biopsy is part of the treatment. The specimen should be adequately oriented for margin analysis by the pathologist and also sent for the appropriate markers such as estrogen-receptor (ER) and progesterone-receptor (PR) status and HER2/neu. Orientation of the specimen is important because a reexcision of an involved margin may need to be subsequently performed.

The incision should be closed with fine suture material with a subcuticular closure. Hemostasis needs to be ascertained before closing and is usually achieved with electrocautery. Weck clips can be placed in the cavity bed if a diagnosis of breast cancer is known and breast conservation is planned. No particular immobilization is required, but a good support bra is recommended to minimize hematoma, induration, and discomfort.

Certain benign lesions on core needle biopsy have a relatively high incidence of coexisting carcinoma found on subsequent surgical excision. The small volume of tissue obtained on core needle biopsy in these cases may not be adequate to rule out cancer. Atypical ductal hyperplasia is the most commonly encountered of these lesions. About 25% of atypical ductal hyperplasia on the core biopsy specimen will have carcinoma on excisional biopsy. Radial scars are reported to have a coexistent carcinoma in 20% and therefore also require surgical excision. The tissue obtained from a core needle biopsy may not be concordant with the imaging findings. In a study by Dershaw and colleagues, repeated biopsy for nonconcordance found carcinoma in 47% of cases. Lesions yielding ALH or lobular carcinoma in situ (LCIS) at core needle biopsy with imaging-histologic discordance warrant surgical excision because they have a high rate of cancer in these lesions (38%; 95% CI 9%–76%) on excision. Core needle biopsy with imaging-histologic concordance of ALH or LCIS, the cancer rate was significantly lower (3%; 95% CI 0%–9%); therefore, these do not always mandate surgical excision unless imaging is discordant with pathologic findings.

EPIDEMIOLOGY OF BREAST CANCER

Table 14.9 lists major risk factors for breast cancer.

RISK FACTORS AND ASSESSMENT

Age

The incidence of breast cancer increases with age. Age is the most significant risk factor for breast cancer.

Family History

Hereditary breast cancers account for 5% to 10% of all breast cancers and are thought to be attributable to highly penetrant mutations in breast cancer–susceptibility genes. Two such tumor-suppressor genes, *BRCA1* and *BRCA2*, have been well characterized. Breast cancer has also been noted to occur in association with other cancers, such as in Li-Fraumeni syndrome and Cowden syndrome.

Prospective data from the Nurses' Health Study noted that the risk of breast cancer doubled among women whose mother had breast cancer diagnosed before the age of 40 years or who

TABLE 14.9 Major Risk Factors for Breast Cancer

Older age
Family history of breast cancer
Benign breast disease
Proliferative changes
Atypical hyperplasia
Endogenous endocrine factors
Early menarche
Late menopause
Long menses duration
Nulliparity
Late maternal age at first pregnancy
Exogenous hormones?
Oral contraceptives
Estrogen replacement therapy

had a sister with breast cancer. The risk decreased with advanced maternal age; however, it remained elevated even with maternal diagnosis at age 70 years (RR 1.5; 95% CI 1.1–2.2). The data did show that the risk associated with a mother or sister with history of breast cancer is smaller than previously suggested. In the population of middle-aged women, the authors found that only 2.5% of breast cancer cases were attributed to a positive family history. In the large Cancer Prevention Study II by the ACS, the authors evaluated the association of fatal breast cancer and family history. They found that family history of breast cancer in a mother or sister was significantly related to fatal breast cancer risk after multivariate analysis. Association was significantly modified by age with a risk ratio of almost 5 in women younger than 40 years at enrollment compared with 1.28 in women aged 70 years or older.

Personal History

A patient's history of prior breast biopsy is important. Although the number of breast biopsies undergone does not increase a woman's risk of breast cancer, certain pathologic entities do play a role. Atypical ductal or lobular hyperplasia and LCIS are considered markers of increased risk of developing invasive breast cancer. A personal history of breast cancer increases the risk for development of another breast cancer. Women treated for breast cancer are at risk for the development of a contralateral breast cancer. Various studies have shown this risk to be between 0.5% and 1.0% per year. In addition, patients treated with breast conservation (lumpectomy and radiation therapy) are at risk for an ipsilateral recurrence. In these women, this risk could be 10% at 10 to 15 years posttreatment.

Reproductive History

Early menarche, late menopause, and nulliparity are thought to be risk factors for breast cancer. Age at first pregnancy is also thought to be an RR factor for breast cancer.

Early age at first pregnancy is often associated with a lower risk for breast cancer. For a woman younger than 19 years of age at first full-term birth, a 50% reduction in the risk of breast cancer compared with that of a nulliparous woman is predicted. If the first full-term pregnancy occurs at age 30 to 34 years, the risk of breast cancer is approximately the same as that noted in nulliparous women. Pregnancy in women after age 35 years is associated with an increased risk compared with that of a nulliparous woman. Pregnancies that are not full term do not show this protection.

Some have suggested that the time interval between the onset of menarche and the first full-term pregnancy is the important factor with regard to the endocrine milieu. This importance has a possible explanation in the "estrogen open window hypothesis." There is, however, some inconsistency in reported data in regard to relationship of age at first full-term pregnancy. The association depends somewhat on control subjects used, and later studies have suggested a less strong association.

Breastfeeding has been reported to reduce risk of breast cancer. Studies in the United States have suggested only a weak protective effect and do not demonstrate an association between reduction in risk and duration of breastfeeding.

The effect of menopause as it relates to breast cancer risk has been examined. Late menopause poses an increase in risk of breast cancer. Early exposure to the hormone milieu is thought by some to be an important etiologic factor. In one large international case-control study, it was noted that for each 2-year delay in the onset of menstruation, breast cancer risk was reduced by about 10%. **The later a woman's menopause occurs, the higher her risk for breast cancer.** For every 5-year difference in age at menopause, the risk for breast cancer changes about 17%. The effect of this later age at menopause in regard to increasing breast cancer is not seen for 10 to 20 years after menopause. It has been suggested that the total duration of menstruation may also be important because the risk increases in the woman who has menstruated more 30 years compared with those who have had less than 30 years of menstruation. Among women who have undergone a natural menopause, the risk among those whose menopause occurred at age 55 years is about twice that of women whose menopause occurred before age 44 years.

Data from observational studies demonstrate that bilateral oophorectomy before natural menopause has been reported to reduce risk of breast cancer compared with those who had a later natural or artificial menopause.

Exogenous Hormone Use

The role of exogenous estrogens in the promotion of breast cancer is still controversial. Studies of OCPs and HRT have yielded conflicting results. Studies of HRT and breast cancer risk indicate that women who are currently using HRT are at increased risk for breast cancer development. A meta-analysis of the largest studies, however, suggests that the increased risk is only about 10%. Women who have taken HRT in the past but are not currently using HRT are not at increased risk. Long-term use of HRT (>10 years) has been associated with a relative increase in breast cancer risk, and the highest risk was noted in those patients using HRT with progestins (RR, 1.41). Of note, multiple studies have shown that patients who develop breast cancer while taking HRT have smaller, less aggressive cancers and a lower risk of death from breast cancer.

Results from the Women's Health Initiative (WHI) RCT were reported. Between 1993 and 1998, 16,609 women with intact uteruses were randomly assigned to receive combination HRT (0.625 mg/day conjugated equine estrogens and 2.5 mg/day medroxyprogesterone acetate) or placebo. The planned duration of the trial was 8.5 years; however, the data and safety monitoring board of the committee recommended halting the trial because the incidence of invasive breast cancer had exceeded the stopping boundary that had been set at the initiation of the trial. This occurred after a mean of 5.2 years of follow-up. The increased risk of breast cancer reported hazard ratio (HR) was 1.25 (95% CI 1.00–1.59). There was also a reported increased risk of coronary heart disease (HR, 1.29; 95% CI 1.02–1.63) and stroke (HR, 1.41; 95% CI 1.39–3.25). Beneficial effects included decreased risk in colorectal cancer (HR, 0.63; 95% CI 0.43–0.92) and hip fracture (HR, 0.66; 95% CI 0.45–0.98). Based on the data, the safety monitoring board initially did not recommend stopping the estrogen-alone arm in women who had had

a hysterectomy. Results of the estrogen-only arm and the WHI study have been reported. The study included 10,739 postmenopausal women (aged 50–79 years) with prior hysterectomy. These women were randomly assigned to receive 0.625 mg/day of conjugated equine estrogen or placebo. In February 2004, the National Institutes of Health decided to terminate the intervention phase of the estrogen-only study, which had been scheduled for a close-out interval of October 2004 to March 2005. With an average follow-up of 6.8 years, there was an increased risk of stroke (HR 1.39; 95% CI 1.10–1.77), a decreased risk of hip fracture (HR 0.61; 95% CI 0.41–0.91), and no effect on coronary heart disease incidence (HR 0.91; 95% CI 0.75–1.12). The investigators noted a possible reduction in breast cancer risk (HR 0.77; 95% CI 0.59–1.01) that warrants further investigation.

The annual increased risk for an individual woman is still relatively small. The increased risk for breast cancer is apparent after 4 years of HRT use. ACOG stresses the importance of addressing the reasons for initiating or continuing on HRT. It is no longer recommended to prevent heart disease in healthy women (primary prevention) or to protect women with preexisting heart disease (secondary prevention). In addition, it is no longer recommended solely for prevention of osteoporosis.

HRT is highly effective in treating vasomotor symptoms with limited effective alternative therapies. In this setting, short-term use (<5 years) can be considered because data on short-term use do not show an increased association with breast cancer. Attitudes of obstetricians and gynecologists toward hormone therapy after the WHI results were published were surveyed. Respondents to the survey remained skeptical of the results; 49.1% did not find them convincing. There was strong support for the use of HRT for vasomotor symptoms, vaginal dryness, and osteoporosis, but most of the physicians surveyed did not find it useful for prevention of cardiovascular disease or dementia.

In the past, most studies addressing OCP use and breast cancer risk concluded that there was a significant increase in risk associated with OCP use. However, the majority of studies regarding OCP use and breast cancer risk have demonstrated little association with breast cancer incidence rates. In women who have used OCPs for extended periods (>10 years), a minimal, nonsignificant increase in breast cancer cases has been reported, seen most commonly in the group of women who began using OCPs at a young age (<20 years). Past or present use of OCPs at the time of diagnosis of breast cancer does not affect mortality from breast cancer. The presence of a family history of breast cancer does not appear to further increase the risk of breast cancer associated with either OCP or HRT use.

Prior Exposure to Radiation Therapy

Exposure to ionizing radiation, such as that which occurs in treatment with mantle radiation for Hodgkin disease, poses a risk for breast cancer. This is noted 7 to 10 years after completion of radiation therapy. The cumulative probability of breast cancer at age 40 years approaches 35% in these women. The risk of breast cancer associated with radiation exposure decreases with increasing age at exposure.

Other Factors

Breast cancer is more frequent in Jewish women than in non-Jewish women and more frequent in black women than in white women. Women of Ashkenazi Jewish descent have a 1 in 40 (2.5%) risk of carrying a mutation in *BRCA1* and *BRCA2* genes, thus accounting for the increased risk in these women. Asian women have a low incidence of breast cancer. Japanese women show lower rates of breast cancer than white women. Although postmenopausal breast cancer is less common in Japanese women who have migrated to Western countries than among the general populations of these countries, after two or three generations, the incidences of breast cancer in these women approach that of white women. The Western diet, with its increased intake of animal fat, has been implicated in these studies.

Alcohol consumption has been reported to increase breast cancer risk in a dose-related manner. Women who drink approximately one drink per day have a slightly elevated risk of breast cancer over nondrinkers. This risk is significantly higher with moderate to high alcohol consumption (two to five drinks per day).

Relative Risk

Relative risk is a ratio that depicts the likelihood over time of an event's occurrence in a study population relative to that in a reference population. It is often used to quantify risk factors for breast cancer. Absolute risk is a percentage that depicts the likelihood over time of the occurrence of an event. For rare events, these two are the same, but for common events, they are not. It is best to discuss risk with patients in terms of absolute rather than RR.

Several models exist to estimate a woman's risk of breast cancer. The Gail model, developed for use in the National Surgical Adjuvant Breast and Bowel Project (NSABP P-1) Breast Cancer Prevention Trial, is available from the NCI and provides a measurement of absolute risk over time for breast cancer. However, in familial-type hereditary cases, it underestimates the risk of breast cancer by overlooking age at onset, bilaterality of disease among affected family members, and breast cancer in non-first–degree relatives (Table 14.10). The Tyrer-Cuzick (IBIS) model is another risk assessment tool that incorporates these aspects of family history, endogenous hormonal factors, benign disease, risk factors such as age and body mass index, as well as genetic factors (including *BRCA* mutations) into a single statistical model.

BRCA1 and BRCA2

BRCA1 and *BRCA2* are breast cancer-susceptibility genes that have expanded our knowledge of familial breast cancer. Linkage studies done in 1990 in early-onset breast cancer families led to cloning of the *BRCA1* gene at the University of Utah in Salt Lake City in 1994. The *BRCA1* gene consists of 22 coding exons distributed over approximately 100 kb of genomic DNA on chromosome 17q21. It is thought to be responsible for approximately 45% of early-onset hereditary breast cancers and nearly 90% of hereditary ovarian cancers in families with a high

TABLE 14.10 Breast Cancer Risk Factors

PERSONAL AND FAMILY HISTORY FACTORS WITH A RELATIVE RISK OF >4.0
Certain inherited genetic mutations for breast cancer
Two or more first-degree relatives with breast cancer diagnosed at an early age
Personal history of breast cancer
Age (≥65 years versus <65 years, although risk increases across all ages until age 80 years)
PERSONAL AND FAMILY HISTORY FACTORS WITH A RELATIVE RISK OF 2.1–4.0
One first-degree relative with breast cancer
Nodular densities seen on mammogram (>75% of breast volume)
Atypical hyperplasia
High-dose ionizing radiation administered to the chest
Ovaries not surgically removed before age 40 years
PERSONAL AND FAMILY HISTORY FACTORS WITH A RELATIVE RISK OF 1.1–2.0
High socioeconomic status
Urban residence
Northern US residence
REPRODUCTIVE FACTORS THAT INCREASE RELATIVE RISK
Early menarche (<12 years)
Late menopause (≥55 years)
No full-term pregnancies (for breast cancer diagnosed at age 40+ years)
Late age at first full-term pregnancy (≥30 years)
Never breastfed a child
OTHER FACTORS THAT AFFECT CIRCULATING HORMONES OR GENETIC SUSCEPTIBILITY
Postmenopausal obesity
Alcohol consumption
Recent hormone replacement therapy
Recent oral contraceptive use
Being tall
Personal history of cancer of endometrium, ovary, or colon
Jewish heritage

Data from American Cancer Society. *Breast cancer facts & figures 2001–2002*. Atlanta, 2001, Author; Hulka BS, Stark AT. Breast cancer: cause and prevention. *Lancet* 1995;346:883 and Kelsey JL. Breast cancer epidemiology: summary and future directions. *Epidemiol Rev* 1993;15:256.

TABLE 14.11 National Comprehensive Cancer Network (NCCN) Guidelines for Recommending Genetic Testing for *BRCA1* or *BRCA2* Mutations*

Personal history of breast cancer and one or more of the following:

- Diagnosed at age 45 years or younger
- Diagnosed with at least two breast cancer primaries (bilateral, separate ipsilateral), the first at age 50 years or younger
- Diagnosed at age 50 years or younger with one or more close relatives† with breast cancer (prostate or pancreatic) at any age
- Diagnosed with triple-negative breast cancer at age 60 years or younger
- Diagnosed at any age with one or more close relatives with breast cancer at age 50 years or younger
- Diagnosed at any age with two or more close relatives at any age
- Diagnosed at any age with one or more close relatives with invasive ovarian cancer (including fallopian tube and primary peritoneal) at any age
- Diagnosed at any age with two or more close relatives with pancreatic and/or prostate cancer
- Having a close male relative with breast cancer at any age

*Individuals with a limited or unknown family history may have an underestimated probability of a familial gene mutation detection.
†Close relative pertains to first-, second- or third degree blood relatives on the same side (either maternal or paternal) of the family.

incidence of breast and ovarian cancers. Two specific mutations, 185delAG and 5382insC, are present in approximately 1.00% and 0.25% of the Ashkenazi Jewish population, respectively. They are thought to be founder mutations (ie, an altered gene or genes seen with a high frequency in a population originating from a small ancestral group, one or more of whose founders were carriers of the mutant gene).

BRCA2 was isolated on chromosome 13q12-13 in 1995. The *BRCA2* gene is composed of 26 coding exons distributed over approximately 70 kb of genomic DNA. This gene appears to account for 35% of families with early-onset breast cancer. It confers a lower risk of ovarian cancer compared with breast cancer. A single mutation, 6174delT, is found in approximately 1.4% of the Ashkenazi Jewish population. Together, both *BRCA1* and *BRCA2* mutations are found in approximately 1 in 40 Ashkenazi Jewish individuals. For both genes, the estimated penetrance is 70% to 90% for breast cancer by age 70 years, but the risk of breast cancer by age 50 years may be lower for *BRCA2* mutations.

The likelihood of a patient having a *BRCA1* or *BRCA2* mutation depends on certain factors, such as age at the time of diagnosis of breast or ovarian cancer and the number and age of first- and second-degree relatives in the same parental lineage and ethnicity with breast or ovarian cancer. The parental lineage can be either maternal or paternal. The National Comprehensive Cancer Network (NCCN) guidelines recommend testing in patients with a personal history of breast cancer and one other risk factor such as bilaterality, other family members with breast or ovarian cancer, or any male breast cancers in the family (Table 14.11). In patients with a personal history of breast cancer and Ashkenazi Jewish heritage, no additional family history may be needed to meet testing criteria. The decision to undergo genetic testing is a complex one because it can affect an individual's personal, psychological, social, financial, and ethical well-being.

Women who have a negative genetic test result should still be considered at risk on the basis of age and environment and because of the possibility of other genetic factors or unknown mutations.

Natural History

The most common site of origin of breast cancer is the upper-outer quadrant (38.5%) followed by the central area (29%),

upper-inner quadrant (14.2%), lower-outer quadrant (8.8%), and lower-inner quadrant (5%). These percentages correlate with the amount of tissue that is present in these quadrants. Metachronous bilateral carcinoma of the breast has been observed in 5% to 8% of patients.

Metastasis to the ipsilateral axilla is the most common route of spread. Metastasis to the internal mammary nodes is more frequent with inner-quadrant lesions and is more likely to occur when involvement of the axillary nodes is also present.

PATHOLOGY

Ductal Carcinoma In Situ

Ductal carcinoma in situ (DCIS) is an abnormal proliferation of malignant epithelial cells within the mammary ductal–lobular system without invasion into the surrounding stroma. It is classified as a heterogenous group of lesions with different growth patterns and cytologic features. Classification of DCIS has traditionally been based on architectural pattern. The most common types are comedo, cribriform, micropapillary, papillary, and solid. The increased use of screening mammography during the past 2 decades has led to a marked increase in the number of patients with a diagnosis of DCIS, and in many centers today, one DCIS is diagnosed for every two or three mammographically detected invasive breast cancers. **Today about 85% of all DCIS are detected solely based on mammography.** Age-specific time trends illustrate that the greatest increase has been in women older than 40 years who are more likely to have mammography. In 1980, only 2% of 10,000 cancer cases were DCIS. Between 1973 and 1992, age-adjusted DCIS incidence increased almost sixfold, but the incidence of invasive cancer has increased only by one-third. This increase is almost entirely a result of mammography screening. Indeed, autopsy series suggest that latent DCIS is relatively common, ranging from 6% to 18% of women who died of causes other than breast cancer. The natural history of DCIS is only partially understood, particularly for small, mammographically detected lesions. The microcalcifications in DCIS are most often secondary to calcification of necrotic cellular debris within the involved ducts, and their extent and characteristics are better defined with magnification views of the microcalcification.

The potential of DCIS to progress to invasive breast cancer is an unresolved issue. Because DCIS has historically been treated with mastectomy, little information on the risk of progression to invasive disease is available. The retrospective study by Page and colleagues of benign breast biopsy specimens revealed 25 patients who were subsequently identified with DCIS; seven (28%) had progressed to invasive disease during the period of observation. When recurrences occur after breast-conserving surgery for DCIS, half of the recurrences are invasive, and half are further in situ disease, suggesting that there is a progression pathway from DCIS to invasive disease.

Paget's Disease

Paget disease is involvement of the nipple with intraductal carcinoma. In the absence of a palpable mass, invasive carcinoma occurs in less than 40% of cases. The malignant cells are large and pale-staining, and are seen in the basal layer and upper portions of the epidermis. Diagnosis is made through a nipple biopsy.

Lobular Carcinoma In Situ

Foote and Stewart initially described LCIS in 1941 as a noninvasive lesion arising from the lobules and terminal ducts of the breast. LCIS is characterized by a solid proliferation of small cells with round to oval nuclei that distort the involved spaces in the terminal duct–lobular units. Three important features of LCIS are as follows:

1. It is usually an incidental microscopic finding that is not detected clinically or by gross pathologic examination.
2. It is multicentric, and the associated cancer may be ductal or lobular.
3. The risk for subsequent cancer is the same for both breasts.

It is unfortunate that Foote and Stewart chose the name they did because it has led to a great deal of confusion over the past several decades. LCIS is a marker for breast cancer risk and is not a malignant finding.

Pleomorphic LCIS or LCIS with necrosis, as opposed to classic LCIS, is of unknown clinical significance and is an area of clinical controversy. It is generally accepted to be a risk factor for invasive disease, as with classic-type LCIS. However, there is a suspicion that pleomorphic LCIS may carry a higher risk of progression to invasive disease because of its histopathologic similarities with those of DCIS. It is generally recommended that pleomorphic LCIS should be considered a nonobligate precursor to invasive disease and managed in a similar way to DCIS, although this is largely based on those histopathologic similarities rather than studies providing evidence on clinical outcomes. Excision to negative margins is usually recommended.

Invasive Duct Carcinoma

Invasive duct carcinoma is the most common group of malignant mammary tumors and comprises 65% to 80% of all mammary carcinomas. Included in this group are special subtypes: tubular, medullary, metaplastic, mucinous (colloid) papillary, and adenoid cystic carcinoma. Each subtype constitutes only 1% to 2% of all invasive breast cancers, except medullary carcinoma, which constitutes 7%, and the rare adenoid cystic carcinomas, which constitute less than 0.1%.

Many of these subtypes, such as tubular and medullary carcinomas, carry an excellent prognosis. Metaplastic carcinomas, however, often have aggressive behavior. These tumors are characterized by the presence of homologous (epithelial) or heterologous (mesenchymal) elements. Two types have been described: squamous and pseudosarcomatous metaplasia.

Invasive duct carcinoma not otherwise specified is a generic term that includes tumors that may express more than one element of the specific forms of duct carcinoma.

Infiltrating Lobular Carcinoma

Infiltrating lobular carcinoma has been reported to constitute 10% to 14% of invasive carcinomas. These carcinomas are characterized by uniform cells with small, round nuclei and limited cytoplasm. The presence of intracytoplasmic mucin

vacuoles often gives the cells the appearance of signet-ring cells. The cells tend to grow circumferentially around ducts and lobules with a linear arrangement. This pattern is referred to as "single-file" or targetoid growth. There is often an associated desmoplastic stromal reaction.

Inflammatory Carcinoma

Inflammatory carcinoma is characterized by cutaneous findings present with an underlying invasive carcinoma. Usually the invasive tumor is a poorly differentiated infiltrating duct carcinoma. Upon microscopic evaluation, skin involvement often reveals tumor emboli in dermal lymphatics with an associated lymphocytic reaction in the dermis.

Metastases From Extramammary Tumors

The most common primary site of an occult extramammary tumor is the lung. Other primary sites include the ovaries, uterus, kidneys, and stomach. In those previously diagnosed, melanoma, prostate, cervix, uterus, and urinary bladder are the most common sites. Metastatic ovarian cancer may simulate papillary or mucinous carcinoma of the breast. A workup and history are often helpful in difficult cases. Often, identification of an in situ component helps to provide definitive evidence of a mammary origin.

BIOLOGIC MARKERS AND PROGNOSTIC FACTORS

Axillary Lymph Node Status

The most important prognostic factor is nodal status. The presence of metastasis and the number of lymph nodes involved is significant and correlates with local failure and distant metastases. It is predictive of overall survival.

Tumor Size

Tumor size correlates with the incidence of lymph node metastases. The size of the tumor is also important, even in the absence of lymph node involvement. Patients with tumors smaller than 1 cm in size, or with good histologic types measuring smaller than 3 cm, do very well.

Histologic Grade

Histologic grade also correlates with breast cancer outcome. Poorly differentiated tumors have been associated with more aggressive behavior.

Molecular Profiling

Molecular classification of breast cancer into different subtypes can be used to stratify breast cancers into different groups. The luminal subtype makes up the hormone receptor–expressing breast cancers. Generally, these have overall better prognosis than the other groups currently identified. The HER2/neu subtypes make up the tumors with HER2/neu overexpression. These subtypes confirm the clinical impression that tumors with HER2/neu overexpression are more aggressive tumors, are more likely to be grade III, and have a higher degree of concomitant *TP53* mutations. The basal-like subtype of breast cancer was named because of the similarity in expression pattern of this subtype to that of basal epithelia cells. Basal subtypes lack estrogen-receptor expression, have low HER2/neu expression, and are more likely to be aggressive tumors. Patients with *BRCA1* mutations have preponderance to this subtype of tumor. Multiple studies have demonstrated that this subtype often carries a poor prognosis because this subtype is more likely than other subtypes to have tumors that are grade III and that have TP53 mutations.

Hormone Receptors

The estrogen and progesterone receptors can be measured by immunohistochemical (IHC) studies using monoclonal antibodies directed against the receptors. Positivity correlates with response to endocrine therapy and better prognosis.

HER2/neu

HER2/neu is an oncogene whose protein product may function as a growth factor receptor. It can be detected by IHC demonstration of the protein product or by gene amplifications. Overexpression or amplification has been shown to correlate with a poor prognosis; however, the studies differ with regard to the method of detection used and the interpretation of results. HER2/neu overexpression has been used as a predictor of response to certain chemotherapeutic agents. Particularly, increased response to doxorubicin-based therapy has been reported in the treatment of patients with positive nodes and overexpression of HER2/neu.

p53

A tumor-suppressor gene, p53 has a protein product that is a nuclear transcription factor with many functions, including regulation of the cell cycle and apoptosis. Most clinical studies have used IHC to study protein expression. Accumulation of p53 protein has been reported to correlate with reduced survival in some studies.

STAGING OF BREAST CANCER USING THE TUMOR–NODE–METASTASIS SYSTEM

The American Joint Committee on Cancer (AJCC) determines staging of breast cancer. The AJCC staging system is a clinical and pathologic staging system based on the tumor–node–metastasis (TNM) system. The 2009AJCC staging system incorporated sentinel node staging. It distinguishes micrometastasis from isolated tumor cells on the basis of size and histologic evidence of malignant activity. In the current AJCC staging system, supraclavicular lymph node metastasis is now classified as N3 disease rather than M1 disease, as in the old system (Tables 14.12 and 14.13).

TREATMENT OF BREAST CANCER

Most patients with intraductal carcinoma and stage I and stage II breast cancer have the options of breast-conservation therapy and mastectomy. For patients with invasive breast cancer, the

TABLE 14.12 American Joint Committee on Cancer Staging for Breast Cancer

DEFINITION OF TNM

Primary tumor (T): Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1 cm increment.

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis (Paget)	Paget disease of the nipple NOT associated with invasive carcinoma and/or carcinoma in situ (DCIS and/or LCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget disease are categorized based on the size and characteristics of the parenchymal disease, although the presence of Paget disease should still be noted.
T1	Tumor ≤20 mm in greatest dimension
T1mi	Tumor ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
T2	Tumor >20 mm but ≤50 mm in greatest dimension
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall and/or to skin (ulceration or skin nodules)
T4a	Extension to chest wall, not including only pectoralis muscle adherence or invasion
T4b	Ulceration and/or ipsilateral satellite nodules and/or edema (including peau d'orange) of the skin, which do not meet the criteria for inflammatory carcinoma
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma

REGIONAL LYMPH NODES: CLINICAL

NX	Regional lymph nodes cannot be assessed (eg, previously removed)
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral level I, II axillary lymph nodes(s)
N2	Metastases in ipsilateral level I, II axillary lymph nodes that are clinically fixed or matted; or in clinically detected* ipsilateral internal mammary nodes in the absence of clinically evident lymph node metastases
N2a	Metastasis in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastasis only in clinically detected* ipsilateral internal mammary nodes and in the absence of clinically evident level I, II axillary lymph node metastasis
N3	Metastases in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement or in clinically detected* ipsilateral internal mammary lymph node(s) with clinically evident level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)

PATHOLOGIC (PN)†

pNX	Regional lymph nodes cannot be assessed (eg, previously removed, or not removed for pathologic study)
pN0	No regional lymph node metastasis identified histologically *Note:* Isolated tumor cells clusters (ITCs) are defined as small clusters of cells not greater than 0.2 mm, or single tumor cells, or a cluster of <200 cells in a single histologic cross-section. ITCs may be detected by routine histology or by immunohistochemical (IHC) methods. Nodes containing only ITCs are excluded from the total positive node count for purposes of N classification but should be included in the total number of nodes evaluated.
pN0(i–)	No regional lymph node metastasis histologically, negative IHC
pN0(i+)	Malignant cells in regional lymph node(s) no greater than 0.2 mm (detected by H&E or IHC including ITC
pN0(mol–)	No regional lymph node metastasis histologically, negative molecular findings (RT-PCR)
pN0(mol+)	Positive molecular findings (RT-PCR) but no regional lymph node metastases detected by histology or IHC
pN1	Micrometastases or metastases in 1–3 axillary lymph nodes and/or in internal mammary nodes with metastases detected by SLNB but not clinically detected‡
pN1mi	Micrometastases (>0.2 mm and/or > 200 cells but none greater than 2.0 mm)
pN1a	Metastases in 1–3 axillary lymph nodes, at least one metastasis >2.0 mm
pN1b	Metastases in internal mammary nodes with micrometastases or macrometastases detected by SLNB but not clinically detected‡
pN1c	Metastases in 1–3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLNB but not clinically detected
pN2	Metastases in 4–9 axillary lymph nodes or in clinically detected§ internal mammary lymph nodes in the absence of axillary lymph node metastases
pN2a	Metastases in 4–9 axillary lymph nodes (at least one tumor deposit greater than 2.0 mm)
pN2b	Metastases in clinically detected§ internal mammary lymph nodes in the absence of axillary lymph node metastases

TABLE 14.12 American Joint Committee on Cancer Staging for Breast Cancer—cont'd

pN3	Metastases in 10 or more axillary lymph nodes; or in infraclavicular (level III axillary) lymph nodes; or in clinically detected[§] ipsilateral internal mammary lymph nodes in the presence of one or more positive level I, II axillary lymph node(s); or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLNB but not clinically detected[‡]; or in ipsilateral supraclavicular lymph nodes
pN3a	Metastases in 10 or more axillary lymph nodes (at least one tumor deposit >2.0 mm); or metastases to the infraclavicular (level III axillary) lymph nodes
pN3b	Metastases in clinically detected[§] ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected[§]
pN3c	Metastasis in ipsilateral supraclavicular lymph nodes
	DISTANT METASTASIS (M)
M0	No clinical or radiographic evidence of distant metastases
cM0(i+)	No clinical or radiographic evidence of distant metastases but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastases
M1	Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven >0.2 mm

*Clinically detected is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine-needle aspiration (FNA) biopsy with cytologic examination. Confirmation of clinically detected metastatic disease by FNA without excision biopsy is designated with an (f) suffix, for example, cN3a(f). Excisional biopsy of a lymph node or biopsy of a sentinel node, in the absence of assignment of a pT, is classified as a clinical N (eg, cN1). Information regarding the confirmation of the nodal status will be designated in site-specific factors as clinical, FNA, core biopsy, or sentinel lymph node biopsy (SLNB). Pathologic classification (pN) is used for excision or SLNB only in connection with a pathologic T assignment.
†Classification is based on axillary lymph node dissection with or without SLNB. Classification based solely on SLNB without subsequent axillary lymph node dissection is designated (sn) for "sentinel node," for example, pN0(sn).
‡"Not clinically detected" is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.
§"Clinically detected" is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on FNA biopsy with cytologic examination.
RT-PCR, Reverse transcriptase-polymerase chain reaction.

Stage IIIB	T4, N0, M0
	T4, N1, M0
	T4, N2, M0
Stage IIIC[†]	Any T, N3, M0
Stage IV	Any T, Any N, M1

*T1 includes T1mic.
†Stage IIIC breast cancer includes patients with any T stage who have pN3 disease. Patients with pN3a and pN3b disease are considered operable and are managed as described in the section on stage I, II, IIIA, and operable IIIC breast cancer. Patients with pN3c disease are considered inoperable and are managed as described in the section on inoperable stage IIIB or IIIC or inflammatory breast cancer.
From Edge SB, Byrd DR, Compton CC, et al. *AJCC cancer staging manual*, 7th e. New York, 2009, Springer.

axillary nodes can be addressed with a sentinel lymph node (SLN) biopsy and, possibly, an axillary dissection. For patients with more extensive disease, a mastectomy may be necessary. The use of postmastectomy chest-wall irradiation in these patients may also be considered.

Surgery

Mastectomy

William Halsted performed a radical mastectomy in 1894. The guiding principle at this time was centered on the belief that cancer originates in the breast and spreads in a stepwise fashion to the regional lymph nodes first and then to distant sites. Removal of all the breast tissue, pectoral muscles, and axillary contents was the standard surgical treatment. Over the next several decades, two simultaneous trends existed. One involved less radical surgery, which included removal of the breast and axillary contents but preserved the pectoral muscles and more skin. This was described by Patey and Dyson in 1948 and is the modern-day modified radical mastectomy. The other trend involved more extensive surgery, the extended radical mastectomy, which included en-bloc removal of the internal mammary chain at the time of radical mastectomy. Retrospective studies found that survival rates were similar regardless of the extent of the operative procedure when the Halsted radical mastectomy was compared with any of the modified approaches; as a result, a modified approach was accepted in 1979 by the NCI Consensus Conference.

To facilitate immediate breast reconstruction, which is increasingly performed, the technique of skin-sparing mastectomy (SSM) is performed, and, more recently, nipple-sparing mastectomy (NSM) is also gaining favor. A recent meta-analysis looking at the oncologic safety of NSM as opposed to SSM or total mastectomy found no significant differences in overall survival, disease-free survival, and local recurrence between the two groups. Studies with follow-up periods longer than 5 years in patients undergoing NSM had mean overall local recurrence rate of 11.4% and nipple areolar recurrence rate of 3.4%. It should be noted, however, that there are no randomized data regarding the NSM approach.

Breast-conservation Therapy

The shift toward less radical surgery at the time of mastectomy occurred for several reasons. As earlier diagnosis of breast cancer with smaller tumors and less involvement of pectoral muscles occurred, the need for radical procedures decreased. In addition, even with radical mastectomy, not all patients were cured and, although regional recurrences were low, patients died of distant disease. The morbidity of the radical mastectomy was well documented, including lymphedema, immobility of the shoulder, and disfigurement. A shift to breast conservation followed the same trends. The initial trials with radiation therapy using radium implants at the Princess Margaret Hospital in Toronto had promising results.

This led to randomization studies comparing breast-conservation therapy with mastectomy. Table 14.14 lists randomized trials that compared radical and modified radical mastectomy in stage I and stage II carcinoma of the breast.

In breast-conserving surgery, a wide-local excision is performed with excision of the tumor and a 1- to 2-cm rim of normal tissue. This excision is referred to as "lumpectomy" or a "tumorectomy." This differs from a quadrantectomy, in which a resection of the tumor with the overlying skin and the involved quadrant of the breast is performed. The six randomized trials differed with respect to the type of wide-local excision performed and with respect to tumor size in the patients who were randomized. In the Milan trial, a quadrantectomy was performed. In the Insitut Gustave Roussy trial, the "tumorectomy" performed was removal of the tumor and a 2-cm margin of normal tissue. In the United States, the NSABP B-06 trial did not specify the margins on the lumpectomy specimen, providing they were grossly free of tumor. In the NCI study, there was a significantly higher local recurrence rate in the breast-conservation group, but only gross tumor removal was required for study entry. Whole-breast irradiation (45–50 Gy) was used in all trials, with a boost to the primary site given in five of the six trials.

In all trials, the authors noted comparable disease-free survival in both arms. The only difference noted was in local recurrence. In addition to the randomized trials, many

nonrandomized reports have been published with similar results in survival between breast conservation and mastectomy.

In a meta-analysis of nine prospective randomized trials comparing conservative surgery and irradiation with mastectomy, no survival differences were found in seven of the trials. Local recurrence was reported in 6.2% of patients treated with mastectomy and in 5.9% of those treated with breast-conservation surgery. No difference was seen in the incidence of contralateral breast cancer or a second malignant neoplasm that was not breast cancer. The incidence of recurrence in the treated breast ranged from 3% to 19%. Most failures in the treated breast can be salvaged with mastectomy, which can result in 70% survival at 5 years. Mastectomy did not prevent local recurrences, which developed in 4% to 14% of patients after this treatment.

In 1992, the American Colleges of Surgeons, Radiologists, and Pathologists, along with the ACS and the Society of Surgical Oncology, began the process of describing standard practice for breast-conservation treatment. Many retrospective and prospective randomized trials suggested equally effective results in appropriately selected patients with early-stage breast cancer, regardless of whether they were treated with mastectomy or breast-conservation surgery. The results of these deliberations were published in 1998.

Radiation therapy is an important component of breast conservation. Adequate surgical margins are required to be negative on pathologic inspection. After healing, the radiation therapy is planned. Treatment to the entire breast should be at a dose of 1.8 to 2.0 Gy per day for a total of 45 to 50 Gy. A 10- to 15-Gy electron-therapy boost is often given to the lumpectomy bed. More recently, data on hypofractionation, which increases the daily dose and shortens the radiation therapy time, have been reported and demonstrate equivalence to standard radiation techniques.

Breast conservation depends on the use of radiation. The question of whether lumpectomy alone would yield similar results has been addressed through randomized trials. Local recurrence rates of 18% to 40% with lumpectomy alone have been reported compared with 2% to 14% with lumpectomy and radiation. In these studies, a significant reduction in relapse was noted in the lumpectomy and radiation arm.

The NSABP B-17 trial is the only prospective randomized trial of lumpectomy alone versus lumpectomy and radiation (50 Gy) in patients with DCIS. There were 818 women randomly assigned, and surgical margins were histologically tumor free. The mean follow-up time was 90 months (67–180 months). The incidence of noninvasive ipsilateral breast tumor was reduced from 13.4% to 8.2% ($P = 0.007$), and the incidence of invasive ipsilateral breast tumor was reduced from 13.4% to 3.9% ($P < 0.001$). All women benefited from radiation therapy regardless of clinical or mammographic tumor characteristics. No difference in mortality was noted. Interest in partial-breast radiation for early-stage breast cancers has prompted single-institution studies to use brachytherapy catheters, the MammoSite balloon (Proxima Company, Alpharetta, GA), and three-dimensional external-beam partial-breast treatment. The FDA-approved MammoSite Radiation Therapy System is a means of administering brachytherapy internally in prescribed doses over a 5-day period. During the lumpectomy, a deflated balloon is placed inside the surgical cavity. A tube connects the balloon to the outside of the breast and may be inflated with saline to fill the cavity. Radiation is delivered within the inflated balloon over 1 to 5 days, after which the balloon is deflated and then removed.

These approaches are being studied as an alternative to the standard 5- to 6-week whole-breast radiation treatment. To shorten the radiation course, the proportion of breast tissue to be radiated is significantly less. Data on local recurrences after radiation show that the majority of recurrences after lumpectomy and whole-breast radiation occur in the same quadrant, hence the reason to consider partial-breast radiation. In this manner, a greater dose will be delivered to the lumpectomy site and the surrounding tissue in a shorter course of therapy. Currently, the National Surgical Adjuvant Breast and Bowel Project and Radiation Therapy Oncology Group (NSABP-RTOG) cooperative groups opened a phase III trial comparing whole-breast radiation therapy to some form of partial-breast radiation. The partial-breast treatment will be delivered using brachytherapy catheters, MammoSite balloon, or external three-dimensional conformal treatment. Randomization to either whole- or partial-breast radiation will occur at entry into the trial. Enrollment to this trial closed in 2013, and results are awaited.

Overall, it appears that clinicians can now be confident in recommending lumpectomy plus irradiation to patients because it seems to be equivalent to mastectomy in terms of survival and optimal local-regional control.

Breast-conserving surgery can also be combined with plastic surgery in a concept known as oncoplastic breast surgery. This combines the oncologic approach of wide-local resection with plastic surgery incisions and tissue transfer techniques aiming to preserve the natural shape of the breast and breast symmetry. Techniques range from volume displacement and redistribution techniques, such as mastopexy and mini-flaps, to more advanced techniques such as reduction mammoplasty and contralateral symmetry procedures.

Patient Selection

Possible contraindications can interfere with offering a patient breast-conservation therapy. Cosmetic result should be considered when deciding whether to offer breast-conserving surgery; tumor size in relation to breast size is an important consideration. In addition, other factors that may affect the ability to receive irradiation must be considered (ie, history of prior breast or chest irradiation, concurrent pregnancy, Li-Fraumeni syndrome, and autoimmune connective tissue disease). Particularly, with a history of systemic lupus erythematosus, radiation may not be a possibility. Women with multiple cancers in the breast are not candidates for this approach and require a mastectomy. In addition, patients with extensive calcifications on a mammogram suggesting a diffuse process may be better treated with mastectomy.

The American Society of Clinical Oncology, the Society of Surgical Oncology, and the American Society of Radiation

Oncology jointly published guidelines in 2014 after a meta-analysis of 33 studies and almost 30,000 patients, which recommended no tumor on ink as a satisfactory margin. **Patients with positive resected margins should undergo reexcision.** If resected margins remain positive on reexcision, mastectomy is the preferred treatment. Positive margins (ink on invasive carcinoma or DCIS) are associated with a twofold increase in the risk of recurrence compared with negative margins. This increased risk is not mitigated by favorable biology, endocrine therapy, or a radiation boost. There was no evidence that tumors with an extensive intraductal component (EIC), which were thought to be at more risk of recurrence benefited from a more widely clear margin. The status of surgical margins is probably the most important aspect of pathologic evaluation of breast tumor excision specimens in patients being considered for conservative surgery.

Extensive intraductal component is a condition that exists when more than 25% of the tumor is associated with DCIS. In these cases, the invasive component may be outside the area of the intraductal carcinoma. This has been reported to have a higher relapse rate with breast conservation; however, it is thought to be secondary to margin status because margin involvement may be an indication of residual intraductal carcinoma. In DCIS, Silverstein and associates developed the Van Nuys prognostic index (VNPI). The system combines the scores for histologic grade, tumor size, and margin status of a lesion to obtain an overall score. It considers margins of 1 cm to indicate a decreased rate of local relapse, even with no radiation. However, margin width has not been shown to be significant in other studies.

Management of the Axilla

The axilla is a pyramidal space between the arm and thoracic wall. It contains the axillary vessels and their branches, the brachial plexus and its branches, and lymph nodes embedded in fatty tissue. The primary route of lymphatic drainage of the breast is through the axillary lymph nodes. The lymph nodes are also divided into levels based on location relative to the pectoralis minor. Level 1 lymph nodes lie lateral to the lateral border of the pectoralis minor muscle, level 2 nodes lie behind the pectoralis minor muscle, and level 3 nodes are medial to the medial border of this muscle.

In an axillary dissection, nerve branches of the brachial plexus are encountered. The lateral and medial pectoral nerves supply the pectoralis muscles. The thoracodorsal nerve runs downward and innervates the latissimus dorsi. The long thoracic nerve is located on the medial wall of the axilla on the serratus anterior. It arises from the C5 to C7 roots, and injury to these nerves results in paralysis to part or all of the serratus anterior. The functional deficit is inability to raise the arm above the level of the shoulder.

At the time of Halsted's radical mastectomy procedure, a complete axillary dissection was performed. The status of the axilla is the most important prognostic factor for breast cancer. Clinical examination of the axilla is inaccurate because even in patients with a T1 lesion, there is a 10% risk of lymph node metastasis. Before the use of SLN biopsy (SLNB), there was no accurate method to adequately stage the axilla without an axillary dissection. Axillary lymph node sampling (ie, removal of only a few lymph nodes) was inadequate.

Metastatic involvement of lymph nodes usually occurs in a stepwise manner. Rosen and coworkers demonstrated the incidence of skip metastasis to be less than 2%. A complete level 1 and level 2 lymph node dissection provides excellent local control, and local recurrence after this procedure has been shown to be less than 1%.

The NSABP B-04 trial was begun in 1971, and the NSABP designed this trial to determine the value of prophylactic regional node dissection. Patients with clinically uninvolved axillary nodes (clinical stage I) were randomly assigned for treatment among radical mastectomy, total mastectomy plus irradiation of the chest wall and regional lymphatics, and total mastectomy alone. Women who had clinically involved axillary nodes (clinical stage II) were randomly assigned to treatment with either radical mastectomy or total mastectomy and irradiation to the chest wall and all lymph node drainage areas for the breast. If ignoring occult axillary metastases permitted continuing dissemination, the patients treated with total mastectomy alone should fare poorly; if having still-functioning nodes improves host defenses, the patients treated with total mastectomy alone should fare better than the others.

A total of 1665 patients were entered and observed for 72 months with no difference found among the three treatment arms in stage I. Overall, patients assigned stage II survived less well, but again, there was no difference between the two treatment alternatives. Only 60 (16%) of the 365 patients who did not undergo prophylactic axillary dissection developed progression in the axilla as a first sign of failure and underwent axillary dissections, predominantly in the first 30 months of follow-up but also as long as 112 months after surgery. In the group in which prophylactic axillary dissection was done, the incidence of positive nodes was 39%. More than half of the patients who should have had positive axillary nodes did not develop clinical evidence of such.

In 1985, Fisher and coworkers reported on this same group of 1665 women observed for a mean of 126 months. There were no significant differences between the two groups of patients who had clinically positive nodes treated by radical mastectomy or by total mastectomy without axillary dissection but with regional irradiation. Survival at 10 years was about 38% in both groups.

The morbidity associated with axillary lymphadenectomy is not inconsequential. About 10% to 15% of patients will develop lymphedema. In addition, numbness, pain, or weakness contributes to a significant decrease in the quality of life in these patients.

Sentinel Lymph Node Biopsy

Sentinel lymph node biopsy in breast cancer evolved out of efforts to minimize the morbidity associated with axillary lymph node dissection while still providing important staging information. Initial studies in melanoma carried out by Morton and colleagues in 1992 demonstrated the feasibility of the concept. Methods used include blue dye and radioisotope.

Several studies have confirmed the accuracy of SLNB. In the majority of the studies, successful identification of the SLN occurs between 92% and 98% of the time. The combination of blue dye and isotope has been reported to be better for identification of the SLN; when used in combination, the positive predictive value of the technique approaches 100%, with a negative predictive value close to 95%. The false-negative rate is about 5% to 10% in most studies.

The validity of the SLN concept lies in the ability of the SLN to predict the status of the regional lymphatic basin. Turner and colleagues performed IHC staining of all lymph nodes, sentinel and nonsentinel, in a series of patients undergoing standard axillary dissection with negative nodes. Of 157 SLNs, 10 (6%) demonstrated IHC positivity compared with 1 of 1087 (0.09%) of the non-SLNs. This provided validity to the SLN concept.

The SLNB procedure is widely used in invasive breast cancer and selectively in DCIS. In certain situations, however, a standard axillary dissection should still be considered, such as when bulky positive axillary nodes are present.

Previously, the presence of metastases in the SLNB prompted a completion axillary dissection. However, the results of the NSABP-B04 trial, in which some patients did not have their axilla dissected, called into question the value of the axillary dissection as a therapeutic instrument.

ACOSOG Z0011, a trial designed by The American College of Surgeons Oncology Group, investigated whether foregoing axillary dissection in patients undergoing breast-conserving therapy with 1 or 2 positive SLNs was safe. They reported no difference in local-regional failure, disease-free survival, or overall survival; the 5-year overall survival rates were 91.8% (95% CI 89.1%–94.5%) with axillary lymph node dissection (ALND) and 92.5% (95% CI 90.0%–95.1%) with SLNB alone; the 5-year disease-free survival rates were 82.2% (95% CI 78.3%–86.3%) with ALND and 83.9% (95% CI 80.2%–87.9%) with SLNB alone. Completion axillary dissection is still recommended in patients with T3 tumors, patients having partial breast irradiation, or those having a mastectomy for management of their primary tumor who are found to have a positive SLNB. In intraductal carcinoma, an SLNB or axillary dissection is generally not indicated. There are special circumstances of intraductal carcinoma, such as high-grade DCIS or extensive DCIS, in which a microinvasive component may be associated with the intraductal carcinoma. In these circumstances, and particularly if a mastectomy is being performed, an SLNB may be considered.

Adjuvant Therapy

Multiple randomized studies have demonstrated that the addition of chemotherapy improves overall survival in patients with breast cancer. The decision to use adjuvant chemotherapy or hormonal therapy depends on certain factors, such as the size of the primary tumor, the expression or lack of expression of ER or PR, lymph node status, HER2/neu status, tumor genomic profiling, and the presence or absence of metastatic disease.

Adjuvant treatment in breast cancer was first used more than 100 years ago. In 1894, Beatson reported on the results of oophorectomy and response rate in the metastatic breast cancer setting. Initially, the use of systemic therapy involved the use of single-agent chemotherapy; later, multiagent chemotherapy was used. As in most breast cancer trials, the initial reports were of patients with metastatic disease. Adjuvant chemotherapy is standard treatment for patients with positive nodes or large tumors. The combination of CMF (cyclophosphamide, methotrexate, and 5-fluorouracil [5-FU]) has been used for many years in the treatment of patients with breast cancer. Anthracycline-based regimens and the possible addition of taxanes had been used in patients with high-risk factors for recurrence. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) was formed in 1985 to analyze all available, properly conducted randomized trials to examine which chemotherapy regimens gave the best results. In the 2012 EBCTCG meta-analysis, adjuvant chemotherapies using either an anthracycline-based regimen or CMF were compared with no treatment. The use of an anthracycline-containing regimen was associated a significant reduction in overall mortality (RR 0.84; 95% CI 0.78–0.91), which translated into an absolute gain of 5.0% at 10 years. Similarly, the use of CMF had a significant reduction in overall mortality (RR 0.84; 95% CI 0.76–0.93), which translated into an absolute gain of 4.7%. There was no improvement in the risk of recurrence, breast cancer, or overall mortality when CMF was compared with standard dose anthracycline-based regimens. However, the use of higher cumulative doses of anthracyclines compared with CMF did result in a reduction in the risk of recurrence (RR 0.89; 95% CI 0.82–0.96) with an absolute gain of 2.6%, breast cancer mortality rate (RR 0.80; 95% CI 0.72–0.88) with an absolute gain of 4.1 percent, and overall mortality rate (RR 0.84; 95% CI 0.76–0.92) with an absolute gain of 3.9%. They also assessed the role of taxanes when incorporated into the adjuvant chemotherapy for early breast cancer. In trials in which the **same control regimen** was used in both arms (n = 11,167 women), incorporation of taxanes into an anthracycline regimen resulted in a reduction in the risk of overall mortality (RR 0.86; 95% CI 0.79–0.93), which translated to a 3.2% improvement in overall survival at 8 years.

The NCCN recently published the 20th annual edition of its comprehensive breast cancer management practice guidelines, including recommendations for adjuvant therapy of breast cancer. The NCCN guidelines for chemotherapy are described in detail on its website (http://www.NCCN.org).

Since the demonstration of their superiority to other combination chemotherapy, anthracycline-based regimens have become the basis for the adjuvant treatment of high-risk patients with breast cancer. A variety of approaches have evolved regarding adjuvant polychemotherapy, including the addition of drugs such as taxanes and targeted agents and the establishment of dose-dense chemotherapy regimens that were based on modeling of human breast cancer growth.

Administration of dose-dense chemotherapy became possible with the introduction of granulocyte colony-stimulating factor, which allows the chemotherapy courses to be condensed without causing unacceptable toxicity. A dose-dense chemotherapy approach using concurrent doxorubicin and

cyclophosphamide (AC) followed by paclitaxel (T) was assessed in the pivotal Cancer and Leukemia Group B (CALGB) 9741 trial, a phase III prospective randomized trial of adjuvant treatment of women with node-positive early-stage breast cancer. This trial showed a statistically significant improvement in disease-free survival and overall survival for dose-dense chemotherapy and has become one of the preferred regimens. Another preferred regimen is the combination of docetaxel and cyclophosphamide.

Estrogen Receptor–Positive Breast Cancer

Estrogen receptors are proteins found in hormonally dependent tissue, both malignant and nonmalignant. The amount of receptor present in the breast cancer specimen is predictive of the success or failure of endocrine therapy. The identification of the ER protein in certain human mammary cancers and the subsequent explanation of the role of estrogen in tumor growth clarified a clinical relationship that had been observed for a century. In 1896, Beatson produced regression of mammary cancer by oophorectomy. Huggins and Bergenstal demonstrated in 1952 that some mammary and prostatic cancers were not autonomous but under the partial control of the endocrine system. Regressions of mammary cancers were continually obtained by removing the source of endogenous circulating hormones by oophorectomy, adrenalectomy, and hypophysectomy. Alternatively, breast cancer regressions were also achieved by administering large doses of estrogen, androgen, progesterone, and glucocorticoids.

The choice of a particular endocrine therapy has been in large part empiric, guided by certain clinical features such as menopausal status, disease-free interval, site of the dominant lesion, and response to previous therapy. As a result of basic investigations by Jensen, Smith, and DeSombre of steroid hormone metabolism, there has been development of a series of assays that can identify with considerable accuracy breast cancers that are not autonomous and that will respond to endocrine manipulation. Such a method of predicting a priori those cancers that will be responsive to changes in the endocrine milieu greatly enhances the usefulness of hormone therapy and allows recommendation of such treatments on a plausible biochemical basis.

Knowledge of the ER content of either the primary or the recurrent mammary cancer must be viewed within the proper clinical perspective. This one determination is but a single piece in the mosaic of the subcellular biochemistry of breast cancer. To deprecate the clinical importance of this determination because some patients with significant ER content will not respond to hormone treatment (because of eventual escape from hormone regulation or because of lack of understanding of the role of other steroid or protein hormone receptors) begs the question. Knowledge of the ER content of either a primary or a metastatic tumor does not allow the physician to predict the hormone dependency of a tumor with enough accuracy for it to be rationally used in the selection of appropriate palliative treatment. It does, however, allow a good assessment of the likelihood that the patient with breast cancer would benefit from endocrine therapy.

HER2/neu–Positive Breast Cancer

In patients with HER2/neu–positive breast cancer, the use of trastuzumab (Herceptin) in addition to combination chemotherapy has been associated with a decrease in relapse. Trastuzumab is a humanized anti-HER2 antibody against the extracellular domain of the 2-neu oncoprotein.

Four major adjuvant trials—Herceptin Adjuvant (HERA), National Surgical Adjuvant Breast and Bowel Project (NSABP) B-31, North Central Cancer Treatment Group (NCCTG) N9831, and Breast Cancer International Research Group (BCIRG) 006—have investigated the use of trastuzumab in the adjuvant setting. These trials have shown that trastuzumab reduces the 3-year risk of recurrence by about 50% in this population. More than 13,000 women with HER2/neu–positive breast cancers were enrolled and received 1 year of adjuvant treatment with trastuzumab. These trials used different chemotherapy regimens but had similar improvements in recurrence-free survival. Cardiac events were at an acceptable level; however, they did note a slightly higher incidence (0.6%–3.3%) of congestive heart failure that was responsive to treatment. There was an overall survival benefit in the NSABP B-31 and NCCTG N9831 trials and a trend toward an overall survival benefit in the HERA and BCIRG trials.

Regimens using AC followed by a taxane are also one of the preferred regimens for HER2/neu–positive breast cancer with the addition of trastuzumab with or without pertuzumab with the taxane. Pertuzumab inhibits HER2 by binding to a different HER2 epitope than trastuzumab and represents a complementary mechanism of action to trastuzumab. The efficacy and safety of pertuzumab in combination with trastuzumab with or without chemotherapy have been demonstrated in both advanced and early stages of HER2-positive breast cancer.

Lapatinib (Tykerb) in combination with capecitabine is approved by the FDA for treatment of patients with advanced or metastatic breast cancer whose tumors overexpress HER2 and who have received previous therapy, including an anthracycline, a taxane, and trastuzumab.

Triple-Negative Breast Cancer

Triple-negative breast cancer accounts for approximately 10% to 15% of all breast cancers and accounts for a disproportionate share of breast cancer mortality. There is specific enrichment for triple-negative subtype in the breast cancers arising in *BRCA1* mutation carriers. By definition, triple-negative cancers do not have estrogen and progesterone receptors, and they are not HER2/neu receptor amplified. Therefore, the only available adjuvant treatment consists of chemotherapy. For patients with stage II and III triple-negative disease, regimens that contain anthracyclines and taxanes are the standard approach. Those with stage I disease are often treated with shorter and less toxic regimens. In general, chemotherapy reduces the overall risk of disease recurrence in the triple-negative setting by as much as 35% to 50%.

Ovarian Ablation

Ovarian suppression is one of the oldest methods for treating premenopausal metastatic breast cancer. This can be

accomplished surgically by use of luteinizing hormone–releasing hormone analogs or radiation. In 1996, the EBCTCG published an overview of randomized trials concerning ovarian ablation in early breast cancer. There were 12 of 17 studies available for evaluation, all of which were begun before 1980. There were 2102 randomized women younger than 50 years and 1354 women aged 50 years and older. **In women younger than 50 years, there were six fewer recurrences or deaths per 100 women allocated to ovarian ablation (45% vs. 39% alive without recurrence) 15 years after randomization.**

The Suppression of Ovarian Function Trial (SOFT) and the Tamoxifen and Exemestane Trial (TEXT) were recent trials dedicated to premenopausal women with hormone-sensitive breast cancer and were developed to determine the role of ovarian ablation in women whose menses return after chemotherapy and are treated with tamoxifen and to test whether adjuvant aromatase inhibitor use improves outcomes in patients treated with ovarian ablation. Overall, in the SOFT trial, patients did not benefit from the addition of ovarian ablation. Nevertheless, for women at higher risk of recurrence who received adjuvant chemotherapy and remained premenopausal, addition of ovarian ablation to tamoxifen reduced the risk of recurrence. The effect was larger in younger patients. In the TEXT trial, adjuvant treatment with exemestane plus ovarian ablation, compared with tamoxifen plus ovarian ablation, significantly improved disease-free and distant disease-free survival, therefore representing a new treatment option. Tailored endocrine treatments should be considered in premenopausal patients with hormone-sensitive tumors.

In the joint analysis of the SOFT and TEXT trials, it should be noted that 13.7% had stopped all protocol assigned treatments early (16.1% of the patients in the exemestane–ovarian suppression group and 11.2% of those in the tamoxifen–ovarian suppression group). Nearly all women (98.3%) treated with ovarian suppression reported adverse events; in 30%, these were grade 3 or 4. The grade 3 or 4 events that were reported most frequently were hot flushes, musculoskeletal symptoms, and hypertension. Depression was reported in 50.2% of patients, with grade 3 or 4 depression in 4.1% of the patients.

Tamoxifen

Many prospective, double-blind, randomized studies have been performed to evaluate the role of adjuvant tamoxifen among women with early breast cancer. In 1998, the EBCTCG published an update on 55 such trials of 37,000 women. In the 18,000 women with ER-positive tumors, the reductions in the recurrence rate at 1, 2, and 5 years of tamoxifen use were 21%, 28%, and 50%, respectively. These figures are all highly significant. Women with ER-positive tumors with at least 100-fmol receptor per milligram of cytosol protein had a greater reduction in recurrence than those with positive receptors but less than 100 fmol (60% vs. 43% after 5 years of tamoxifen). The reduction in mortality was also greater in those with a higher receptor level (36% vs. 23%). Patients with ER-positive, PR-negative tumors had results (reduction of recurrences and mortality) similar to those of patients with ER-positive tumors (progesterone receptor status unknown). Among the 800 women with ER-poor tumors, the reduction in recurrence was only 10%, irrespective of length of time of tamoxifen treatment. Although this reduction is statistically significant, the apparent benefit is small, and the lower confidence limit is close to zero. Irrespective of the duration of tamoxifen use, the mortality rate reduction was only 6%. In the 2000 women with ER-poor, PR-poor tumors, tamoxifen had no apparent effect on recurrence or mortality rates (≈1%), but in the 602 women with ER-poor, PR-positive tumors, recurrence reduction was 23%, and mortality reduction was 9%. There were 12,000 women with unknown ER status. It can be estimated that about two-thirds of these women would have ER-positive tumors if measured. The data suggest highly significant benefits among women with unknown ER status.

Tamoxifen has been shown to reduce the risk of relapse and mortality in randomized trials of women with ER-positive breast cancer, with treatment for 5 years showing greater effectiveness than treatment for 2 years. Results of the Adjuvant Tamoxifen: Longer Against Shorter (ATLAS) trial showed that extending treatment to 10 years reduced the risk of relapse, breast cancer mortality ($P = 0.01$), and all-cause mortality ($P = 0.01$) compared with discontinuation. Most of this benefit seemed to accrue after completion of treatment with recurrence rates during the 5 extra years of tamoxifen (rate ratio, 0.90) and a more impressive carryover benefit during the 5 years of follow-up after completion of 10 years of tamoxifen (rate ratio, 0.75).

In addition, the reduced mortality rate was only apparent after completion of 10 years of treatment with tamoxifen. Previous trials of 5 years of tamoxifen have shown a similar carryover benefit more than 10 years after discontinuation. The benefit of continuing tamoxifen for a further 5 years gives rise to a total relapse risk reduction of 39% ($P < 0.0001$) and risk reduction of breast cancer mortality of 36% ($P < 0.0001$). After completion of 10 years of treatment, this estimated risk was reduced by 30% for relapse ($P = 0.01$) and 48% for mortality ($P < 0.0001$), continuing for at least 5 years. These carryover benefits contribute substantially to the cumulative benefits of treatment with tamoxifen because toxic effects only occur while on therapy. Overall, the benefits of extended tamoxifen seemed to outweigh the risks substantially.

There are well-described adverse effects with tamoxifen. Endometrial cancer is significantly more common among women who receive extended therapy with tamoxifen compared with those who did not. Five years of adjuvant tamoxifen is estimated to result in an absolute 15-year endometrial cancer risk of about 2% to 3%, and that use of 10 years rather than 5 years of tamoxifen would produce an additional risk by year 15 of about 2%. The numerical instances of death as a result of endometrial cancer were higher with extended tamoxifen treatment, although such events were rare. There was also a higher risk for pulmonary embolism with tamoxifen. There was a lower risk of ischemic heart disease in women who received extended tamoxifen therapy in ATLAS.

Following this and similar data, the American Society of Clinical Oncology guidelines now recommend that if women are pre- or perimenopausal and have received 5 years of adjuvant tamoxifen, they should be offered 10 years' total duration

of tamoxifen. If women are postmenopausal and have received 5 years of adjuvant tamoxifen, they should be offered the choice of continuing tamoxifen or switching to an aromatase inhibitor for 10 years' total adjuvant endocrine therapy.

Aromatase Inhibitors

Aromatase inhibitors suppress estrogen levels by inactivating aromatase, the enzyme responsible for synthesizing estrogens from androgens. In contrast to tamoxifen, these compounds lack partial agonist activity. The Anastrozole, Tamoxifen Alone or in Combination (ATAC) trial compared 5 years of tamoxifen versus anastrozole versus the combination. Anastrozole was found to have a significantly better survival time, prolonged time to recurrence, reduced distant metastases, and lower incidence of contralateral breast cancer compared with tamoxifen. Letrozole, another aromatase inhibitor, was compared with tamoxifen in the multicenter Breast International Group (BIG) trial of 8028 postmenopausal women with metastatic breast cancer. Letrozole reduced significantly the risk of recurrent disease when compared with tamoxifen, especially at distant sites in these postmenopausal women. Another international study of 5187 women administered letrozole after completing 5 years of tamoxifen. The results from the data indicated a nearly 50% lower recurrence rate. As a result, letrozole is now an accepted treatment choice for postmenopausal women with hormone receptor–positive breast cancers who have used tamoxifen for a 5-year period. The American Society of Clinical Oncology now recommends aromatase inhibitors be used to lower the risk of recurrence in receptor-positive postmenopausal breast cancers as initial therapy or after treatment with tamoxifen.

Three double-blind, randomized, prospective studies—ATAC, the Intergroup Exemestane Study (EIS), and the BIG 1-98 trial—have confirmed the superiority of aromatase inhibitors over tamoxifen in early-stage cancers in postmenopausal women. All three studies have demonstrated an increase in disease-free survival. Short-term side effects were acceptable, but all had a negative impact on bone health. Based on the results of these trials, patients who are postmenopausal have the option of starting on anastrozole as first-line therapy after initial diagnosis. Patients who have been on tamoxifen for 2 to 3 years can be switched to an aromatase inhibitor to complete a total of 5 years of therapy.

The MA.17 trial, which examined whether extended endocrine therapy with letrozole after completion of 5 years of tamoxifen, found a significant increase in disease-free survival in postmenopausal patients with hormone-sensitive breast cancer irrespective of whether patients were node positive or node negative. The MA.17 trial was unblinded at the first planned interim analysis, after 171 events (median follow-up, 2.4 years), because of a significant difference in events that favored the letrozole arm and far exceeded predefined unblinding boundaries. The results of this pivotal trial led to the approval of letrozole as extended adjuvant treatment of early breast cancer in postmenopausal women who had received standard adjuvant tamoxifen therapy in the United States and in several European countries.

Gene Expression Assays

Two gene-expression assays used to determine the risk of breast cancer recurrence in patients with stage I or II node-negative breast cancer are currently available. Onco*type* DX (Genomic Health Institute, Redwood City, CA) is an assay performed on RNA extracted from paraffin-embedded tumor tissue. It analyzes the expression of 21 genes: 16 cancer-related genes and 5 reference genes. The results are used to calculate a recurrence score to identify the likelihood of cancer recurrence in patients treated with tamoxifen. The results of two studies evaluating the ability of Onco*type* DX to predict the risk of breast cancer recurrence suggest that patients with ER-positive, node-negative breast cancer, and a low recurrence score may need only adjuvant treatment with tamoxifen, but intermediate- and high-risk patients may require additional treatment with adjuvant chemotherapy. MammaPrint, an oligonucleotide microassay performed on fresh-frozen tumor samples, analyzes the expression of 70 genes. Studies have found that MammaPrint allows young patients (<61 years) with early-stage breast cancer to be categorized as having a high or low risk of distant metastasis. High-risk patients may then be managed with more aggressive therapy.

Metastatic Disease

The goal of therapy in metastatic disease is palliation of symptoms because cure is unlikely. The majority of patients with metastatic disease receive antihormonal therapy. First-line agents include tamoxifen or aromatase inhibitors such as letrozole or anastrozole. These agents offer a 20% response with ER- or PR-positive tumors. Disease stabilization is the goal of therapy, and because these therapies are less toxic than chemotherapy, most patients remain on them for prolonged periods. Upon failure of these agents, however, chemotherapy is the next step.

High-dose Chemotherapy

Five large randomized trials have been conducted addressing the use of high-dose chemotherapy with bone marrow or stem cell rescue in metastatic breast cancer. Only one trial, conducted in South Africa, showed a lower rate of relapse. The other four trials showed no increase in overall survival. The investigators of the trial conducted in South Africa subsequently admitted to fraud. Thus, it is believed that high-dose chemotherapy offers no survival advantage over conventional treatment approaches.

Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy in patients with breast cancer has never demonstrated an improvement in overall survival compared with conventional adjuvant therapy; nevertheless, the downstaging of the primary tumor may increase the possibility for breast conservation and includes the potential to tailor systemic therapy based on responses observed in the neoadjuvant setting. This has led to increased utilization.

The surgical approach to the axilla in patients after neoadjuvant chemotherapy is still being elucidated. SLNB after neoadjuvant chemotherapy accurately stages the axilla and is associated with a low rate of nodal recurrence in patients presenting with clinically negative axillary lymph nodes. The

SENTINA (SENTinel NeoAdjuvant) trial investigated the appropriate timing and feasibility of SLNB in different settings of neoadjuvant chemotherapy. Patients who had clinically N1 nodal disease before chemotherapy who clinically downstaged to N0 underwent SLNB followed by axillary dissection. The false-negative rate was 24% with assessment of one node and 18.5% with two. The false-negative rate was less than 10% only when three or more sentinel nodes were identified. However, nodal recurrence rates after SLNB alone in this population are unknown. Boughey et al. reporting from a similar trial (ACOSOG Z1071) urged caution when they found a false-negative rate of 12.6% when two more nodes were assessed, which was greater than their predetermined upper limit of acceptable false-negative rate of 10%. However, their data also demonstrated a false-negative rate of 9.1% when three or more nodes were assessed. Therefore many believe that SLNB is safe after neoadjuvant chemotherapy if three or more nodes are assessed. Dual mapping with radioisotope and blue dye is recommended to ensure successful mapping. Patients who become clinically node negative after neoadjuvant chemotherapy (downstaging of axilla) may safely avoid axillary node dissection.

Radiation Therapy

As discussed, radiation therapy is used in conjunction with lumpectomy for patients opting for breast conservation. For whole-breast radiation, the dose used is 1.8 to 2.0 Gy in 25 fractions for a total of 45 to 50 Gy to the entire breast. A 10- to 15-Gy electron-therapy boost is often given to the lumpectomy bed. The Ontario Clinical Oncology Group and the UK START trials looked at hypofractionated schedules and have reported no difference in recurrence rates compared with standard radiation protocols with acceptable cosmetic outcomes. The Canadian protocol is a schedule of 42.5 Gy given in 16 fractions over a period of 22 days. The American Society of Radiation Oncology guidelines do support use of hypofractionated schedules but caution that these trials had a majority of patients in these trials who were older than 50 years of age, had small node-negative tumors, and did not receive adjuvant chemotherapy.

Postmastectomy chest-wall irradiation is used with increasing frequency. Women with a high risk of local recurrence benefit from radiation therapy after mastectomy. Patients with large tumors (T3 lesions) and more than three positive nodes or presence of extranodal extension are at risk for local-regional failure. Chest-wall radiation is 50 Gy over 5 weeks, with a 10-Gy boost to the mastectomy scar. In women with one to three positive nodes, the benefit of the use of postmastectomy irradiation is uncertain and is being tested in RCTs. For patients with a chest-wall recurrence, the option of surgical debulking followed by chest-wall irradiation is used.

Radiation therapy can also be used in the palliative setting. It can be used for metastatic lesions to the bone or brain and can help to alleviate the patient's symptoms.

Breast Reconstruction

Breast reconstruction represents a major advance in cancer rehabilitation for patients undergoing a mastectomy. Previously, a 2-year surveillance period was recommended before reconstruction for detection of local disease recurrence. Immediate reconstruction has not interfered with disease detection, however, and it has the advantage of combining the two procedures into one. In addition, a greater amount of skin can be saved with planned immediate reconstruction, and the scar tissue that would be encountered with a delayed procedure can be avoided.

A delayed reconstruction can be performed if the patient is ambiguous about the reconstruction or if operative risk is increased with prolonged anesthesia. It is also considered in patients with locally advanced disease if a delay in adjuvant irradiation or chemotherapy is anticipated because of the reconstruction.

Reconstruction options include expandable breast prosthesis (implant) and autologous tissue transfer. Tissue-transfer operations may yield the greatest symmetry between breasts, especially with larger breasts; however, they take longer, require greater surgical expertise, involve a longer recovery, and result in another scar at the donor site. A variety of donor sites are possible such as free flap options (eg, deep inferior epigastric perforator [DIEP] flap, transverse/diagonal upper gracilis [TUG/DUG]) or pedicled flaps (eg, transverse rectus abdominis muscle [TRAM] or latissimus dorsi).

SPECIAL ISSUES

Breast Cancer in Older Women

The challenge in older patients is to balance effective treatment against potential comorbidities and to minimize both under- and overtreatment. However, patients older than the age of 70 years are underrepresented in clinical trials, and as such there is a paucity of data to guide our treatment decisions. Advanced age in itself should not be a limitation to treatment. In 2011, the average life expectancy of a 70-year-old woman in the United States, was 16 years and for an 80-year-old woman, it was almost 10 years. Trials have shown that surgery and tamoxifen in women older than 70 years are associated with both decreased risk of local recurrence and improved survival times than with tamoxifen alone. In the 2006 Cochrane review, data based on an estimated 869 deaths in 1571 women were unable to show a statistically significant difference in favor of either surgery or tamoxifen in respect of overall survival. However, there was a statistically significant difference in terms of progression-free survival (PFS), which favored surgery with or without tamoxifen. The HR for overall survival were 0.98 (P = 0.9) for surgery alone versus tamoxifen and 0.86 (P = 0.06) for surgery with tamoxifen versus tamoxifen alone. The HRs for PFS were 0.55 (P =0.0006) for surgery alone versus tamoxifen alone and 0.65 (P =0.0001) for surgery plus tamoxifen versus tamoxifen alone. For elderly patients, the 2015 St. Gallen expert consensus was very clear that for standard chemotherapy, there is no absolute age limit; rather, disease factors, comorbidities, life expectancy, and patient preferences should factor in the treatment decisions. Treatment-related mortality, however, is higher in women older than 65 years of age (1.5%) compared with those younger than age 50 years (0.2%).

Randomized trials strongly suggest that older women with small breast cancers on endocrine therapy after surgery may gain little or nothing from adjuvant radiotherapy. The EBCTCG published an updated analysis using individual patient data from 10,801 patients included in 17 randomized trials of radiation after breast-conserving surgery. This revealed that the addition of radiation therapy was associated with a highly significant absolute benefit of 15.7% in any first recurrence (local, regional, or distant recurrence) at 10 years (P <0.00001). The benefits of radiation therapy varied when adjusted for ER status, grade, and age. The absolute benefit of radiation therapy depended on the baseline risk of recurrence, which is a function of age. With increasing age, the baseline risk of recurrence is lower, leading to a smaller but still significant absolute benefit of radiation overall. In women older than age 70 years, the baseline risk of recurrence and therefore the benefit derived from radiation was about half—an 8.9% absolute reduction in a 10-year risk of a locoregional or distant recurrence. This analysis was based on chronologic age and included healthy older women as well as those with comorbidities.

Hereditary Breast Cancer

Approximately 10% of newly diagnosed breast cancers are likely to be hereditary. Most are ascribed to the *BRCA1* and *BRCA2* mutations, but increasingly, with genome-wide association studies, further mutations are being identified with possible increased risks of breast cancer. One of the most characteristic features of hereditary breast cancer is its tendency to manifest at a young age. In the Breast Cancer Consortium's study of *BRCA1*-linked families, more than 80% of breast cancers occurred in women younger than 50 years of age. *BRCA1*-associated cancers tend to occur at a younger age than their *BRCA2* counterparts.

Pathologic Features

There is a strong association between the type of *BRCA* mutation and the pathological features of the tumors they develop. About 70% to 90% of *BRCA1* mutation-associated breast cancers are triple negative, and approximately 80% of *BRCA2* mutation-associated cancers are hormone receptor positive.

Stage

Most studies demonstrate that *BRCA*-associated breast cancers are seen at a stage comparable to non–*BRCA*-associated breast cancers. The incidence of axillary metastasis does not appear to be significantly different in patients with *BRCA*-associated breast cancers. In the literature, conflicting study data exist regarding the prognosis of patients with *BRCA*-associated breast cancer. A recent meta-analysis has looked at the effect of *BRCA1* and *BRCA2* mutations on survival after a diagnosis of breast or ovarian cancer.

BRCA mutation-associated ovarian cancers (in particular *BRCA2*) have a better overall and PFS than their nonmutation carrier counterparts. In breast cancer outcomes, this positive effect was not seen. *BRCA1* mutation carriers had worse prognoses than noncarriers for overall survival but were not different from noncarriers in PFS. *BRCA2* mutation was not associated with breast cancer prognosis.

Treatment

The surgical management of hereditary breast cancer must take into account many variables that may be potentially different to sporadic breast cancers, namely, local recurrence risk and future contralateral breast cancer risk.

Studies comparing local recurrence risk after breast conservation between *BRCA* mutation carriers and noncarriers have conflicting results and have been generally retrospective. A meta-analysis that included 526 *BRCA* mutation carriers showed no difference in local recurrence in the first 7 years of follow-up. However, on longer follow-up, the rate of ipsilateral recurrence started to substantially increase in the *BRCA* mutation group, although this may be suggestive of new ipsilateral breast cancers rather than true recurrences. *BRCA1* or *BRCA2* mutations did not differ with respect to local recurrence risk. Adjuvant chemotherapy and oophorectomy were associated with lower rates of local recurrence.

There was a marked difference in *BRCA* carriers compared with noncarriers and between *BRCA* mutation types with respect to their risk of contralateral breast cancer development. Analyses of 807 carriers showed a pooled contralateral breast cancer rate of 23.7% versus 6.8% in noncarriers (P <0.001). A study of a larger pooled *BRCA* carrier population of more than 2000 patients analyzed by subtype showed a 21.1% contralateral breast cancer rate in the *BRCA1* group compared with a 15.1% rate in the *BRCA* patients ($\underline{P} = 0.04$)

Factors that were shown to decrease contralateral breast cancer risk were oophorectomy, tamoxifen use, and increasing age. A study that looked more specifically at age and contralateral breast cancer risk showed that at 15 years, those younger than 50 years old at diagnosis had a much higher rate (37.6%) than those older than 50 years at diagnosis (16.8%) ($P = 0.001$). *BRCA2* mutation breast cancers, given their higher rate of hormone receptor positivity, are likely to be on endocrine treatment and to have stronger protective effect from oophorectomy.

Chemoprevention

Chemoprevention is the principle that cancer prevention can be achieved through pharmacologic intervention. It refers to the use of a medication in a healthy patient to reduce the risk of a particular cancer. It is an option for all women with significant risk for future breast cancer development. Currently, the only FDA-approved medication for prevention of breast cancer is tamoxifen. Tamoxifen is a SERM that acts as an antiestrogen in breast tissue. It has been used in the adjuvant setting in breast cancer since 1972 for both metastatic and early breast cancers. A reduction of 40% to 50% in contralateral breast cancer was seen in the adjuvant setting; thus, it was thought to be an ideal agent to use in a chemopreventive setting.

The trial to determine the role of tamoxifen in chemoprevention was performed by the NSABP. In this randomized, double-blinded trial, women with a projected risk of breast cancer of greater than 1.66% over a 5-year period received either tamoxifen or a placebo for a period of 5 years. The Gail model was used to assess the risk. This multivariate logistic regression model combines risk factors to estimate the probability of recurrence of breast cancer over time. Variables

included in the model are age, number of first-degree relatives with breast cancer, nulliparity or age at first live birth, number of breast biopsies, pathologic diagnosis of atypia or hyperplasia, and age at menarche; the model then predicts the risk for breast cancer in 5 years or life expectancy. Participants eligible for this study were 60 years of age or older, between the ages of 35 and 59 years with a 5-year predicted risk of breast cancer of at least 1.66%, or had a history of LCIS. A total of 368 invasive and noninvasive breast cancers occurred, of which 244 were in the placebo group and 124 in the tamoxifen group. With invasive cancer, there was a 49% reduction in the overall risk (P <0.0001), with a cumulative incidence through 69 months of 43.4 per 1000 women and 22.0 per 1000 women in each of the two groups, respectively. For noninvasive breast cancer, the reduction was 50% (P <0.002). Reduction in noninvasive cancers was related to a decrease in the incidence of both DCIS and LCIS. Tamoxifen reduced the recurrence of ER-positive tumors by 69%, but there was no difference in recurrence of ER-negative tumors. There was, however, no survival difference between the two groups, with only nine deaths attributed to breast cancer, six in the placebo group, and three in the tamoxifen group.

Additionally, there was a 2.5-fold greater risk for development of endometrial cancer in the tamoxifen group compared with patients receiving placebo. There appeared to be no difference in ischemic heart disease or fatal myocardial infarction in the tamoxifen group versus the control group. Vascular events, including stroke, venous thrombosis, and pulmonary embolism, were greater in the tamoxifen-treated patients compared with those receiving placebo (91 vs. 52). There was a reduction in the risk of fracture of the hip, radius, and spine in the tamoxifen group compared with the placebo group, although the reduction was not statistically significant.

When an independent reviewing agency verified a 50% reduction in both invasive and noninvasive breast cancer cases in the population taking tamoxifen, the trial results were unblinded earlier than expected. Shortly thereafter, the use of tamoxifen was approved for chemoprevention. In patients who are desirous of tamoxifen for risk reduction, a discussion of the risks and benefits is important.

Two other chemoprevention trials using tamoxifen have been reported: the Italian tamoxifen-prevention study and the Royal Marsden Hospital tamoxifen trial in the United Kingdom. These two trials did not reveal a statistically significant reduction in breast cancer risk in women randomly assigned to tamoxifen. However, the studies differed in respect to subject numbers, median age, eligibility criteria, risk, and use of HRT.

Another SERM, raloxifene, is approved by the FDA for use in osteoporosis. In studies in which raloxifene was used for the treatment of osteoporosis, a secondary finding was a noted reduction in breast cancer risk of 50% to 70% in the population taking the medication. The women in the trials were at fairly low risk of breast cancer development. Results from the randomized double-blind trial to compare raloxifene with tamoxifen in a population of postmenopausal women at increased risk for breast cancer development, the Study of Tamoxifen and Raloxifene (STAR) trial/P-2 study, were recently reported.

The STAR trial randomized 19,747 postmenopausal women with an increased 5-year Gail risk to receive either tamoxifen or raloxifene. There were 163 and 168 invasive breast cancers in each group, respectively. The conclusion was that they were equivalent in reducing risks of breast cancer in postmenopausal women at high risk. Raloxifene had a better side effect profile, with fewer uterine cancers and thromboembolic events compared with tamoxifen. The risk reduction is thought to be about 50%, which is extrapolated from the P-1 study of tamoxifen and placebo. There was no placebo arm in this study; the conclusions were based on raloxifene having the same risk reduction as tamoxifen in the STAR trial.

In the NSABP P-1 study, there was an increased risk of developing endometrial cancer with tamoxifen use (annual risk, 2.3 of 1000 women versus 0.9 of 1000 women in the placebo group). All cases of endometrial cancer in the patients taking tamoxifen were early stage. Another important side effect noted was a higher incidence of thromboembolic phenomena. Raloxifene does not increase the risk of endometrial cancer and thus may prove to be an adequate alternative to tamoxifen in a chemopreventive role. An ideal SERM would have antiestrogenic effects on breast and uterine tissues but estrogenic effects on bone and the cardiovascular system, among others. Current investigations into other SERMs are being conducted.

Surveillance Versus Prophylactic Surgery in High-risk Patients

Patients with a genetic predisposition to breast cancer often ask about managing their risk. Many of these patients are young women. The diverse issues related to prophylactic mastectomy include both physical and psychologic factors. Appropriate counseling should encompass the extent of cancer risk reduction, surgical risks, and breast reconstruction options. Prophylactic mastectomy has been reported to have a risk reduction of approximately 90% in larger retrospective series with over 10 years of follow-up. Smaller prospective series with shorter follow-up suggest that this may be even higher. However, this reduction often relates to the type of mastectomy performed (eg, subcutaneous mastectomy may not remove all breast tissue).

Women with a genetic predisposition to breast cancer are also candidates for chemoprevention with tamoxifen. In the NSABP P-1 trial, women who had *BRCA* mutations were not protected by tamoxifen. However, because the number of such patients was small and CIs were wide, more data are needed. In addition, it is likely that chemoprevention may have no significant impact in women with *BRCA1,* in whom the tumors are predominantly ER negative. The data are still inconclusive regarding *BRCA*-predisposition genes and the use of tamoxifen for chemoprevention.

Participation in a screening program is another option. The NCCN screening recommendations in *BRCA* mutation carriers include a semiannual breast examination from the age of 25 years. Annual breast MRI from ages 25 to 29 is preferentially recommended but can be replaced with standard mammography if MRI is not available. From ages 30 to 75 years, both annual breast MRI and mammography are recommended.

These women are also at risk for developing ovarian cancer, and prophylactic oophorectomy at approximately age 40 years is an option. In addition, prophylactic oophorectomy before the age of 40 years has been reported to decrease the risk of breast cancer significantly (≈50%). But even prophylactic risk-reducing salpingo-oophorectomy does not exclude the risk of primary peritoneal cancer, which is estimated at 2%. Ovarian cancer screening programs currently use serum CA-125 and pelvic ultrasonography. Ovarian screening is not recommended for the general population, however, because of the low specificity of the tools currently available.

CONCLUSIONS

Screening for breast cancer is clearly indicated for all women at the appropriate age. Determining a woman's unique risk factors will help to determine both the age at which that screening should begin and the intensity of that screening. It will also help to identify women who need to be counseled regarding options for prevention of breast cancer. The hope is that by correctly identifying high-risk populations and then applying appropriate screening schedules and chemopreventive agents, many cases of breast cancers will be averted completely and that those that still occur will be found at the earliest stages. In addition, the understanding of breast disease, both benign and malignant, is crucial not only in the diagnosis of disease but also in helping to guide women in their treatment and follow-up.

OUTLINE

Background and Epidemiology of Cancer in Pregnancy
- Report From the European Society of Gynecological Oncology Cancer in Pregnancy Task Force

The More Common Solid Tumors in Pregnancy
- Cervical Cancer
- Ovarian Cancer
- Breast Cancer

Evaluation and Therapeutic Modalities
- Anesthesia and Surgery in Pregnant Patients
- Diagnostic and Therapeutic Radiation in Pregnancy
- Chemotherapy
- Serum Tumor Markers in Pregnancy

Hematologic Malignancies in Pregnancy
- Leukemia
- Hodgkin Disease

Other Tumors in Pregnancy
- Melanoma
- Thyroid Cancer
- Rare Gynecologic Malignancies in Pregnancy
- Placental and Fetal Tumors

KEY POINTS

1. Data from the Surveillance, Epidemiology, and End Results database indicate that cancers during the reproductive ages, in order of decreasing frequency are breast, melanoma, thyroid, cervix, and lymphoma.
2. The most critical period for cancer treatment during pregnancy extends from the 3rd to 8th weeks of development (5th through 10th weeks of gestational age), when susceptibility to teratogenic agents is maximal. In the human fetus, the period of organogenesis usually ends by the 13th week of gestation.
3. Preterm babies have limited ability to metabolize drugs because of immaturity of the hepatic and renal systems. Neonates exposed to chemotherapy 3 weeks before delivery should be assessed for transient bone marrow suppression, and long-term neurologic and developmental follow-up is recommended.
4. As more women opt for conservative management of invasive cancers in an effort to preserve fertility, we may anticipate a larger number of referrals than what was seen previously for patients with persistent or even recurrent malignancy during pregnancy.
5. Many recommend that any child born to a mother with active or suspected malignancy should initially have a thorough physical examination with a complete blood count, comprehensive metabolic panel, liver function tests, coagulation battery, serum lactate dehydrogenase level, uric acid levels, and a urinalysis. In addition, the placenta should be macroscopically and microscopically examined for tumor involvement. It has been our practice to also obtain imaging studies, including magnetic resonance imaging of the brain and computed tomography scans of the chest, abdomen, and pelvis, when maternal breast cancer, hematopoietic malignancy, or melanoma is at issue or in the setting of confirmed placental metastases.

BACKGROUND AND EPIDEMIOLOGY OF CANCER IN PREGNANCY

Cancer in pregnancy poses significant challenges to both the clinician and the pregnant woman. This is undoubtedly the result of the trend to defer childbearing into the fourth decade of life, when the incidence of some of the more common malignant neoplasms begins to rise (Fig. 15.1). The tragedy of the presence of a malignant neoplasm discovered during pregnancy raises many issues (Table 15.1). Fortunately, the peak incidence years for most malignant diseases do not overlap the peak reproductive years (Table 15.2). Thus, as in any unusual situation that physicians rarely encounter, clear therapeutic decisions are not readily at hand. However, a significant number of well-studied reviews can provide some guidance in this dilemma. The largest series ever reported was that of Barber and Brunschwig in 1968, which consisted of 700 cases of cancer in pregnancy. The most common malignant neoplasms in that series were breast tumors and leukemias–lymphomas as a category, melanomas, gynecologic cancer, and bone tumors, in that order. Other authors suggest that gynecologic malignant neoplasms are second only to breast carcinoma and remind us that cancer of the colon and thyroid are also seen in pregnancy (Table 15.3).

The incidence of cancer in pregnancy is unclear but is estimated to be one in 1000. From historical case series collected at a variety of referral institutions, many commentators have concluded that cervical cancer is the most frequent malignancy

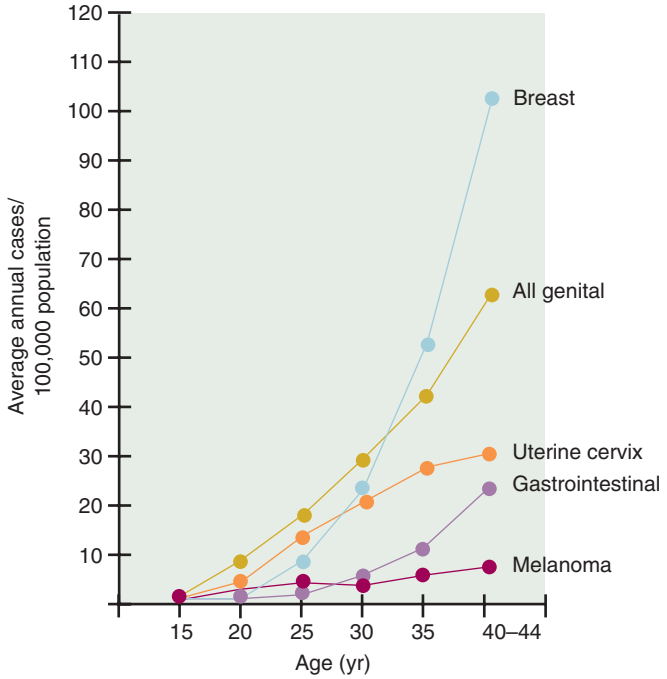

FIGURE 15.1 Incidence by age of the more common malignancies seen in pregnancy. (Data from the American Cancer Society Facts and Figures, 1995.)

TABLE 15.1 Cancer in Pregnancy: Issues to Consider

Oncologic Issues	Obstetric Issues	Ethical, Religious, Medicolegal, and Socioeconomic Issues
Timing of surgery	Fetal effects of therapy	Pregnancy termination
Type of therapy	Antepartum fetal surveillance	Independent advocate for the fetus
Maternal effects of therapy	Corticosteroid administration	Fetal viability
Maternal surveillance	Amniocentesis	Maternal risk
Fertility-sparing therapy	Timing of delivery	Healthcare costs
	Route of delivery	Principle of beneficence
	Neonatal effects of therapy	Right to autonomy
	Long-term effects of therapy	Mother's overall prognosis*

*It is important to take into account the estimated length of time the mother will realistically live to spend with the baby.

TABLE 15.2 Probability of Developing Invasive Cancers (%) Over Selected Age Intervals in Girls and Women, United States, 2003 to 2005

	Birth–39 Years	40–59 Years
All sites	2.07 (1 in 48)	8.97 (1 in 11)
Breast	0.48 (1 in 208)	3.79 (1 in 26)
Melanoma	0.27 (1 in 370)	0.58 (1 in 189)
Uterine cervix	0.15 (1 in 651)	0.27 (1 in 368)
Leukemia	0.12 (1 in 835)	0.14 (1 in 693)
Non-Hodgkin lymphoma	0.08 (1 in 1191)	0.32 (1 in 316)
Colon and rectum	0.07 (1 in 1343)	0.72 (1 in 138)
Uterine corpus	0.07 (1 in 1499)	0.72 (1 in 140)
Lung and bronchus	0.03 (1 in 2997)	0.81 (1 in 124)
Urinary bladder	0.01 (1 in 10,185)	0.12 (1 in 810)

Modified from The American Cancer Society, Surveillance and Health Policy Research, 2009.

TABLE 15.3 Distribution of Tumor Types Among 215 Women Diagnosed With Cancer in Pregnancy From 1998 to 2008 in Belgium, the Netherlands, and the Czech Republic

	Patients (*n*)	Patients (%)
Breast cancer	99	46
Hematologic malignancies	40	18
Dermatologic malignancies	21	10
Cervical cancer	17	8
Brain tumor	8	4
Ovarian cancer	8	4
Colorectal cancer	5	2
Other (eg, sarcoma, lung, liver, kidney, GI)	17	8

to complicate pregnancy. This finding is likely to be inaccurate because the incidence of cervical cancer in the United States and in most developed nations is steadily declining. In a 1984 population-based study, Haas reviewed the National Cancer Registry of the German Democratic Republic for the years between 1970 and 1979, and from a total of 31,353 cancer cases and 2,103,112 live births among women between the ages of 15 and 44 years, 355 pregnant women were diagnosed with a malignancy. Dinh and Warshal emphasized that in the Haas study, the incidence of cancer in pregnancy per 1000 live births rose from 0.02 for women aged 15 to 19 years to 2.3 for women aged 40 to 44 years. In order of decreasing frequency, cancer of the cervix, breast cancer, ovarian cancer, lymphoma, melanoma, brain cancer, and leukemia were found to complicate pregnancy.

In a recent study using data from the Swedish Multi-Generation Register and the National Cancer Registry from 1963 to 2007, Andersson et al. noted that the three most common malignancies during pregnancy were melanoma (n = 232), breast cancer (n = 139), and cervical cancer (n = 139). Interestingly, with a slightly different rank order, these cancers are also the most common to occur in women of childbearing age. Overall the investigators believed that the number of observed cases during pregnancy was lower than expected for all cancers, the reasons of which were unclear. In this study, it was noteworthy that a rebound in the number of observed cases during the postpartum period was restricted to melanoma, nervous system malignancies, and breast and thyroid cancer.

Data from the Surveillance, Epidemiology, and End Results (SEER) program in the United States from 1992 to 1996 estimate that among women aged 15 to 44 years, in order of decreasing frequency, cancer of the breast, melanoma, thyroid cancer, cervical cancer, lymphoma, and ovarian cancer are coincident with pregnancy. The Centers for Disease Control and Prevention have highlighted pregnancy trends in the United States over the preceding 25 years. Although the birth rate for women younger than 30 years of age rose slowly until the early 1990s, it has steadily declined since then. In contrast, the birth rate for women older than 30 years of age has risen steadily over the past 2 decades by an average of 67%. Because of the changing attitudes regarding the role of women as part of the workforce, the delay in childbearing observed in this country will be associated with at least three considerations that are germane to the subject of this chapter.

1. Because many malignancies manifest with advancing age, it is reasonable to expect an increase in the occurrence of some specific types of cancers during pregnancy.
2. Theoretic concerns regarding possible effects of pregnancy-derived hormones among cancer survivors contemplating pregnancy will need to be addressed.
3. With the popularization of investigational fertility-sparing medical and surgical therapy for nulliparous patients with seemingly early lesions who strongly desire to retain childbearing capacity, there exists an increased potential for the oncologist to encounter recurrent disease irrespective of whether pregnancy occurs.

The enormous physiologic changes of pregnancy suggest many possible influences on the malignant state. First, it has been assumed by many that malignant neoplasms arising in tissues and organs influenced by the endocrine system are possibly subject to exacerbation with pregnancy, and this has often been erroneously extrapolated to a recommendation for "therapeutic" abortion. Second, the anatomic and physiologic changes of pregnancy may obscure the subtle changes of an early neoplasm. Third, the increased vascularity and lymphatic drainage may contribute to early dissemination of the malignant process. Although all these hypotheses are interesting, the validity of each is variable, even within the same organ.

Several additional points must be emphasized when caring for a pregnant patient with symptoms suggestive of cancer or in whom the diagnosis has been established. **Although pregnancy is usually characterized by extensive medical observation, a delay in diagnosis can occur if attention is not paid to the subtle presentation of malignancies.** Thus, although pregnancy has not been shown to increase the virulence of any tumor type, many pregnancy-associated cancers portend a poor prognosis for the woman. Even though many essayists have claimed that the conduct of the pregnancy is not affected by the cohabitation of malignancy, the oncologist must recognize that some tumor types have been shown to metastasize to the placenta and even to the fetus. In all cases of pregnancy complicated by malignancy, it is advisable to have a multidisciplinary team of specialists involved in the care of the patient.

When considering therapy in pregnancy, surgery is rarely contraindicated, with the optimal time being in the second trimester. Chemotherapy for the most part should have restricted use during the first trimester but can generally be safely administered thereafter. Certain diagnostic imaging procedures can be safely performed during pregnancy, but in most cases, radiation therapy should be postponed until after delivery. Aggressive nutritional support is a mandatory requirement for pregnant women with cancer. In the majority of cases, with a proper coordination of effort, the pregnancy need not be terminated to begin treatment.

Report From the European Society of Gynecological Oncology Cancer in Pregnancy Task Force

Amant et al. recently reported updated guidelines from the Second International Consensus Meeting arranged to disseminate experts' knowledge and form consensus guidelines for medical and oncologic intervention to address maternal malignancy diagnosed during pregnancy and the postpartum period. Protocols for management of pregnancy-associated cervical cancer, ovarian cancer, and vulvar cancer were reviewed. The guidelines developed advocate following standard treatment protocol as for nonpregnant patients to maximize maternal outcome but with the caveat that iatrogenic prematurity should be avoided. The experts committee stressed effective psychologic support throughout the pregnancy and endorsed diagnostic procedures including open or laparoscopic surgical staging examinations, as well as imaging being preferably performed using nonionizing radiation modalities such as magnetic resonance imaging (MRI) and ultrasonography. Importantly, most chemotherapy regimens were thought to be tolerable and safe from 14 weeks' gestational age onward. Although term delivery should be the goal, apart from cervical and vulvar cancer (with concomitant vulvar scarring), the mode of delivery should be based in most cases on obstetric indications.

THE MORE COMMON SOLID TUMORS IN PREGNANCY

Cervical Cancer

Cervical cancer complicates approximately 1 in 1200 pregnancies. As a consequence of widespread cytologic screening, the dramatic decrease in invasive cervical cancer observed in recent years has been paralleled by a rise in cervical intraepithelial neoplasia (CIN), especially in younger women. Because the peak incidence for both CIN and childbearing occurs during the third decade of life, abnormal Papanicolaou smears are common among gravid women, occurring at a rate of 0.5% to 5%. **The diagnosis of cervical dysplasia in pregnancy may occur in up to 5% of some populations.** For these reasons, screening for cervical neoplasia is an essential component of prenatal care. All pregnant women should have a cervical smear submitted for cytology. The ectocervix and endocervical canal should be sampled adequately. **Patients noted to have a visible lesion should undergo cervical biopsy immediately because cervical smears taken directly from tumors often contain only inflammatory cells.** A recent review from the

Magee Gynecologic Cancer Program in Pittsburgh noted that in some populations, up to 20% of pregnant women have an abnormal Pap result during pregnancy. Nearly 3% of newly diagnosed cervical cancer cases occur in pregnant women, probably because it is the one cancer that is screened for as part of routine prenatal care.

In concordance with the known risk factors for invasive cervical cancer, pregnant women who develop CIN tend to marry at an earlier age, have a higher parity, and are diagnosed at an earlier age than nonpregnant women with CIN. Hacker and colleagues compiled data from nine reports and noted that the average age of patients with carcinoma in situ (CIS) during pregnancy was 29.9 years, and the average parity was 4.0. Among nonpregnant women, the average age of CIS is 35 years. The investigators noted that the median age of patients diagnosed with invasive carcinoma of the cervix during pregnancy is 33.8 years (range, 17–47 years), and the average parity is 4.5. The average parity among pregnant women with cervical cancer was 5.4 in a study reported by Creasman and colleagues; in this group, increasing parity was not associated with a more advanced lesion, nor did it have an impact on prognosis.

Human Papillomavirus in Pregnancy

Although human papillomavirus virus (HPV) is strongly associated with cervical dysplasia and carcinoma in both nonpregnant and pregnant women, a significant relationship between pregnancy and HPV prevalence has not been established. Eversion of the endocervical epithelium results in exposure to the acidity of the vaginal environment, producing a high degree of squamous metaplasia. This metaplasia is important because HPV requires active cellular machinery to reproduce and transform cells. Schneider and colleagues examined the negative cervical smears of 92 pregnant and 96 nonpregnant, age-matched control participants for the presence of HPV DNA by Southern blot hybridization. The investigators demonstrated both an increased prevalence of HPV (preferentially the oncolytic HPV subtype 16) and a higher replication rate of viral DNA during pregnancy. Using the ViraPap/ViraType dot blot DNA hybridization procedure, Smith and coworkers detected an increase in HPV prevalence with advancing gestational age, suggesting that as estrogen levels increase, pregnant women may be more vulnerable to HPV infection. Using similar hybridization methods, however, Kemp and colleagues and Chang-Claude and colleagues were unable to demonstrate a higher prevalence of HPV infection during pregnancy.

Castellsague and colleagues performed a prospective study in Barcelona to quantitate the mother-to-child transmission of HPV subtypes. This study included 66 HPV-positive and 77 HPV-negative pregnant women and their offspring. To estimate HPV prevalence and genotypic distribution in pregnancy, the investigators also carried out a related screening survey of cervical HPV DNA detection among 828 pregnant women. Exfoliated cells from the mouth and external genitalia of the infants were collected at birth and at several intervals up to 2 years of age. At 418 infant visits and a mean follow-up time of 14 months, 19.7% of infants born to HPV-positive mothers and 16.9% of those born to HPV-negative mothers tested HPV positive at some point during the infants' follow-up. The most frequently detected genotype both in infants and in mothers was HPV-16. Of note, there was a strong and statistically significant association between mother's and child's HPV status at the 6-week postpartum visit in that children of mothers who were HPV positive at the postpartum visit were five times more likely to test HPV positive than children of corresponding HPV-negative mothers ($P = 0.02$). The authors concluded that the risk of vertical transmission of HPV genotypes is relatively low and that vertical transmission may not be the sole source of HPV infections in infants. There exists the potential for horizontal mother-to-child transmission.

Evaluation of the Papanicolaou Smear in Pregnancy

The cytopathologist frequently encounters atypical cells when reviewing the cervical smear from a pregnant patient. Cells within the endocervical canal that undergo the Arias–Stella reaction may contain a vacuolated clear or oxyphilic cytoplasm, intraglandular tufts, hobnail patterns, delicate filiform papillae, intranuclear pseudoinclusions, cribriform intraglandular growth, and even occasional mitotic figures. Distinguishing features of dysplastic and frankly malignant cells would include an infiltrative pattern, spectrum of cytologic atypia, a high nuclear-to-cytoplasmic ratio, and increased mitotic activity. Other atypical cells exfoliated by the endocervix in pregnant women include small decidualized cells with sharp cytoplasmic borders and hypochromatic nuclei, but unlike dysplastic cells, decidualized cells contain regular chromatin and distinct nuclei. Finally, large, multinucleated trophoblastic cells may be discharged from the uterus. At this time, it is not clear if liquid-based cytology can decrease the false-positive rate. Nevertheless, careful inspection of the cervical smear maintains its reliability as a screening test for dysplasia among pregnant patients.

The Performance of Colposcopy in Pregnancy

Colposcopy is facilitated by the pregnancy-induced eversion of the normal cervical ectropion. **However, pregnancy results in dramatic alterations in the colposcopic appearance of the cervix, the most significant changes resulting from the elevated levels of circulating estrogen, which produces a significant increase in cervical volume through hypertrophy of the fibromuscular stroma.** The increased vascularity produces a bluish hue, which is then exaggerated with application of acetic acid to the metaplastic epithelium in pregnancy. Toward the end of the first trimester, eversion and metaplasia produce areas of fusion of columnar villa and distinct islands or fingers of immature metaplastic epithelium. Fine punctation and even mosaicism may accompany metaplasia, which in and of itself produces an acetowhite effect. Tenacious endocervical mucus develops, which further hinders colposcopic examination. Finally, stromal edema, enlargement of glandular structures, acute inflammatory responses, and stromal decidualization may occur in the second and third trimesters, which, although physiologic, may appear suspicious to the inexperienced colposcopist. For these reasons, colposcopy in pregnancy is difficult and should be reserved for an experienced gynecologist.

The aim of colposcopy in pregnancy is to exclude cancer, and only one directed biopsy of the site compatible with the most advanced area of dysplastic change should be performed to establish the histologic level of disease. Because of false-negative results ranging from 8% to 40%, random or nondirected biopsies should be avoided. **Great care must be exercised because the increased vascularity may lead to precipitous, heavy bleeding.** A Tischler or baby Tischler biopsy forceps should be used followed by immediate placement of a cotton-tipped applicator above the cervical epithelium. If bleeding occurs, it may be controlled with three silver nitrate sticks or with dehydrated Monsel's solution. An endocervical curettage, however, is best avoided during pregnancy.

Yoonessi and colleagues conducted a retrospective analysis of suspected CIN associated with pregnancy and concluded that colposcopic examination with or without directed biopsy eliminated the need for cervical conization in 104 of 107 patients. In their classic paper, Hacker and colleagues noted that serious morbidity, such as hemorrhage, preterm labor, miscarriage, or infection, only infrequently occurs when directed biopsies are performed. For 1064 reported colposcopic examinations during pregnancy, the diagnostic accuracy was 99.5%, and the complication rate was 0.6%. No case of frankly invasive carcinoma was missed, and the two cases of microinvasion missed on colposcopic biopsy both had a colposcopic pattern suggestive of microinvasion, which was confirmed by subsequent conization. Thus, in experienced hands, colposcopy reduces the need for cone biopsy in pregnancy, with a false-negative rate of less than 0.5%.

Recently, Wetta and colleagues presented the University of Alabama experience on 625 pregnant women with CIN. The most common referral cytology was low-grade squamous intraepithelial lesions (LSIL; 41%) followed by atypical squamous cells of undetermined significance (ASC-US; 34.1%) and high-grade squamous intraepithelial lesions (HSILs; 13.6%). Of the 269 patients with ASC-US and LSIL cytology, 20 of 78 patients who underwent cervical biopsy were diagnosed with CIN II or III. Of the 128 patients with HSIL, 31 of 60 patients who underwent cervical biopsy were diagnosed with CIN II or III. Repeat colposcopy in the third trimester was performed on 47 patients, and only three of 13 patients who had a repeat biopsy had CIN II or III. The authors concluded that pregnant patients with ASC-US or LSIL cytology rarely have colposcopically suspected CIN II or III at their initial colposcopy that warrants a cervical biopsy. The investigators consider it reasonable to defer the initial colposcopy in these cases until at least 6 weeks postpartum.

Onuma and colleagues have evaluated the diagnosis of ASC-H (atypical squamous cells with possible HSIL) in 60 patients. Among 30 who had histologic follow-up, three women (10%) had HSIL, and 13 (43%) had LSIL. Among 32 women who had cytologic follow-up, two (6%) had HSIL, three (9%) had LSIL, one (3%) had ASC-H, and three (9%) had ASC-US. High-risk HPV DNA was detected in 24 of 43 patients (56%). The authors suggest that ASC-H in pregnant women has a lower predictive value for an underlying HSIL compared with the general population. Although a positive high-risk HPV DNA test result was not a good indicator for underlying SIL, a negative result appeared useful for ruling out an underlying HSIL. The authors advocated for a more conservative follow-up for pregnant women with ASC-H and support using high-risk HPV DNA testing as an adjunctive test.

The Natural History of Cervical Intraepithelial Neoplasia in Pregnancy

It appears that in an immunocompetent host evaluated colposcopically and pathologically by experienced eyes, CIN rarely, if ever, progresses to microinvasive disease during pregnancy. In fact, there appears to be a subset of patients who will experience disease regression after delivery of the neonate. Postpartum regression rates for abnormal cervical cytology consistent with dysplasia (combining both LSIL and HSIL) have ranged from 25% to 77%. This wide range is hard to explain, with some authors postulating that regression occurs in at least one-third of patients as a consequence of resolution of pregnancy-induced changes in the maternal immunologic system. An Italian study published in 2008 detailed the natural history of CIN in 78 pregnant women. Among those with CIN II or III (n = 36; 46.2%), no invasion was suspected during pregnancy, and at the postpartum evaluation, no invasive or microinvasive cancer was diagnosed. Of note, there were 19 (52.7%) cases of persistent CIN II or III and 42 (53.8%) regressions. The authors noted that CIN I has a significantly higher tendency to spontaneous regression compared with nonpregnant women with CIN I. High-risk HPV testing may improve the follow-up of patients with SIL in pregnancy and postpartum to assist in the diagnosis of persistent infections.

Some authors have advanced the theory that vaginal birth trauma may result in the complete debridement of dysplastic tissues. This phenomenon was observed by Ahdoot and colleagues in a prospective collection of abnormal cytology during pregnancy and in the postpartum period. The investigators observed a 60% regression rate among women with HSILs who delivered vaginally versus 0% in those with HSILs who delivered by cesarean section (P <0.0002). A study by Siristatidis and colleagues demonstrated a 66.6% regression rate among women with HSILs who delivered vaginally versus 12.5% of those with HSILs who delivered by cesarean section (P <0.002). In direct contradistinction, the cytologic study by Murta and colleagues (LSILs in pregnancy) and the pregnancy-related histologic investigations by Murta and colleagues (CIN CIN II or III), Yost and colleagues (CIN II or III), and Coppola and colleagues (CIS) failed to show any statistically significant difference in postpartum regression rates for patients who delivered vaginally versus those who labored and went on to deliver by cesarean section versus those who underwent elective cesarean delivery.

A recent report by Ueda and colleagues describes the experience with CIN in pregnancy at Osaka University Hospital. The investigators observed regression of CIN in 34 (76%) of 45 cases of vaginal delivery and in six (50%) of 12 cases of cesarean delivery, indicating that the outcome of an initially diagnosed CIN and the delivery routes appear not to be significantly related. However, a different result was obtained when only

patients whose CIN lesions persisted until the delivery were analyzed. Among the 35 such cases in the vaginal delivery group, 24 cases (69%) regressed after the delivery; in eight such cases from the cesarean delivery group, only two cases (25%) regressed after delivery. There was also significantly more frequent postpartum regression of biopsy-proven CIN lesions after vaginal delivery compared with cesarean section ($P = 0.042$; odds ratio [OR] 6.55; 95% confidence interval [CI], 1.13–37.8).

Conization and Related Procedures in Pregnancy

The performance of a cone biopsy during pregnancy is a formidable undertaking, and one must weigh the risks of the procedure against the anticipated yield of microinvasive carcinoma (MIC), which would remain otherwise undetected. **Maternal risk appears to be restricted to either immediate or delayed hemorrhage, occurring in up to 14% of cases and exceeding 400 mL when the procedure is performed during the third trimester.** Averette and colleagues reported the largest series of cold knife cervical conization biopsies in pregnancy and noted that 9.4% of the study group ($n = 180$) required a blood transfusion. Maternal death has not been reported. Injury to the pregnancy, resulting in spontaneous abortion, intrauterine infection, and preterm birth, however, places the fetus at considerable risk. Rogers and Williams presented a series of 72 pregnancy conizations and reported a perinatal complication rate of 19.4%. Across the literature, the risk of pregnancy loss when the procedure is performed during the first trimester ranges from 15.2% to 33%. **Overall, cone biopsy in pregnancy is associated with a 3% to 6% risk of perinatal death as a consequence of profuse hemorrhage or from delivery of a previable or extremely premature fetus through an incompetent cervix.** A further point that needs emphasizing is that 30% to 57% of pregnant cones will have dysplasia, microinvasive tumor, or both at the endocervical or ectocervical margins. For this reason, the procedure should not be considered therapeutic in the pregnant patient.

The large-loop electrosurgical excision of the transformation zone (LLETZ) may be used in the operating room to excise a shallow cone of sufficient breadth and depth to permit treatment decisions during pregnancy. Robinson and colleagues reported on 20 women who underwent LLETZ from 8 to 34 weeks of gestational age and noted significant morbidity in patients treated between 27 and 34 weeks of gestational age, including two blood transfusions, three preterm births, and one unexplained intrauterine fetal demise 4 weeks postprocedure. Mitsuhashi and Sekiya performed a LLETZ on nine women during the first 14 weeks of pregnancy, none of whom experienced spontaneous abortion, premature delivery, or excessive bleeding. These preliminary results suggest that LLETZ can be performed safely during the first trimester of pregnancy, but there are insufficient data to determine whether this procedure can replace the traditional cold knife cone biopsy. LLETZ is also associated with a significant proportion of patients left with residual disease.

Hacker and colleagues commented that most authors reserve conization for patients in whom the transformation zone was not fully visualized, microinvasion was shown on biopsy or suspected colposcopically, or possible adenocarcinoma was found on biopsy. If colposcopy is unsatisfactory, one alternative to a full cone is a wedge resection of the cervix, removing only areas incompletely visualized colposcopically. **Another option is to place six hemostatic sutures, evenly distributed around the perimeter of the cervix close to the vaginal reflection (Fig. 15.2). These sutures reduce blood flow to the cone bed, evert the squamocolumnar junction, and facilitate performance of a shallow "coin" biopsy with little interruption of the endocervical canal (Fig. 15.3).**

To offset the risk of cervical incompetence, Goldberg and colleagues performed 17 cone cerclages between 12 and 27 weeks of gestation. All procedures were performed with the patient under general anesthesia. After injection of the entire ectocervix with vasopressin (20 units in 60 mL of normal saline), lateral hemostatic 2-0 polyglycolic acid sutures were

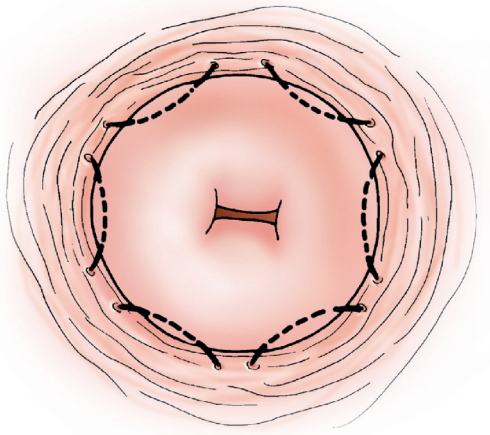

FIGURE 15.2 The locations of six hemostatic sutures. (From Creasy RK, Resnick R. *Maternal–Fetal Medicine: Principles and Practice*. Philadelphia, 1987, Saunders.)

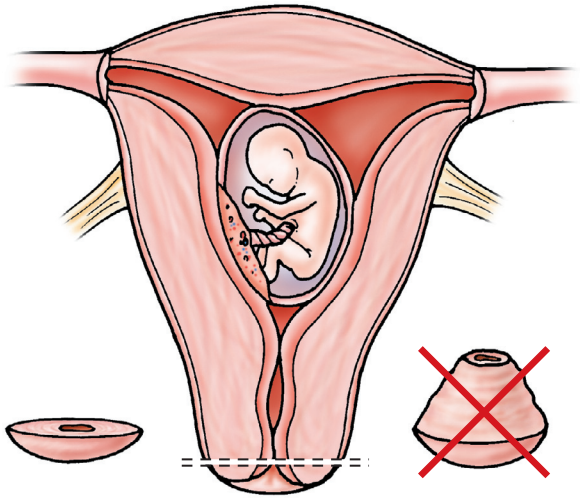

FIGURE 15.3 Demonstration of shallow "coin" biopsy appropriate in pregnancy. (From Creasy RK, Resnick R. *Maternal–Fetal Medicine: Principles and Practice*. Philadelphia, 1987, Saunders.)

placed at the 10 and 2 o'clock positions on the cervix, and a standard McDonald cerclage using #1 nylon suture material was inserted as high and as close to the internal cervical os as technically possible without reflection of the bladder. After the cervical cone was excised, the McDonald suture was tied with the knot placed anteriorly, and an iodoform vaginal pack inserted for 24 hours. All 17 patients had uneventful pregnancies, delivering viable infants at or beyond 34 weeks of gestation.

Tsuritani and colleagues have reported on the safety and efficacy of CO_2 laser conization in pregnant women with CIN III or CIS ($n = 30$) and MIC ($n = 19$). The median gestational age was 17 weeks, and the median length of cervix resected was 14 mm. The median duration of surgery was 20 minutes, and median blood loss was 78 mL. Laser conization identified one case of International Federation of Gynecology and Obstetrics (FIGO) Ia2 carcinoma and three cases of FIGO IB1 disease. Of the 35 women who were able to be followed through until delivery, 27 (77.1%) delivered vaginally. Although eight (22.9%) had cesarean sections and six (17.1%) delivered preterm, no CO_2 conization–related obstetric complications were observed.

Fambrini and colleagues have performed CO_2 laser conization in 26 pregnant patients with biopsy-proven CIS or CIN III whose colposcopic evaluation was suspicious for invasion. The procedures were performed during the 18th week of gestation, and no major intraoperative or postoperative complications occurred. Two cases of occult FIGO stage IA1 carcinoma with free surgical margins were diagnosed. Twenty patients (76.9%) delivered vaginally, and six patients underwent cesarean section for indications not related to the prior conization. After a mean postpartum follow-up time of 18 months, 92.3% of patients were cytologically and colposcopically negative for persistent or recurrent disease. Two cases of persistent CIN were managed successfully by reconization.

Management of Cervical Intraepithelial Neoplasia in Pregnancy

An algorithm that illustrates several key points concerning the management of CIN in pregnancy is proposed in Fig. 15.4. The critical issue is to exclude the coexistence of microinvasive disease with pregnancy. This is because everything else,

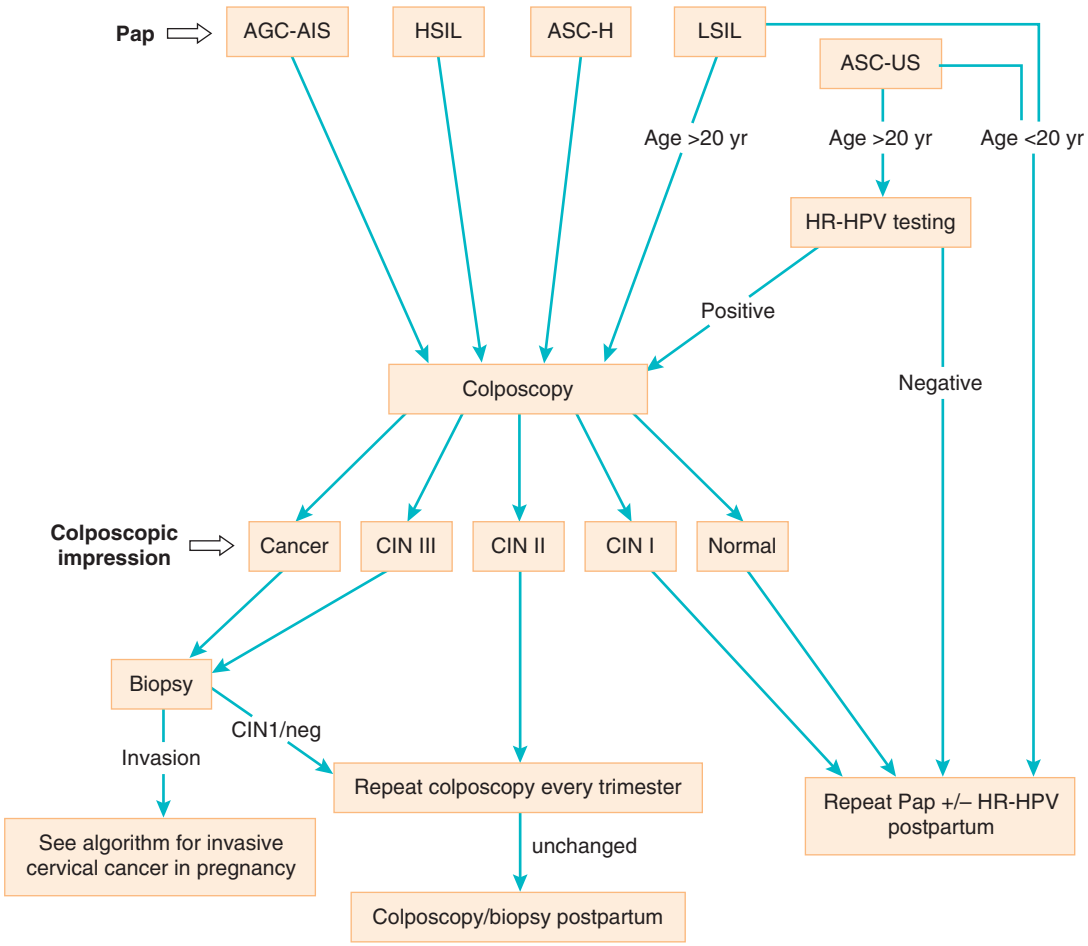

FIGURE 15.4 Management of abnormal cytologic findings in pregnancy. *AGC-AIS,* atypical glandular cells-adenocarcinoma in situ; *ASC-H,* atypical squamous cells with possible high-grade squamous intraepithelial lesion; *ASC-US,* atypical squamous cells of undetermined significance; *CIN,* cervical intraepithelial neoplasia; *ECC,* endocervical curettage; *HR-HPV,* high risk-human papillomavirus; *HSIL,* high-grade squamous intraepithelial lesion; *LSIL,* low-grade squamous intraepithelial lesion; *Pap,* Papanicolaou smear.

the gamut between cellular atypia and CIS, can be followed expectantly during pregnancy, with treatment deferred after its conclusion. We emphasize the following steps:

1. All abnormal cervical smears in pregnancy (excluding HPV-negative atypia) should prompt an evaluation by colposcopy.
2. An experienced colposcopist must accurately assess the disease to determine whether a directed biopsy is indicated.
3. In cases involving a CIS on directed biopsy, a coordinated effort between the gynecologist and the pathologist should be undertaken to determine whether an excisional biopsy is required to exclude invasion.

Management of Squamous Cell Abnormalities

In 2006, the American Society for Colposcopy and Cervical Pathology (ASCCP) updated its recommendations for cervical cancer screening in pregnancy and management of CIN and AIS in pregnancy. Highlights of these recommendations (which were published in 2007) include the following:

For squamous cell abnormalities:

1. Expectant management during pregnancy is acceptable for CIN I to III and CIS.
2. In patients for whom there is no concern for microinvasion, serial colposcopy during pregnancy (eg, every trimester) is not necessary.
3. Definitive management of CIN and CIS should be deferred to the postpartum period in most cases.

Pregnant women with normal prenatal cytologic screening traditionally undergo repeat screening during the postpartum period. Patients with a prenatal Papanicolaou test consistent with ASC-US may undergo reflex testing for oncolytic HPV subtypes if the Hybrid Capture II test (Digene Corporation) is available. Patients who test HPV negative may be reevaluated with cervical cytology 6 to 8 weeks after delivery. Pregnant women who are found to have cytology consistent with ASC-US and are high-risk HPV positive should be referred for colposcopic evaluation. Patients with cytology consistent with atypical squamous cells favoring a high-grade lesion, LSILs, HSILs, and squamous cell carcinoma (SCC) (and all Papanicolaou tests suggesting glandular cell abnormalities) should be referred for colposcopic evaluation. Because of the high prevalence of HPV in cytologic smears consistent with intraepithelial lesions and carcinoma, HPV testing is not indicated.

If the colposcopic impression is normal or consistent with CIN I, the Papanicolaou test with or without colposcopy can be repeated in the postpartum period provided that the original Papanicolaou test was not consistent with a high-grade lesion; if colposcopy was performed because of HSILs or SCC, the colposcopic evaluation should be repeated each trimester of the pregnancy, with a directed punch biopsy taken if the impression is consistent with progressive disease (above CIN II).

Patients for whom colposcopy is consistent with CIN II or greater should undergo a single directed biopsy. If this reveals CIN III or worse, the patient should undergo repeat colposcopic evaluation each trimester, with definitive treatment reserved for after delivery, provided there is no evidence for disease progression.

Patients whose biopsies are suspicious for microinvasion should undergo one of the excisional procedures described previously (ie, conization or LLETZ with or without cerclage, coin biopsy, or wedge biopsy). **If microinvasion is excluded, the patient should be observed during the pregnancy with colposcopy.** If microinvasion is established either by directed punch biopsy or by excisional biopsy, recommendations specific for malignant disease must be sought (see later).

In some circumstances, the colposcopic evaluation will be unsatisfactory, in that the entire transformation zone cannot be completely evaluated. If there is no evidence of a severe lesion in the evaluable areas and the original Papanicolaou test was not consistent with SCC or adenocarcinoma in situ (AIS), close observation with repeat colposcopy during each trimester of the pregnancy may be considered. Under more dire scenarios, a coin biopsy of the cervix or a wedge biopsy of the hidden part of the transformation zone may be necessary.

Management of Glandular Cell Abnormalities

Cervical smears containing glandular cell abnormalities may be reported as atypical cells not otherwise specified (AGC-NOS), atypical cells favor neoplasia, AIS, or even adenocarcinoma. **Of note, 40% of cervices associated with an atypical glandular cells of undetermined significance (AGUS) smear will have a significant tissue abnormality, with greater than 50% harboring an SIL.** The significance of an AGUS Papanicolaou result in pregnant and in postpartum women is not yet clear. In a recent manuscript by Chhieng and colleagues, 30 pregnant women and five within the immediate postpartum window were evaluated for a cytologic diagnosis of AGUS. Of 27 women for whom there was follow-up, 17 underwent colposcopic examination and biopsy. Five women (29.4%) had CIN, including three high-grade and two low-grade lesions on biopsy. It is interesting that the remaining patients (70.6%) had benign pathology, which included chronic cervicitis ($n = 5$), endocervical endometrial polyps (or both) ($n = 4$), Arias–Stella reaction ($n = 2$), and microglandular hyperplasia ($n = 1$); of the 10 patients who had repeat Papanicolaou tests, only two had persistent AGUS or ASC-US. Nevertheless, the finding that up to 30% of patients with pregnancy-associated AGUS had a significant preneoplastic lesion warrants careful evaluation.

The clinician's diagnostic armamentarium is limited during pregnancy. In the absence of a visible lesion or a significantly expanded cervix (ie, the barrel-shaped cervix), all patients with AGUS smears should undergo colposcopic evaluation with directed biopsy. Patients diagnosed with a squamous lesion or AIS should be evaluated by colposcopy during subsequent trimesters. It is not known whether a patient with AIS on directed biopsy should undergo wedge resection of that area to rule out invasion in a nearby "skip" lesion. A diagnostic LLETZ cold knife cervical conization (or both) during pregnancy is best reserved only for those few cases in which an AIS or squamous lesion suspicious for microinvasion is encountered on directed biopsy.

If colposcopy is unrevealing, however, the concern is raised that an endocervical lesion high in the canal or even within the endometrial compartment is being missed. Nevertheless, an endocervical curettage, cervical dilatation with fractional uterine curettage, or endometrial aspiration biopsy is best

deferred until the postpartum period, when even a full cervical conization can be performed if needed. Therefore in these clinical scenarios, consultation with the cytopathologist should be arranged to determine if the original Papanicolaou slide contains troublesome features such as inflammatory cells, polyps, glandular hyperplasia, or the Arias–Stella reaction, any of which could confuse the picture, especially when dealing with an AGC-NOS Papanicolaou smear. Gravid women with a negative colposcopic survey for an atypical glandular cell (AGC) favoring neoplasia cervical smear can be evaluated safely in pregnancy with either endovaginal ultrasonography or MRI of the pelvis to search for a lesion within the endometrium or endocervical canal. In these latter circumstances, referral to a gynecologic oncologist should be contemplated.

The 2006 ASCCP management schema for AIS includes the following:

1. Expectant management during pregnancy is acceptable for AIS.
2. In patients for whom there is no concern for microinvasion, serial colposcopy during pregnancy (eg, every trimester) is not necessary.
3. Definitive management of AIS should be deferred to the postpartum period.

Intrapartum Hysterectomy

Some authors have described a program in which an intrapartum hysterectomy (after either vaginal or cesarean birth) is performed for patients with CIS or AIS who have completed childbearing or have proved to be noncompliant. Because there is not sufficient evidence to suggest that an immunocompetent patient is at risk for rapid progression of disease during pregnancy, the need to remove the diseased segment of the cervix is not urgent. Intrapartum hysterectomies, both elective and nonelective, can be associated with significant blood loss. Furthermore, among inexperienced obstetricians, the bladder is particularly at risk for injury. One must balance the noncompliance of a given patient with the possibility that microinvasion may not have been sufficiently excluded during pregnancy, especially in cases of CIS or AIS with positive margins. The observation that postpartum regression may also occur with even CIS argues against the routine performance of an intrapartum hysterectomy for the management of CIN in pregnancy.

Invasive Cervical Cancer

Presenting symptoms in order of frequency among pregnant women with cervical carcinoma include abnormal vaginal bleeding (63%), vaginal discharge (13%), postcoital bleeding (4%), and pelvic pain (2%). Of importance, in the review by Hacker and colleagues, 18% of patients were asymptomatic, as were 30% of the patients in the study by Creasman and colleagues. When bleeding occurs, this symptom must be investigated and not automatically attributed to the pregnancy. Examination during the first trimester will not lead to abortion. Third-trimester bleeding can be adequately assessed in the operating room as a double setup procedure. Many times, visual inspection is all that is needed for diagnosis of this malignant neoplasm. **The FIGO staging system applies also in pregnancy. To avoid the risks of radiation exposure to a developing fetus, the author recommends ultrasonography of the kidneys to evaluate for the presence of hydronephrosis and an MRI of the pelvis when there is concern for parametrial extension of the tumor.** Chest radiography may be performed with appropriate abdominal shielding to exclude pulmonary metastases. An algorithm for the suggested management of invasive cervical cancer in pregnancy appears in Fig. 15.5.

A working group was set up in 2007 in France to propose national recommendations for the management of pregnant patients with invasive cervical cancer. The management of cervical cancer during pregnancy is affected by five factors:

1. **FIGO stage (and tumor size)**
2. **Nodal status**
3. **Histologic subtype of the tumor**
4. **Gestational age at diagnosis**
5. **Patient's wishes regarding continuation of pregnancy**

In patients with early-stage disease diagnosed during the first two trimesters of pregnancy, there is an increasing tendency to preserve the pregnancy while awaiting fetal maturity in patients with absence of nodal involvement.

Microinvasive Disease

The diagnosis of MIC in pregnancy is typically established with colposcopic directed biopsy, and in a minority of cases in which the colposcopic biopsy cannot exclude microinvasion, a shallow coin biopsy or the cervix or wedge excision of the area under suspicion as outlined earlier is suggested. This is the only absolute indication for conization during pregnancy. Conization distinguishes patients who have "early stromal invasion" and who can proceed to term without appreciable risk to their survival from those with frank invasion in whom consideration must be given to early interruption of the pregnancy. **The author advises patients with early stromal invasion (ie, FIGO stage Ia1) that the pregnancy may continue safely to term, provided the surgical margins are free.** Karrberg et al. recently published their 16-year experience from the Western Region of Sweden and emphasize that early detection of cytologic atypia and proper follow-up during pregnancy will likely lead to detection of a high proportion of stage 1 cases, many of which could be cured via cervical conization, thus preserving current and future fertility.

Cesarean section is not thought to be necessary for this group of patients, and the route of delivery should be determined by obstetric indications. Patients with FIGO stage Ia2 or occult Ib1 lesions should undergo cesarean delivery when fetal pulmonary maturation is demonstrable followed by an immediate modified radical abdominal hysterectomy with bilateral pelvic lymphadenectomies. The author advocates the deployment of a vertical uterine incision so as to leave the lower uterine segment undisturbed for subsequent detailed pathologic examination. It is interesting that the physiologic changes of pregnancy actually enhance the performance of radical surgery by providing the surgeon with multiple levels of distinct tissue planes.

Recently, reports of laser conization for microinvasive disease have originated from Japan. As described earlier, Tsuritani and

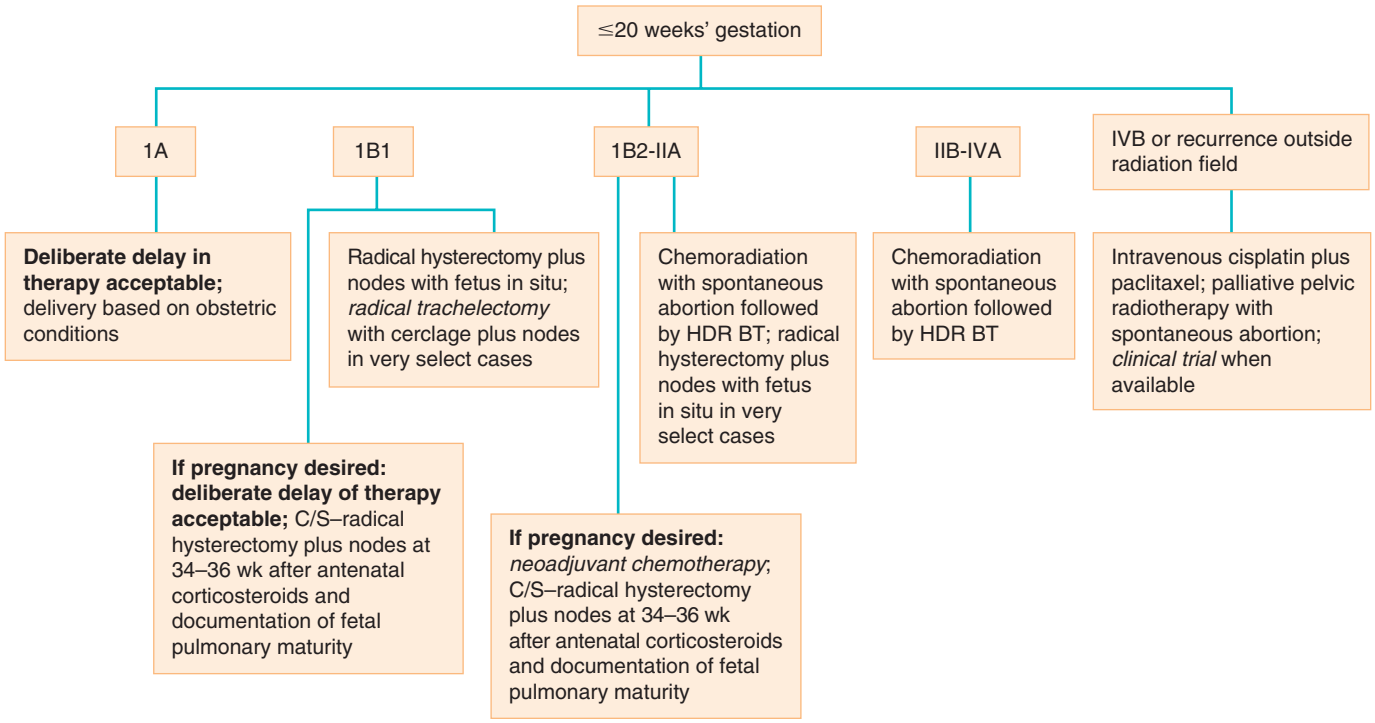

FIGURE 15.5 Suggested therapy for cervical cancer in pregnancy. *C/S,* cesarean section; *HDR BT,* high dose rate brachytherapy.

colleagues have included 19 women with MIC in their series of 49 women and considered CO_2 laser conization within 20 mm of length to be safe in pregnant patients. Yahata and colleagues have reported their experience with four patients diagnosed with stage IA1 cervical adenocarcinoma who underwent KTP (potassium titanyl phosphate) laser conization and vaporization from 16 to 23 weeks of gestation. All patients delivered at term, at which point they underwent radical hysterectomy with lymphadenectomy ($n = 3$) or cold knife conization ($n = 1$). None have developed recurrent disease during a 2- to 13-year follow-up period.

Cesarean–Radical Hysterectomy With Pelvic Lymphadenectomies

In deciding on therapy for frankly invasive cervical cancer in pregnancy, the physician must consider both the stage of disease and the duration of pregnancy. The decision can often be influenced by the religious convictions of the patient and family and the desire of the mother for the child. For FIGO stage I and FIGO stage IIa lesions, radical hysterectomy with bilateral lymphadenectomy is acceptable during any trimester (Fig. 15.6). **We prefer the surgical approach because of the overall result, which includes ovarian preservation, improved sexual function, and elimination of unnecessary delays for the patient.** The complication rate of radical surgery for cervical carcinoma in pregnant patients does not exceed that in nonpregnant patients when normal surgical principles are scrupulously followed.

Monk and Montz examined their institutional experience in treating invasive cervical cancer complicating intrauterine pregnancy with radical hysterectomy. They identified 13 patients treated with radical hysterectomy and bilateral pelvic lymphadenectomy with the fetus in situ and eight others treated with cesarean delivery followed by radical hysterectomy and bilateral pelvic lymph node dissection. The mean operative time was 281 minutes, and the mean blood loss was 777 mL for radical hysterectomy with the fetus in situ plus lymphadenectomy and

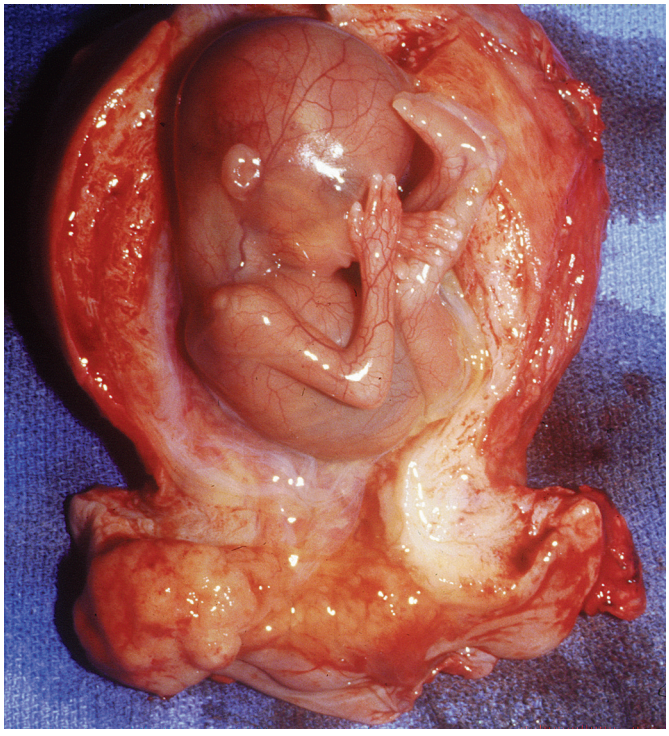

FIGURE 15.6 An 18-week-old fetus. Cervical cancer with a vaginal cuff and an extruding placenta are seen in a radical hysterectomy specimen from a 32-year-old patient.

1750 mL when cesarean section preceded the cancer operation. The surgical morbidity was minimal for the whole group, and after documentation of fetal maturation, seven healthy infants were delivered. Twenty patients (95%) are alive and free of disease with a mean follow-up of 40 months. The authors concluded that radical surgery offers immediate treatment for early-stage cervical cancer during intrauterine pregnancy, with low associated morbidity, acceptable survival, and preservation of ovarian function.

Radical Trachelectomy With Lymphadenectomy

In recent years, several reports have appeared describing the successful performance of radical trachelectomy during pregnancy. Abu-Rustum and colleagues treated a 37-year-old pregnant woman at 15 weeks of gestational age for a FIGO stage IB1 poorly differentiated lymphoepithelioma-like cervical carcinoma found on conization. The procedure was performed abdominally and included bilateral pelvic lymphadenectomies and permanent cerclage placement. The final pathology revealed 7-mm (of 19-mm) invasion with no lymphovascular involvement, negative margins, and negative nodes. The pregnancy was delivered by elective planned cesarean hysterectomy at 39 weeks of gestational age. This procedure has also been safely performed during the 19th week of gestation by Mandic and colleagues. Again, the abdominal approach was used, and the patient underwent successful cesarean section at 36 weeks of gestation. At the time of manuscript acceptance, the patient was in the 15th week of a new pregnancy and had normal cytologic screening and no evidence of metastatic or recurrent carcinoma. Finally, Gurney and Blank have described a patient diagnosed with FIGO IB1 disease at 21 weeks of gestational age who underwent postpartum radical abdominal trachelectomy. Ungar and colleagues reported five cases of radical abdominal trachelectomy during pregnancy and the birth of two healthy term infants.

The first case of vaginal radical trachelectomy was reported by van de Nieuwenhof and colleagues to have occurred at 16 weeks of gestation for a FIGO stage IB1 lesion. This patient underwent an uneventful cesarean section followed by radical hysterectomy at 36 weeks of gestational age, and at 9 months of follow-up, both the mother and infant were doing well.

Alouini and colleagues reported laparoscopic pelvic (with and without aortic) lymphadenectomy during pregnancy in eight patients from 12 to 32 weeks of gestation. There were no surgical or general anesthetic maternal or fetal complications. The mean number of lymph nodes removed was 18 (range, 11–28), and in five patients (stage IB1, $n = 4$; stage IB1, $n = 1$), there was pathologic evidence of nodal metastases. One patient experienced a spontaneous abortion after radical trachelectomy, but the remaining seven reached fetal maturity and had healthy babies by cesarean section. Laparoscopic staging with retrieval of 19 negative nodes for a FIGO stage IB1 carcinoma complicating a twin pregnancy was safely performed at 17 weeks of gestation by Favero and colleagues.

Finally, Silva and colleagues explored the possibility of sentinel lymph node (SLN) mapping in pregnant patients with cervical cancer. They reported the first case of SLN detection using technetium-labeled radiocolloid. Histologic analysis of the operative specimen demonstrated a poorly differentiated squamous carcinoma with metastasis n the sentinel and a neoplastic embolus in a blood vessel of the placental bed.

Whole-Pelvis Radiotherapy With Intracavitary Brachytherapy

Radiation therapy is equally efficacious in treating patients with early-stage (ie, FIGO stage Ib1) cervical cancer in pregnancy and, together with radiosensitizing chemotherapy, is the treatment of choice in more advanced stages (FIGO stages Ib2–IVa). In the first and second trimesters when the pregnancy is to be disregarded, treatment should begin with whole-pelvis irradiation. Spontaneous abortion usually occurs during therapy, and the treatment is then completed with intracavitary radium or cesium applications. **Spontaneous abortion usually occurs at about 35 days in the first trimester and at 45 days in the second trimester after onset of radiotherapy.** Some second-trimester patients will go 60 to 70 days before abortion occurs. An alternative approach in the patient who has not aborted is to evacuate the uterus by means of a hysterotomy followed by conventional intracavitary irradiation delivered within 1 to 2 weeks.

If spontaneous abortion does not occur by completion of the external-beam therapy, as occurs commonly after the 16th week of gestation, a modified radical hysterectomy without pelvic lymphadenectomy should be done to excise the remaining central neoplasm. This strategy delivers potentially curative doses of radiation to pelvic lymph nodes with microscopic foci of metastatic tumor followed by surgical resection of the remaining central tumor because the gravid uterus is not suitable for intracavitary radium or cesium. Although some clinicians prefer an extrafascial hysterectomy after 5000 cGy of whole-pelvis irradiation in patients who have early lesions, the author prefers the more extensive modified radical hysterectomy. This approach accomplishes adequate excision of the cervix and accompanying medial parametria and upper vagina, which includes all the tissues that would have been effectively irradiated by the pear-shaped isodose distribution of a tandem and ovoid application of radium or cesium. Those who advocate an extrafascial hysterectomy centrally often advise further vaginal vault irradiation after the surgical procedure to treat the upper vagina and medial parametria more completely.

Sood and colleagues assessed the effects of pregnancy on tumor control, survival, and morbidity associated with radiation therapy administered to pregnant patients. They identified 26 women treated primarily with radiation therapy before the era of concurrent chemoirradiation and matched these patients with 26 control participants based on age, histology, stage, treatment, and year of treatment. Patients were treated with external-beam radiation (mean dose, 46.7 Gy) and intracavitary radiation (mean dose, 56.5 Gy to point A). Three patients diagnosed during the first trimester were treated with radiation with the fetus in situ, and all had spontaneous abortions 20 to 24 days after the start of radiation (mean dose, 34 Gy). In all of these cases, radiation was interrupted for only 3 days or less. There were no statistically significant differences in recurrence

rates or survival between the pregnant group and the control participants.

Benhaim and colleagues have reported two patients with locally advanced disease who were treated with chemoradiation during the first trimester with the fetus in utero. The first patient (FIGO stage IVA) was treated at 12 weeks of gestation and experienced recurrence at 20 months. The second patient (FIGO stage IIB) was also treated at 12 weeks of gestation and underwent completion surgery (radical hysterectomy with lymphadenectomy) and has survived disease free for 2 years.

Episiotomy Site Recurrence

Patients in whom the diagnosis of invasive cervical cancer is made in the postpartum period may have undergone vaginal delivery. This group of patients warrants immediate therapy and specialized surveillance. Recurrence of cervical cancer at the episiotomy scar is a rare event and is thought to occur through implantation at the time of vaginal delivery from an occult tumor, with subsequent early, isolated recurrence as opposed to regional spread. At least 15 cases have appeared in the literature since 1986, including one patient who experienced relapse along a perineal laceration scar (Table 15.4). In the majority of these patients, the primary diagnosis of cervical cancer was made during the postpartum period, with recurrence at the episiotomy site typically occurring within 6 months of primary treatment.

In a matched case-control study of women with cervical cancer diagnosed during pregnancy ($n = 56$) or within 6 months of delivery ($n = 27$), Sood and colleagues noted that among the patients diagnosed postpartum, one of seven who was delivered by cesarean section developed a local and distant recurrence, but 10 of 17 (59%) of those who delivered vaginally developed recurrences ($P = 0.04$). In multivariate analysis, vaginal delivery was the most significant predictor of recurrence. **We recommend delivery by cesarean section when the diagnosis is known antenatally, and in patients diagnosed in the postpartum period, vigilant examination of the episiotomy and vaginal laceration sites is warranted.** Although the mode of delivery in the setting of known microinvasive disease may be based on obstetric indications, it should be pointed out that among the 14 cases of episiotomy site recurrences, there was one patient who had been diagnosed with a stage Ia endocervical adenocarcinoma.

Neither the time of diagnosis nor time to recurrence appears to affect survival after episiotomy site recurrence. Goldman and Goldberg noted that no patient who received chemotherapy or radiotherapy for recurrent disease without excision survived 1 year. The treatment policy should include wide local excision of the entire nodule with adjuvant external radiotherapy plus brachytherapy. Of seven patients treated by this method, 71% were without evidence of disease at longer than 1 year.

There have been at least two cases of cervical cancer with concomitant episiotomy metastasis in the literature. Baloglu

and colleagues reported one of these patients for whom the diagnosis was unknown antenatally. This patient was diagnosed with locally advanced disease and an episiotomy site metastasis and received primary chemoradiation. She was without evidence of recurrence at 1 year of follow-up when the report was published. Women diagnosed with cervical cancer in the postpartum period should have the episiotomy or vaginal laceration site carefully examined if they experience vaginal delivery.

Planned Delay of Therapy

Historically, when invasive carcinoma was diagnosed before 20 weeks of gestation, recommendations included immediate treatment of the tumor, either by radical hysterectomy or radiation therapy, leaving the fetus in utero in both instances. This dogma has been challenged during the preceding decade, with multiple reports of a safe outcome for mother and child with a deliberate delay in therapy to permit gestational advancement (Table 15.5). For example, Duggan and colleagues reported a mean diagnosis-to-treatment interval of 144 days (range, 53–212 days) in eight patients with FIGO stage Ia or FIGO stage Ib cervical cancer who postponed therapy to optimize fetal outcome. All of these women were rendered disease free after a median follow-up period of 23 months. Sorosky and colleagues identified eight pregnant women with FIGO stage I squamous cell cervical carcinoma who declined immediate therapy to improve fetal outcome. They were observed prospectively until the late third trimester, with a mean diagnosis to treatment interval of 109 days (range, 21–210 days). No clinical progression of disease was detected, and after therapy, all were alive and disease free after a mean follow-up time of 37 months (range, 13–68 months). Takushi and colleagues reported a delay in treatment of 6 to 16 weeks for four women with FIGO stage Ia2, Ib1, or 1b2 lesions. No disease progression was documented, and after cesarean–radical hysterectomy, all patients have been disease free at a follow-up period of 70 to 156 months.

Although most patients with FIGO stage Ib disease have fared well with deliberate delays in therapy, four patients are noted in whom progression of disease was observed ($n = 2$) or in whom recurrence and death from disease occurred ($n = 2$). Five patients with FIGO stage II disease who opted to delay therapy were reported by Lee and colleagues, and although they did not progress during the pregnancy, it should be noted that their cancers were diagnosed in the third trimester, and the treatment delays were relatively limited. Long-term follow-up data were not presented for this subset of patients. **Thus, for patients with FIGO stage Ia1 to Ib1 squamous cell lesions**

*Treated with neoadjuvant chemotherapy during pregnancy.
DOD, Died of disease; *NED,* no evidence of disease.
Modified from Tewari K, Cappuccini F, Gambino A, et al. Neoadjuvant chemotherapy in the treatment of locally advanced cervical carcinoma in pregnancy: a report of two cases and review of issues specific to the management of cervical carcinoma in pregnancy including planned delay of therapy. *Cancer* 1998;82:1529.

diagnosed before and after 20 weeks of gestation, a limited treatment delay to await fetal maturity may be acceptable. The counseling in such situations should be analogous to obtaining an informed consent from the mother.

Neoadjuvant Chemotherapy in Pregnancy

Patients with advanced disease (ie, FIGO stage Ib2 and greater) should be offered immediate therapy. A novel approach to patients with locally advanced disease who refuse interruption of pregnancy was first reported by our group in 1998. Two women with FIGO stage Ib2 and FIGO stage IIa lesions refused interruption of their pregnancies and received neoadjuvant chemotherapy consisting of vincristine (1 mg/m^2) and cisplatin (50 mg/m^2) during the early second and third trimesters. Both patients experienced significant tumor regression, rendering radical hysterectomy feasible at the time of cesarean delivery after documentation of fetal pulmonary maturation at 32 weeks and 34 weeks of gestation. At the time of publication, one patient had remained without evidence of recurrence for more than 2 years; unfortunately, the second patient experienced a lethal relapse 5 months after primary therapy. Both children have experienced normal development. Another early report was by that of Marana and colleagues, who treated a pregnant woman with a FIGO stage IIb tumor with bleomycin (30 mg on day 1) and cisplatin (50 mg/m^2 on day 2 and day 3) from 17 weeks to 38 weeks of gestation and achieved both tumor regression and a healthy infant, who continued to thrive long after the mother succumbed to recurrent disease 13 months after delivery. Although such a treatment approach remains investigational, the use of neoadjuvant chemotherapy while awaiting gestational advancement may be entertained when the pregnant woman with cervical cancer, for whom a treatment delay is ill advised, refuses interruption of therapy.

Since these initial publications, there have been at least eight additional case reports of patients who received neoadjuvant chemotherapy during pregnancy for cervical cancer along with a recent 21-patient case series reported by Kohler et al. Most patients were treated for locally advanced disease (FIGO IB2–IIIB), but two patients received neoadjuvant chemotherapy for FIGO stage IB1 lesions. Neoadjuvant therapy was usually administered during the mid-second trimester to the early third trimester (range, 17–33 weeks of gestation) and single-agent cisplatin (eg, 75 mg/m^2 every 10 days) has been used most often. The combination of cisplatin (50 mg/m^2) plus vincristine (1 mg/m^2) every 21 days has also been of continued interest in some cases. Obstetric outcomes have been universally favorable, as have maternal outcomes, although there was one case of rapid tumor progression. It should be emphasized, however, that despite the good results, follow-up in several cases has been of short duration.

In the aforementioned study by Kohler et al., 21 pregnant women at a mean gestational age of 17 weeks (range, 13–23 weeks) received a median of three cycles (range, two to four cycles) of platinum-based chemotherapy with cesarean delivery carried out between 30.4 and 36.5 weeks of gestation, resulting in 22 healthy babies without renal, hepatic, auditory, or hematopoietic impairment. Platinum concentrations in the umbilical cord blood and amniotic fluid were 23% to 65% and 11% to 42%, respectively. Because the observed in vivo measurement of platinum was consistently lower in the fetoplacental unit, the authors suggest that a placental filtration mechanism of platinum may exist.

Neoadjuvant chemotherapy should be considered for patients with locally advanced disease diagnosed in the early to mid second trimester who are adamant about continuing the pregnancy. Again, these patients need to be counseled regarding the investigational nature of this treatment modality under the clinical circumstances in question.

Prognosis for Patients With Cervical Cancer in Pregnancy

The overall prognosis for all stages of cervical cancer in pregnancy is similar to that in nonpregnant women (Table 15.6). **The favorable overall prognosis for pregnant patients is related to a greater proportion of pregnant patients with stage I disease.** In a report by Allen and colleagues of 96 cases of cervical cancer occurring in pregnancy, the disease-free survival rates for 87 patients who were available for analysis were noted to be 92.3% for FIGO stage Ia1, 68.2% for FIGO stage Ib, 54.5% for FIGO stage II, and 37.5% for FIGO stage III. The overall survival rate was 65.5%, which is slightly better than that reported by Hacker and colleagues. They also observed an association of advanced clinical staging with diagnosis in the third trimester and postpartum. Of 49 cases of FIGO stage Ib cervical carcinoma, 64.5% were diagnosed in the third trimester and postpartum; of 22 cases of FIGO stage II cervical carcinoma, 77.3% were diagnosed in the third trimester and postpartum; and all nine cases of stage III cervical carcinoma were diagnosed in the third trimester and postpartum. Of the 32 patients who underwent pelvic lymphadenectomy, 10 were noted to have positive nodes. This increase in frequency has not been our experience.

Zemlickis and colleagues compared 40 women who had carcinoma of the cervix in pregnancy with 89 nonpregnant women matched for age, stage, and tumor type. Long-term

survival rates were similar between the two groups. When pregnant women were compared with a series of 1963 cervical cancers in women younger than 45 years treated during the same time, the pregnant women were three times more likely to have stage I disease and had a lower chance of having FIGO stage III to IV cancers.

In 1993, Sivanesaratnam and colleagues reported surgical management of early invasive cancer of the cervix in a series of 18 patients who underwent radical hysterectomy and pelvic lymphadenectomy, with a 5-year survival rate of 77.7%. A comparable group of nonpregnant patients who also underwent radical surgery had a survival rate of 92.3%. Nisker and Shubat also reported that there was a slightly better survival in the nonpregnant group than in the pregnant group. These reports are in contrast to the previous reports by Creasman and colleagues, Sablinska and colleagues, and Lee and colleagues, who found no appreciable difference in the 5-year survival rates of pregnant versus nonpregnant patients with cervical cancer.

A multicenter, retrospective study conducted by the Korean Gynecologic Oncology Group (KGOG-1006) contained 40 pregnant subjects treated from 1995 to 2003. Each case was matched to three control participants on the basis of age, stage, histology, and date of treatment. Among 12 patients who delayed treatment for fetal maturity, two died of disease. There was no difference in overall survival between pregnant and nonpregnant patients with stage IB lesions.

Pettersson and colleagues recently published a 90-year experience from the Radiumhemmet. The 10-year actuarial survival rate improved significantly during the study period from 27% (1914–2004) to 79% (1960–2004). The 10-year cause-specific cumulative actuarial survival rate for 41 pregnant women treated during 1960 to 2004 did not differ statistically from the rate for an age-matched, stage-matched, and histopathology-matched control series of nonpregnant women treated at the Radiumhemmet during the same period. The authors concluded that during the study period, the incidence of cervical cancer during pregnancy declined, the cases were discovered at earlier stages, and survival improved.

For more advanced disease, pregnancy may have an unfavorable effect on prognosis as a result of problems with radiation dosimetry in pregnancy and the need to interrupt radiation therapy more frequently because of genital tract sepsis. **Clinical stage remains the most important determinant of prognosis.**

Obstetric Outcomes

Dalrymple and colleagues analyzed the obstetric outcomes among women in California with pregnancy-associated cervical cancer. Using computer-linked infant birth and death certificates, discharge records, and cancer registry files, cases were identified and then assigned to a prenatal or postpartum cancer diagnosis group. Among 434 cases, those diagnosed prenatally ($n = 136$) had higher rates of cesarean section, hospitalization longer than 5 days, low birth weight, very low birth weight, prematurity, and fetal deaths compared with pregnant control participants without cancer. No neonatal deaths were attributable to elective premature delivery. Very low birth weight, prematurity, and fetal death rates remained elevated among those diagnosed postpartum.

Key summary points for the management of invasive cervical cancer during pregnancy:

1. **Reports describing the successful performance of trachelectomy during pregnancy, occasionally using robotic surgical platforms, continue to appear in the literature for management of early-stage disease.**
2. **For patients with locally advanced disease who insist on a definitive treatment delay to allow gestational advancement with concomitant fetal maturation, platinum-based neoadjuvant chemotherapy has been reported in more than 30 cases without significant maternal or fetal sequelae despite the observation that platinum does cross the maternal–fetal placental interface.**

Ovarian Cancer

Ovarian cancer is reported to occur in 1 per 10,000 to 1 per 25,000 pregnancies. Pregnancy does not alter the prognosis of most ovarian malignant neoplasms, but complications such as torsion and rupture may increase the incidence of spontaneous abortion or preterm delivery. In a survey by Kohler of the largest studies in the literature, about 1 in 600 pregnancies will be complicated by an adnexal mass. More contemporary accounts suggest that adnexal masses may complicate as many as 1 in 190 pregnancies. At least one-third of pregnant women are asymptomatic, with the adnexal mass often discovered during obstetric ultrasonography.

Most cysts in pregnant patients are follicular or corpus luteum cysts and are usually no more than 3 to 5 cm in diameter. Functional cysts as large as 11 cm in diameter have been reported but are rare. More than 90% of these functional cysts will disappear as pregnancy progresses and are undetectable by the 14th week of gestation. **It appears that the size of the adnexal mass at the time of diagnosis is inversely related to the likelihood of spontaneous regression. Only 6% of masses smaller than 6 cm persisted during serial examinations, but 39% of masses larger than 6 cm persisted.** The complication rate increases with increasing size of the mass. In addition, a solid or complex ultrasonographic appearance and the presence of bilateral adnexal or ovarian abnormalities may also be indications to proceed with laparotomy. Adnexal masses with blood flow characterized by a high resistive index by Doppler ultrasonography are less likely to be malignant, independent of size. MRI may be useful when ultrasonographic findings are equivocal.

The most pressing problems associated with ovarian tumors in pregnancy are the initial diagnosis and the differential diagnosis. When the tumor is palpable within the pelvis, it must be differentiated from a retroverted pregnant uterus, a pedunculated uterine fibroid, a carcinoma of the rectosigmoid, a pelvic kidney, and a congenital uterine abnormality (eg, rudimentary uterine horn). Analysis of serum tumor markers is a complex undertaking and can be misleading because the titers for each of the markers, especially α-fetoprotein and β-human chorionic gonadotropin (hCG), and even CA-125, are routinely elevated in pregnancy for reasons unrelated to malignancy.

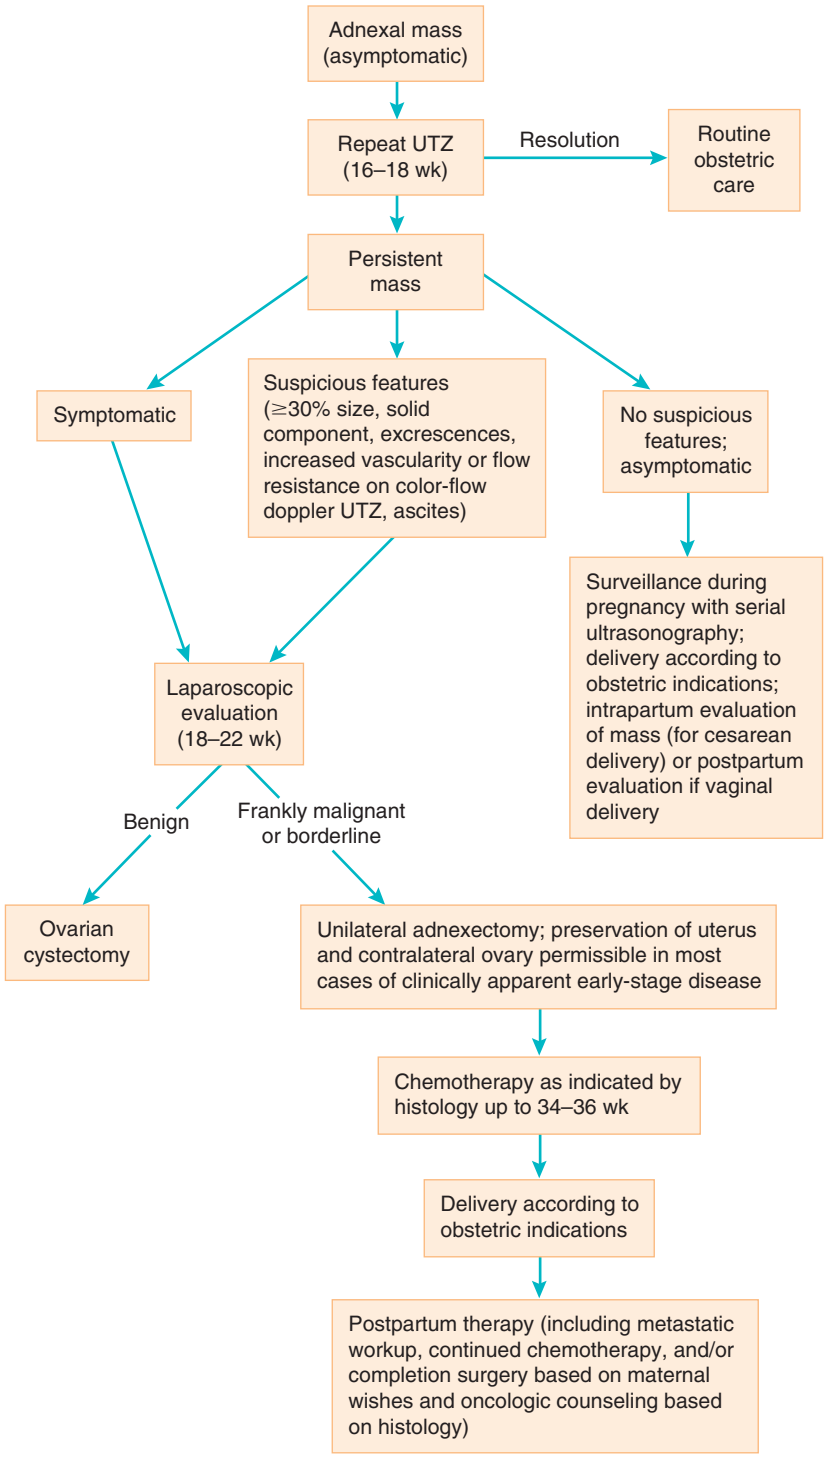

FIGURE 15.7 Management of an ovarian mass in pregnancy. UTZ, Ultrasonography.

A proposed management algorithm for the adnexal mass in pregnancy appears in Fig. 15.7. **Our experience has been that patients operated on around the 18th week of gestation have negligible fetal wastage associated with the exploration.** Therefore, 18 weeks of gestation appears to be a judicious period for laparotomy in terms of its safety both for the fetus and for the elimination of functional ovarian cysts. If the cyst is complex and suspicious for malignancy and increases in size, the patient should undergo exploration earlier than 18 weeks. **Whenever exploration is conducted, our recommendation is that the uterus not be manipulated during surgery (ie, the so-called hands-off-the-uterus approach) in an effort to minimize its irritability.**

Torsion is common in pregnancy, with 10% to 15% of ovarian tumors reportedly undergoing this complication. Most torsions (ie, 60%) occur when the uterus is rising at a rapid rate

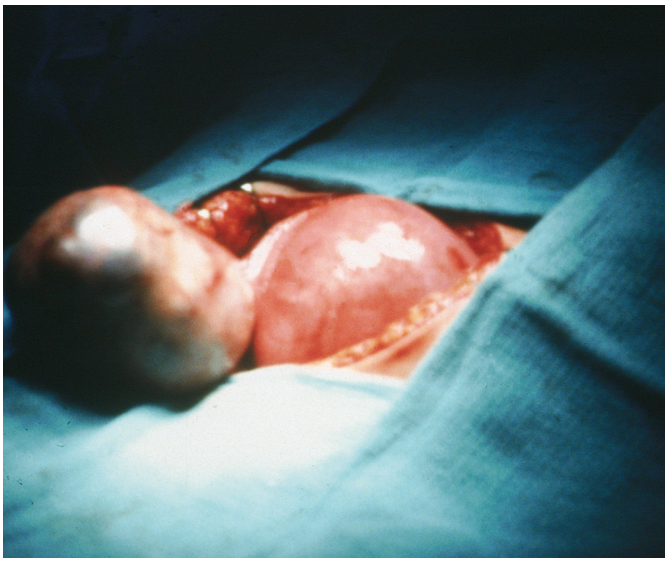

FIGURE 15.8 Benign cystic teratoma. Gross appearance at 18 weeks of gestation.

(8–16 weeks) or when the uterus is involuting (in the puerperium). The usual sequence of events is sudden lower abdominal pain; nausea; vomiting; and in some cases, shocklike symptoms. The abdomen is tense and tender, and there is rebound tenderness with guarding. If exploration must be undertaken during the first trimester and extraction of the ovary (or ovaries) is required, supplemental progesterone can be administered to decrease the likelihood of pregnancy loss.

In many instances, the presence of an ovarian tumor may not be suspected until delivery (Fig. 15.8). The large uterus obscures the growth of the ovarian neoplasm. The tumor may be growing in the abdomen behind the large uterus and may not fall back into the cul de sac until it is large. If there is a mechanical obstruction of the birth canal, exploratory laparotomy is indicated for both delivery of the baby and management of the ovarian neoplasm. Allowing labor to proceed when an ovarian neoplasm is causing obstruction of the birth canal may result in rupture of the ovarian cyst. Even if the cyst is not ruptured, the trauma of labor may cause hemorrhage into the tumor followed by necrosis and suppuration.

Asymptomatic Adnexal Masses

Before detailing the clinical approach to managing the different ovarian malignancies that may occur during pregnancy, some consideration should be given to asymptomatic adnexal masses. Admittedly, asymptomatic masses can be malignant; however, the vast majority are likely to be benign, particularly in the pregnant population. There has been a movement during the past decade that has challenged the dogma of operating on every asymptomatic mass larger than 5 cm that persists into the second trimester. Most of these masses can be followed conservatively in the absence of symptoms and in the absence of concerning sonographic ovarian and extraovarian findings (eg, ascites).

Endovaginal pelvic ultrasonography is essential in the evaluation of adnexal masses. Approximately 10% of masses are complex, and the examination should determine the origin of the mass and its location, size, and internal structure (eg, vegetations, septations). The mass should be classified unilocular, unilocular-solid, multilocular, multilocular-solid, or solid. Color Doppler imaging may be used to obtain a vascular road map of an ovarian mass. Pelvic MRI with gadolinium injection can be performed after the first trimester and should only be used during pregnancy to remove further doubt regarding possible malignancy or to provide additional information if ultrasonography is inconclusive.

Laparoscopic Management of the Ovarian Mass

Laparoscopy was previously thought to be contraindicated in pregnancy because of the unknown effect of the pneumoperitoneum on the gravid uterus, the possible injection of carbon dioxide into the amniotic cavity, and the potential for acidosis in the fetal environment as a result of maternal conversion of carbon dioxide into carbonic acid. Growing evidence, however, suggests that laparoscopy can be performed safely during pregnancy.

The recommended time for laparoscopic intervention mirrors that for open procedures and is between 16 and 20 weeks of gestation. There have been reports of laparoscopy up to the 28th week of gestation, but this appears to be the upper limit. Larger uteri increase surgical difficulty, and surgery after 23 weeks can be linked to adverse fetal outcomes and preterm labor. Intervention before the second trimester is not advisable because this does not give time for the ovarian mass to resolve on its own and could compromise ovarian hormone production before the placenta is fully functional.

The table should be tilted to the left or the right with the patient supine to move the uterus away from the site of trocal insertion. The left upper quadrant or subxiphoid insertion of the trocar should be used with at least 6 cm between the point of entry and the top of the fundus. The open Hasson technique is preferred over the Veress technique, although both have been used successfully in pregnancy. Ultrasound guidance may be used with the Veress technique together with elevation of the abdominal wall to reduce the risk of uterine injury.

Intraabdominal pressure should be kept below 15 mm Hg with the patient in the Trendelenburg position to ensure adequate venous return and uteroplacental blood flow during the operation. Positioning in this manner may require positive pressure ventilation to maintain adequate lung volumes. Depending on the circumstances and gestational age, fetal monitoring may be advisable.

Robotic-Assisted Laparoscopic Management of Adnexal Masses During Pregnancy

With widespread adoption of robotic surgical platforms for management of adnexal masses, cervical cancer, and endometrial cancer in the nonpregnant population, it is not surprising to see reports of robotic surgical applications applied to the pregnant patient. Eichelberger et al. evaluated their experience in planned robotic resection of adnexal masses in 19 pregnant

women, all of which were performed without fetal or maternal complications. When compared with 50 consecutive laparoscopic cases from a recent historical database, the authors noted no differences in operative time, conversion to laparotomy, intraoperative or postoperative complications, or negative observed obstetric outcomes. Interestingly (and not altogether unexpected given the reported advantages of robotics in the nonpregnant population), in this study, the patients undergoing robotic surgery had a significantly shorter length of hospital stay and estimated blood loss. We anticipate surgeons continuing to report further experiences with robotic pelvic surgery in the coming years.

Ovarian Masses Specific to Pregnancy

Two adnexal conditions may specifically be associated with pregnancy. The operating surgeon must be cognizant of their possibility so that unnecessary oophorectomies will not be performed. **The luteoma of pregnancy can vary in size from microscopic to 20 cm in diameter and usually consists of multiple, well-circumscribed nodules that can be bilateral in one third of cases.** The luteoma may be associated with significant elevations in plasma testosterone and other androgens in about 25% of the cases. Maternal hirsutism or virilism may occur during the latter half of pregnancy, which may cause virilization in up to 70% of female infants born to masculinizing mothers. If the lesion is not recognized grossly, a biopsy may be taken for definitive diagnosis. Because these regress spontaneously postpartum, nothing further needs to be done. **Theca-lutein cysts may occur when hCG concentrations are abnormally elevated, such as in a molar pregnancy, fetal hydrops, or multiple gestations.** These are usually multiple and thin-walled cysts. Sometimes, massive bilateral theca-lutein cysts manifest that are considerably different from the solid nodules of the luteoma of pregnancy. These also regress postpartum and should not be resected unless acute complications develop.

Histologic Types of Ovarian Tumors

Struyk and Treffers reported on 90 pregnancies complicated by ovarian tumors. No functional cysts were noted in patients operated on after the 18th week. In eight patients, ovarian tumor enlargement was noted during a period of observation; two were malignant, one serous cystadenoma occurred, and five were teratomas. Fifty-four percent of the tumors were diagnosed in the first trimester. Severe pain occurred in 26%, torsion in 12%, obstruction of labor in 17%, and rupture in 9%. Only 37% of the patients had no complications. Fetal wastage was high, with death in utero occurring in three cases and neonatal death in seven cases.

Thornton and Wells reviewed 131 ovarian enlargements in pregnancy, 81 of which were removed (including one carcinoma and six borderline lesions). Thirty-nine were greater than 5 cm in diameter and had simple internal echo patterns and smooth walls; three of these were borderline malignant neoplasms. Hoffman reviewed 13 reports of ovarian neoplasms removed in pregnancy and found benign cystadenomas or cystic teratomas most frequently diagnosed. The Hoffman review also included a summary of 127 malignant ovarian lesions found during pregnancy. A recent literature review by Kwon and colleagues describing the various histologies of ovarian tumors found in pregnancy appears in Table 15.7. Borderline and frankly malignant epithelial lesions were the most commonly encountered during pregnancy.

Borderline Ovarian Tumors

Adnexal masses larger than 6 cm that persist into the second trimester warrant removal at approximately 18 weeks of gestational age. Between 2% and 5% of these lesions will be malignant, with dysgerminoma being most common. Among epithelial tumors, serous carcinoma and serous tumors of low malignant potential are readily encountered. Thirty-five cases of serous ovarian tumors of low malignant potential in conjunction with pregnancy have been reported since 1988. In the 33 cases in which a FIGO stage was assigned, 30 were stage I (14 stage Ia, 1 stage Ib, 4 stage Ic, and 11 nonsubstaged I). All 33 patients for whom follow-up data were available were found to be alive without disease (range, 1 year to 20 years, 5 months). Recent evidence suggests that the hormonal influence of pregnancy can lead to histologic changes in serous low malignant potential tumors that, if not sorted out and characterized appropriately, could be mistaken for frankly invasive carcinoma. The group at the MD Anderson Hospital and Tumor Institute collected 10 cases from 1944 to 1993 and conducted a slide review, noting some very peculiar histologic features distinct from those seen in nonpregnant patients, including epithelial atypia and proliferation, eosinophilic cells, mucin production,

decidual changes, and frequent microinvasion. Although these lesions remained within the spectrum of low malignant potential tumors, the histologic features were worrisome for a more aggressive clinical course, yet all 10 patients remained disease free after a variety of treatment modalities. We advise prompt recognition of these histologic findings after cystectomy or oophorectomy during pregnancy so as to classify them accordingly as being borderline rather than to confuse them with low-grade serous papillary carcinomas. Of additional interest is that in two cases, the tumor was resected both during pregnancy and after parturition (2 months and 3 years), and there was significant regression of the epithelial proliferation, the number of eosinophilic cells, and the amount of mucin production the second time around; this regression after parturition supports a hormonal etiology of these unusual histologic features. In contrast to frankly malignant ovarian carcinomas, unilateral adnexectomy is all that is required during pregnancy for the serous low malignant potential tumor.

Frankly Malignant Ovarian Tumors

Malignant ovarian tumors account for only 2% to 5% of all ovarian neoplasms found in pregnancy. The incidence for all pregnancies is 1 in 8000 to 1 in 20,000 deliveries. The diagnosis is usually fortuitous in that the patient undergoes laparotomy for an adnexal mass that is subsequently found to be malignant. In many instances, the close observation of the pregnant patient has led to the discovery of a lesion in the earlier stages. These include not only malignant germ cell tumors and sex cord–stromal cell cancers but also some epithelial malignancies. **If an ovarian malignant neoplasm is found at the time of abdominal exploration, the surgeon's first obligation is to properly stage the disease, as outlined in** Chapter 10**.** Although the gravid uterus hinders the surgeon's ability to access the retroperitoneum, every effort should be made to remove the tumor intact. The contralateral ovary should be carefully inspected and biopsied if anything suspicious is detected. In the scenario of a clinical stage I ovarian carcinoma, unilateral adnexectomy, omentectomy, unilateral pelvic and aortocaval lymph node sampling, peritoneal biopsies, and four-quadrant washings can be safely carried out during pregnancy, with chemotherapy reserved for those patients who are upstaged on histopathologic analysis. The chemotherapy regimen is similar to what is used for advanced disease (eg, a platinum compound and a taxane for the epithelial cancers); however, for patients with FIGO stage Ia or Ib, grade I non–clear cell tumors, no chemotherapy will be recommended.

Malignant Germ Cell Tumors in Pregnancy

Fortunately, ovarian germ cell neoplasms in pregnancy are usually benign. **Dermoid cysts are by far the most common neoplastic cysts found in pregnancy; however, malignant ovarian germ cell tumors such as the dysgerminoma, embryonal carcinoma, immature teratoma, and yolk sac tumor (formerly called "endodermal sinus tumor") have also been reported.** Although a considerable number of these cancers present with early-stage disease (in both pregnant and nonpregnant patients), there are several reports of advanced cancers

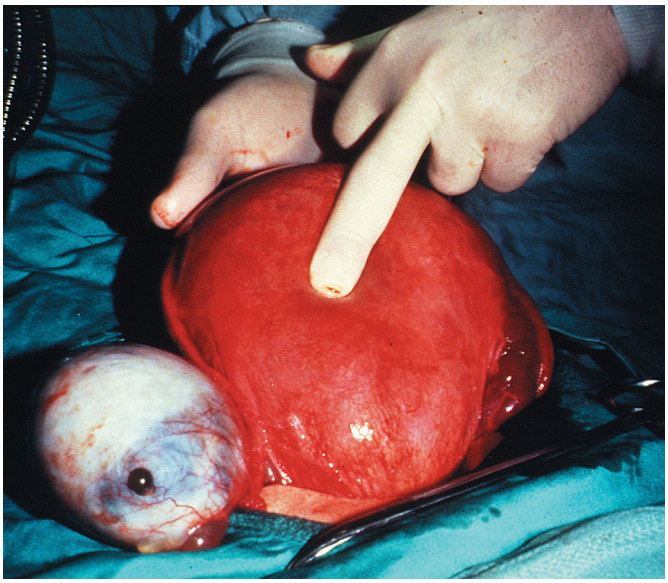

FIGURE 15.9 Immature teratoma in pregnancy.

associated with pregnancy. Combination chemotherapy during pregnancy has been given without deleterious effects on the fetus.

The management of malignant ovarian germ cell tumors is predicated on the histologic identity of the tumor (see Fig. 15.7). Patients with clinical stage Ia dysgerminoma and those with clinical stage Ia-Ib grade I immature teratoma require surgical staging to determine the need for adjuvant chemotherapy (Fig. 15.9). All other histologic types require adjuvant chemotherapy, and therefore unilateral adnexectomy is all that is typically accomplished at the time of laparotomy, along with removal of all gross metastatic disease. Because most malignant germ cell tumors are unilateral (the dysgerminoma is the exception in 10% of cases), it is inappropriate to remove both ovaries. Even when the opposite side may harbor an occult dysgerminoma, it is often not necessary to remove the entire contralateral ovary. If, however, both ovaries are grossly involved by malignancy and the pregnancy is in the second trimester and thus free from hormonal support by the corpus luteum, both ovaries should be extracted. The prognosis for this stage is not improved with more extensive surgery. Chemotherapy regimens currently used for this disease comprise bleomycin, etoposide, and cisplatin. This regimen has been used safely during pregnancy.

Combined chemotherapy has improved survival markedly for malignant germ cell ovarian tumors and can permit preservation of childbearing capacity and maintenance of the existing pregnancy if the disease is stage I. If the diagnosis is made during the first or second trimester, the patient must decide whether to permit the pregnancy to continue to viability before adjuvant chemotherapy is instituted. Because these tumors characteristically grow rapidly and often recur within months when therapy is withheld, delays in initiating systemic therapy can be harmful. Indeed, the high success rate obtained with adjuvant chemotherapy has been recorded with use of this modality in the immediate postoperative period. The effect of a treatment-free interval of several months before the commencement of adjuvant chemotherapy has not been tested

adequately. Thus, a patient with a malignant ovarian germ cell tumor discovered early in pregnancy and in need of chemotherapy is faced with a dilemma for which no data are available. Malone and colleagues described a patient with stage Ic endodermal sinus tumor diagnosed in the 25th week of gestation who two cycles of combination chemotherapy consisting of vinblastine, bleomycin, and cisplatin and delivered a healthy boy by cesarean section at 32 weeks of gestation. She subsequently completed three more cycles of chemotherapy and remained well at the time of Malone and colleagues' report 18 months after initial diagnosis. To our knowledge, this was the first report of a case of a patient who had endodermal sinus tumor treated with combination chemotherapy during pregnancy that apparently had a successful outcome for both mother and infant. Subsequently, we and others have had similar experiences. Therapeutic decisions for patients who have more advanced stages of these tumors are also difficult and controversial. Many such patients can be cured with early adjuvant chemotherapy after surgery. As in earlier stages, the uterus and opposite ovary can be preserved if metastatic tumor is not found in these locations. Some clinicians preserve the uterus and opposite ovary under all conditions in the hope that postoperative chemotherapy will sterilize those organs also. No long-term follow-up of this approach is available. Delays in withholding chemotherapy are not warranted, and uterine evacuation is often requested because of fear of potential teratogenic effects when chemotherapy is required during the first trimester. The subject of adjuvant chemotherapy in pregnancy is discussed later, but we emphasize that all chemotherapeutic agents are theoretically teratogenic. Although retrospective studies have not shown frequent congenital abnormalities in patients treated in the second and third trimesters, many newer agents have not been used frequently in pregnancy.

Dysgerminoma in Pregnancy

Ovarian dysgerminomas are unique among the malignant germ cell tumors because of their overall good prognosis in FIGO stage Ia treated by surgery alone. **Dysgerminoma is particularly common and accounts for 30% of ovarian malignant neoplasms in pregnancy.** We believe that these tumors can be managed with a unilateral adnexectomy and continuation of the pregnancy without additional therapy in FIGO stage Ia. Optimal staging should include a pelvic and periaortic lymphadenectomy on the side of the tumor mass because dysgerminomas metastasize primarily through the lymphatic system to the ipsilateral pelvic and periaortic lymph nodes. Because lymphangiography and computed tomography (CT) are contraindicated when the pregnancy is to be continued, patients who have not had adequate exploration at initial surgery should be considered for reexploration before further therapy and continuation of the pregnancy are recommended. Appropriate diagnostic studies, including lymphangiography and CT scan of the abdomen and pelvis, may be performed in the postpartum period. A mass on scan or a suspicious lymph node on lymphangiography should be evaluated at reexploration.

Emergency surgical intervention and obstetric complications are common in patients with dysgerminomas. Karlen and associates reviewed 27 cases of dysgerminoma associated with pregnancy. Torsion and incarceration were found commonly in this group of patients who had rapidly enlarging neoplasms averaging 25 cm in diameter. Obstetric complications occurred in nearly half the patients, and fetal demise occurred in one-quarter of the reviewed cases. There were recurrences in 30% of 23 stage Ia tumors treated by unilateral oophorectomy, which calls into question the philosophy of treating these patients conservatively. The extent of exploration was not known in most cases, however, and therefore accuracy of staging cannot be assessed. This information is essential for appropriate interpretation of the findings. In our experience, lesions that are confined to one ovary have a 10% recurrence rate. Although most of these lesions recur in the first 2 years after surgery, we believe that this group of patients can continue their pregnancies safely with completion of their proper evaluation in the puerperium. Because radiation therapy and chemotherapy are successful in curing more than 75% of patients, even those with metastatic or recurrent dysgerminoma, and because there is a low incidence of recurrence in patients with FIGO stage Ia disease, we maintain a philosophy of conservatism for the treatment of these tumors.

Sex Cord–Stromal Tumors in Pregnancy

Granulosa and Sertoli–Leydig cell tumors together account for only 2% to 3% of all ovarian neoplasms. Although granulosa cell tumors are most commonly discovered in perimenopausal or postmenopausal women, 10% to 20% are encountered during the reproductive years. Sertoli–Leydig cell tumors occur in women in the reproductive age group in 74% of cases. Of note, sex cord–stromal tumors are rarely found in pregnancy. It is critical that these entities are distinguished from ovarian decidualization, luteoma of pregnancy, or even benign granulosa cell proliferations observed with pregnancy. **Typically, the sex cord–stromal ovarian tumors behave as they do in nonpregnant women, presenting with early-stage disease and having a slow, low-grade, and indolent course.** Thus, because their biologic behavior is akin to that of neoplasms of low malignant potential, it is recommended that they be managed conservatively (ie, unilateral adnexectomy without comprehensive surgical staging) as in young nonpregnant patients (see Fig. 15.7). It is important, however, to resect all visible tumor whenever possible.

Young and colleagues reported a series of 17 granulosa cell, 13 Sertoli–Leydig cell, and six unclassified sex cord–stromal tumors diagnosed during pregnancy or the puerperium. Eleven patients had abdominal pain or swelling when they were first seen by a physician, five were in shock, two had virilization, and one had vaginal bleeding. Three asymptomatic patients underwent exploration because of palpable masses, and one underwent exploration because of an adnexal mass found on ultrasound examination. In 13 patients, the tumors were discovered during cesarean sections; five patients had dystocia, and the tumors were incidental findings in eight patients. All of the tumors were FIGO stage I, but 13 of the tumors had ruptured. All but one were unilateral. Hemoperitoneum was present in seven cases.

Young and colleagues uncovered four major sources of difficulty in the interpretation of their series of 36 cases:

1. The young age of the patients
2. An alteration in the histologic appearance of the tumors during pregnancy
3. A decreased frequency of associated endocrine manifestations
4. Pregnancy-induced changes in other neoplastic and nonneoplastic lesions of the ovary that cause them to simulate sex cord–stromal tumors both morphologically and in terms of endocrine function.

Indeed, the pregnancy-associated tumors commonly exhibited alterations related to the pregnant state that tended to obscure characteristics and familiar features that are apparent in tumors removed from nonpregnant patients. The most striking changes included intercellular edema and increased extent of luteinization in the granulosa cell tumors and of Leydig cell maturation in the Sertoli–Leydig cell tumors. It is important to note that the edema often blurred the architectural patterns of the tumors and distorted the cytologic features of the neoplastic cells. The marked luteinization and Leydig cell maturation interfered with the recognition of these cells. The end result was that these pregnancy-associated changes made identification of the tumor type more difficult.

Granulosa cell tumors are clinically estrogenic in approximately two-thirds of cases, and Sertoli–Leydig cell tumors are virilizing in nearly 50% of cases. These hormonal manifestations often suggest the correct diagnosis to the gynecologist. However, during pregnancy, the hyperestrogenic clinical manifestations do not appear, with none of the 17 tumors in the series by Young and colleagues associated with estrogenic manifestations. It is quite probable, however, that many of these tumors were secreting estrogens in large quantities. Furthermore, only 16% ($n = 5$) of the 36 sex cord–stromal tumors were associated with clinical evidence of excess androgens (virilization in four cases and hirsutism in only one case). This low frequency may have been the result of the placenta's ability to aromatize androgens produced by the tumor. In fact, one of the masculinizing tumors was the largest in their series (32 cm in maximal diameter) and may have been secreting androgens in such great abundance that the aromatizing capacity of the placenta was exceeded.

Several other types of ovarian neoplasms and nonneoplastic disorders are more frequently associated with virilization during pregnancy than Sertoli–Leydig cell tumors. Tumors with functioning, proliferative ovarian stroma such as Krukenberg tumors and the mucinous cystic tumors may be confused morphologically with sex cord–stromal tumors. Other primary ovarian tumors that can cause virilization include luteinized thecomas and Leydig and lipid cell tumors. Finally, as described earlier, two nonneoplastic lesions of the ovary that develop during pregnancy and can be associated with virilization include the luteoma of pregnancy and the hyperreactio luteinalis (multiple luteinized follicle cysts). All of these virilizing tumors and lesions must be considered in the differential diagnosis when confronted with virilization of the pregnant mother so as to not make an erroneous clinical diagnosis of a sex cord–stromal tumor.

With one exception, the patients in the study by Young and colleagues were initially treated by conservative surgical procedures. Two of them received chemotherapy, and two received radiation therapy postoperatively. Hysterectomies and salpingo-oophorectomies were performed as second operations in eight cases; no residual tumor was found in any of these specimens. Only one patient had a recurrence, which was treated surgically. Follow-up for the average of 4.7 years was available for 30 of the 36 patients; all of them were free of disease at their last examination. Adjuvant therapy has not been demonstrated to improve the outcome in this group of patients and is not recommended during pregnancy.

Chemotherapy for Nonepithelial Ovarian Cancer During Pregnancy

A recent literature review by Azim and colleagues identified 18 cases of nonepithelial ovarian malignancies treated with systemic chemotherapy during pregnancy. Most patients had a yolk sac tumor ($n = 10$) and were treated after the first trimester with the bleomycin, etoposide, and cisplatin (BEP) regimen or the cisplatin, vinblastine, and bleomycin (PVB) regimen. Other histologies reported included three cases of dysgerminoma, three cases of immature teratoma, one mixed germ cell tumor, and one Sertoli–Leydig tumor. Fifteen of the 18 women completed their pregnancies without complications; there was one case of premature delivery after maternal dehydration at 28 weeks after BEP, there was one case of pregnancy-induced hypertension after three cycles of BEP, and a third patient developed oligohydramnios after three cycles of etoposide-platinum. Postnatal chemotherapy-induced adverse events were restricted to one baby who developed minor anemia and transient respiratory distress at delivery at the 35th week of gestation. This baby had been exposed to three cycles of carboplatin plus paclitaxel for a maternal dysgerminoma, and the condition resolved quickly, and the authors reported normal development at 20 months of follow-up.

Epithelial Ovarian Cancer in Pregnancy

Very few series of malignant ovarian carcinomas in pregnancy have been published. Reported in 2002, the most recent series contains nine ovarian cancers concurrent with pregnancy from Libya and Saudi Arabia. Among these cases were included seven epithelial cancers (four serous, two mucinous, one undifferentiated), one dysgerminoma, and one granulosa cell tumor. As expected, the latter two lesions occurred in younger women, aged 18 and 21 years, respectively. All seven women with epithelial cancers were multiparous (range, 3–10), which is of some interest given the epidemiologic data suggesting increasing parity to be inversely related to the risk of developing ovarian carcinoma. Four patients with FIGO stage Ia tumors, including two with epithelial lesions, underwent unilateral adnexectomy before 25 weeks of gestation. None of the patients with more advanced disease who went on to receive chemotherapy did so during pregnancy. The obstetric outcome was favorable for all patients except for one with a FIGO stage Ia serous cystadenocarcinoma whose infant died from complications of meconium aspiration. It is of sufficient interest that five of the epithelial

tumors were early stage (three FIGO stage Ia and two FIGO stage Ic), and one was assigned FIGO stage IIa. The only death occurred in a patient with a FIGO stage III undifferentiated carcinoma. Thus, fully six of seven women with epithelial ovarian cancers were diagnosed with early or locally advanced disease only, which does not reflect what is typically observed in the general population. It is quite certain that antenatal care, including serial physical examinations and ultrasonography, contributed to these early pick-ups.

After the diagnosis of ovarian carcinoma is made during pregnancy, appropriate therapy should not be withheld (see Fig. 15.7). In patients who present with metastatic disease manifesting as malignant ascites and carcinomatosis, surgical exploration is warranted, with an attempt to remove as much of the tumor burden as is feasible. Depending on the degree of tumor involvement of the uterus and the mother's desire for the pregnancy, uterine preservation may be considered, and if so, the "hands-off" approach to the uterus and removal of mobile intraperitoneal deposits can be attempted. Certainly, the typical aggressive cytoreductive approach (eg, bowel resection, splenectomy) taken in nonpregnant women with advanced-stage ovarian carcinoma can result in significant morbidity, and if the pregnancy is to be continued, we advise against this approach unless the patient has presented with a bowel obstruction.

An untested option in this group of patients is measurement of the serum CA-125 and aspiration of ascites fluid under ultrasound guidance for cytologic analysis. After malignancy is confirmed and considered likely to be of ovarian origin, systemic chemotherapy during the second and third trimesters in a "neoadjuvant" fashion can be considered, with plans for interval cytoreductive surgery after delivery. The standard regimen for metastatic epithelial ovarian cancer in nonpregnant patients includes platinum-based chemotherapy. Regimens containing cisplatin alone and cisplatin plus paclitaxel and even administration of a full six cycles of carboplatin and paclitaxel (the current standard among nonpregnant women), have been used during the second and third trimesters of pregnancy. **Because there does not appear to be any significant risk to the fetus when these drugs are used in the second and third trimesters, pregnant patients diagnosed during these periods should be offered the opportunity to receive platinum-based therapy without terminating their pregnancies.** Postpartum, the patient may return to the operating room to undergo definitive surgical staging or comprehensive tumor debulking.

Patients remote from term (eg, during the first trimester) with metastatic disease should be advised to undergo hysterectomy with the fetus in situ in conjunction with tumor debulking. Because the prognosis for women with advanced carcinoma is poor, patients must be counseled regarding the realities of how much time they would have with their child when making decisions regarding pregnancy termination.

It should be noted that there are at least two reports of an advanced-stage epithelial carcinoma of the ovary in which the uterus and pregnancy were preserved at 15 and 20 weeks of gestation. Patients were treated with six cycles of single-agent cisplatin or four courses of carboplatin plus paclitaxel followed by cesarean section and completion hysterectomy. One patient was disease free at a short follow-up of 6 months, but the other recurred in the pelvis at 24 months after delivery. This second patient underwent secondary cytoreduction and was retreated with platinum-based therapy and has remained disease free at 42 months. Although some have advocated sparing the uterus if it appears to be uninvolved and the pregnancy is remote from term, this approach should be used with extreme caution when dealing with advanced-stage epithelial ovarian cancer for which the outcome remains exceedingly poor irrespective of pregnancy status.

Chemotherapy for Epithelial Ovarian Cancer During Pregnancy

Azim and colleagues have collected 20 patients from the literature who were treated with chemotherapy during pregnancy for epithelial ovarian cancer. The histologic subtypes included serous ($n = 13$), mucinous ($n = 3$), endometrioid ($n = 2$), clear cell ($n = 1$), and undifferentiated ($n = 1$). The chemotherapy regimens used included cyclophosphamide plus cisplatin ($n = 5$); single-agent cisplatin ($n = 4$); single-agent carboplatin ($n = 3$); paclitaxel plus carboplatin ($n = 2$); and cyclophosphamide, doxorubicin, and cisplatin ($n = 2$). There also was one case each of the use of the following regimens: cisplatin plus paclitaxel, cisplatin plus docetaxel, carboplatin plus cyclophosphamide, and single-agent paclitaxel. Seventeen of the patients received their first cycle during the second trimester and three in the third trimester. Sixteen patients delivered at week 34 or after, and 16 had experienced no pregnancy-related complications. There was one case each of intrauterine growth restriction, premature rupture of the membranes, and preeclampsia. Nineteen fetuses had a normal outcome, with nine of these children reported to be normal at 1 year or longer follow-up. There was one neonatal death from multiorgan failure in a baby with congenital anomalies identified before starting cisplatin plus docetaxel at week 20.

Intravenous carboplatin plus paclitaxel is the most commonly used regimen for epithelial ovarian cancer. Although use of platinum derivatives appears to be feasible during the second and third trimesters, their administration does raise concern regarding the transplacental transfer of these drugs in late pregnancy, and the short- and long-term effects have not been well-studied. Intraperitoneal chemotherapy in combination with intravenous chemotherapy has been associated with higher survival rates for patients with epithelial ovarian cancer. In patients opting for this type of therapy, delivery should be induced as soon as fetal pulmonary maturation can be documented before starting intraperitoneal therapy. Catheters can be placed at the time of cesarean section or laparoscopically in the postpartum period if the pregnancy was delivered vaginally.

A recent trial by the Gynecologic Oncology Group demonstrated an improvement in progression-free survival among patients treated with intravenous carboplatin plus paclitaxel and the antiangiogenesis agent bevacizumab. To date, there are no reports of use of bevacizumab in pregnancy, and one cannot comment on its potential for maternal, fetal, and neonatal effects.

Targeted (biologic) therapy for ovarian cancer in pregnancy. After an 8-year drought beginning in 2006, during

which time there were no new drug approvals for ovarian cancer (in nonpregnant patients), finally in 2014, the management of epithelial ovarian cancer entered the modern area of targeted therapy with two approvals by the US Food and Drug Administration. Bevacizumab, a fully humanized monoclonal antibody (mAb) that targets the vascular endothelial growth factor (VEGF) ligand and sequesters it to prevent binding to the VEGF receptor (VEGFR) and thereby prevent tumor angiogenesis was approved in combination with chemotherapy (physician's choice of pegylated liposomal doxorubicin or topotecan or weekly, dose-dense paclitaxel) for platinum-resistant recurrent ovarian carcinoma. For patients with recurrent ovarian carcinoma harboring germline *BRCA* mutations (*BRCA1* or *BRCA2*), the poly-ADP-ribose polymerase I (PARP) inhibitor was approved for fourth-line therapy and beyond.

It is unclear whether mAbs are safe when used to treat cancer in pregnancy. Sarno et al. performed a literature search encompassing the years 2000 through January 2013 and reviewed the safety of mAbs during pregnancy. As will be discussed later under the section concerning breast cancer in pregnancy, the anti-HER2 monoclonal antibody, trastuzumab, has been associated with oligohydramnios and poor neonatal outcomes. There are very few reports on the use of bevacizumab in pregnant women, but because its antiangiogenic effects may have possible negative consequences on fetal development, the consensus that has been reached is one in which this drug should be avoided during pregnancy. Not only has VEGF blockade during pregnancy been associated with maternal preeclampsia and fetal intrauterine growth restriction, but in murine models, administration of anti-VEGF receptor tyrosine kinase inhibitors (TKIs) has led to abnormal vascular patterning in the mouse retina. Another VEGF receptor TKI, sunitinib, has been associated with embryo and fetal developmental toxicity in rats and rabbits at clinically relevant dose levels. Parenthetically, there have been reports of intravitreal bevacizumab being given safely to pregnant women for choroidal neovascularization with resulting improvement in vision and no untoward fetal effects. However, given the significant potential for adverse fetal developmental outcome resulting from inhibition of the VEGF access, the use of mABs and oral TKIs in pregnancy should be avoided.

With respect to PARP inhibitors in pregnancy, as in the case of bevacizumab, there essentially are no data. It is known that PARP1 expression in the murine uterus is under regulation by estrogen and that successful embryo implantation requires upregulation of PARP1. This suggests that PARP inhibitors should be contraindicated during early pregnancy, and until reasonable data become available, the author does not recommend their use during the entire conduct of pregnancy.

Other Types of Malignant Ovarian Tumors

Some ovarian cancers are particularly aggressive, and chemotherapy should be started immediately upon diagnosis. These include small cell ovarian cancer and metastatic Krukenberg tumors. The only long-term survivor of an advanced-stage small cell ovarian cancer was reported by Tewari and colleagues, who described a patient diagnosed with the disease during pregnancy. After the histology was confirmed, the patient returned to the operating room in the second trimester and underwent cytoreductive surgery with the fetus in situ and postoperatively was treated with a six-drug regimen that contained both epithelial-cell and germ-cell activity. Another patient diagnosed with small cell ovarian cancer with hypercalcemia underwent conservative surgery during pregnancy followed by chemotherapy and died of disease 10 months after diagnosis. Taylor and colleagues reported the surgical removal of a Krukenberg tumor at 15 weeks of gestation followed by treatment with 10 cycles of 5-fluorouracil (5-FU), folinic acid, and irinotecan every 2 weeks until the 36th week of pregnancy. The neonate was born without complications and at age 4 months showed normal development.

Summary of the Adnexal Mass and Ovarian Cancer in Pregnancy

The problem of an adnexal mass in pregnancy is simple: One must have a high index of suspicion for malignancy, make the diagnosis early, and treat promptly. The difficulty arises when both patient and physician resist abdominal exploration during pregnancy because of fear of precipitating fetal wastage. However, the potential danger to the mother far exceeds the imagined danger to the child. Most of the difficulties seen with ovarian tumors are those of omission rather than of commission. The probability of ovarian cancer must be kept foremost in the minds of physicians caring for these patients. At laparotomy, most malignant ovarian tumors apparently confined to one ovary will require complete surgical staging. A technique of "hands off the uterus," whenever possible, appears to reduce postoperative uterine contractions.

Breast Cancer

Pregnancy-associated breast cancer (PABC) is defined as breast cancer diagnosed during pregnancy or lactation up to 12 months postpartum. The disease is a disaster for all involved. Both the patient and physician find it difficult to accept this dreaded disease in a healthy young pregnant woman. Because breast cancer is rare in women younger than 35 years, this problem, fortunately, is a rare complication of pregnancy, with an incidence of approximately one case for every 3000 deliveries. Conversely, of all patients with breast cancer, 1% to 2% are pregnant at the time of diagnosis. PABC provides a challenging scenario for the mother and oncologist. **It is the second most common malignancy to complicate pregnancy, but unlike cervical cancer, it is not screened for during pregnancy, and because delays in diagnosis are common and the diagnosis itself is elusive, often patients are diagnosed with advanced tumors for which prognosis is poor.** Furthermore, the management of breast cancer often involves a coordination of surgery, radiotherapy, chemotherapy, and even hormonal therapy, all of which may affect the pregnancy. Finally, there are several distinct hormonal issues related to pregnancy that may have an influence on the course of breast cancer.

Recently, a group of specialists convened to review guidelines and provide guidance on how to implement recent advances in breast cancer diagnosis and treatment in the pregnant population. The consensus was that the majority of women with PABC will be considered for definitive treatment during pregnancy and that many treatments, including sentinel lymph node biopsy (SLNB) and systemic therapy with taxanes, platinum agents, and dose-dense regimens can be given safely after the first trimester of pregnancy. Radiation therapy and anti-HER2–directed therapy (eg, trastuzumab, lapatinib, trastuzmab emtansine [T-DM1], and pertuzumab) are best avoided during pregnancy but may be considered in some rare instances.

In a population-based cohort study using data from Swedish registries from 1963 to 2002 encompassing women aged 15 to 44 years at the date of breast cancer diagnosis, Andersson and colleagues noted that the incidence of PABC increased from 16.0 to 37.4 per 100,000 deliveries comparing the first and last calendar periods under study. The authors attributed the increasing incidence in Sweden partly to the trend of postponement of childbearing to an older age.

Historically, PABC has been associated with a poor prognosis, with accounts from the 19th century describing exceedingly rapid growth and a malignant course. In 1943, Haagensen and Stout reinforced this feeling of doom when they decided that the outcome for this group of patients was so poor that they recommended surgical treatment not be offered. Contemporary opinion for the most part maintains the dismal prognosis associated with PABC. It must be acknowledged that the literature comprises mainly single-institution retrospective experiences and case reports. The only series containing greater than 100 patients are four in number (White, Bunker and Peters, Ribeiro and Palmer, Clark and Reid), none of which were published after 1978.

Although the overall survival rate for breast cancer is greater than 60%, the overall survival rate in pregnancy is reported by some to have dropped to 15% or 20%. Pregnant patients tend to have a higher incidence of positive axillary lymph nodes. Locoregional spread of the tumor portends a poor prognosis and in all likelihood suggests that the neoplasm has metastasized at the time of the initiation of therapy. The advanced stage of the presentation of disease in pregnant patients has been attributed to multiple factors. First, the engorged breast can successfully obscure a lesion for a much longer period. Survival rates are lower for cases diagnosed late in pregnancy than for those recognized in the first trimester. Others emphasize the 30 to 50 multiples of increase in serum levels of estrogens and progesterone. In addition, there may be increased vascularity and lymphatic drainage from the pregnant breast, assisting the metastatic process to regional lymph nodes. If a lesion is detected early (present <3 months, smaller than 2 cm, and no positive nodes), the chance of survival (70%–80%) is the same for pregnant and nonpregnant patients. If, however, there is involvement of the subareolar region; diffuse inflammatory carcinoma; edema or ulceration of the skin; fixation of the tumor to the breast wall; or involvement of the high axillary, supraclavicular, or internal mammary nodes, the prognosis is poor for both pregnant and nonpregnant patients.

Presentation

At least 10% of patients with breast cancer who are younger than 40 years will be pregnant at diagnosis. PABC typically presents as a painless mass or thickening. In some cases, there may be an associated nipple discharge, and in the lactating breast, the infant may exhibit the "milk rejection sign," effectively refusing the breast that contains the cancer. The mean breast weight normally doubles in pregnancy from 200 to 400 g, resulting in breast firmness and increased breast density. Mammographic evaluation of the pregnant breast is difficult to interpret, and the clinical examination may be deceptive. This has profound implications in terms of delays in diagnosis and treatment, which, as discussed earlier, are common in PABC. Many patients with PABC will have a delay in diagnosis ranging from 1 to 2.5 months during pregnancy and up to 6 months during lactation. In a 1991 series from the Memorial Sloan-Kettering Cancer Center in New York, 44 of 56 patients did not have the diagnosis of cancer made until the postpartum period. **Overall, in a review of the literature by Puckridge and colleagues, a delay of 2 to 15 months longer from manifestation of the first symptoms to the diagnosis of cancer occurs in PABC.** Given the tumor-doubling time of 130 days, a 1-month delay in primary tumor treatment increases the risk of axillary metastases by 0.9%, and a 6-month delay increases the risk by 5.1%. **For this reason particularly, PABC has been considered an ominous diagnosis, but when age and stage are taken into account, there is no difference in the survival rate of PABC cases compared with non-PABC cases.** Pregnancy is not thought to be an independent risk factor.

Evaluation

A proposed management algorithm for PABC appears in Fig. 15.10. Early diagnosis has been associated with improved survival rates and relies on the liberal use of imaging strategies and the core and fine-needle biopsy techniques for this group of patients. Mammography in conjunction with abdominal lead shielding can be safely used during pregnancy, but as discussed earlier, the engorged and lactating breast increases tissue density and may mask abnormalities. Ultrasonography yields equivalent information with no known adverse effects to the fetus. Fine-needle aspiration (FNA) may be difficult to interpret cytologically secondary to cellular changes that take place during pregnancy and lactation and is often associated with an increase in the false-negative rate. Core biopsy remains the gold standard in making the diagnosis. When necessary, an open biopsy under local anesthesia is also appropriate. Stopping lactation with ice packs and breast binding or bromocriptine (2.5 mg three times daily for 1 week) beforehand will reduce the risk of a milk fistula. The breasts should be emptied of milk before the biopsy, and a pressure dressing will decrease the risk of hematoma that may develop from the hypervascularity of the pregnant breast.

Approximately 75% to 90% of PABCs are ductal carcinomas, mirroring what is observed in the nonpregnant population. Historically, there was a perceived increase in inflammatory carcinoma of the breast during pregnancy; however, this has since been refuted in contemporary series, in which the

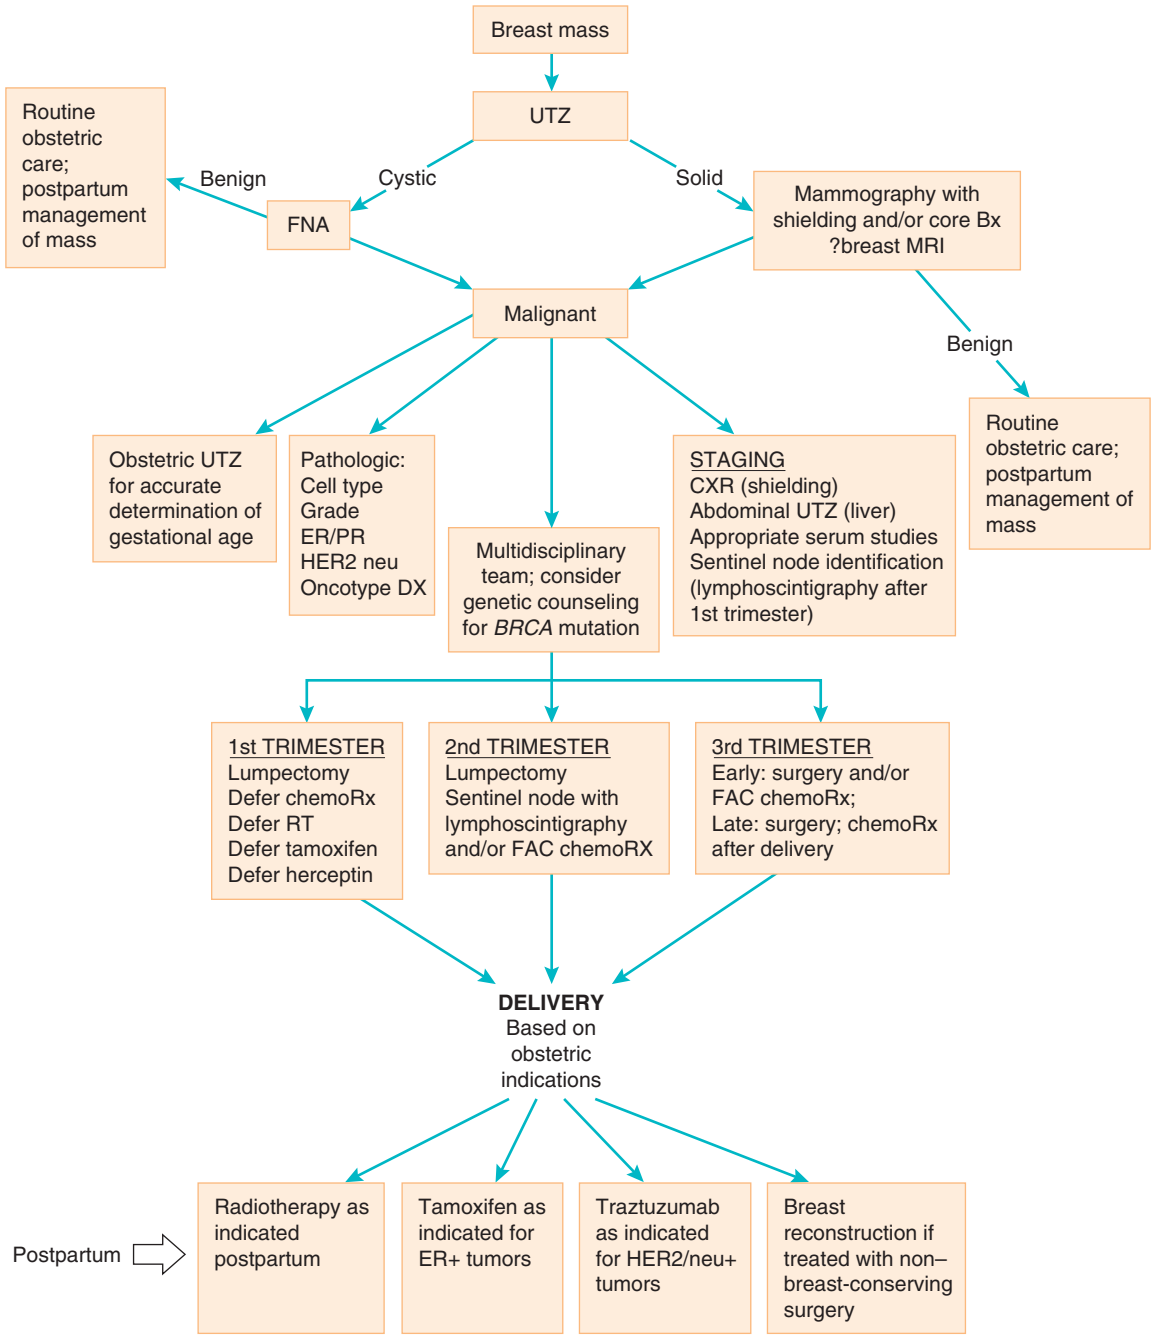

FIGURE 15.10 Management algorithm for pregnancy-associated breast cancer. *chemoRX,* chemotherapy; *CXR,* chest radiography; *ER,* estrogen receptor; *FAC,* 5-fluorouracil, doxorubicin (Adriamycin), and cyclophosphamide; *FNA,* fine-needle aspiration; *UTZ,* ultrasonography.

incidence ranges from 1.5% to 4.2% among pregnant and nonpregnant patients. Several studies have demonstrated adverse pathologic features in PABC. Most patients with PABC have estrogen receptor (ER)–negative and progesterone receptor (PR)–negative tumors. This may be a result of the production of false-negative results by the ligand-binding assay used for ER and PR when high circulating levels of estrogen and progesterone downregulate receptors. Immunohistochemistry has not been able to detect a difference in the number of hormone receptor–positive tumors when PABC cases are compared with cases of breast cancer in nonpregnant patients of similar ages. Additionally, higher levels of c-ERBB-2 overexpression and p53 mutations have been reported in lactational carcinomas but not in tumors diagnosed during pregnancy. Furthermore, there have been reports of increased HER-2/neu–positive tumors compared with nonpregnant control participant. It is interesting that the HER-2/neu oncogene product p105 is overexpressed not only in ductal carcinomas but also in fetal epithelial cells and the placenta and that toward the end of the third trimester of pregnancy, serum levels of p105 normally rise.

It is known from epidemiologic studies that there is an increased incidence of breast cancers in certain families; the risk increases 5 to 10 times if a patient's mother or sister has had the disease. It is interesting that women with a genetic predisposition to breast cancer may be overrepresented among cases of PABC, with a significant family history of breast cancer being three times more common in women with PABC than among nonpregnant patients with breast cancer. Along these lines, PABC has been associated with a higher rate of *BRCA2* allelic mutation compared with sporadic breast cancer. Indeed, a Swedish report of 292 women with breast cancer before the age of 40 years demonstrated a greater likelihood of known *BRCA1* and *BRCA2* carriers to develop cancer during pregnancy.

Staging of breast cancer currently uses a complicated system jointly recommended by the International Union Against Cancer and the American Joint Committee on Cancer (AJCC) (see Table 14.12). The Haagensen clinical staging for breast cancer is more useful in pointing out the unfavorable prognostic indicators in this disease process. Lateral and posteroanterior chest radiographs in conjunction with lead shielding are considered safe during pregnancy, with an estimated fetal dose of only 0.6 mGy. Provided a catheter is placed to allow rapid drainage of radioactive material from the bladder, a low-dose labeled technetium-99 bone scan is also safe. The low-dose bone scan exposes the fetus to 0.0008 Gy instead of the standard 0.0019 Gy. The higher radiation exposure to the fetus excludes the use of CT in planning a metastatic workup, but MRI may be used to study the thorax and abdomen and to image the skeleton. **MRI is preferred to ultrasonography for hepatic imaging and is also the safest and most sensitive way to study the brain.**

Surgical Management

Surgery is the definitive treatment for PABC (see Fig. 15.10). The extent of surgery in the treatment of breast cancer is being debated throughout the world, and this issue cannot be adequately addressed here. Lumpectomy or partial mastectomy is more commonly used, especially when the lesion is not large, although the preferred surgical treatment for stage I, stage II, and some stage III tumors involves mastectomy, thus avoiding the need for adjuvant radiotherapy in most cases (ie, early-stage breast cancer). Because nodal metastases are commonly identified in PABC and nodal status dictates the choice of adjuvant chemotherapy, axillary dissection has been routinely recommended, especially in light of the potential risk to the fetus from radioisotope if SLNB was attempted.

The timing of surgery for cancer diagnosed late in pregnancy is another source of debate. Some reports suggest that patients treated postpartum survive longer than those treated in the second and third trimesters. This suggests that postponement of therapy for patients near term may be of benefit. These reports fail to consider the possibility that patients selected for postponed treatment might have been those with small, more favorable cancers discovered late in pregnancy, but larger, aggressive, anaplastic cancers with rapid progression received immediate treatment. If such treatment bias exists, prompt treatment would not be expected to correlate with good results, and treatment after delivery would appear favorable because of a preponderance of favorable patients in that group.

Sentinel Lymph Node Identification

Keleher and colleagues assessed the risk to the embryo or fetus associated with SLNB and lymphoscintigraphy of the breast in pregnant patients. After peritumoral injection of 92.5 MBq (2.5 mCi) of filtered ^{99m}Tc sulfur colloid the day before surgery in two nonpregnant women with breast cancer, they calculated the absorbed dose to the embryo or fetus for three theoretic extreme scenarios of biodistribution and pharmacokinetics and described the maximum absorbed dose to the fetus being 4.3 mGy calculated for the worst-case scenario. The authors concluded that breast lymphoscintigraphy during pregnancy presents a very low risk to the embryo or fetus. In 2008, Khera and colleagues searched a prospectively accrued breast database for cases of SLNB in patients with PABC and identified 10 patients. The mean gestational age at the time of biopsy was 15.8 weeks. All patients were successfully mapped, and a positive SLN was identified in five patients (50%). Nine patients (90%) delivered healthy babies without reported complications, and one patient elected to terminate the pregnancy in the first trimester to start chemotherapy. The authors concluded that SLNB can be safely performed in pregnancy with minimal risk to the fetus.

Spanheimer and colleagues measured abdominal, perineal, and urinary radiation in 14 women with breast cancer and total uterine doses were calculated. The average dose to the uterus from bladder radioactivity determined from voided urine was 0.44 ± 0.44 microGy. The average radiation dose to the uterus of 1.14 ± 0.76 microGy was derived through an average of abdominal and perineal doses plus contribution from the bladder dose. One patient was 16 weeks' pregnant at the time of SLNB, and the total calculated uterine dose was 1.67 microGy, suggesting that pregnancy does not significantly alter measured uterine radiation. When compared with average background radiation (ie, 3,000 microGy per year or 8.2 microGy per day), it was concluded that the measured uterine dose of radiation from lymphoscintigraphy for SLN biopsy was significantly less than the average daily background radiation.

In a recent report by Gentilni and colleagues, 12 patients with PABC received low-dose (10 MBq on average) lymphoscintigraphy using ^{99m}Tc human serum albumin nanocolloids. The SLN was identified in all patients. In 10 patients, the SLN was pathologically negative. One patient had a micrometastasis in an SLN, and another who had a metastasis in the SLN underwent axillary clearance. Eleven healthy babies were born with no malformations and appropriate birth weight. One baby who underwent lymphatic mapping during the 26th week of gestation was operated on at the age of 3 months for a ventricular septal defect and at 43 months was in good health. The malformation was suspected at the anatomy scan performed during the 21st week of gestation, well before lymphoscintigraphy. At a median follow-up period of 32 months, no overt axillary recurrence appeared in the patients with negative SLNs. This experience, together with those described earlier, supports the safety and efficacy of SLN identification in women with

PABC when performed with a low-dose lymphoscintigraphic technique.

Breast Reconstruction

Although the performance of a transverse myocutaneous flap of the rectus abdominis muscle (TRAM flap) is a satisfying, one-step, immediate reconstruction of good aesthetic quality without need for prosthetic materials, it is not recommended in patients with PABC who undergo mastectomy. The procedure should be deferred to the postpartum period. The problem of residual functional capacities of the abdominal wall deprived of a part or of all its rectus muscle also has important implications for future pregnancies. In fact, for some authors in the past, the desire for future childbearing was a contraindication to TRAM flap breast reconstruction because it was thought that the abdominal wall, weakened by rotation of one or both of its rectus muscles, would not be capable of withstanding the stress induced by pregnancy. **To avoid the development of a hernia in the abdominal wall at the donor site, an interval of at least 12 months between breast reconstruction with a TRAM flap and pregnancy is recommended.**

Adjuvant Therapy

Women with early lesions may opt for a tissue-sparing procedure. In these cases, local irradiation is often required. Radiotherapy to the breast, chest wall, or axillary lymph nodes, even with shielding, results in a significant fetal dose because of scatter in excess of that which is considered safe. The doses of internal scatter of radiation have been calculated. Embryonic exposure resulting from breast radiotherapy with a dose of 0.1 Gy during organogenesis in the first trimester not only increases the risk of malformations but can also cause mental retardation. Using anthropomorphic phantoms simulating the geometry of a pregnant woman, the dose to the fetus resulting from tangential breast irradiation in each trimester has been well-summarized by Toesca et al. in their review of locoregional treatment of PABC. With fetal shielding and x-ray energies from 4 to 10 MV as used for breast radiotherapy, the fetal irradiation dose in the first and second trimesters is lower than the threshold values associated with organ malformations. However, during the third trimester when the fetus moves out of the pelvis and into the abdomen, the dose exceeds this threshold. For example, at 12 weeks of gestation, the fetus would receive 10 to 15 cGy. In the third trimester, this dose can be as high as 200 cGy. This is because, although during the first trimester, the fetus is in a safer position and can be better shielded, it is more sensitive to the effects of radiation. In contrast, as the fetus enlarges and is less sensitive to radiation, it moves upward out of the pelvis, where it is less readily shielded and exposed to higher levels of ionizing radiation. Local irradiation should be deferred until after delivery of the fetus (see Fig. 15.10). **Women treated with adjuvant radiation during the postpartum period will not be able to lactate from the irradiated breast.**

Locally advanced disease is difficult to manage with the pregnancy in place. Chemotherapy or local radiotherapy, followed in 6 weeks by mastectomy, is the usual treatment plan for these lesions. For advanced disease, chemotherapy has been used after the first trimester when the mother is reluctant to terminate the pregnancy and the disease appears to be progressing at an alarming rate. The issue of whether chemotherapy should be administered to patients with node-positive breast cancer in pregnancy is complicated by reports suggesting that both single-agent and combination chemotherapy may significantly improve survival rates in premenopausal patients in an adjuvant setting. Follow-ups of 10 and 15 years are always necessary in breast cancer, but it appears that premenopausal patients are the best candidates for aggressive adjuvant chemotherapy and a resulting improved survival rate. This is especially pertinent to patients in whom positive nodes are discovered at the time of the initial procedure.

Table 15.8 contains reports of chemotherapy use during pregnancy, with favorable neonatal outcomes noted when treatment was administered only after the first trimester.

In a recent review by Azim and colleagues, the authors identified 56 different reports that have described the systemic treatment of PABC and separated them into four groups, as described in the following discussion.

Neoadjuvant and Adjuvant Chemotherapy for Pregnancy-Associated Breast Cancer

The FAC regimen (5-FU, doxorubicin, and cyclophosphamide) is the most commonly administered regimen in the neoadjuvant or adjuvant setting. The safety of this regimen was prospectively examined by Hahn and colleagues at the MD Anderson Hospital and Tumor Institute in Houston. Fifty-seven patients were treated, and the regimen was well tolerated and did not adversely affect the pregnancy. All women had live births, with three congenital defects reported, including Down syndrome, clubfoot, and congenital bilateral ureteral reflux. The investigators did not consider these anomalies to have resulted directly from chemotherapy exposure when the incidences were compared with those in the general population. Eighteen of the children have been followed until school age, and only two required special attention schools (including the child with Down syndrome).

Peccatori and colleagues from the European Institute of Oncology in Milan prospectively evaluated the safety of weekly epirubicin (35 mg/m^2) starting in the second trimester in 20 women with PABC. The schedule was selected to potentially allow lower peak plasma concentration of the drug, thus lowering the risk of maternal myelotoxicity and possible placental transfer of the drug. There were no grade III or IV toxicities and only one congenital anomaly (polycystic kidney). All children have had normal development at 2 years' median follow-up.

Based on these two studies and other retrospective series and case reports from the literature, Azim and colleagues suggested that anthracycline-based regimens are probably safe starting in the second trimester. FAC is the most commonly studied regimen, but offering epirubicin instead of doxorubicin is an option.

In recent years, taxanes have been incorporated into the adjuvant and neoadjuvant settings to improve outcomes. There have been seven reports of docetaxel treatment and two reports of paclitaxel therapy for PABC. In six of these cases, the taxane

was given as a single agent. None of the nine cases were associated with a poor obstetric or fetal outcome. Although the experience using taxanes in PABC is clearly limited, this early evidence is reassuring.

The CMF regimen (cyclophosphamide, methotrexate, 5-FU) has been used for many years as standard adjuvant therapy in breast cancer. As a result of the potential for teratogenicity by methotrexate (after first-trimester exposure), this regimen is not recommended for PABC.

Chemotherapy for Metastatic Breast Cancer

In contrast to early PABC for which neoadjuvant or adjuvant therapy is administered in a good-prognosis setting, patients with metastatic disease have fewer options because treatment of the mother must take priority, especially in pregnancies remote from term. Anthracyclines remain the most studied agents for management of metastatic breast cancer, but data are extremely limited in PABC. Patients with bone metastases are frequently treated with bisphosphonates to decrease the risk of skeletal events. There has been some concern for the development of genital and skeletal defects with bisphosphonate use in pregnancy. In addition, the potential for hypocalcemia exists with bisphosphonate therapy, which may lead to stimulation of uterine contractions. There has been very limited experience in PABC, but no adverse events associated with bisphosphonate use have been reported. Among 21 pregnant women exposed to bisphosphonates for osteoporosis during the first trimester, there were no adverse events for the fetus or to the conduct of the pregnancy.

HER2/Neu–Targeted Agents in Pregnancy

Trastuzumab and lapatinib are two HER2/neu–targeted agents that have been used increasingly in recent years for the management of breast cancer. Azim and colleagues identified 13 cases of trastuzumab use for PABC and one report of lapatinib therapy for a patient with metastatic breast cancer who inadvertently became pregnant during therapy. For this patient, lapatinib was discontinued at 11 weeks of gestation, and the pregnancy continued with a normal outcome.

For the 13 patients exposed to trastuzumab, only one patient elected to undergo therapeutic abortion. Eight patients received the drug as a single agent; the others were treated in combination with taxanes, vinorelbine, or tamoxifen. Metastatic disease was the setting for three patients, and seven patients received the drug during the preconception period and the first trimester. There were five cases of anhydramnios, one case of oligohydramnios, one case of intrauterine growth restriction, and one case of preterm premature rupture of the membranes. Four neonatal deaths were reported secondary to respiratory and renal failure. Three additional babies developed transient respiratory or renal failure but recovered. None of the reports described any fetal or maternal serious cardiac events despite the pivotal role of HER2/neu in cardiogenesis and cardiac repair pathways.

The increased risk of oligo- or anhydramnios is thought to result from the effect of trastuzumab on the fetal renal epithelium in which HER2/neu is strongly expressed. Some have correlated the effect of trastuzumab to an inhibition of the VEGF, which regulates the production and reabsorption

of amniotic fluid. Prolonged exposure to trastuzumab was consistently associated with serious adverse events both on the pregnancy and on the fetus in these cases. Azim and colleagues have advised that in the case of accidental pregnancy, the drug should be discontinued, and the patient should be counseled that brief exposure to the drug is unlikely to be detrimental to the fetus and pregnancy. Elective administration of trastuzumab during pregnancy is not advisable.

Hormonal Treatments for Pregnancy-Associated Breast Cancer

Preclinical models have shown that in utero exposure to tamoxifen increases the incidence of genital abnormalities. Tewari and colleagues reported the first case of fetal teratogenicity developing from maternal exposure to tamoxifen. The drug was discontinued at 20 weeks of gestation, but the fetus developed ambiguous genitalia with labial fusion and clitoromegaly. A second case has been reported in which tamoxifen was stopped at 26 weeks of gestation, and the fetus developed Goldenhar syndrome. A third patient had the drug discontinued during the first trimester, and the pregnancy outcome was normal; at 27 months' follow-up, the baby's development was without sequela. The literature contains only one patient who elected to receive tamoxifen as a therapeutic intervention for metastatic PABC; the pregnancy resulted in a normal baby. There are also two cases in which tamoxifen was administered in conjunction with trastuzumab, and pregnancy was accidentally discovered at 20 weeks of gestational age. In both cases, fetal mortality was reported, but this was likely secondary to trastuzumab exposure. Finally, normal outcomes have been reported in two cases in which tamoxifen was given together with FAC and with CMF plus vincristine.

As with trastuzumab, we recommend active contraception use during tamoxifen therapy, and in those cases in which pregnancy inadvertently occurs, the drug should be discontinued. Although 85 pregnancies with normal fetal outcomes are contained in a tamoxifen chemoprevention study, women should be counseled regarding the possibility of genital or more complex malformations associated with in utero exposure to this drug.

Prognosis of Pregnancy-Associated Breast Cancer

Thirty-two women with PABC referred to two European Union oncology centers between 1995 and 2007 were analyzed by Halaska and colleagues. Sixteen cases were diagnosed during pregnancy, and 16 were diagnosed within 1 year after delivery. The investigators matched each patient for age at diagnosis, tumor size, and stage to a control group of 32 nonpregnant patients. Overall survival was similar in the PABC and non-PABC patients ($P = 0.449$). The subgroup of patients with PABC diagnosed within 1 year after delivery showed a shorter time to relapse than controls or patients in whom PABC was diagnosed during pregnancy ($P = 0.0178$). Such findings concerning poorer prognosis among postpartum diagnoses had not been identified in previous series and warrant continued attention.

Cardonic and Iacobucci analyzed the maternal and fetal outcomes of 130 women with PABC that were reported to the voluntary Cancer and Pregnancy Registry and followed prospectively. Among the 130 patients, 120 were diagnosed with a primary tumor, eight with recurrent disease, and two with a new primary malignancy. The mean maternal age at diagnosis was 34.8 years, and the mean gestational age at diagnosis was 13.2 weeks. For 113 women who were followed for a mean of 3.14 years, recurrence was reported in 30 women at a mean of 16.2 months from delivery. Twenty-one patients are deceased at a mean interval of 24.71 months from delivery to death. Only 42% were diagnosed with an ER-positive tumor, and 35% of cases had PR-positive disease. Human epidermal growth factor receptor 2 was positive in 25% of patients. Survival rates by stage for a primary diagnosis in pregnancy included stage I, 100%; stage II, 86%; stage III, 86%; and stage IV, 0%. These survival rates are similar to what is observed in the nonpregnant breast cancer population.

A very large study was conducted by Rodriguez and colleagues evaluating 797 PBAC cases identified by linking the California Cancer Registry (1991–1997) with the California Patient Discharge Data Set; 4177 age-matched, non-PBAC breast cancer control participants were also identified. PABC cases were significantly more likely to have more advanced-stage, larger primary tumor, hormone receptor–negative tumor, and mastectomy as a component of their treatment. In survival analysis, PABC had a higher death rate than non-PABC (39.2% vs. 33.4%; $P = 0.002$). In multivariable analysis, advancing stage, African American ethnicity (68% increased risk over non-Hispanic whites), hormone receptor–negative tumors (20% increased risk), and pregnancy (14% increased risk) were all significant predictors of death.

Lactation

Whether breastfeeding is safe or possible has also been debated. Many have postulated that breast cancer is at least in part of viral origin, and the possibility exists that the contralateral breast will be contaminated with the causative agent, which will be passed to the fetus. This theory has never been borne out in fact, but most surgeons recommend artificial feeding of the infant, ostensibly to avoid vascular enrichment in the opposite breast, which may also contain a neoplasm.

Reports by Higgins and Haffty and by Tralins suggest that successful lactation in the breast treated by lumpectomy and irradiation is possible. Apparently, the location of the breast incision is important. **It is not surprising that circumareolar incisions were associated with diminished ability to lactate because such incisions interrupt a large number of major milk ducts. Radial incisions in the breast interrupt fewer ducts but may be cosmetically inferior.** In addition, the size, shape, and orientation of the nipple are important to allow its normal mechanical function. Patients whose nipples did not extend sufficiently, were not oriented properly, or were not supple found that the infant would not nurse from the treated breast. Finally, concerns have been expressed by some clinicians that attempts to breastfeed after conservative surgery may lead to a greater incidence of mastitis secondary to disruptions of the ductal system.

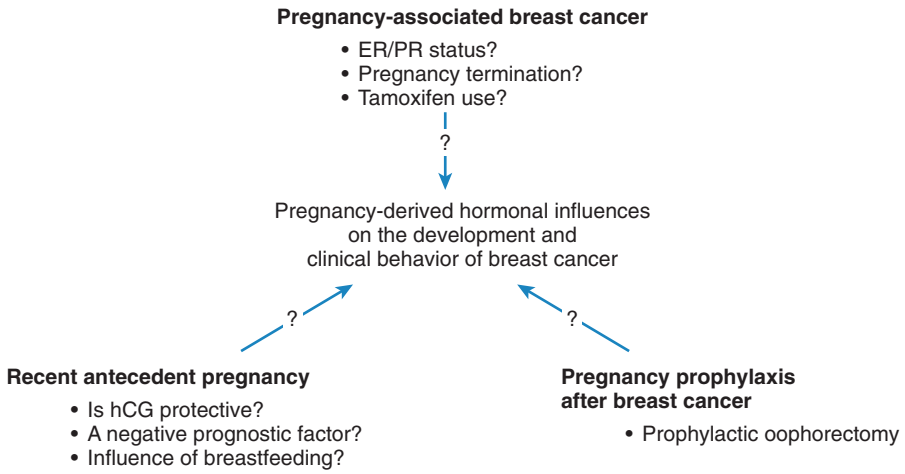

FIGURE 15.11 Hormonal considerations in breast cancer. *ER,* Estrogen receptor; *hCG,* human chorionic gonadotropin; *PR,* progesterone receptor.

Hormonal Considerations: Pregnancy Preceding Breast Cancer

Protective effect of human chorionic gonadotropin. **The hormonal issues specific to breast cancer appear in** Fig. 15.11. Epidemiologic data have demonstrated a 50% reduction in the risk of breast cancer in women who complete full-term pregnancies before 20 years of age. The benefit is seen among all ethnic groups worldwide and increases with increasing parity. There is a declination in risk reduction beyond the age of 30 years. Both human and animal breast tissues and human breast cell lines contain low levels of receptors that bind hCG and its structural and functional homolog luteinizing hormone. These gonadotropins exert numerous anticancer effects in breast cancer models and cells, prompting some investigators to speculate that the elevated levels of hCG associated with full-term pregnancies may exert a protective effect against the later development of breast cancer.

Recent antecedent pregnancy. The previous discussion notwithstanding, concerns have been raised that the protective benefit of pregnancy on the risk of later breast cancer may be biphasic, with a transient increase in the risk of breast cancer shortly after pregnancy followed by a greater long-term reduction in risk. Russo and colleagues have postulated that this may occur via the short-term stimulation of any existing malignant clones under the influence of the hormonal milieu of pregnancy, but longer term inhibition of breast carcinogenesis is a consequence of induction of differentiation of normal mammary stem cells in the later stages of pregnancy that otherwise have the potential for neoplastic change.

Further extrapolation leads to the possibility that a recent childbirth before the diagnosis of breast cancer may increase a woman's risk of dying from the disease. Whiteman and colleagues observed 4299 US women ages 20 to 54 years enrolled between 1980 and 1982 as incident breast cancer patients in the population-based, case-control study known as the Cancer and Steroid Hormone Study. The 15-year survival rates were 38%, 51%, and 60% among women aged 20 to 45 years whose last birth was 12 months or less, 13 to 48 months, and more than 48 months before diagnosis, respectively, compared with 65% among nulliparous women. Phillips and colleagues prospectively studied 750 women diagnosed with breast cancer before age 45 years who were part of the population-based Australian Breast Cancer Family Study and demonstrated that the proximity of last childbirth to subsequent breast cancer diagnosis was a predictor of mortality independent of histopathologic tumor characteristics. Specifically, compared with nulliparous women, the investigators found that women who gave birth within 2 years before diagnosis were more likely to have axillary node–positive (58% vs 41%; $P = 0.01$) and ER-negative (58% vs 39%; $P = 0.005$) tumors. The unadjusted hazard ratios for death were 2.3, 1.7, and 0.9 for patients who gave birth less than 2 years, 2 to 5 years, and 5 or more years before diagnosis, respectively.

Breastfeeding. In an effort to determine what contribution (if any) breastfeeding has on the subsequent development of breast cancer, the Collaborative Group on Hormonal Factors in Breast Cancer examined the individual data from 47 epidemiologic studies in 30 countries that included information on breastfeeding patterns. In total, 50,302 women with invasive breast cancer were compared with 96,973 control participants. The investigators noted that women with breast cancer had fewer births than did control participants (2.2 vs. 2.6) and that fewer parous women with cancer than parous control participants had ever breastfed (71% vs. 79%), with their average lifetime duration of breastfeeding being shorter (9.8 vs. 15.6 months). The relative risk for breast cancer decreased by 4.3% for every 12 months of breastfeeding, and a relative risk reduction of 7.0% was seen for each birth. Thus, the longer women breastfed, the more they were protected against breast cancer. The lack of or short lifetime duration of breastfeeding typical of women in developed countries may contribute greatly to the high incidence of breast cancer in industrialized nations.

Hormonal Considerations: Pregnancy Coincident With Breast Cancer

Although there is no clear evidence that pregnancy adversely affects the course of this disease, the suspicion persists. It has

been established that after the diagnosis is made, stage for stage, pregnant patients do as well as nonpregnant patients. However, the low incidence of stage I lesions in pregnancy strongly suggests an acceleration of the disease process in the preclinical period. Many cell kinetic studies of breast cancer suggest that lesions are harbored within the breast for 5 to 8 years before becoming clinical entities. Because the period of gestation is no longer than 9 months, it is difficult to believe that the sole explanation for the high incidence of advanced disease in pregnancy is related to late diagnosis caused by the engorged breast.

The massive endogenous hormone production in pregnancy may adversely affect the course of breast cancer. Urinary excretion of all three major fractions—estrone, estradiol, and estriol—rises progressively after the eighth week of gestation, although there is a disproportionate rise in estriol production by the placenta. Serum concentrations of total estrogens rise nearly 2000-fold, from 4 μg/dL early in pregnancy to mean values of 8 to 22 mg/dL at term. The ability of estrogens to promote growth of breast cancer in animals and humans has been amply illustrated. Whether the stimulatory effect of increased estrogen production has an adverse effect on prognosis or whether the disproportionate rise of estriol, a relatively weak estrogen and a possible antagonist of estrone and estradiol, confers some measure of protection is unknown.

Additional hormone substances secreted in increased quantities in pregnancy that might influence neoplastic growths in the breast include the glucocorticoids and prolactin. Elevated corticosteroid levels are a regular accompaniment of pregnancy and might influence the outcome of breast cancer. Mean production of 17-hydroxycorticosteroids increases from 12 mg/24 hours to approximately 18 mg/24 hours in late pregnancy. Because glucocorticoids can reduce cellular immunity and perhaps promote the implantation and growth of malignant neoplasms, this increased production has grave clinical implications.

Similarly, elevated levels of prolactin produced by the hypophysis and of human placental lactogen by the placenta late in pregnancy and during milk production might affect breast cancer adversely. Prolactin promotes the growth of dimethylanthracene-induced mammary tumors in mice. Its role is not established in humans, but it is a subject of current investigation. The levels of prolactin in patients with breast cancer are not appreciably different from those in control subjects, and prolactin suppression with ergot compounds or with L-dopa has not proved to be of therapeutic value. However, the observation that women with bone pain from metastatic breast cancer sometimes obtain relief from prolactin suppression implicates prolactin as a possible promoter of breast cancer in humans.

Estrogen-Receptor and Progesterone-Receptor Status

A recent paper by Middleton and colleagues detected ER positivity in seven and PR positivity in six of 25 patients with PABC whose tumors were studied by immunohistochemistry. Although most tumors associated with PABC are ER and PR negative, a proportion will be ER positive, thus bringing to the discussion the possibility of tamoxifen use during pregnancy (see later). There has been one report of acquired resistance to tamoxifen during the treatment of a patient with PABC, in which the investigators suggest that the changing expression of ER isoforms in pregnancy may have contributed to drug resistance.

Pregnancy Termination

Historically, pregnancy was of concern to surgeons primarily because the risk of excess hemorrhage and shock with mastectomy was increased greatly in the gravid state. Billroth advocated premature induction of labor for this reason but did not find that abortion contributed to cure. More contemporary commentators have argued that the striking rise in estrogen production during pregnancy is of sufficient concern to warrant pregnancy termination and that future pregnancy avoidance should be an important principle of continuing care. Indeed, although many clinicians think that localized breast cancer in the first trimester is a valid reason to recommend termination, reports by Peters and Rosemond illustrate that therapeutic abortion has no effect on survival, and the presence of a fetus does not compromise proper therapy in early stages. Similarly, therapy for localized disease in later pregnancy can be carried out when the diagnosis is made without pregnancy termination. Of interest, in an updated presentation of 413 patients with PABC referred to the Princess Margaret Hospital in Canada between 1931 and 1985, Clark and Chua observed that therapeutic abortion in breast cancer with coincident, lactational, and subsequent pregnancies is associated with decreased survival. The reasons for this remain unclear. **Therapeutic abortion is not currently believed to be an essential component of effective treatment of early disease despite the theoretic advantage of removing the source of massive estrogen production.**

It is critically important to emphasize that treatment of breast cancer should not be delayed provided there are no major obstetric issues. In advanced breast cancer, therapeutic abortion is usually a necessity to achieve effective palliation. In the first trimester of pregnancy, the termination can be accomplished by suction curettage of the uterus; later in pregnancy, termination is accomplished by dinoprostone (Prostin) suppositories, oxytocin (Pitocin) administration, hysterotomy, or hysterectomy. When pregnancy enters the third trimester, the decision for preterm delivery depends heavily on the patient's wishes and the urgency for palliation. A short wait until a viable fetus can be obtained might not be accompanied by significant progress of the neoplasm. Continued gestation represents no threat to the fetus, and the risk of transplacental metastases to the fetus is negligible.

Tamoxifen

Tamoxifen citrate is a nonsteroidal weak estrogen that has found successful applications for each stage of breast cancer in the treatment of selected patients. Tamoxifen was originally introduced for the treatment of advanced disease in postmenopausal women; however, the drug is now also available for the palliative treatment of premenopausal women with ER-positive disease. The proven efficacy of tamoxifen and the low incidence of side effects made the drug an ideal agent to test as an adjuvant

therapy for ER-positive women with axillary lymph node–positive breast cancer. Tamoxifen is a selective ER modulator that is often prescribed for up to 5 years after completion of primary therapy.

The long-term effects of tamoxifen use and whether it may increase gynecologic cancers in daughters are unknown. In pregnant rats, tamoxifen administration has been associated with breast cancer in the female offspring. Cunha and colleagues examined 54 genital tracts isolated from 4- to 19-week-old human female fetuses and grown for 1 to 2 months in untreated athymic nude mice or host mice treated by subcutaneous pellet with the antiestrogen clomiphene, tamoxifen, or the synthetic estrogen diethylstilbestrol. The investigators noted that condensation and segregation of the uterine mesenchyme were greatly impaired and that the fallopian tube epithelium was hyperplastic and disorganized with distortion of the complex mucosal plications in drug-treated specimens as compared with untreated age-matched control participant.

Table 15.8 also summarizes six reports of tamoxifen use during pregnancy. In 1997, Tewari and colleagues described the first patient to have given birth to a child with congenital anomalies after systemic tamoxifen therapy through 20 weeks of gestation. This 46,XX child had ambiguous genitalia, including labial fusion and clitoromegaly; her internal genitalia were normal according to ultrasonography. Another fetus exposed to tamoxifen during all the first, second, and early part of the third trimesters was born at 26 weeks' gestation with oculoauriculovertebral dysplasia (ie, Goldenhar syndrome). A third case appeared in 2001 and involved a fetus delivered at 31 weeks of gestation whose mother was given tamoxifen as the sole systemic therapy and locoregional irradiation before pregnancy was determined. In addition to moderate hyaline membrane disease and necrotizing enterocolitis that was attributable to prematurity, the child had preauricular skin tags but an appropriate birth weight and no major malformations. At 2 years of follow-up, this last child was meeting all developmental milestones. The presentation of these three cases has prompted the creation of a tamoxifen registry. It is not clear whether women with ER-positive tumors receiving tamoxifen should temporarily discontinue the medication if and when they become pregnant.

Hormonal Considerations: Pregnancy After Breast Cancer

It has been estimated that only 7% of fertile women go on to conceive after the diagnosis and treatment of breast cancer. Nevertheless, a patient with breast cancer may have several concerns regarding future fertility, not least of which is whether she will remain fertile after treatment. In addition, the risk of recurrence conferred by subsequent pregnancy needs to be addressed because several authors have postulated that the immunosuppressant and hormonal effects of pregnancy so close to diagnosis may have a significant deleterious effect. Finally, a patient may express fear that a child may inherit a genetic predisposition toward the later development of breast cancer. The recommendations given to such patients should be influenced by two major considerations:

1. Whether pregnancy promotes recurrence of cancer
2. The probability of having been cured

Thirty percent of women younger than age 40 years will become amenorrheic after chemotherapy for breast cancer, and 90% of women older than age 40 years will cease menstruating. **For those who continue to ovulate and who are desirous of future childbearing, it has been common practice to recommend a waiting period of 2 years after the diagnosis of breast cancer before attempting to conceive because most recurrences occur within the first 2 years of diagnosis.** In 1985, Nugent and O'Connell described a poor prognosis for women with early subsequent pregnancy, but many investigators have since refuted this. Of note, women who have a subsequent pregnancy have equivalent or possibly better survival when matched for stage. Gelber and colleagues evaluated 94 patients from the International Breast Cancer Study Group who became pregnant after the diagnosis of early-stage breast cancer and compared them with 188 control participants (ie, no subsequent pregnancy) matched for nodal status, tumor size, age, and year of diagnosis. Whereas the overall 5- and 10-year survival rates from the diagnosis of early-stage breast cancer among the study group were 92% and 86%, respectively, that of the comparison group was 85% and 74%, respectively. Some have speculated an antitumor effect of the pregnancy, but of course this could reflect the "healthy mother" bias in that only select women who feel healthy will go on to conceive. Although it may be presumptuous to conclude on the basis of retrospective studies that pregnancy protects against recurrence after mastectomy, it is reasonably safe to conclude that it does not promote it. **In summary, therefore, it appears that future pregnancies are safe for the mother unless she has an ER-positive tumor and has not been placed into remission. Consequently, if a pregnancy occurs, there appears to be no justification for recommending its termination in patients without evidence of recurrence.** The converse, that pregnancy with recurrence should be terminated in most instances and that an uneventful pregnancy in no way guarantees against a subsequent recurrence, is also true. Indeed, there are cases on record in which multiple pregnancies have eventually been followed by recurrence.

Prophylactic Oophorectomy

Surgical castration for patients with early-stage breast cancer has been advocated to prevent further pregnancy, which might cause recrudescence of the disease through hormone stimulation. Oophorectomy also serves to eliminate the ovarian source of estrogen production, ideally preventing or delaying subsequent recurrence. Neither argument is substantiated by data to support a role for "prophylactic castration." In many patients, chemotherapy will cause a cessation of ovarian hormone production. As discussed earlier, pregnancy after treatment for breast cancer has no influence on the disease, and a few reports even suggest that future pregnancies might be protective. The rationale for eliminating the ovarian source of estrogens in the primary treatment of early disease is based on an observation that castration in the presence of observable recurrent disease results in partial or complete temporary tumor regression in approximately one-third of cases. This argument has been refuted by two large clinical trials conducted in the United

States that failed to demonstrate a significant benefit from castration and adjuvant therapy. For example, the National Surgical Adjuvant Breast and Bowel Project (NSABP) conducted a randomized trial of prophylactic castration in premenopausal women involving 129 women who were castrated and 70 control women. After an observation period of 10 years, there was no evidence that those who were castrated derived any benefit from the procedure.

Survival Among Patients With Pregnancy-Associated Breast Cancer

Most of the datasets from the preceding few decades show that women with PABC have the same survival stage for stage as nonpregnant women with breast cancer. Women with PABC may do poorly in the aggregate because these patients tend to present with advanced disease. Table 15.9 is adapted from Keleher and colleagues and shows selected 5-year survival data by axillary nodal status for women with PABC. Holleb and Farrow reported a series of 283 patients with carcinomas of the breast in pregnancy, including 73 who had inoperable disease and 210 who underwent surgery with or without postoperative radiation. Of patients with inoperable disease, 93% died within 2 years of the diagnosis, including all seven of those who had interruption of pregnancy. The majority of the remaining 210 patients underwent radical mastectomy and were given postoperative radiation therapy. Of 28 patients with a diagnosis in the first trimester, seven survived for 5 years. Peters and Meakin described 70 patients with breast cancer in pregnancy, all of whom were treated with preoperative, postoperative, or palliative radiotherapy in conjunction with radical mastectomy. The overall survival rates in this series were 32.9% at 5 years and 19.5% at 10 years. Of 12 patients treated during the first and second trimesters, three survived 5 years; only one of the nine patients treated during the third trimester survived 5 years, and she had active disease at the time of the report. The remaining 49 patients who were treated postpartum had a 39% 5-year survival rate, prompting the author to suggest that a delay in the treatment of breast carcinoma until after delivery should be considered.

It is now recognized that the independent variable of youth results in an unfavorable prognosis in patients with breast cancer, presumably because of the likelihood of more aggressive tumors in these young women. Previously, only young patients had an opportunity of having breast cancer coincident with pregnancy, but as women postpone childbearing, pregnancy coincident with breast cancer will become more common. Physicians must treat patients with breast cancer in pregnancy aggressively and with curative intent.

TABLE 15.9 Literature Review of Case-Control Series of Patients With Pregnancy-Associated Breast Cancer

Authors	Years	PABC	Matched Patients	Outcome
Petrek et al., 1991	1960–1980	56	166	No survival difference
Zemlickis et al., 1992	1958–1987	118	269	No survival difference
Ishida et al., 1992	1970–1988	192	192	Worse prognosis in PABC group
Chang, 1994	1979–1988	21	199	No survival difference
Nugent, 1985	1970–1979	19	157	No survival difference
Lethaby, 1996	1976–1985	20	362	Worse survival when diagnosed during lactation; no difference when diagnosed during pregnancy
Bonnier et al., 1997	1960–1993	154	308	Worse prognosis in PABC group
Ibrahim et al., 2000	1992–1996	72	216	No survival difference

EVALUATION AND THERAPEUTIC MODALITIES

Anesthesia and Surgery in Pregnant Patients

Anesthesia

Anesthetic considerations in pregnant patients must take into account both the potential teratogenicity of the anesthetic agents and the maternal physiologic changes that result from both the pregnancy and the use of anesthetic agents. The vast majority of analgesics and anesthetics are category C drugs (Table 15.10). When a drug has demonstrated teratogenicity in animals, it is likely to have the same effect in humans. Therefore, although category C drugs lack human studies, the existing animal studies may be useful in predicting risk to the fetus. A consensus statement published in 1998 in the pages of *The New England Journal of Medicine* did not list any anesthetic agents as definitive causes of fetal anomalies. **Inhalational and local anesthetics, muscle relaxants, narcotic analgesics, and benzodiazepines are known to be safe in pregnancy.**

The hyperdynamic cardiovascular system of pregnancy is characterized by an increased cardiac output and increased

TABLE 15.10 Drug Safety Categories in Pregnancy

Category	Description
A	Safety established using human studies
B	Presumed safety based on animal studies
C	Uncertain safety; no human studies; animal studies show adverse effect
D	Unsafe; evidence of risk that may in certain clinical circumstances be justifiable
X	Highly unsafe

resting heart rate. **The total blood volume is increased by 40% and that of the red blood cells by 25%, resulting in the physiologic anemia of pregnancy that decreases the hematocrit by approximately 30%.** As the pregnancy progresses, a decrease in blood return to the heart from the inferior vena cava occurs via increasing intraabdominal pressures caused by the enlarging uterus.

A 30% to 40% increase in the tidal volume occurs during normal pregnancy as oxygen consumption increases and the abdominal organs undergo mechanical displacement by the gravid uterus. Anesthesiologists may expect a compensatory respiratory alkalosis in pregnancy with a P_aCO_2 of 30 to 35 mm Hg. Cricoid pressure should be applied during intubation to prevent aspiration, the risk of which is increased as a result of the pregnancy-associated decrease in lower esophageal sphincter pressure and delayed gastric emptying. Small-diameter endotracheal tubes are recommended to facilitate intubation later in pregnancy when airway edema is increased. Intraoperatively, the end-tidal CO_2 is monitored.

Surgery

With the improvements in neonatal care, fetal survival rates continue to increase, and although actual figures vary between different neonatal intensive care units, survival rates greater than 90% can be expected beyond 28 weeks of gestation. Table 15.11 contains neonatal intensive care unit survival statistics based on gestational age and birth weight. Patients in need of surgery during the second trimester can be permitted a short delay to attain fetal viability in many cases. When the clinical suspicion for malignancy is high or the diagnosis is established by biopsy, it is recommended that surgery not be delayed in the first or third trimesters. If an asymptomatic and clinically isolated adnexal mass is discovered during the first trimester, as discussed earlier, it is reasonable to repeat an imaging study around 17 to 18 weeks of gestation to determine the need for surgery.

Pregnant patients undergoing surgery during the second trimester before fetal viability (≈23–24 weeks of gestation) should have the fetal heart tones documented by Doppler preoperatively and postoperatively. Later in pregnancy, continuous fetal heart rate monitoring can be used perioperatively. After documentation of an adequate amniotic fluid volume of approximately 10 to 18 mL via ultrasonography, preoperative and postoperative prophylactic indomethacin at a rectal dose of 25 to 50 mg can be used to minimize uterine contractions in patients undergoing surgery before 30 weeks of gestation. The use of indomethacin is not advisable beyond this period because of concerns of premature closure of the patent ductus arteriosus. It must be recognized that, although prophylactic tocolytic agents can decrease uterine irritability, they have not been shown to decrease the incidence of preterm birth in patients undergoing surgery. The liberal use of lower extremity sequential compression devices intraoperatively and during periods of bed rest is advisable. Finally, an external tocodynamometer can be used in the postoperative period to monitor uterine irritability and preterm uterine contractions.

Laparotomy

Historically, laparotomy during pregnancy was a frequent cause of fetal wastage. A 17% loss rate was reported by Brant in 1967 after appendectomy during pregnancy. In 1973, Saunders and Milton observed a 23% rate of fetal wastage after laparotomy. In modern hospitals, however, loss of the fetus as a consequence of laparotomy is uncommon. For example, Kort and colleagues reported in 1993 that for 78 women who underwent nonobstetric operations, the perinatal mortality rate was not increased provided that fetal viability was established preoperatively. The most common indications for surgical treatment in their series were appendicitis, adnexal mass, and cholecystitis. Nonobstetric surgery was associated with an increased risk of preterm labor, and the authors identified no measurable benefit from the use of perioperative prophylactic tocolytic agents. The premature delivery rate was 21.8% after major surgery, which was twice the rate in pregnant control participants.

With rare exceptions, when laparotomy is required to evaluate a pregnant woman for suspected or known malignancy, the author uses the midline, vertical approach. This permits excellent visualization and inspection of the entire pelvis and upper abdomen and, perhaps as important, facilitates the "hands-off-the-uterus" approach the author has toward surgery in gravid patients.

Laparoscopy

Laparoscopy can be used to evaluate adnexal masses during pregnancy and has been shown to be well tolerated by both the mother and the fetus. By the end of the second trimester, the enlarging uterus interferes with the laparoscopic view, and a celiotomy is generally required. Two million deliveries in Sweden from 1973 to 1993 were the subject of a review by Reedy and colleagues, who evaluated 2233 laparoscopic and

TABLE 15.12 Recommendations for Laparoscopy in Pregnancy

16–20 wk of gestational age
Tilting table to left or right
Left upper quadrant or subxiphoid insertion (6 cm between point of entry and top of fundus)
Open Hasson technique preferable
Ultrasound guidance with elevation of abdominal wall if Veress technique used
Intraabdominal pressure 15 mm Hg
Trendelenburg position
Fetal monitoring as indicated

2491 open laparotomy cases. The outcome measures included gestational age at delivery, birth weight, intrauterine growth restriction, congenital malformations, stillbirths, and neonatal deaths. Although both groups were at increased risk for preterm delivery and neonatal birth weights less than 2500 g, there were no statistically significant differences between the two. Highlights from the Society of American Gastrointestinal Endoscopic Surgeons recommendations for the conduct of laparoscopy in pregnancy appear in Table 15.12.

For seemingly isolated 6- to 10-cm adnexal masses that persist into the second trimester, we defer laparoscopic evaluation until 18 weeks of gestation and typically use pelviscopy to determine which direction (ie, transverse or midline-vertical) to make the laparotomy incision. For persistent masses larger than 10 cm, we recommend proceeding directly to laparotomy via a vertical incision in an effort to maximize exposure and allow surgical removal of the mass without any manipulation of the uterus.

Diagnostic and Therapeutic Radiation in Pregnancy

The primary concern of both the oncologist and the obstetrician regarding radiation therapy during pregnancy is its possible effect on the baby. The embryo undoubtedly represents the most radiosensitive stage of human life because many of the cells are differentiating and thus relatively more sensitive to radiation injury. In addition, the high rate of mitotic activity in the cells of the embryo contributes to its radiosensitivity because the mitotic phase of the cell is the most radiosensitive period in the life cycle of the cell. Of note, if the embryonic cell is genetically altered or killed during development, the fetus will be deformed or will not survive. Finally, there is the concern that irradiation of the fetal and maternal gonads may contribute to reproductive difficulties in the future, of both the mother and her offspring.

Radiobiology

For the fetus, the most sensitive period is day 18 through day 38. After day 40, the primary organ systems have developed, and much larger doses of x-rays or gamma rays are necessary to produce serious abnormalities. Three periods of fetal development are highly significant from a radiologic point of view.

1. Preimplantation: In this phase, radiation produces an all-or-none effect, in that it either destroys the fertilized egg or does not affect it significantly.
2. Organ system formation: This is the period from day 18 through day 38, when doses of 10 to 40 cGy may cause visceral organ or somatic damage. Microcephaly, anencephaly, eye damage, growth restriction, spina bifida, and foot damage are reported with doses of 4 cGy or less. Cause and effect have not been proved with these lower doses.
3. Period of fetal development after day 40, when larger doses are likely to produce external malformations but organ systems, especially the nervous system, may still be undamaged

The dose to the fetus is related to internal scatter of radiation after it enters the supradiaphragmatic tissues. Some scatter may also come from the treatment head of the machine and the collimator. Zucali and colleagues used a tissue-equivalent phantom to measure scatter dose to the uterus. In this study, doses of 1.5% of the total dose were measured at the estimated top of the uterus, with less than 1% being measurable in the true pelvis. This occurs even with abdominal shielding.

It is estimated that 1 cGy of radiation produces five mutations in every 1 million genes exposed. Fortunately, most mutants are recessive. Mutant effects are not seen in the first generation and may not be expressed for many generations until two people with the same mutation mate. Most estimates of genetic damage are empiric, but it is estimated that to double the rate of gene mutation, 25 to 150 cGy must be given from birth to the end of reproductive age.

Constant changes are being made in what is considered the permissible body dose of radiation. Some authorities cite 14 cGy in the first 30 years of life; others cite 10 cGy or less as the maximum. This includes medical and background sources. Radiation doses in excess of 200 cGy during the first 20 weeks of gestation will result in congenital malformations in the majority of fetuses exposed (frequently microcephaly and mental retardation). With doses above 300 cGy, there is increasing risk of abortion. If therapeutic irradiation is necessary for a pregnant patient and therapeutic abortion is refused, delay in the initiation of treatment until at least the mid-second trimester is recommended. Irradiation of even supradiaphragmatic structures during pregnancy will deliver fetal doses ranging from 1.2% to 7.1% of the total treatment dose.

Radiation-induced Anomalies

There are varying sensitivities within the tissues in human embryos. Various abnormalities have been attributed to irradiation of embryos; microcephaly and associated conditions are most common. Other abnormalities of the central nervous system (CNS), the eye, and the skeleton have also been ascribed to irradiation. However, an accurate prediction of incidence with regard to dose has not been possible. It is widely accepted that irradiation of human beings, especially of their gonads, has certain undesirable effects. Any irradiation of gonadal tissue involves possible genetic damage because the photons can cause gene mutation or chromosome breakage with subsequent translocation, loss, deletion, and abnormal fusion of chromosome material. The effect is basically additive and cumulative;

the changes are generally in direct proportion to the total dose. Unfortunately, there is no threshold for genetic damage, and even relatively small doses of irradiation can cause gene mutations, most of which can be harmful.

Doses greater than 50 cGy may produce significant mental retardation and microcephaly, even in the second trimester (Fig. 15.12). An analysis of children exposed in utero to the atomic bomb in Hiroshima and Nagasaki shows a 30 in 1600 incidence of severe mental retardation. Most of the mentally retarded children were exposed at 8 to 15 weeks of life; no cases were reported before the eighth week of gestation. A rough linear relationship is suggested, with a probability of mental retardation occurring at 0.4% per cGy (rad).

As noted previously, the exposure dose that is associated with developmental abnormalities remains controversial. Hammer-Jacobsen suggests that 10 cGy received in the first 6 weeks of gestation should be considered a threshold for therapeutic abortion. Others disagree and suggest that the minimal level increases as the pregnancy progresses. Low-dose exposure (<100 cGy) seems acceptable only in the third trimester. Evidence suggests that an exposure of even 3 to 5 cGy can result in an increase in benign or malignant tumors in the child after birth.

Most of the data to date on the effects of irradiation on the fetus are from single-dose exposure; few data are available concerning the effects of fractionated irradiation. Reported cases of fractionated irradiation during pregnancy show a low incidence of fetal anomalies.

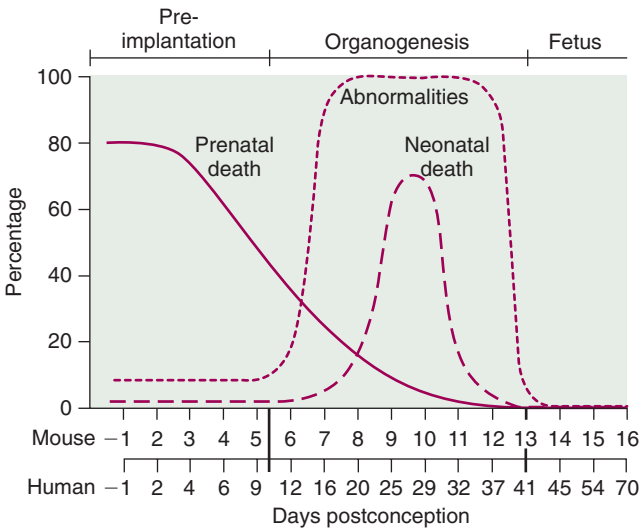

FIGURE 15.12 Incidence of abnormalities and of prenatal and neonatal death in mice given a dose of 200 cGy at various times after fertilization. The lower scale consists of Rugh's estimates of the equivalent stages for the human embryo. (From Hall EJ. *Radiobiology for the Radiologist*. Low levels of x-irradiation and the early mammalian embryo. *AJR Am J Roentgenol* 1962;87:559.)

Diagnostic Radiology

The metastatic evaluation using diagnostic imaging and the treatment of malignancy by radiotherapy in the pregnant woman underscores an inherent maternal–fetal conflict in that the mother would be the major beneficiary, but the fetus could be at substantial risk. Several recommendations have been widely applied in this scenario, including delaying radiation therapy for breast cancer until after delivery, avoidance of SLN identification procedures during pregnancy, and termination of pregnancy when doses greater than 0.05 to 0.1 Gy are received by the fetus. It must be recognized that these recommendations are not based on sufficient knowledge of the radiation risks to the unborn child. Although individual doses are highest in association with radiation therapy, the greatest risk to both the general population and the cancer patient comes from diagnostic procedures. Most radiologic diagnostic procedures should be avoided during the first and second trimesters of pregnancy. The exposure to the fetus and gonads will vary with the procedure performed and the precautions taken. A chest radiograph will result in an exposure of 300 mcGy per plate, and a barium enema study will result in a total dose to the gonads and pelvis of 6 cGy. In a pregnant patient, the barium enema study is obviously a greater threat because of the greater dose and the area irradiated.

The International Commission on Radiological Protection prepared two reports on medical irradiation in pregnant women. The biologic effects of prenatal irradiation of the embryo and fetus were derived from animal studies, data from survivors of nuclear explosions, data from children exposed in utero to diagnostic radiographs, and data on children who were exposed to radiation from the Chernobyl accident in utero. As outlined in Table 15.13, lethality, malformations, mental retardation, and

TABLE 15.13 Effects and Risks After Exposure to Ionizing Radiation in Utero and Spontaneous Frequency (Without Exposure)

Time After Conception (wk)	Effect(s)	Risk Per 0.01 Gy	Spontaneous Frequency

cancer induction comprise the expected effects of radiation exposure of fetuses.

Ionizing Radiation

In diagnostic radiograph or CT, ionizing radiation passes through the body to create an image, and ionizing radiation from radiopharmaceuticals used in nuclear medicine procedures are retained in the tissues for a period of time and are subsequently removed by elimination from the body and by radioactive decay.

Nonionizing Radiation

Both ultrasonography imaging and MRI form images using nonionizing radiation; however, theoretic risks to fetuses exist. Thermal effects occur in tissues with the absorption of ultrasonic energy, but cavitation (ie, mechanical) effects may occur through motion initiated by the ultrasonic. Both thermal and cavitation effects occur only with very high-intensity ultrasonography, and no confirmed biologic effects associated with the use of diagnostic ultrasonography with standard power levels have been reported. Potential injury at the cellular level in MRI may result from exposure to high static magnetic fields. In addition, heating can result from energy deposited by radiofrequencies used to generate the pulse sequences. The diagnostic magnets create static magnetic fields from 0.1 to 1.5T, and no adverse behavioral or physiologic effects are anticipated with fields up to 2T. Of note, there have been no immediately observable adverse effects or delayed sequelae encountered among fetuses from an MRI examination. Table 15.14 lists the imaging modalities used to diagnose metastatic disease.

Ionic or nonionic iodinated intravenous contrast media used in CT appear to be safe for fetuses; however, only animal studies have been performed using iodinated contrast agents. These agents are pregnancy category B drugs. Gadolinium-based contrast medium is not advisable during pregnancy because the gadolinium crosses the placenta, is filtered through the fetal kidneys, and is then reingested through the amniotic fluid. Gadolinium is a category C drug. The accuracy of bone scans is improved through the addition of single-photon emission computed tomography imaging. Whereas MRI is the most sensitive for studying the bone marrow, CT is highly sensitive for cortical destruction. Positron emission tomography scanning with 2-[fluorine-18]fluoro-2-deoxy-D-glucose is being used with increasing frequency in the metastatic workup, although the potential dose to the fetus precludes its use when the pregnancy is to be preserved.

Radionuclides

Most diagnostic nuclear medicine procedures use short-lived radionuclides (eg, ^{99m}Tc), resulting in a dose to the fetus generally less than 0.01 Gy. Special mention should be made regarding whole-body radionuclide scanning using iodine-131 for the metastatic workup of thyroid carcinoma. It is well established that oral administration of radioactive iodine to a mother will have deleterious effects on the thyroid gland of the fetus, with placental transfer of radioactive iodine occurring as early as 8 weeks after conception. The fetal thyroid gland will concentrate iodine and synthesize thyroxine by 11 to 12 weeks of gestation. The radiation dose delivered by 2 μCi of ^{131}I to the fetal thyroid gland ranges from 10,000 to 40,000 cGy. Stoffer and Hamburger studied 237 cases in which radioactive ^{131}I at doses from 10 to 150 μCi was administered during pregnancy. In 55 patients, therapeutic abortion was performed on medical recommendation, and among the remaining 182 pregnancies, there were two spontaneous abortions, two stillborn infants, and two infants born with abdominal or chest anomalies. Of note, there were six infants with hypothyroidism (3%), four of whom exhibited mental deficiencies. Pregnancy is a contraindication to the administration of ^{131}I.

Radiation Therapy

When the patient wishes to continue her pregnancy, delay of initiation of therapeutic radiation as long as possible without compromising cure is recommended. Fortunately, most cancers in pregnant women that require radiation therapy are remote from the pelvis. Any radiation therapy to the abdomen should be postponed until after delivery, if at all possible. Therefore, with the exception of a locally advanced cervical tumor, radiation therapy can be used during pregnancy provided that the fetal dose is precisely estimated during the radiation planning sessions. **The dose to the fetus can be calculated from the internal scatter, which largely depends on the source of irradiation and on the size of the treatment fields and their proximity to the fetus.** Leakage radiation from the tube head of the linear accelerator, scatter from the collimator, and blocks also contribute to the fetal dose. Leakage and scatter can be reduced by proper shielding with four to five half-value layers of lead stacked over the patient's uterus.

Kal and Struikmans tabulated the dosimetry data and pregnancy outcomes of women who received radiation therapy during pregnancy for breast cancer (Fig. 15.13), Hodgkin disease, and brain or head and neck tumors (Table 15.15). Successful radiotherapy of breast cancers during pregnancy with fetal doses below the deterministic threshold (0.039-0.18 Gy) have resulted in the birth of healthy children. Similarly, several healthy children, some who have been observed for up to 11 years, have been delivered after radiation therapy for Hodgkin disease during pregnancy with fetal doses ranging from 0.014 to 0.136 Gy. Radiation treatment portals are now more restricted in size, and patients with stage I and II Hodgkin disease currently receive polychemotherapy followed by involved field radiotherapy, thus resulting in potentially less harm to the unborn child. Finally, the successful radiotherapeutic management of neck and cranial tumors in pregnancy suggests that high doses can be achieved with fetal exposures of less than 0.1 Gy, a dose below the deterministic threshold.

Radiation-induced Carcinogenesis

The subject of the carcinogenic effects of x-ray radiation was first raised nearly half a century ago by Stewart and Webb from Oxford University in the United Kingdom. Monson and Macmahon summarized the bulk of the data accumulated before the 1980s in their monograph that focused on prenatal x-ray exposure and cancer in children. Most of the available information on radiation-induced embryonic damage during the preceding 2 decades is derived from animal studies, extended follow-up of individuals exposed to atomic bomb explosions in Japan, and statistical analyses.

Of interest is a paper by Chen and colleagues, who studied the records of 37 women radiated for Hodgkin disease around the time of pregnancy and of 345 women who were not pregnant. They detected a higher risk of breast cancer after irradiation around the time of pregnancy, suggesting that pregnancy represents a time of increased sensitivity of breast tissue to the carcinogenic effects of radiation.

Genetic Damage and Infertility

In addition, the possibility that human exposure to ionizing radiation might have a detrimental genetic consequence remains a matter of concern and uncertainty. There is concern because recessive mutations may not become apparent for several generations, and there is uncertainty because, although

FIGURE 15.13 Irradiation of a pregnant woman after breast-conserving treatment. Shielding of leakage radiation is done with a mobile lead screen usually used for shielding of personnel in the brachytherapy room. (From Kal HB, Struikmans H. Radiotherapy during pregnancy: fact and fiction. *Lancet Oncol* 2005;6:328.)

no human data are available, experimental animal studies have demonstrated significant radiation-induced genetic effects. There appears to be no apparent threshold dose for genetic damage, but the effect of any particular radiation dose is considerably reduced if that dose is administered during a prolonged period. Of importance also for patients planning childbearing after significant exposure of gonadal tissue to irradiation is that the genetic effect of radiation on the gonad may be minimized by delaying conception after exposure. **In humans, pregnancy should be delayed 12 to 14 months after significant exposure.**

Chemotherapy

Because nearly all antineoplastic drugs have been shown to be teratogenic in animal studies, the available data suggest endangerment to human fetuses even for drugs for which no human data are available. Their use often evokes moral, philosophic, and emotional decisions. Both the mother and fetus are at risk, with abortion, intrauterine fetal demise, malformations, and growth restriction being foremost considerations. These potential dangers to the fetus must be weighed against the possible detrimental effect to the mother of withholding these agents. The long-term effect on the fetus is unknown. The problem of long-term observation has been dramatically emphasized by the occurrence of adenosis of the vagina in young women exposed to diethylstilbestrol in utero during the first trimester of pregnancy. A similar long-term effect is possible when chemotherapeutic agents are used in pregnancy.

All chemotherapeutic agents profoundly affect rapidly growing tissues, and a high rate of cell division is characteristic of the fetus. Following this reasoning, one would expect a much greater effect than is actually observed. Unquestionably, the first trimester of pregnancy is when fetuses are most vulnerable to cancer chemotherapeutic agents. The two aspects to the problem of fetal damage are as follows:

- Death of the fetus
- Induction of fetal abnormalities inadequate to cause fetal death

Most of the available data suggesting the teratogenicity and mutagenicity of chemotherapeutic agents have been derived from experiments in laboratory animals. Rats, mice, and rabbits have placentas very similar to human placentas, and because the teratogenic effects of a drug are species specific, these animals provide models in which to study chemotherapy exposure in utero. These experiments indicate potential danger to human fetuses only. Teratogenic properties of chemotherapeutic agents also are predicated on the type, dose, and threshold dose of the drug. When considering an extrapolation of animal data to humans, it is important to note that the therapeutic doses used in humans are often lower than the minimum teratogenic dose studied in animal models. Thus, teratogenic data are useful only if the dose resulting in injury to the model does not also cause maternal toxic effects. Another important caveat is that many antineoplastic exposures in pregnancy that have resulted in malformations or even fetal deaths have typically been associated with multiagent therapy, sometimes also with concomitant radiation therapy, so that it is difficult to single out one specific agent as the cause of an adverse outcome. It is important to note that in the majority of exposures, even during the first trimester, the outcome of the fetus is unremarkable. **Still, unless the mother's life is in grave danger, we do not recommend chemotherapy use during the first trimester.**

Teratology and Embryology

Teratology is the study of the causes, mechanisms, and manifestations of abnormal fetal development. Environmental factors, such as infectious diseases, drugs, chemicals, and radiation, have been shown to cause abnormal development by inducing chromosome abnormalities, specific gene changes, vascular changes, or mechanical disruption. In many instances, the exact cause of a fetal abnormality is unknown. Although different classes of teratogens have been established, certain general principles apply to all. There are three stages of embryonic development. In the first 2 weeks of life, the blastocyst is resistant to teratogens. It is during this period that a large insult is necessary to kill the blastocyst. A surviving blastocyst will not manifest any organ's specific abnormalities as a result of that teratogen. Early embryonic cells have not differentiated sufficiently, so if one cell dies, another can take over. The second stage is organogenesis, or the process of organ differentiation. **The most critical period extends from the third to eighth weeks of development (fifth through tenth weeks of gestational age), when susceptibility to teratogenic agents is maximal. In human fetuses, the period of organogenesis usually ends by the 13th week of gestation.** The third and final period of growth, organ development, is characterized by an increase in fetal and organ size. However, brain and gonadal tissue are exceptions because they continue to differentiate beyond the second period. Exposure to the teratogenic agent beyond the third period can affect general fetal growth but will not produce organ-specific morphologic malformations.

Fig. 15.14 depicts prenatal development from implantation through embryonic progression and into the fetal period. Drug responses vary among individuals because of differences in absorption, protein binding, and excretion rate and differences in placental transfer and fetal metabolism of the teratogen. Both polygenic and mendelian factors can be responsible for different responses to identical doses of a teratogen in two fetuses of the same species. Administration of small intermittent doses of a teratogen may enable a system to safely metabolize the teratogen and prevent malformation. The effect would be different if the total dose were administered at one time. However, small constant doses of a teratogen may interfere with cellular metabolism and cause more serious malformations than might be expected.

Transplacental Studies

Antineoplastic agents and their metabolites can be detected in placental tissue, amniotic fluid, umbilical cord blood, and breast milk. By enzyme-linked immunosorbent assay and spectrometry, Henderson and colleagues measured cisplatin–DNA adducts in placental tissues but were unable to do so in the

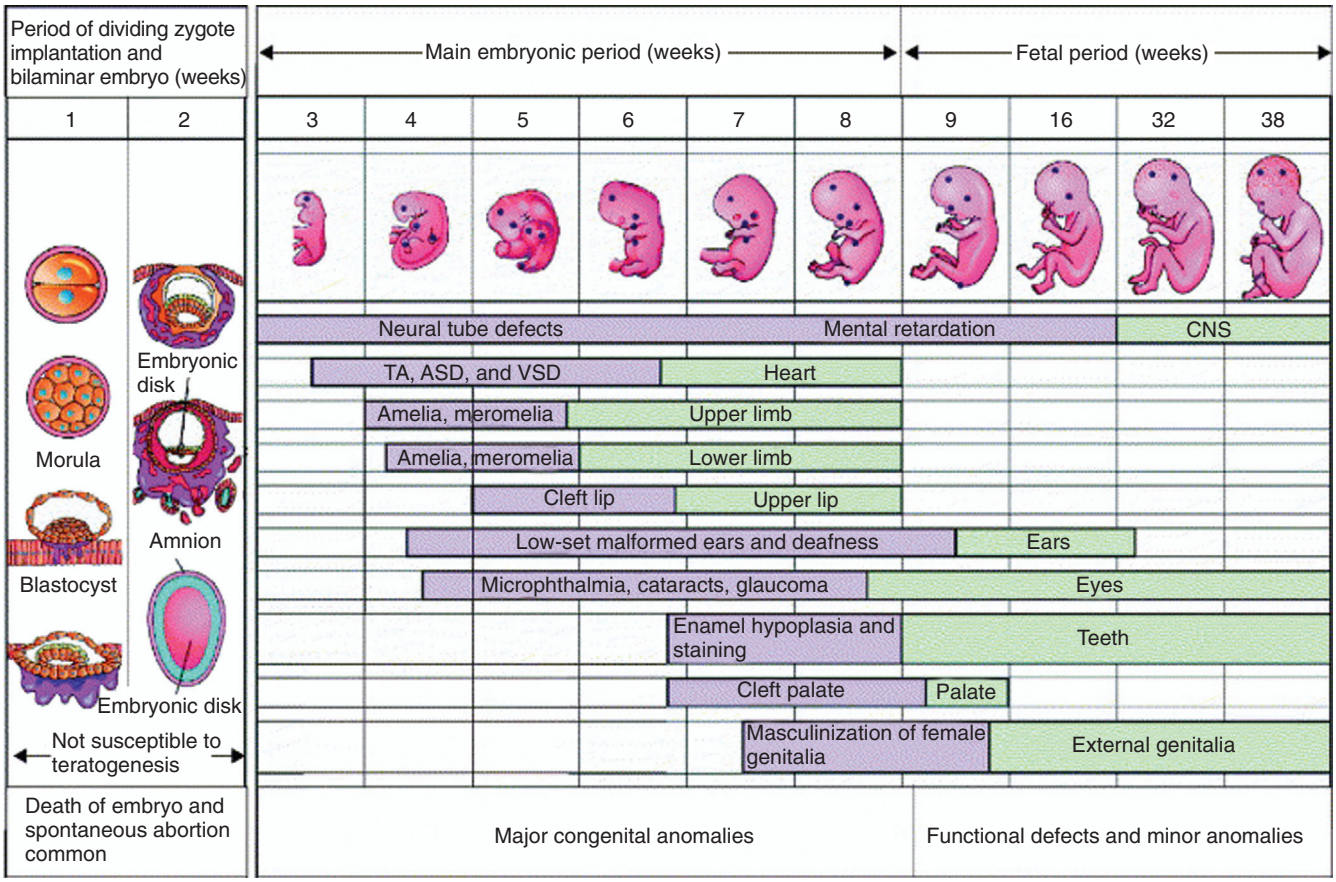

FIGURE 15.14 Crucial periods in prenatal development. *Dots* on the developing fetus show common sites of action of teratogens. *Horizontal bars* indicate fetal development during a highly sensitive period *(purple)* and a less sensitive period *(green). Philadelphia, 1998, Saunders.)

umbilical cord tissues or in amniotic cells. Karp and colleagues reported high levels of doxorubicin in placental tissue; the drug was absent in umbilical cord tissue or in the blood of a healthy child born 48 hours after maternal treatment. Separately, Roboz and colleagues and Barni and colleagues were unable to identify doxorubicin in the amniotic fluid after maternal administration. Transplacental conduct of antineoplastic drugs may occur. Although doxorubicin was not detected by liquid chromatography in the amniotic fluid, fetal brain, or fetal gastrointestinal tract 15 hours after its administration to the mother, d'Incalci and colleagues found the drug in the fetal liver, kidney, and lungs after elective termination. It would have been interesting to have had data from the fetal myocardial tissue. A metabolite of doxorubicin was present in the umbilical cord, placental tissue, and neonatal spleen of a stillborn baby delivered 36 hours after maternal treatment. Egan and colleagues reported a case in which milk and plasma concentrations of doxorubicin and cisplatin were measured after intravenous administration of these agents to a lactating patient who had ovarian cancer. Although the concentrations of doxorubicin in milk at times exceeded those detected in concomitant plasma samples, the total amount of drug delivered in the milk was negligible. However, the authors concluded that it is prudent to advise lactating women who are receiving these antineoplastic drugs to refrain from breastfeeding.

Classes of Antineoplastic Agents

Antimetabolites. Antimetabolites are small, weakly acidic molecules that are cell cycle nonspecific, inhibiting cellular metabolism by acting as false substrates during RNA and DNA synthesis. Examples of these agents include methotrexate, 5-FU, aminopterin, cytarabine, thioguanine, and mercaptopurine. **The aminopterin syndrome has been reported after in utero exposure during the first trimester and is characterized by cranial dysostosis with delayed ossification, hypertelorism, wide nasal bridge, micrognathia, and ear anomalies.** Similar malformations have been associated with methotrexate administration when doses greater than 10 mg per week are used during the first trimester. There have been 53 reported cases of exposure to 5-FU during human pregnancy; when used after the first trimester (usually in combination with other agents), the development of intrauterine growth restriction without anomalies manifested in 11% of cases ($n = 6$). There have been four reports of limb malformations after cytarabine administration during the first trimester; among 89 additional cases in which the drug was given during all trimesters (usually

in combination with other agents), adverse fetal events included transient cytopenia (5%), intrauterine fetal demise (6%), intrauterine growth restriction (13%), and two neonatal deaths from sepsis and gastroenteritis. Finally, 49 women have been treated with mercaptopurine during pregnancy, including 29 who were exposed to the drug during the first trimester, none of whom gave birth to an anomalous neonate.

There is no doubt that the antifolics aminopterin and methotrexate almost invariably result in spontaneous abortion or an abnormal fetus when they are given in the first trimester of pregnancy. These drugs should not be given to pregnant women in the first trimester unless there is life-threatening disease that can be counteracted by the drug. If an antifolic is used and the mother does not have a spontaneous abortion, therapeutic abortion should be seriously considered. A small amount of data seems to indicate that aminopterin and methotrexate do not cause harm when they are given after the first trimester of pregnancy.

Alkylators. Alkylating agents are an integral component of many combination chemotherapy regimens and include cyclophosphamide, busulfan, ifosfamide, chlorambucil, carmustine, and dacarbazine. First-trimester use of cyclophosphamide has resulted in absent toes, eye abnormalities, low-set ears, and cleft palate. When used during the second and third trimesters, cyclophosphamide appears to be safe, although from a combined experience involving 92 cases, there have been two fetal demises, seven cases of growth restriction, and one neonatal death. A very interesting case involves the twins reported by Reynoso and colleagues who were exposed to cyclophosphamide throughout the pregnancy. The girl had no abnormalities, but the twin boy was born with esophageal atresia, right-arm deformity, abnormal inferior vena cava, and growth restriction and went on to develop thyroid cancer at 11 years of age. There have been 19 reported cases of combined regimens containing dacarbazine in pregnancy, resulting in one case of growth restriction and possibly one minor malformation. Of interest, although there have been eight reports of busulfan use during the first trimester without anomalies, two patients who received the drug during the second trimester delivered anomalous neonates (one case each of pyloric stenosis and unilateral renal agenesis with liver calcifications).

Anthracycline and Antitumor Antibiotics

These high-molecular weight antibiotics interpose between DNA strands and include doxorubicin (Adriamycin), idarubicin, epirubicin, dactinomycin, bleomycin, and mitoxantrone. Turchi and Villasis collected 28 cases of doxorubicin and daunorubicin treatment after the first trimester. After one elective termination, two spontaneous abortions, and two maternal deaths from malignancy with the fetus in utero, 21 pregnancies were delivered without complications. Two of three limb abnormalities seen after doxorubicin exposure during the first trimester ($n = 25$) may be confounded by concomitant radiation or cytarabine treatment.

It has been recognized for a number of years that children and adults receiving anthracyclines are at risk of developing dose-related cardiotoxicity as a result of free radical damage that results in myocardial apoptosis and hypertrophy. It is not known whether in utero exposure to these agents places fetuses at risk for this complication. Meyer-Wittkopf and colleagues performed serial fetal echocardiograms on a pregnant patient receiving doxorubicin and on unexposed fetuses and were unable to detect any significant differences in systolic function. Postnatal echocardiograms revealed no evidence of myocardial damage up to 2 years after birth. There have been at least two cases of transient right-sided cardiomyopathy after second-trimester exposure to anthracyclines, including one case involving idarubicin, which is more lipophilic and favors increased placental transfer. **Until more information becomes available, we suggest that pregnant women requiring an anthracycline be given doxorubicin. Although the cardiac profile of fetuses exposed to anthracyclines appears to be safe in the majority of cases, because cancer treatment advances at a faster pace than the accumulation of safety data in human pregnancy, caution is always warranted before new agents are given to pregnant women.**

Plant Alkaloids

The vinca alkaloids are highly protein bound and include vincristine, vinblastine, and vinorelbine. They have been regarded as less potent teratogens than the antimetabolites. One of 29 patients treated with a four-drug regimen containing vincristine during organogenesis was delivered with malformations, including an atrial septal defect and no radii or fifth digits. There have been a total of 11 exposures to either vincristine or vinblastine during pregnancy, and excluding those malformations found only in first-trimester use, there have been nine cases of growth restriction, two fetal demises, and two neonatal deaths.

Taxanes

Paclitaxel and docetaxel inhibit microtubule disassembly, a process that is important for cell division and intracellular and intercellular functions. Because of their unique mechanism of action, many commentators have been concerned that taxanes may be detrimental to the fetus in many aspects. Animal studies have demonstrated lethality of paclitaxel to chick, rat, and rabbit embryos. Of note, when administered during the period of organogenesis, few malformations have been recorded. There have been only a handful of scattered reports of paclitaxel use during pregnancy in which the drug, when administered after the first trimester, has been shown to be safe for the fetus. As experience with these relatively newer chemotherapeutic agents increases, we anticipate an increase in the reporting of taxane use during pregnancy.

Platinum Analogs

The precise mechanism by which the platinum agents exert their antineoplastic effect has not been fully elucidated but may be similar to that of the classic alkylators. Drugs in this group include cisplatin, carboplatin, and oxaliplatin. There have been reports of exposure to single-agent cisplatin or cisplatin-based regimens, which have resulted in sensorineural hearing loss and cerebral atrophy resulting from impaired anterior cerebral

circulation, respectively. In both of these cases, the babies were born before 30 weeks' gestation, so the complications associated with extreme prematurity may be confounding the clinical picture. Nevertheless, close assessment of the fetal CNS may be advisable when cisplatin is used during pregnancy. Among 24 cases of cisplatin exposure, five have been complicated by growth restriction, fetal demise, hearing loss, and ventriculomegaly. The two reports that have appeared in the literature describing carboplatin use during pregnancy have been associated with unremarkable neonatal outcomes at up to 30 months of age.

Pharmacokinetics, Sublethal Fetal Effects, and Maternal Risks

The increased blood volume and increased renal clearance of pregnancy should be considered when treating a pregnant woman for life-threatening disease. Together, these physiologic changes, along with the more rapid turnover of the hepatic mixed function oxidase system, may lead to a decrease in active maternal drug concentration. For example, because pregnant women receive similar weight-based dosages (adjusted with the continuing weight gain of pregnancy) as nonpregnant women, the increased drug clearance from the body may lead to a reduced area under the concentration versus time curve. In addition, changes in gastrointestinal function may have an impact on drug absorption of some agents. Fortunately, with the pregnancy-associated decrease in plasma albumin, the unbound active drug concentration should rise, and thus the efficacy of the drug should not be compromised when administered during pregnancy. As long as the increase in drug balances potential decrease in serum levels, toxicity should not be increased. This may indeed be the case because Zemlickis and colleagues have noted higher concentrations of free cisplatin in pregnant women compared with those who were not pregnant, but all were asymptomatic. Countering this is the argument that estrogens are known to increase other plasma proteins and thereby decrease active drug fractions. Accordingly, Cardonic and Iacobucci have reported more frequent nausea, vomiting, fatigue, alopecia, and neutropenia during postpartum chemotherapy compared with identical antenatal treatment. The volume of distribution, peak drug concentrations, and half-life of administration are likely to be changed during pregnancy, although to date we do not have pharmacokinetic data on pregnant patients receiving chemotherapy.

Concerns regarding sublethal fetal effects of maternally administered chemotherapy have been raised. When a multidrug regimen was used in a pregnant woman with leukemia, Morishita and colleagues reported consistently normal fetal hematopoiesis via percutaneous umbilical cord blood sampling 2 and 5 weeks after treatment. Chemotherapy-induced neonatal alopecia is also a reasonable concern parents may have, but this condition has been reported only in three newborns and involved administration of bleomycin, etoposide, and cisplatin or doxorubicin, cyclophosphamide, and 5-FU. Microscopic scanning of the hair of neonates exposed to chemotherapy for maternal acute monocytic leukemia by Gokal and colleagues did not reveal any cytotoxic damage.

Attention must also be directed to specific maternal risks associated with chemotherapy administration during pregnancy. The safe use of recombinant erythropoietin in pregnancy has been reported to offset the triple insult of pregnancy-associated dilutional anemia, iron-deficiency anemia, and chemotherapy-induced marrow suppression. Along similar lines, granulocyte-colony stimulating factor has been used without adverse sequelae during human pregnancy to counter the maternal and fetal susceptibilities to infection brought about by the generalized immunosuppression of pregnancy and chemotherapy-induced neutropenia. **Finally, because the pulmonary damage associated with bleomycin use is exacerbated by oxygen therapy, we do not advise the administration of oxygen during labor in women who have received bleomycin during pregnancy.**

Estimating the Stillbirth Rate

The background stillbirth rate associated with chemotherapy administration throughout pregnancy can be estimated. In 1992, Zemlickis and colleagues reported their experience with 21 pregnancies after in utero exposure to chemotherapy. Of the 13 women exposed during the first trimester, two of five whose pregnancies continued to term had major malformations in their infants, four had spontaneous abortions, and four had therapeutic abortions. Of four women with second-trimester exposure to chemotherapy, two had normal live births, one had a stillbirth, and one had a therapeutic abortion. All four pregnancies exposed to chemotherapy during the third trimester resulted in healthy live births. However, infants exposed to chemotherapy had statistically significantly lower birth weights than did matched-control infants, owing to significantly lower gestational age and substantial intrauterine growth restriction. The rate of stillbirth was 1 per 11; this was too small a series for comparison with matched control participants. However, the authors analyzed 223 births in their community occurring to women who had any form of cancer in the same 30-year period and found 10 stillbirths among the 223 deliveries, significantly more than in the general population ($P < 0.0005$); this stillbirth rate was calculated at a relative risk of 4.23 (95% CI 2.0–7.8).

Occupational Exposure

In a 1985 case-control study, Selevan and colleagues examined the relationship between fetal loss and occupational exposure to antineoplastic drugs in nurses in 17 Finnish hospitals. The pregnancies studied occurred in 1973 through 1980 and were identified using national sources. Each nurse with fetal loss was matched with three nurses who gave birth. A statistically significant association was observed between fetal loss and occupational exposure to antineoplastic drugs during the first trimester of pregnancy, with an odds ratio equaling 2.30 (95% CI 1.20–4.39). Analyses suggested associations between fetal loss and cyclophosphamide, doxorubicin, and vincristine, although the independent effect of each individual drug could not be specifically identified because many nurses reported handling more than one of these agents.

Recommendations on the Use of Chemotherapy During Pregnancy

In summary, the administration of chemotherapy during the first trimester can be associated with morphologic abnormalities and fetal loss. Although first-trimester use of chemotherapy is inadvisable, if a pregnant patient has an aggressive hematologic malignancy, chemotherapy at full doses can often be safely administered, even during the first trimester, if cure of the hematologic malignancy is considered reasonable.

Chemotherapy administered in the second and third trimesters appears not to be associated with a significant risk of structural anomalies, but some reports suggest an association with preterm delivery, fetal death in utero, and intrauterine growth restriction. The background incidence of growth restriction varies according to the population, geographic location, and standard growth curves used as a reference. We must also keep in mind that the pregnant woman's underlying illness may affect perinatal complications. When more than one regimen is available and effective for a particular cancer, clearly the agents for which the most extensive investigation during pregnancy has been conducted should be selected. Some form of antepartum fetal surveillance is advisable, and close coordination with a perinatologist can determine the need and schedule for serial ultrasonography and fetal heart rate monitoring (Table 15.16). Placental pathology is mandatory in all cases after delivery or termination.

Timing of Delivery

We recommend withholding chemotherapy after 35 weeks of gestation so as to avoid the maternal nadir period because spontaneous labor may occur before the bone marrow has recovered. Chemotherapy administered to the mother within 3 weeks of delivery may not be adequately excreted by the fetus and therefore persist in the newborn.

Preterm pregnancies are also problematic. Iatrogenic preterm delivery is not advisable, and impending preterm delivery should be treated aggressively. In pregnant patients for whom preterm delivery seems inevitable, it is important to withhold chemotherapy 3 weeks before delivery when possible. **Preterm babies have limited ability to metabolize drugs because of immaturity of the hepatic and renal systems. Neonates exposed to chemotherapy 3 weeks before delivery should be assessed for transient bone marrow suppression, and long-term neurologic and developmental follow-up is recommended.**

Breastfeeding

Durodola reported one case of neonatal neutropenia occurring in a breastfed infant whose mother was treated with cyclophosphamide during late pregnancy and early lactation. As described earlier, some drugs have been detected in the placental tissues and the breast milk. The ability of a drug to cross the placenta, however, has not correlated with its ability to pass into breast milk. Drug concentrations in breast milk are related to the dose and timing of therapy. **Because there are no breastfeeding data available for most agents, the author considers breastfeeding to be contraindicated during therapy.**

Long-term Neonatal Follow-up

Although children and adults treated for lymphoma are at risk for secondary leukemia within 10 years, the risk of secondary malignant disease after in utero exposure to chemotherapy is unknown. No cases of secondary leukemia in exposed fetuses have been reported. As described elsewhere, only one case of malignant disease (ie, thyroid cancer at age 11 years and neuroblastoma at age 14 years) in an anomalous child exposed to chemotherapy in utero has been published. It must be acknowledged, however, that there is a paucity of satisfactory long-term results among children exposed to chemotherapy in utero.

In one of the few studies to address this important subject, Aviles and Neri reported the outcomes of 84 children born to mothers with hematologic malignancies who received chemotherapy during pregnancy, including 38 during the first trimester (acute leukemia, $n = 29$; Hodgkin disease, $n = 26$; malignant lymphoma, $n = 29$). These children were examined for physical health, growth, and development and for hematologic, cytogenetic, neurologic, psychologic, and learning disorders. The occurrence of cancer or acute leukemia in these children was also considered by the investigators. In addition, some of their subjects had become parents, and their children were also considered in the analysis. In all the children studied, including the 12 second-generation children, the birth weight was normal, as was the learning and educational performance. Specifically, school performance and standardized intelligence testing did not differ significantly from unrelated matched children and unexposed siblings. No congenital, neurologic, laboratory, or psychologic abnormalities were observed. Tolerance of infections was also normal, as was secondary sexual development among the older children. With a median follow-up of 18.7 years (range, 6–29 years), no cancer or acute leukemia was detected.

The lack of adequate observation of the long-term status of the fetus or infant prevents any definite conclusions as to the relative safety or danger of anticancer chemotherapy during pregnancy, even in the second and third trimesters. It is surprising how often the detailed status of the fetus is not mentioned in available reports. The infant is often described as "normal," with few if any details on the physical or laboratory profile of the baby. **Long-term observation is necessary to establish normalcy because many of the defects may not be obvious on inspection and may emerge as derangements of growth, development, function, reproduction, and heredity.**

Supportive Therapy

Granulocyte-colony stimulating factors (G-CSFs), recombinant erythropoietin, and antibiotics are associated with very limited data sets in the medical literature. Among seven reports of G-CSF use during pregnancy (all after the first trimester), there were no adverse pregnancy- or neonatal-related events. Use of G-CSF appears to be reasonable for patients in desperate need of this drug. Although recombinant human erythropoietin (rhEPO) does not cross the placenta, evidence for its safety remains scarce, and blood transfusion should remain the first line of therapy for pregnant patients with severe anemia,

TABLE 15.16 Examples of Tests Used in the Antepartum Fetal Surveillance of Pregnant Patients With Cancer

Biochemical parameters	Progesterone		E3	hCG	Triple screen (E3, hCG, α-fetoprotein)		Human placental lactogen		
Fetal movements	Kick counting after 25 wk of gestation								
Electronic fetal heart rate monitoring	Nonstress test			Contraction stress test	Sinusoidal rhythms (correlate with fetal anemia)				
Ultrasonography	Accurate pregnancy dating	Confirm fetal well-being (viability)	Uterine and adnexal abnormalities	Cervical length	Serial growth assessment	Assessment of the placenta	Assessment of fetal anomalies		Four-dimensional imaging
Fetal echocardiography	Evaluation for fetal cardiac defects								
Color Doppler	Systolic-to-diastolic ratio in the umbilical cord artery				Systolic-to-diastolic ratio in the fetal middle cerebral artery ultrasonography				
Fetal biophysical profile	Fetal breathing movements			Gross body movement			Fetal tone	Qualitative amniotic fluid volume	Reactive fetal heart rate
Chorionic villus sampling	9 wk								
Amniocentesis	Genetic: 16–20 wk				Pulmonary maturation: third trimester				
Percutaneous umbilical blood sampling	Fetal hematocrit				Fetal infection				
Fetal fibronectin	22–34 wk								
Fetal pulse oximetry	Acidemia with P_aO_2 <30%								

E3, Estriol; *hCG,* human chorionic gonadotropin.

particularly during the first trimester. Among the multitude of antibiotics available, penicillins are able to cross the placenta freely, but harmful fetal effects have not been reported. The combination of amoxicillin plus clavulanate is a regimen used frequently in patients receiving chemotherapy, but it is associated with an increased incidence of necrotizing enterocolitis in newborns and therefore should be avoided during pregnancy. Cephalosporins and metronidazole can be safely used during pregnancy; however, aminoglycosides, quinolones, trimethoprim, and tetracycline should not be administered. Aminoglycosides can cause eighth cranial nerve damage, and quinolones have been linked to congenital arthropathy in animal models. Similar to methotrexate, trimethoprim is a folate antagonist and is therefore contraindicated during pregnancy. Finally, tetracyclines are hepatotoxic to the mother and inhibit fetal bone growth. Although no adverse events have been reported with imipenem and meropenem, available data in human pregnancy are even more limited.

Serum Tumor Markers in Pregnancy

Table 15.17 **lists serum tumor marker ranges for pregnant and nonpregnant women. Although the serum CA-125 has been found to fluctuate during pregnancy, comprehension of the established trends may assist in following pregnant women with a history of epithelial ovarian cancer and those being evaluated during pregnancy for a pelvic mass.** Specifically, the CA-125 values are highest during the first trimester, with levels as high as 1250 U reported. The values decrease during the late first trimester and should remain below 35 U/mL of serum until delivery, at which point the CA-125 transiently increases 1 hour postpartum. It should be mentioned that Jacobs and Bast have reviewed the literature and found cases in which the maternal serum CA-125 remained within normal limits throughout uncomplicated pregnancies.

Bon and colleagues evaluated the concentrations of maternal CA-125 and CA-15-3 (a breast cancer tumor marker) in normal and 120 pathologic pregnancies (eg, spontaneous abortion, fetal death, growth restriction, chromosomal and structural abnormalities, and preeclampsia). The maternal CA-125 serum values were higher during the first and third trimesters during pregnancy, and the CA-15-3 serum levels were higher only during the third trimester. Neither antigen showed any relation with a pathologic outcome of pregnancy.

Of interest, Kiran and colleagues performed simultaneous measurements of CA-125, CA-15-3, CA-19-9, and carcinoembryonic antigen (CEA) in the maternal serum and umbilical cord blood in 53 pregnancies that were terminated by cesarean section. CA-19-9 is a pancreatic cancer tumor marker, and CEA is a marker of mucinous adenocarcinomas with levels that are normal or marginally elevated in normal pregnancy. With the exception of CEA, which was more elevated in the multigravida, all marker levels in maternal serum were significantly different than those of the umbilical cord, irrespective of fetal sex, fetal weight, and maternal parity.

Mammalian α-fetoprotein is classified as a member of the albuminoid gene superfamily. Molecular variants and genetic variants of α-fetoprotein differing in messenger ribonucleic acid (mRNA) kilobase length have been extensively described in the biomedical literature. After the discovery of the molten globule form in 1981, the existence of transitory, intermediate forms of α-fetoprotein was acknowledged, and their physiologic significance was realized. The maternal serum α-fetoprotein is a useful marker for women harboring a malignant germ cell tumor containing an endodermal sinus tumor or embryonal component. Initially produced by the yolk sac and later by the fetal liver and gastrointestinal tract, α-fetoprotein is also the predominant protein synthesized during fetal development. Maternal serum α-fetoprotein levels are routinely measured

TABLE 15.17 Serum Tumor Markers in Nonpregnant and Pregnant Patients

Marker	Malignancy	Normal Level	Effect of Pregnancy
CA-125	Serous papillary ovarian carcinoma and tumors of low malignant potential	<35 U/mL	Elevated during the first trimester
Human chorionic gonadotropin	Gestational trophoblastic neoplasia, malignant germ cell tumors of the ovary	<5 IU/L	Peak at 14–16 wk: 12,000–270,000 IU/L
α-Fetoprotein	Malignant germ cell tumors of the ovary, hepatocellular carcinoma	<15 ng/mL	Peaks at 200–300 mg/dL at 13 wk
Lactate dehydrogenase	Dysgerminoma, tumors of the liver	45–90 U/L	Fluctuates minimally
Inhibin	Granulosa cell tumors of the ovary	33–45 pg/mL	Increased with preeclampsia
Testosterone	Sertoli cell tumors of the ovary	30–95 ng/dL	May rise four- to ninefold over nonpregnant levels during normal pregnancy
DHEA-S	Tumors of the adrenal gland	35–430 mcg/dL	Can be increased (usually not >700 mcg/dL)
Carcinoembryonic antigen	Colorectal carcinoma, mucinous cystadenocarcinoma of the ovary, pseudomyxoma peritonei	<5 ng/mL	Normal or marginally elevated levels
CA-27.29	Breast cancer	≤38 U/mL	Not well studied
CA-15-3	Breast cancer	<40 U/mL	Elevated during third trimester in one study
CA-19-9	Pancreatic cancer	<40 U/mL	Not well studied
Prolactin	Pituitary tumor (prolactinoma)	<20 ng/mL	20–400 ng/mL
Total thyroxine	Thyroid carcinoma	5–12 mcg/dL	Increased because of increases in serum thyroxine-binding globulin

CA, Cancer antigen; *DHEA-S,* dehydroepiandrosterone sulfate.

between 16 and 20 weeks of gestation to screen for neural tube defects. **Pregnant women with marked elevations of serum α-fetoprotein should have a germ cell cancer or liver tumor included in the differential diagnosis.**

As Boulay and Podczaski point out in their excellent review on ovarian cancer complicating pregnancy, the use of α-fetoprotein levels to monitor women with a history of endodermal sinus tumor who subsequently become pregnant poses a distinct clinical dilemma. One way to distinguish between ovarian (ie, yolk sac) α-fetoprotein and fetal (ie, liver) α-fetoprotein is to divide the heterogeneous human α-fetoprotein into various subfractions stratified by differential reactivity with lectins, such as concanavalin A. Assay chromatography with concanavalin sepharose A will separate the α-fetoprotein into either the yolk sac or liver variant because the yolk sac form of α-fetoprotein contains the carbonal sugar and is the type produced by the endodermal sinus tumor.

The use of the hCG level to monitor pregnant women in remission after treatment for gestational trophoblastic disease is also problematic. **The hCG steadily increases during the first trimester of pregnancy and may reach levels beyond 100,000 U at 10 weeks of gestation.** Accordingly, women with a history of trophoblastic neoplasia must undergo transvaginal ultrasonography to document intrauterine pregnancy, and a metastatic workup should be conducted if the hCG remains markedly elevated during pregnancy or if focal symptoms manifest.

The glycolytic enzyme lactate dehydrogenase (LDH) is involved in the conversion of pyruvate to lactate. LDH is also a marker for gonadal and extragonadal dysgerminomas. Because the enzyme is ubiquitous, the heterogeneity afforded its multiple molecular forms permits electrophoretic separation into five isoenzymes. Isoenzyme fractions 1 and 2 are specifically elevated in women with dysgerminomas. **During pregnancy and the puerperium, LDH values fluctuate very little unless the patient has preeclampsia.** In 1992, our group used the LDH level to observe two women with dysgerminoma diagnosed during pregnancy; in both cases, the LDH value was correlated to disease activity.

Inhibin is a glycoprotein hormone produced by normal ovarian granulosa cells and testicular Sertoli cells. In the ovary, it inhibits the secretion of follicle-stimulating hormone. Patients with granulosa cell tumors have elevated serum levels of inhibin, and this finding has been used to detect recurrent tumor. In pregnancy, serum levels of inhibin do not rise significantly unless the patient has preeclampsia or gestational hypertension. The use of an inhibin mAb can preferentially mark inhibin secreted from granulosa cell tumors and Sertoli–Leydig cell tumors.

HEMATOLOGIC MALIGNANCIES IN PREGNANCY

Leukemia

Arising from bone marrow progenitor cells that have arrested along a line of differentiation, the leukemias manifest clinically when the arrested cells proliferate, overtake the bone marrow, and spill out into the peripheral blood. Without immediate therapy, patients with acute leukemia, particularly acute myelogenous leukemia (AML), survive a median of 3 months. In the United States, there are 30,000 new cases of leukemia and 20,000 deaths are attributable to the disease each year. Table 15.18 summarizes a classification scheme for the leukemias, with the major subtypes being AML (comprising 46% of all leukemias), chronic lymphatic leukemia (29%), chronic myelocytic leukemia (CML, 14%), and acute lymphatic leukemia (11%). **Leukemia is estimated to occur in 1 in 75,000 pregnancies, with AML accounting for more than 60% of reported cases, of which there are approximately 500.**

TABLE 15.18 Classification of the Leukemias

Acute	Chronic
Acute myelogenous leukemia	Chronic myelogenous leukemia
Acute promyelocytic leukemia	Chronic myelomonocytic leukemia
Acute myelomonocytic leukemia	Chronic lymphatic leukemia
Acute monoblastic leukemia	T cell
Acute erythroleukemia	B cell
Acute megakaryoblastic leukemia	Prolymphocytic leukemia
Acute lymphatic leukemia	Sézary syndrome
Common	Hairy cell leukemia
T cell	
B cell	
Pre–B cell	
Acute mast cell leukemia	

From Jandi JH. *Blood: Textbook of Hematology*, 2nd ed. Boston, 1996, Little, Brown.

The attainment of a morphologic normal bone marrow containing less than 5% blasts, the absence of any signs of extramedullary leukemia, and the return of normal neutrophil counts (>1500/μL) and platelet counts (>150,000/μL) is the treatment goal of acute leukemia. Auer rods must not appear in the peripheral blood, and anemia, if present, does not preclude complete remission because this is often slow to recover. Bone marrow aspiration is performed weekly during the induction phase.

Because of severe myelosuppression caused by intensive chemotherapy, the achievement of complete remission is predicated on supportive care and the necessary maintenance of more than 500/μL circulating neutrophils and more than 20,000 circulating platelets to prevent infectious and hemorrhagic deaths. Cytosine arabinoside and daunorubicin are used to induce remission in AML, with postremission therapy requiring maintenances doses of cytosine arabinoside. When the analysis of the cerebrospinal fluid establishes CNS involvement, intrathecal chemotherapy with or without cranial radiation is administered. Finally, the treatment and maintenance of acute lymphatic leukemia uses multiagent regimens involving vincristine and CNS prophylaxis.

The ability to enter into complete remission is age dependent, with the overall rate for acute leukemia being 65%. The median survival time is approximately 2 years, with 25% of patients becoming long-term, disease-free survivors. The prognosis for

patients undergoing treatment of leukemia after therapy for another disease, or in the recurrent setting, is very poor. Indeed, the majority of adult patients who achieve remission subsequently experience recurrence. The long-term survival rate seen in children is not obtained in adults.

Leukemia in Pregnancy

In pregnant patients, persistent fever, weight loss, lymphadenopathy, or an abnormal differential on the complete blood count should prompt an investigation and raise the clinician's suspicion for leukemia. As in the case of non-Hodgkin lymphoma (NHL) in pregnancy, patients with acute leukemia are often very ill, and the primary concern is to save the pregnant woman's life through induction chemotherapy or radiotherapy. Therefore, if the patient is remote from delivery, appropriate treatment will place the fetus at risk of exposure to chemotherapeutic agents, radiation therapy, or both. **Chronic myelogenous leukemia in pregnancy, however, can be managed similar to Hodgkin disease, with a justifiable delay in definitive treatment of several weeks if indicated.** The outcome of pregnancy-associated acute leukemia is only worse when compared with nonpregnant cases when therapy is delayed. Regardless of gestational age, the induction of remission with combination chemotherapy is the primary objective. Seventy-five percent of pregnant women enter into complete remission after therapy for acute leukemia, owing to their favorable age. During the first and early second trimesters, termination of pregnancy should be seriously considered, especially in acutely ill pregnant women. When the diagnosis is made later in pregnancy, it should be recognized that there are obvious advantages of delivery before the onset of chemotherapy, and this should be encouraged, if possible.

The average age of the patient with acute leukemia in pregnancy is 28 years. Premature labor is common in these women, and the average period of gestation is approximately 8 months. Postpartum hemorrhage occurs in 10% to 15% of cases. The fibrinogen level in patients with acute leukemia in pregnancy may be reduced from the level anticipated at that stage of gestation. Frenkel and Meyers stated that pregnancy exerts no specific effect on the course of acute leukemia except that early gestation poses an obstacle to vigorous treatment of leukemia. Other authors have observed that infants born of mothers with leukemia are as well as normal control participants. Lilleyman and colleagues and Bitran and Roth have written comprehensive reports on this subject.

The following factors are associated with the delivery of a normal baby:

1. Antimetabolite drugs not administered
2. Radiotherapy to the uterus not given
3. The fetus reaches the age of viability

The decision to interrupt a pregnancy in patients discovered to have leukemia is primarily based on the desires of the patient. Prompt therapy is always advisable for the possibility of obtaining remission. However, the physician's advice to the patient should be influenced by the aggressiveness of the disease process. For instance, patients with CML are less likely to be harmed by deferring termination of pregnancy than are patients with acute myelocytic leukemia demonstrating symptoms and having a somewhat fulminating course.

Chemotherapy for Acute Leukemia in Pregnancy

There are many reports of successful chemotherapy for patients who have acute leukemia in pregnancy, and there has been little, if any, significant increase in fetal wastage or congenital anomalies. In 1984, Catanzarite and Ferguson published a review of management and outcome of acute leukemia in pregnancy for the years 1972 to 1982. The investigators collected 14 pregnancies reported in patients cured of acute lymphocytic leukemia, of which there was one early spontaneous abortion and 13 term infants. All mothers survived. They also collected 47 reports of pregnancy in association with acute leukemia. In 40 pregnancies in which acute leukemia was treated, there were five abortions, three perinatal demises, one infant "live-born in grave condition," and 31 surviving infants. Median maternal survival was at least 6 months and possibly longer than 12 months from delivery. In the remaining seven cases, the leukemia was untreated. Despite this, there were two perinatal deaths, one abortion, and four living infants.

During the years of Catanzarite and Ferguson's study, effective combination chemotherapy was in widespread use. Previous reviews covered cases reported before the introduction of effective combination chemotherapy. There were fewer than 300 reported pregnancies, with a 36% to 69% perinatal mortality rate and a median maternal survival period from diagnosis of shorter than 6 months. Advances in the fields of hematology and oncology, maternal and fetal medicine, and neonatology have resulted in marked improvements in both perinatal survival statistics and median maternal survival time.

In women who refuse pregnancy termination or in whom delivery is not expected imminently, induction of remission should be attempted. When combination therapy is used during the first trimester (and for acute leukemia in pregnancy, this is not a contraindication), the stillbirth rate is 25%—this decreases to 13% in the second and third trimesters. **A combination of cytarabine, doxorubicin, and etoposide has been used with good results for both mother and fetus, and when possible, we recommend this regimen.** Delivery should be timed to precede the next course of chemotherapy; however, the majority of patients should be counseled to expect preterm delivery, either spontaneous or induced. It is mandatory to perform a hematologic evaluation of the newborn because the drugs used cross the placenta and can result in pancytopenia. Although no growth or developmental abnormalities have been demonstrated, the follow-up of children exposed to in utero chemotherapy for the management of acute leukemia has been limited.

Acute Myelogenous Leukemia

Acute myelogenous leukemia is the most common leukemia diagnosed during pregnancy. Azim and colleagues identified 87 patients (88 pregnancies) treated with systemic therapy during pregnancy in their literature review. Among those treated during the first trimester, nearly 50% had poor fetal outcomes. Among those treated after the first trimester, the combination

of cytarabine and daunorubicin was most commonly used during the induction phase. Of 32 patients exposed to these two agents starting from the second trimester, only 15 had normal pregnancy outcomes. It is unclear whether this is secondary to cytarabine or daunorubicin. Whereas previous reports of single-agent cytarabine have been associated with normal pregnancy outcomes, single-agent daunorubicin has been associated with one case of maternal–fetal death. Idarubicin is also used for AML induction therapy and is more lipophilic compared with other anthracyclines; therefore, placental transfer of this drug is more likely to occur. There have been seven pregnant women exposed to idarubicin and cytarabine after the first trimester from which reports of stillbirth, limb deformities, and cardiomyopathy have appeared. It is of significant concern that the combination of cytarabine with daunorubicin or idarubicin is associated with significant fetal morbidity and mortality, even if administered after the first trimester. However, doxorubicin is an active agent in AML and has been associated with normal pregnancy outcomes both in AML and in PABC. Given the poor safety data of daunorubicin and idarubicin and probably noninferiority of doxorubicin when compared with other anthracyclines, Azim and colleagues consider it the treatment of choice for gestational AML for patients wishing to preserve the pregnancy.

Acute Lymphoblastic Leukemia

Approximately one-third of gestational leukemia is of acute lymphoblastic leukemia (ALL). Many of the patients in the literature treated with chemotherapy during the first trimester were unintentionally exposed. The expected findings of limb, ear, and lung deformities along with a case of esophageal atresia and even stillbirth emphasize the importance of active contraception in patients with ALL during the maintenance phase. Azim and colleagues have identified 21 patients treated after the first trimester. As was observed with daunorubicin and idarubicin exposure during the second trimester in patients with AML, these agents have also been associated with adverse fetal outcomes when given for ALL. Acute cardiac failure, premature delivery, and intrauterine fetal demise have been reported. Fortunately, data on doxorubicin in ALL is reassuring and again Azim and colleagues consider this agent as the anthracycline of choice during pregnancy after the first trimester.

Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APL) accounts for 13% of AML cases and commonly occurs in young adults. The specific chromosomal translocation, t(15/17), is found in the neoplastic promyelocytic proliferation that characterizes this disease. Disseminated intravascular coagulation (DIC) is a lethal complication of AML. All-trans retinoic acid (ATRA) targets t(15/17) and reduces the incidence of DIC and consequently increases the likelihood of achieving long-term remission. Azim and colleagues collected 22 cases of ATRA treatment during pregnancy, in which 14 patients received single-agent therapy and eight were treated with a combination of ATRA plus idarubicin or daunorubicin. No congenital anomalies or spontaneous abortions have been reported to have occurred among newborns exposed to single-agent ATRA in utero. One baby who had been diagnosed earlier with Potter syndrome during the first trimester before exposure to ATRA died after the mother went into spontaneous labor; this newborn had been exposed to ATRA for 1 day during week 29 of gestation. Although two patients exposed to ATRA during the first trimester have been reported to have had normal outcomes, there are data that link first-trimester retinoic acid ingestion to craniofacial, cardiac, and brain malformations (ie, retinoic acid embryopathy).

Among patients treated with combined therapy, atrial septal defects were reported in two newborns exposed to ATRA plus idarubicin. Postnatal fetal death secondary to pulmonary hemorrhage was reported in a newborn exposed to ATRA plus daunorubicin and cytarabine. In patients with APL who received chemotherapy alone, again, daunorubicin has been associated with a high incidence of complications, including intrauterine fetal demise, spontaneous abortion, bone marrow aplasia, cerebral bleeding, and child maceration.

Management of Chronic Leukemia

Chronic myelocytic leukemia represents approximately 90% of all chronic leukemias in pregnancy. An additional 5% of the chronic leukemias in pregnancy are chronic lymphocytic leukemias. Several reports show that pregnant patients with chronic granulocytic leukemia treated during the first trimester with chemotherapy and radiation therapy to the spleen usually deliver apparently healthy, viable babies if the uterus is protected with lead shields. Lee and coworkers reported 12 cases of leukemia associated with pregnancy. Using lead shields to protect the uterus from radiation therapy to the spleen, six of seven women with chronic leukemia who also received chemotherapy went on to deliver six apparently healthy infants. The prognosis for these patients is poor; the median survival time is 45 months.

There has been some experience in treating CML during pregnancy with interferon-α. Mubarak and colleagues reported the outcomes of three women, ages 23 to 32 years, with Philadelphia chromosome–positive CML who received interferon-α during the first trimester of pregnancy. No maternal complications occurred, and three normal-appearing babies were delivered, one of whom had a transient mild thrombocytopenia. Subsequently, these children were followed for 4, 12, and 30 months, and all had normal growth and development.

Chronic Myelocytic Leukemia

Chronic myelocytic leukemia is rare among pregnant women. The disease accounts for only 15% of adult leukemias, with only 10% occurring during the childbearing years. The main driving force for development and maintenance of the leukemic clone is the BCR/ABL fusion gene, which is a target of imatinib mesylate. Complete responses with this agent are dependent on the continuous administration of this drug. Pye and colleagues have identified 55 pregnant women exposed to imatinib, 40 of whom (72%) delivered live births without any congenital anomalies. Seventy-five percent of the congenital anomalies encountered in this series ($n = 9$) were in fetuses exposed to imatinib during the first trimester. Exomphalos occurred

in three neonates; renal agenesis or malformation in two; hypospadias in two; cleft palate, hydrocephalus, meningocele, pyloric stenosis and premature closure of skull bones in one; and warfarin syndrome in one. Among the 38 patients (21%) exposed to imatinib throughout the course of pregnancy, seven had a spontaneous abortion, and one developed the previously mentioned warfarin syndrome secondary to warfarin exposure. Azim and colleagues identified 26 additional cases of gestational imatinib exposure. Sixty percent were exposed during the first trimester and discontinued the drug when pregnancy was diagnosed. In these patients, one preterm delivery, two cases of newborn hypospadias, and one child with a fatal meningocele were reported. Nine patients became pregnant while taking imatinib and continued the pregnancy to term with no adverse events. Four patients who started imatinib therapy during the second and third trimesters were able to control their disease without affecting the pregnancy outcome. A total of 11 newborns have been followed for more than 1 year with no delayed adverse effects reported. It appears that early exposure to imatinib is associated with a high risk of spontaneous abortion and congenital anomalies. Imatinib therapy during the second and third trimester does not appear to add significantly to the risk associated with first-trimester exposure.

In the pre-imatinib era, both interferon (IFN) alpha and hydroxyurea (HU) were used to treat patients with CML. IFN was considered the standard of care for patients not eligible for bone marrow transplantation. Because of its high molecular weight, IFN is unlikely to cross the placenta. Approximately 15 patients have been exposed during the first trimester with no congenital anomalies reported. Preclinical data also support the safe use of IFN throughout the course of pregnancy.

Preclinical models have been less favorable for HU with significant evidence for teratogenicity in all animal species. Congenital anomalies of the heart, CNS, and skeleton as well as neural tube defects have been described. Among the 49 pregnant patients with CML exposed to HU in the literature review by Azim and colleagues, there was one neonatal death on day 10 of life secondary to intracranial bleeding not associated with congenital anomalies. Three intrauterine fetal deaths were reported, two cases of hip dysplasia, and one case each of pilonidal sinus and unilateral renal dilatation. Although chromosomal anomalies have not been reported in humans after HU exposure in utero, this drug should not be the treatment of choice for CML during pregnancy, particularly in light of its nonsuperiority to other agents used to treat this disease.

Hairy Cell Leukemia, Multiple Myeloma, and Chronic Lymphocytic Leukemia

Hairy cell leukemia (HCL), multiple myeloma (MM), and chronic lymphocytic leukemia (CLL) are among the rarest hematologic malignancies encountered during pregnancy. A few cases of IFN therapy for HCL and MM have been reported with normal outcomes. The standard of care for HCL is cladribine, but its use during pregnancy has not yet been reported. For the rare patient of childbearing age who develops CLL during pregnancy, a watch-and-wait approach is advisable in the absence of symptoms. Chlorambucil has been associated with normal pregnancy outcomes for patients with symptomatic CLL.

Hodgkin Disease

The importance of staging in Hodgkin disease was recognized by Peters as early as 1950, when she devised the first clinical staging classification. Lymphangiography then made possible the earlier detection of retroperitoneal lymph node involvement, and it became important to distinguish two subgroups: those with widespread disease confined to lymphatic organs and those with spread of disease beyond the lymph nodes, thymus, spleen, and Waldeyer ring to one or more extralymphatic organs or tissues, which is now recognized as stage IV disease. The subtype classification scheme for Hodgkin lymphoma appears in Table 15.19. The staging system as proposed by the Cotswolds meeting appears in Table 15.20. **Surgical staging has gained popularity in Hodgkin disease, and when evaluating young women in whom preservation of ovarian function is desired and pelvic irradiation is planned, surgical oophoropexy can be performed at the time of staging laparotomy.**

TABLE 15.19 Classification of Hodgkin Disease

Subtype	Frequency (%)	Characteristics
Nodular sclerosis	40	Mediastinal and pulmonary involvement
Mixed cellularity	30	Often advanced at presentation
Lymphocyte predominance	15	Rare classic Reed-Sternberg cells
Lymphocyte depletion	15	Oldest median age, worst prognosis

TABLE 15.20 Staging of Hodgkin Disease as Proposed in the Cotswolds, England, 1990

Stage*	Characteristics
I	Involvement of a single lymph node or lymphoid region (eg, spleen, thymus, Waldeyer ring) or a single extralymphatic site (Ie)
II	Involvement of two or more lymph node regions on the same side of the diaphragm; localized contiguous involvement of only one extranodal organ or site and lymph node region(s) on the same side of the diaphragm (IIe)
III	Involvement of lymph node regions on both sides of the diaphragm, which may also include spleen (IIIs) or one extranodal localized contiguous site (IIIe), or both (IIIes)
III1	With or without involvement of splenic, hilar, celiac, or portal nodes
III2	With involvement of paraaortic, iliac, and mesenteric nodes
IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues

*Applicable designations: *a,* no symptoms; *b,* night sweats, fever, weight loss; *cs,* clinical staging; *e,* involvement of a single extranodal site contiguous or proximal to a known nodal site; *ps,* pathologic staging (by laparotomy); *x,* bulky disease (diameter >one-third of the mediastinum).

From Peleg D, Ben-Ami M. Lymphoma and leukemia complicating pregnancy. *Obstet Gynecol Clin North Am* 1998;25:365.

The feature of the disease most helpful in selecting therapy and estimating the prognosis at the time of onset is its clinical extent. In general, the more widespread the disease, the poorer the prognosis, even if all apparent disease is confined to the lymphoid regions. The poorer prognosis of patients who have involvement of sites beyond the usual lymphoid tissues is well known. Five-year survival rates of 50% are often reported for patients who have widespread lymph node disease, and rates of 8% are reported for those who have involvement of extranodal sites such as the lung, liver, bone, and bone marrow. Survival depends more on the patient's age and stage than on the subtype. Overall, 36% survive for 20 years, and about 70% do not have a relapse after primary treatment. Patients 17 to 34 years old have an 80% long-term survival rate compared with 35% for those 60 years or older.

The treatment of Hodgkin disease has undergone radical changes in the past 40 years. Present recommendations are based on the assumptions that radiotherapy is the mainstay of treatment of early-stage disease, combination chemotherapy is the primary treatment of advanced-stage disease with parenchymal organ involvement, and a combination of the two is required for patients with bulky disease (eg, a large mediastinal mass) or generalized abdominal lymph node involvement. Aggressive therapy has resulted in considerable improvement in overall survival rates for patients with Hodgkin disease. The most successful and widely tested combination of drugs has been developed at the National Cancer Institute (DeVita and colleagues) and consists of six 2-week cycles of therapy with nitrogen mustard, vincristine, procarbazine, and prednisone, the so-called MOPP program, although other combinations have been used successfully.

The major technical factors that determine the efficacy of radiation therapy in Hodgkin disease are the total radiation dose per field; the size, shape, and number of treatment fields; and the beam energy. Permanent eradication of any given site of involvement can be achieved consistently with doses of 3500 to 4500 cGy delivered at a rate of 1000 cGy/week. The desirability of irradiating apparently uninvolved lymph node regions has long been advocated by experienced radiotherapists. This approach is based on the knowledge of the clinical behavior of Hodgkin disease, the inadequacies of our diagnostic techniques to discover minute or microscopic foci of the disease, the advantage and efficacy of avoiding patchwork and overlapping fields, and the possible reseeding of previously irradiated regions from unrecognized and untreated sites. Extended-field irradiation, so-called total lymphoid or total radial therapy, is technically demanding and potentially hazardous.

Hodgkin Disease in Pregnancy

With a peak incidence between the ages of 18 and 30 years, Hodgkin disease commonly affects young people. It is now being cured and controlled for long periods with irradiation and chemotherapy. Hodgkin disease in pregnancy occurs in approximately 1 in 6000 deliveries. Young women diagnosed with Hodgkin disease are usually asymptomatic. **The nodular sclerosis subtype of Hodgkin disease is the most common subtype encountered in pregnancy and carries a favorable prognosis.**

Most reports suggest that the onset of Hodgkin disease during pregnancy does not adversely affect survival. Chemotherapy and radiation therapy to the abdomen can usually be postponed until the pregnancy is terminated. The drugs commonly used for Hodgkin disease are contraindicated in the first trimester of pregnancy and are preferably withheld until the postpartum period. The amazing successes achieved with early stages of this disease allow much more flexibility and improved regard for the fetus. **Pregnancy itself does not appear to adversely affect the course of the disease, and interruption of pregnancy during the course of the disease is not definitely indicated.** The management of the pregnant patient with Hodgkin disease should be individualized and should involve a multidisciplinary team of physicians and other professionals. Three of four patients diagnosed with Hodgkin disease will be cured.

Management of Hodgkin Disease in Pregnancy

Hodgkin lymphoma is the second most commonly diagnosed cancer in people aged 15 to 29 years and is the most common lymphoma diagnosed during pregnancy. The literature contains 68 pregnancies in 67 women with Hodgkin lymphoma who received systemic chemotherapy, immunotherapy, or both. Twenty-six of these cases were published by Aviles and colleagues, and an additional 42 were identified in the review by Azim and colleagues. In the former study, most patients had advanced disease and nodular sclerosis histology. More than one-third of patients were treated during the first trimester without sequelae (ie, no low birth weight or anomalies). These results are challenged by the finding of six congenital anomalies and three spontaneous abortions occurring in the 17 patients exposed to chemotherapy during the first trimester in the report by Azim and colleagues. The standard Hodgkin lymphoma regimen ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) was given to 16 of the 42 patients. Those treated after the first trimester had normal pregnancy outcome with no adverse fetal events with the exception on one case of intrauterine fetal demise in the third trimester, one case of atrial septal defect, and one case of hemolytic anemia with jaundice at birth. It seems reasonable to start treating patients with the standard ABVD regimen in the second trimester.

For patients with localized disease in the cervical, occipital, or axillary regions, radiotherapy has been reported to be safe because the average embryo dose does not exceed 0.1 to 0.2 Gy in such sites. This represents the threshold dose at which stochastic effects (eg, mental retardation, organ malformation) could manifest.

The complexity of the management of Hodgkin disease during pregnancy cannot be overstressed. Thorough staging of the pregnant patient is significantly compromised without termination of the pregnancy by one means or another. Surgical staging of the pregnant patient after the 18th week of pregnancy is feasible and often avoids the necessity of many of the diagnostic techniques that might be harmful to the fetus, such as lower extremity lymphangiography, intravenous

pyelography, and bone and liver scans. Splenectomy is often performed during these staging procedures, and no contraindication in pregnancy is known. The purpose of staging with this disease is to achieve the best differentiation between those curable with local therapy (radiation) and those who require systemic therapy (chemotherapy or radiation) for cure. After a criterion for systemic therapy has been uncovered, no additional diagnostic procedures are required.

Treatment is obviously easier if the pregnancy is terminated, but that may not be an option. Current data suggest that the course of Hodgkin disease does not seem to be affected by an ongoing pregnancy. Other studies have also noted a survival rate of pregnant women with Hodgkin disease comparable with that of nonpregnant patients with Hodgkin disease. Hodgkin lymphoma is not associated with an increase in miscarriage, stillbirths, or congenital anomalies unless treatment is started in the first trimester. Metastasis to the placenta has been reported, although it is rare.

Hodgkin lymphoma is a potentially curable disease, and stage I and II disease typically are treated with megavolt radiotherapy unless bulky disease is present. Given in fractions over 3.5 to 4.5 weeks, a dose of 3500 to 4500 cGy is prescribed. In early-stage disease, the lymphoid areas that need to be irradiated include the mediastinum, Waldeyer ring and axilla (ie, mantle field), and the paraaortic area and splenic pedicle (spade field). When necessary, total nodal irradiation includes the pelvis (inverted Y field), as illustrated in Fig. 15.15.

Pregnant women with Hodgkin lymphoma present with typical manifestations, with painless enlargement of lymph nodes above the diaphragm, usually the cervical, submaxillary, or axillary nodes. In patients without obvious lymphadenopathy, a delay in diagnosis is common because symptoms of fatigue, weight loss, chest discomfort, and anemia may be overlooked and considered "normal" during pregnancy. The role of staging laparotomy in Hodgkin disease is diminishing, and if necessary, it should be delayed until after delivery, at which time bilateral oophoropexy can be performed. **It has been our practice to bring the ovaries as close to the midline as possible behind the uterus, where they can be shielded underneath a protective block placed between the two arms of the Y.**

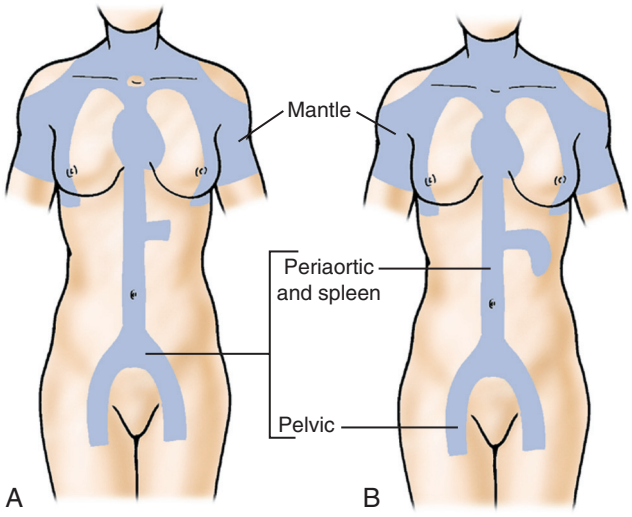

FIGURE 15.15 Schematic representation of "mantle" and "inverted Y" fields for total lymphoid irradiation. **A,** Two-field technique, with a small extension to include the splenic pedicle, used in splenectomized patients. **B,** Three-field technique usually used when the spleen is still present. (From.)

Pohlman and Macklis carefully reviewed previously published guidelines for Hodgkin disease associated with pregnancy and have proposed the following management scheme, which the author of this chapter has endorsed (Fig. 15.16). The earlier the pregnancy, the stronger the recommendation for pregnancy termination so that proper staging and treatment can begin. Patients diagnosed during the first trimester of pregnancy may be observed until the second trimester, when therapy can commence. Those first-trimester patients with B symptoms, bulky or advanced-stage disease, or rapid progression have an indication to initiate treatment immediately and should undergo therapeutic abortion. **If the mother does not wish to sacrifice the pregnancy, single-agent vinblastine, which has a 7% anomaly rate when used in the first trimester, should be administered until the second trimester or until significant disease progression.** If combination chemotherapy is required, the ABVD regimen without dacarbazine during the first trimester should be given and then standard ABVD subsequently.

Patients presenting in the second or third trimester can be closely observed, and the fetus should be delivered as soon as viability and pulmonary maturation are demonstrable. **Delivery should be delayed as long as possible after the last dose of chemotherapy (before the next dose) to decrease the risk of marrow suppression in the neonate.** It may be worthwhile to consider a cesarean section so that surgical staging can be performed at the same time. **Umbilical cord blood should be collected and stored as a possible source of human leukocyte antigen–compatible stem cells.** Because the drugs used in Hodgkin disease can reach significant levels in breast milk, mothers receiving chemotherapy must avoid breastfeeding.

If treatment is necessary during the second and third trimesters of pregnancy, the standard ABVD regimen should be used. Postchemotherapy-involved field radiation therapy can be postponed until after delivery but should be initiated within 9 weeks after the last cycle of chemotherapy. Mantle and spade field radiotherapy with extensive abdominal shielding is also an acceptable alternative until the third trimester, when the uterus starts to impinge on the field. **The inverted Y field is not an option at any time during pregnancy.**

Among women with refractory or relapsed Hodgkin disease for whom the ABVD regimen and radiotherapy are not treatment options, MOPP and MOPP-like regimens have demonstrable efficacy with limited adverse effect on the fetus if administered after the first trimester.

Several older series that predate modern therapy suggest that Hodgkin disease has no biologic effect on pregnancy and vice versa. More contemporary reports have substantiated these claims. Investigators from the Hospital for Sick Children and Princess Margaret Hospital in Toronto identified 48 women

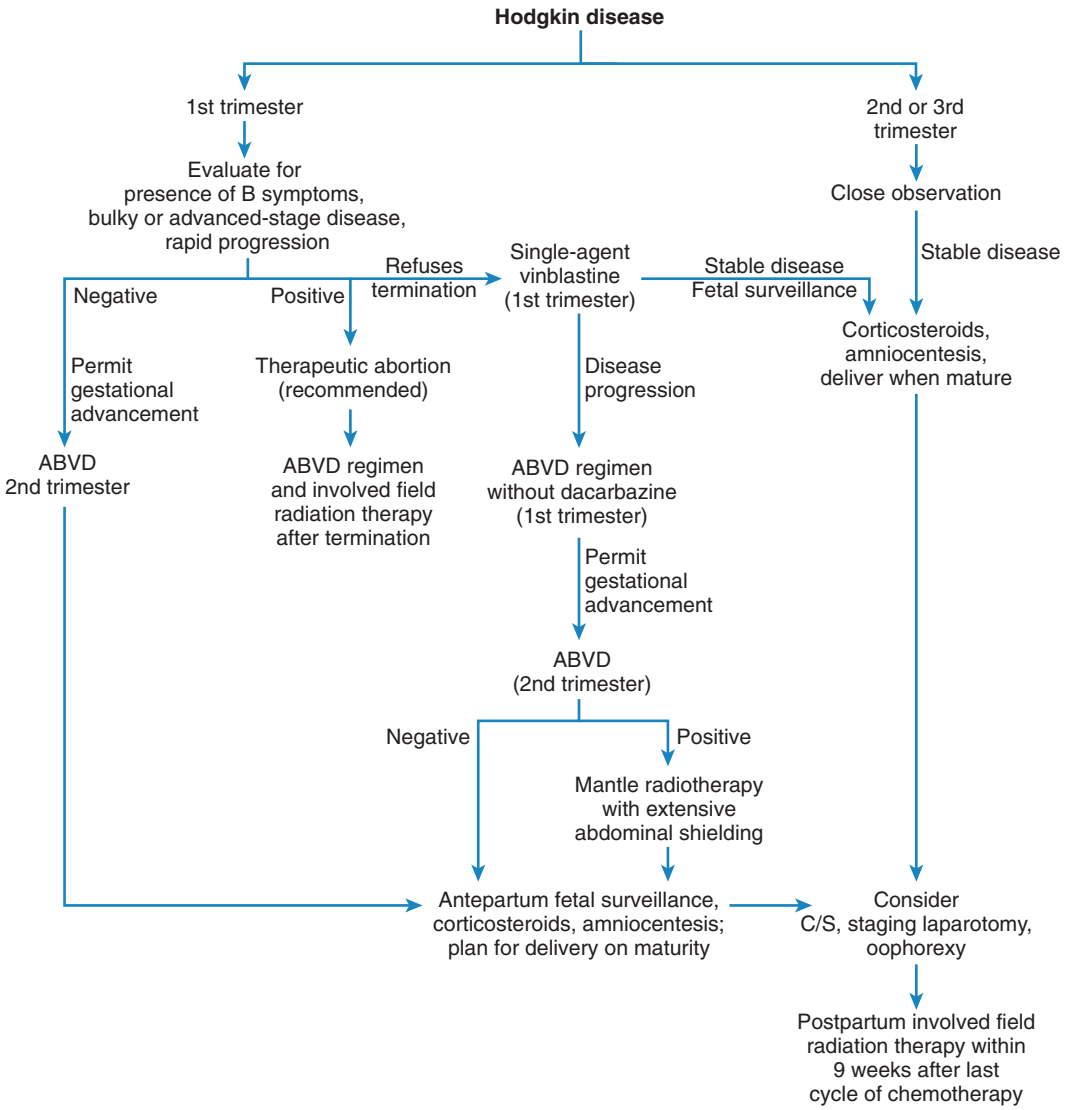

FIGURE 15.16 Management algorithm for Hodgkin disease in pregnancy. *ABVD,* Doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine; *C/S,* cesarean section.

with 50 pregnancies from 1958 to 1984 and matched them with three nonpregnant control subjects of similar age, stage, and year of diagnosis. Twelve women were diagnosed with Hodgkin disease before conception, 10 during pregnancy, and 27 after delivery or pregnancy termination. No statistically significant difference in stage at diagnosis, maternal outcome, or pregnancy outcome was identified between any of these subgroups and the similar control group. It should be noted that 16 patients received radiotherapy while pregnant, and five received combination chemotherapy and radiotherapy while pregnant.

In an investigation focusing on fetal effects of therapy, Ebert and colleagues identified 24 cases in the literature between 1983 and 1995. Among 15 women who received cyclophosphamide, vincristine, procarbazine, and prednisone (COPP; $n = 1$); mechlorethamine, vincristine, procarbazine, and prednisone (MOPP; $n = 4$); ABVD; ($n = 7$); or MOPP/ABVD ($n = 3$) beginning in the first ($n = 5$), second ($n = 8$), and third ($n = 2$) trimesters, all had healthy infants who went on to develop normally during a median follow-up period of 9 years (range, 0–17 years) after delivery. Of the remaining nine women, most received one of the aforementioned regimens during the first trimester and either had therapeutic abortions or experienced spontaneous abortions, delivering fetuses with multiple anomalies.

In a study from Stanford University, the outcome of 17 pregnancies associated with Hodgkin disease between 1987 and 1993 was reported. Patients received radiation therapy ($n = 6$), chemotherapy ($n = 4$), or combined modality therapy ($n = 5$), although the specific timings of therapy in relation to pregnancy were not stated. Excluding four women who had a therapeutic or spontaneous abortion, no congenital anomalies were noted at delivery, and all children were reported to be healthy at the time of last follow-up. With a median follow-up time of 35 months (range, 6–79 months), 15 of the 17 mothers remain in complete remission.

A final report of interest was provided by Sutcliffe, who describes three women with stage II nodular sclerosing Hodgkin

disease who received ABVD chemotherapy during the second and third trimesters of pregnancy. Two of these patients also received mantle-field radiation therapy after delivery. All three delivered healthy infants between 32 and 35 weeks of gestation. The chromosomal analyses of all three children were normal, and at more than 1 year, 5 years, and 7 years of follow-up, all three mothers and children remain healthy.

Non-Hodgkin Lymphoma

A total of 45,000 new cases of NHL are diagnosed in the United States each year. The mean age at diagnosis is 42 years. NHLs comprise a mixed family of diseases characterized by clonal neoplasms arising from one of the cellular constituents of the lymph node. Approximately 85% of NHLs are B-cell tumors; 15% are T-cell tumors; and a small percentage arise from other cells, primarily macrophages. A multitude of infectious agents (eg, the Epstein–Barr virus, the human T-cell leukemia/lymphoma virus), noninfectious agents (eg, radiation, radiation therapy, chemotherapy), and diseases (eg, ataxia telangiectasia, Sjögren syndrome, systemic lupus erythematosus) are associated with NHLs. Most patients present with painless lymphadenopathy, but NHLs may arise outside the lymphoid system in any tissue accessible to lymphocytes, most commonly in the gastrointestinal tract, pharynx, CNS, skin, and bone. Because the disease is usually widespread when peripheral lymph nodes have become involved, staging laparotomy is not used. The prognosis of NHL has been divided into favorable, intermediate, and poor. The Working Formulation is a classification scheme for NHL that is used in determining prognosis and treatment (Table 15.21). Unfortunately, NHLs are cured in fewer than 25% of the general population, although women of reproductive age have a 50% cure rate.

Early-stage (stage I or II), low-grade NHL is treated with extended-field or total lymphoid irradiation, with 5-year survival rates of 84%. Intermediate-grade tumors are managed with combination chemotherapy (prednisone, methotrexate, doxorubicin, cyclophosphamide, etoposide, cytosine arabinoside, bleomycin, vincristine, and leucovorin [ProMACE-CytaBOM]) with or without radiotherapy, resulting in sustained remissions at 4 years in approximately 45% of patients.

Non-Hodgkin Lymphoma in Pregnancy

Most women with NHL in association with pregnancy have an aggressive histologic subtype and advanced-stage disease, possibly as a result of a delay in diagnosis in many cases. **An unexpectedly high incidence of breast, uterine, cervical, and ovarian involvement among pregnant women has been noted when NHL is associated with pregnancy, with the predilection for these organs attributed to hormonal influences and increased blood flow to these organs.** In a review of 96 women with pregnancy-associated NHL, Pohlman and colleagues reported fully 50% of women presenting with stage IV disease. Seven percent of pregnancies ended in therapeutic abortion, and 4% of women experienced a spontaneous abortion. Eleven percent of infants were born prematurely, and 7% died. Only 31 mothers were known to have achieved a complete remission, and for 90 subjects in whom their long-term outcome was known, only 39 were alive and disease free a median of 21 months (range, 2–132 months) after delivery, four were alive with disease, and 47 had died with a median of 6 months (range, <1–36 months) after delivery. Women who were diagnosed during the third trimester of pregnancy appeared to have a better outcome than those diagnosed earlier. Seventy-one of 96 children were reported alive, although the follow-up period for the majority was either less than 1 month or unknown.

TABLE 15.21 Working Formulation for Classification of Non-Hodgkin Lymphoma

	Histologic Type	Description	Prognosis
I	Low grade	Small lymphocytic cell Follicular (nodular) small cleaved cell Follicular mixed small cleaved cell	Favorable
II	Intermediate grade	Follicular large cell Diffuse small cleaved cell Diffuse mixed small and large cell Diffuse large cell cleaved or noncleaved	Intermediate
III	High grade	Diffuse large cell, immunoblastic Small noncleaved cell (Burkitt or non-Burkitt) Lymphoblastic (convoluted or nonconvoluted)	Unfavorable
IV	Miscellaneous	Composite Mycosis fungoides Extramedullary plasmacytoma Histiocytic Unclassified	—

From Peleg D, Ben-Ami M. Lymphoma and leukemia complicating pregnancy. *Obstet Gynecol Clin North Am* 1998;25:365.

Aviles and colleagues reviewed the outcome of both the mother and fetus in 19 pregnancies between 1975 and 1986. All patients received doxorubicin-based combination chemotherapy during pregnancy, including eight who received chemotherapy during the first trimester. Three mothers and their fetuses died during induction, and the 16 remaining women delivered healthy infants between 35 and 39 weeks of gestation. Eight of 12 mothers remained in complete remission 4 to 9 years after delivery, seven mothers died of lymphoma, and one was lost to follow-up.

Overall, the prognosis for all patients with NHL is worse than the prognosis for patients with Hodgkin disease. This is explained, in part, by the dissemination of disease at presentation. For this reason, although many dispute the claims that NHL arising in pregnancy is more virulent, the management of NHL in pregnancy needs to be aggressive. **A delay in treatment cannot be justified, and a woman who has not completed the first half of pregnancy should be advised to undergo therapeutic abortion unless she is willing to expose herself and**

her fetus to the risks of combination chemotherapy. After 24 weeks of gestation, premature delivery may be necessary, depending on the mother's medical condition.

Patients with localized disease should receive three to eight cycles of cyclophosphamide, doxorubicin, vincristine, and prednisolone (CHOP) chemotherapy and then, after delivery but within 9 weeks of the last dose of chemotherapy, involved field radiation therapy should be prescribed. Patients with advanced-stage disease should be treated with six to eight cycles of CHOP chemotherapy. **Because high-dose methotrexate is an integral component of most effective regimens for Burkitt lymphoma, therapeutic abortion for women diagnosed in the first trimester is essential.** Finally, for women with relapsing NHL associated with pregnancy, treatment should not be compromised because the disease is highly aggressive, and therapeutic abortion is generally advisable during the first half of pregnancy because the fetal effects of standard salvage chemotherapy regimens are unknown.

A special consideration can be made for pregnant patients with indolent or low-grade NHLs. These patients may be safely observed until delivery or significant disease progression, provided they are asymptomatic, have a relatively normal complete blood count, and show no impending organ compromise. Such a profile has not yet been reported for NHL associated with pregnancy.

Ward and Weiss reviewed the cases of 42 patients with NHL during pregnancy. Twenty-four of the cases were reported from 1976 to 1985. Three first-trimester cases resulted in two surviving infants. Twenty-one second- and third-trimester cases resulted in 15 surviving infants. Whereas infants who were born to mothers who were untreated or treated with surgery had a 38% prenatal mortality rate, 87.5% of infants of mothers treated with chemotherapy survived. Eight of the 21 second- and third-trimester patients received single-agent or combination chemotherapy. Four of these patients survived. Spitzer and coworkers reported that radiotherapy treatments given to six women in the second or third trimester of pregnancy resulted in no harm to the fetus, yet four of the mothers died of their disease. Of the four cases with a successful delivery and maternal survival, two were treated with combination chemotherapy, one with chemotherapy and radiotherapy, and one with radiotherapy alone. High-grade lymphomas have a particularly poor outcome. In the review by Ward and Weiss, none of the patients diagnosed with Burkitt lymphoma during pregnancy ($n = 18$) survived; however, only five of the patients were treated with chemotherapy. Only five cases ended with fetal survival. The most important factor influencing the well-being of the fetus is the health of the mother.

Seventy-five cases of pregnant women receiving systemic therapy for NHL have appeared in the literature. The majority of patients have had diffuse large B-cell lymphomas, and the CHOP regimen is the most widely used. Most patients have been treated after the first trimester, although at least four were exposed to CHOP unintentionally during the first trimester. All patients have had a normal course and outcome of pregnancy with no fetal mortality or congenital anomalies encountered. It appears that CHOP is a safe regimen in pregnancy. The combination of CHOP plus bleomycin has also been used safely during pregnancy.

For patients with indolent and aggressive NHL, rituximab (an anti-CD20 mAb) has been shown to improve outcomes. There have been seven patients exposed to rituximab during pregnancy, six in combination with chemotherapy. One patient was exposed to rituximab during the first trimester, and the remaining six had the drug initiated during the second trimester. Five patients had normal pregnancy outcomes, including the patient who had first-trimester exposure. There was one case of postnatal B-cell depletion and one case of transient pulmonary insufficiency secondary to prematurity, which resolved after 46 days.

In summary, if the hematologic malignant disease is early stage or low grade, treatment can be deferred, or nontoxic therapy can be used. However, many NHLs present with dissemination or aggressive histologic features, for which the most effective therapy is chemotherapy. The pregnant patient deserves the most effective chemotherapeutic regimen despite its teratogenic potential.

OTHER TUMORS IN PREGNANCY

Melanoma

Melanoma accounts for 1 of every 50 cancer-related deaths in the United States. **The incidence is rising, with approximately 10,000 cases occurring annually among women aged 20 to 40 years.** Congenital nevi may be found within the first 6 months of life and have the highest chance of all nevi for malignant degeneration. Congenital melanocytic nevi may be found in up to 2% of newborns, and giant congenital nevi may cover large areas of the body. Nevi arising later in life are known as the common mole or acquired melanocytic nevi.

The common mole represents more than 95% of nevi and may be subdivided into junctional nevi, compound nevi, and dermal nevi. The blue nevus is another type that usually appears on the dorsal aspects of the extremities and has a very low tendency to become malignant. Nevertheless, any nevi, whether congenital, acquired, or blue, that undergoes suspicious changes should be biopsied. The "ABCD" warning signs that herald changes in nevi that are associated with melanoma are asymmetry, irregular borders, color changes, and moles that increase in diameter. All melanomas masquerade as nevi before diagnosis. The average individual has 15 to 20 nevi, and removal of all these lesions prophylactically is hardly practical. Lesions on the feet, palms, genitals, and areas of persistent irritation from clothing are potentially dangerous nevi and should be removed during childhood.

There are five main types of melanoma, the most common of which is the superficial spreading melanoma, which accounts for 70% to 75% and tends toward horizontal growth before becoming invasive. Approximately 15% of melanomas are nodular and become invasive early. In sun-damaged areas, a lentigo maligna may develop, and in darker-skinned persons, the acral-lentiginous melanoma can be found on the palms and

TABLE 15.22 Microstaging Systems for Melanoma

Level	Clark et al.	Breslow et al.
I	All tumor cells above basement membrane (in situ)	<0.75-mm depth of invasion
II	Tumor extends to papillary dermis	0.76- to 1.5-mm depth of invasion
III	Tumor extends to interface between papillary and reticular dermis	1.51- to 2.25-mm depth of invasion
IV	Tumor extends between bundles of collagen of reticular dermis	2.26- to 3.0-mm depth of invasion
V	Tumor invasion of subcutaneous tissue	>3-mm depth of invasion

From Tewari KS. Cancer of the vulva. In Manetta A, ed. *Cancer Prevention and Early Diagnosis in Women*. Philadelphia, 2004, Mosby.

soles. Finally, the least common are the amelanotic melanomas, which are difficult to diagnose.

Staging of Melanoma

Reference may be made to the final version of the AJCC staging system for cutaneous melanoma that was published in 2001. Both depth of penetration of the lesion and the extent to which the lesion has involved local and regional tissues are brought into the staging system. This new system is a blend of the Clark and Breslow microstaging classifications (Table 15.22). **The Clark microstaging classification provides a histologic staging scheme for classifying melanomas on the basis of level of penetration of the melanoma under the epidermis and dermis.** Prognosis for the patient relates well to this microstaging system. Data indicate that a Clark level I melanoma should be viewed as an in situ lesion requiring no lymph node dissection. Clark's level II indicates superficial dermal penetration, with lymph node metastases in 1% to 5% of patients not justifying an elective lymph node dissection. At the other end of this pathologic spectrum are melanomas of Clark's level IV and level V, which metastasize to regional lymph nodes in approximately 40% and 70% of patients, respectively, necessitating lymphadenectomy as part of initial therapy.

An alternative classification suggested by Breslow (see Fig. 8.28) and used by some clinicians is a simple micrometer measurement of lesion thickness. Lesions larger than 4 mm have a high incidence of distant metastasis. Lesions 1.5 to 4 mm have a 57% incidence of regional node involvement and 15% incidence of distant metastasis. Lesions between 0.76 and 1.5 mm have a 25% incidence of regional node involvement and an 8% incidence of distant metastasis. Lesions 0.75 mm or less are usually not associated with any spread.

Melanoma in Pregnancy

It is rare that pregnancy adversely affects a malignant process, but for many years, melanoma was placed in this category. **The average age of patients with melanoma is 45 years, and 35% of women will be diagnosed during childbearing years.** This is suggested by many case reports in which pregnancy has been incriminated in the induction or exacerbation of a melanoma. Partial or complete regressions of melanoma after delivery have been reported. In contrast, Stewart describes a case in which a tumor recurred three times; each recurrence was a few weeks after the patient delivered a child. Female patients have improved survival compared with male control participants matched for age and tumor thickness. This suggests that some hormonally based mechanisms are operational in the biologic behavior of melanoma. Contemporary studies fail to substantiate any effect previously attributed to pregnancy.

After the second month of pregnancy, the pituitary gland increases production of melanocyte-stimulating hormone. Melanocyte-stimulating hormone activity is also increased by the pregnancy-associated increase in adrenocorticotropic hormone. This results in the increased pigmentation that is characteristic of pregnancy and often found in the nipples, vulva, linea nigra, and preexisting nevi. In animal studies, the high circulating levels of estrogens in pregnancy have been shown to control melanocyte activity. These observations have led some to believe that pregnancy can have an inciting influence or a deleterious impact on the course of melanoma and have given rise to several myths about this disease in relationship to pregnancy, including the following:

1. Pregnancy increases the risk of developing malignant melanoma.
2. Pregnancy worsens the prognosis.
3. Future pregnancies have an adverse effect both on prognosis and on recurrence.
4. Oral contraceptives and hormone replacement therapy are contraindicated in women with a history of melanoma because of theoretic stimulatory effects of hormones on melanocytes.

None of these claims are substantiated by the medical literature.

Historical Series of Melanoma in Pregnancy

The original report published by Pack and Scharnagel in 1951 contained 1050 patients with melanoma. Ten of these patients were pregnant, five of whom died within 3 years of diagnosis. Later authors would cite these observations, which suggested that melanomas in pregnancy grow with unusual rapidity and metastasize widely. Subsequently, many series have challenged the findings of Pack and Scharnagel.

In 1960, George and coworkers gave a comprehensive report of 115 patients with melanoma in pregnancy compared with 330 control participants from the same institution. In disagreement with an earlier report from their institution, they found that spread to regional nodes appeared to be more rapid in pregnant patients but that there was no significant difference stage for stage in the outcome for the patient. This was directly contradictory to the earlier philosophy popularized by Pack and Scharnagel that melanoma is indeed aggravated by the pregnant state.

In 1961, White and coworkers reported a study of 71 young women (aged 15–39 years), 30 of whom had melanoma during pregnancy. The 5-year survival rate in the pregnant group was 73%, and for the 41 nonpregnant patients, the survival rate was

54%. They concluded that on the basis of the 5-year survival rates in pregnant and nonpregnant women with age and stage of disease taken into account, survival was equal in the two groups. No deleterious effect of pregnancy on survival of women with melanoma was demonstrated in this series.

Reintgen and colleagues described 58 women who were pregnant when the disease was diagnosed and another 43 patients who became pregnant within 5 years of diagnosis. Control groups were extracted from a total of 1424 women who were registered at the Duke University Melanoma Clinic. The mean age of patients in the series was 28 years. Both actuarial disease-free intervals and survivals were calculated for the study populations and their respective control groups. There was no statistical difference in survival between patients who had mole changes and diagnosis of melanomas during pregnancy and the control population. The results of the study also indicated no difference in survival for women who became pregnant within 5 years of diagnosis.

Despite these equivalency studies, many authorities continue to recommend survivors of melanoma to avoid pregnancy for approximately 3 years after complete surgical excision because this is the period of highest risk of relapse. Obviously, each case must be individualized, and the recommendation should be heavily influenced by the size, depth of invasion, and any detected dissemination. The role of previous pregnancy as a protective factor in melanomas has been suggested by some but also remains controversial. Patients surviving disease free for 5 years have a 95% chance of long-term cure. Conversely, after a woman has had a diagnosis of having a cutaneous melanoma, subsequent pregnancy has no effect on recurrence rates or survival.

Contemporary Studies of Melanoma in Pregnancy

Contemporary studies also note no survival difference in patients with melanoma who are pregnant compared with nonpregnant patients. MacKie and associates evaluated 388 women with stage I melanoma divided into four groups: 85 treated before pregnancy, 92 treated while pregnant, 143 treated after completion of all pregnancies, and 68 treated between pregnancies. Of interest, poor prognostic factors (eg, tumor thickness and tumor occurring at a poor prognostic site, such as the head, neck, and trunk) occurred more frequently in pregnant patients than in nonpregnant patients. However, in multivariate analysis, pregnancy status was not significantly related to prognosis.

In 1998, Grin and colleagues critically reviewed controlled clinical trials to assess the effect of pregnancy on the prognosis of melanoma and examined the available epidemiologic data to evaluate the risk of melanoma after exposure to oral contraceptives and hormone replacement therapy. The investigators concluded that pregnancy before, during, or after the diagnosis of melanoma did not influence 5-year survival rates, and exposure to oral contraceptives and hormone replacement therapy did not appear to increase the risk of melanoma.

In a recent paper retrospectively evaluating a cohort of 185 women diagnosed with melanoma during pregnancy and 5348 women of the same childbearing age with melanoma not associated with pregnancy, Lens and colleagues noted no statistically significant difference in overall survival between pregnant and nonpregnant groups (Table 15.23). Women with higher Breslow tumor thickness categories had a significantly higher risk of death than those with lower Breslow categories. Also, women with axial tumors (ie, head and neck, trunk) had a poorer prognosis than those with tumors localized on the extremities. Neither pregnancy status at the time of diagnosis of melanoma nor pregnancy status after the diagnosis of melanoma was a significant predictor of survival.

TABLE 15.23 Multivariable Cox Regression Analysis for the 2101 Women With Melanoma With Known Breslow Thickness, Clark's Level, and Tumor Site

Variable	Hazard Ratio	95% Confidence Interval	*P*
Pregnancy at the time of diagnosis of primary melanoma*	1.08	0.60–1.93	0.804
Breslow thickness (per additional category)	2.16	1.80–2.58	<0.0001
Axial site vs. limb site of primary melanoma	2.51	1.78–3.56	<0.0001
Clark's level (>3 vs. <3)	1.39	0.92–2.14	0.12
Age (per year increase)	1.02	0.99–1.05	0.06

*Pregnant women at the time of diagnosis of melanoma (n = 185) vs. nonpregnant women at the time of diagnosis of melanoma (n = 5348).

From Lens MB, Rosdahl I, Ahlbom A, et al. Effect of pregnancy on survival in women with cutaneous malignant melanoma. *J Clin Oncol* 2004;22:4369.

The cumulative retrospective case-controlled studies have involved more than 450 pregnant women with melanoma. The anatomic location of the primary tumor does not differ between pregnant and nonpregnant women, and no analysis identified any differences in survival from nonpregnant women. **Multivariate analyses have been performed and have revealed that the stage of disease at diagnosis, and not the pregnancy,** is the only consistent finding that influences prognosis. Thus, we conclude that pregnancy does not confer a worse prognosis for this diagnosis when matched for stage of disease.

Management of Melanoma in Pregnancy

It is essential that all physicians and midwives conduct a full examination of the skin of their patients. **A changing skin lesion should be subjected to an excisional biopsy. Early diagnosis of stage I disease often leads to curative therapy. Irrespective of pregnancy, treatment of melanoma is related to depth and stage. Lesions smaller than 1 mm in thickness usually require a wide, deep local excision with a 1-cm margin, and those between 1 mm and 4 mm need a 2-cm margin of excision.** Whereas a wide excision is curative for stage I lesions, the role of IFN-α for stage II and stage III disease is currently under investigation. Although the use of IFN-α in pregnancy has been

reported for the management of chronic leukemia, there has been no published experience using this drug for melanoma in pregnancy.

A changing skin lesion should be subjected to excisional biopsy. Early diagnosis of stage I disease often leads to curative therapy. Irrespective of pregnancy, treatment of melanoma is related to depth of invasion and stage. Lesions less than 1 mm in thickness usually require a wide, deep excision with a 1-cm margin, and those between 1 mm and 4 mm need a 2-cm margin. Wide, deep local excision can be performed safely before 30 weeks of gestation, and for those beyond 30 weeks of gestation SLN identification can be offered after delivery.

Melanomas constitute nearly 50% of all tumors that metastasize to the placenta and account for nearly 90% of those that metastasize to the fetus. Although there have been no reported adverse fetal effects associated with IFN therapy for melanoma during the second trimester, experience with this drug in pregnancy is limited. Pregnant women with advanced or recurrent disease should undergo ultrasound examination during pregnancy for assessment of any obvious fetal tumor masses. Attention should be directed to placental thickness, the fetal liver, and the size of the fetal spleen.

Contemporary studies note no survival difference in patients with melanoma who are pregnant compared with nonpregnant patients. Multivariate analyses demonstrated that the stage of diseased at diagnosis, and not the pregnancy, is the only consistent finding that influences prognosis. In a recent series by Pages and colleagues, 22 patients were included: 10 with AJCC stage III and 12 with AJCC stage IV melanoma. Three patients elected to withhold therapy during pregnancy, 14 underwent surgery, four received chemotherapy, and one was treated with brain radiotherapy. The median gestational age was 36 weeks. Neither neonatal metastases nor deformities were observed, although placental metastases were found in one case. Among 18 newborns, 17 are currently alive at a median follow-up at 17 months; one experienced sudden infant death. The 2-year maternal survival rates were 56% for stage III and 17% for stage IV.

Pregnancy does not confer a worse prognosis for melanoma when matched for stage of disease. At delivery, cord blood should be examined for malignant cells, and the placental tissue should be sent for detailed pathologic evaluation.

The value of regional lymphadenectomy in clinically negative nodes has been controversial. The debate has been defused to some degree with the development of lymphatic mapping to identify the SLN. Pathologic evaluation of the SLN is predictive of regional lymph node metastasis in 96% to 98% of cases. Thus SLN identification and evaluation are indicated for lesions penetrating beyond 1 mm. Lloyd and colleagues emphasize that data regarding the effect of radioactive colloid on the fetus are insufficient to permit its use in pregnant women. The dose to the patient from lymphoscintigraphy is 0.4 mSv, with a dose to the uterus of 0.5 mGy. Most of the injected radioactivity stays at the injection site or moves to the SLNs, which are resected the following day during surgery. Despite the small amounts of injected activity, the local dose rate at the injection site is high, and injection sites close to the fetus (over the lower abdomen or back) combined with next-day rather than same-day resection may result in greater doses to the fetus at any stage of the pregnancy.

It is the author's practice to perform a wide, deep local excision only in women at less than 30 weeks of gestation; for those beyond 30 weeks of gestation, we offer SLN identification after delivery. Because small quantities of radioactivity can be excreted into the breast milk, breastfeeding is contraindicated if SLN identification is performed postpartum.

Melanoma Metastatic to the Products of Conception

The reported low incidence of metastasis of malignant neoplasms to products of conception is probably caused by several factors. One factor is the unexplained resistance of the placenta to invasion by maternal cancer, as demonstrated in many animal studies. Metastasis of maternal cancer to products of conception is rare despite the sizable number of pregnancies at risk. **However, although melanoma accounts for only a small number of all cancers associated with pregnancy, almost half of all tumors metastasizing to the placenta and nearly 90% metastasizing to the fetus are melanomas.**

A few cases of transplacental transmission of melanomas with subsequent death of the fetus or newborn child from disseminated melanoma have been described, but this situation is extremely rare and occurs only when the mother has widespread bloodborne metastatic disease during pregnancy. Schneiderman and colleagues reported a case of a primary fetal melanoma fatal to a newborn. Microscopic metastases were present in the lungs and liver, and the placenta showed widespread metastases to the chorionic villi but no evidence of invasion of the intervillous spaces. The mother had no evidence of disease 1 year after delivery. To date, no instances of metastasis from fetus to mother have been documented. Moller and associates reported a case of maternal melanoma with metastasis to the placental intervillous sinuses. Tumor cells were also present in the fetal cord blood. The mother died postpartum, and the infant survived. **Cord blood should be examined for malignant cells, and placental tissue should be carefully inspected.** A further discussion on the predilection of melanoma to metastasize to placentas and fetuses is presented in a separate section of this chapter.

Thyroid Cancer

Papillary, follicular, and anaplastic carcinomas are the most common primary thyroid malignant neoplasms, with medullary carcinoma accounting for only 5%. The disease usually manifests as a relatively asymptomatic nodular mass in the thyroid gland. The lesion is multifocal, as seen on careful sectioning in approximately 30% to 40% of patients, but in only 5% do these become clinically evident if thyroid tissue remains after surgery. Laboratory indices of thyroid function are contributory only if they indicate a hyperthyroid state, thus supporting the diagnosis of a toxic adenoma. Although studies show that these tumors involve regional lymphatics microscopically in 50% to 70% of patients, this subclinical involvement does not affect the prognosis. The growth of papillary carcinoma may depend on thyroid-stimulating hormone (TSH); therefore, thyroid hormone administration to suppress TSH is

used routinely as an adjuvant in all patients. The prognosis for patients who have this cancer is favorable, especially in the younger age group. Specifically, in women younger than 49 years, a 90% to 95% survival rate at 15 years is consistently reported.

Papillary and follicular thyroid carcinomas are two to three times more common in women than in men (5.5 vs. 2.4 per 100,000, respectively). This female predominance is especially notable during the reproductive years, such that the diagnosis of thyroid carcinoma in pregnancy does occur. **In fact, approximately 10% of differentiated thyroid carcinomas in women of reproductive age are diagnosed during pregnancy or within the first year after delivery.** The actual incidence of thyroid cancer in pregnancy has not been established.

During pregnancy, nonpathologic enlargement of the thyroid gland to twice its normal size is common. Histologic examination shows this enlargement to be caused by an apparent hyperplasia of the follicular cells and abundant colloid formation. A mild suppression of TSH and slight elevation of free thyroxine is common in early pregnancy as a result of the stimulation of the TSH receptor by hCG. A rise in thyroxine-binding globulin during pregnancy results in elevated levels of total thyroid hormone.

Thyroid Cancer in Pregnancy

Because papillary carcinomas are the most common lesions to occur in the reproductive age group, a solitary nodule in an otherwise normal gland is the most common presentation of thyroid carcinoma in pregnancy. Sam and Molitch noted that the incidence of thyroid nodules during pregnancy may be increased, with some data suggesting a higher incidence of malignancy in these nodules. In a 1986 series of 30 pregnant women with thyroid nodules, Rosen and Walfish observed a 43% incidence of malignancy. In 1995, Doherty and colleagues reported the incidence of malignancy to be 39% among 23 women with pregnancy-associated thyroid nodules. In contrast, the incidence of malignancy of thyroid nodules in the nonpregnant population ranges from 8% to 17%. hCG may stimulate the growth of thyroid nodules by cross-reacting with the thyrotropin-stimulating hormone receptor.

Thyroid function tests and a FNA should be performed in pregnant patients with newly discovered thyroid nodules. The latter procedure is especially important when the nodule is larger than 2 cm in size. If the results of cytologic examination are benign, a course of thyroid suppression using 0.2 mg of L-thyroxine daily is indicated for the duration of the pregnancy. Repeated cytologic evaluation may be necessary if the nodule does not diminish on suppression or if it enlarges during pregnancy because 6% of needle aspirations give a false-negative result. The theoretic risk of two false-negative diagnoses is about 0.05%, thus providing excellent confirmation of a conservative approach if the aspirate is repeatedly negative.

If the FNA reveals a papillary or follicular carcinoma, the author advises patients to undergo surgery in the second trimester (Fig. 15.17)**.** If the carcinoma has been discovered in the third trimester, the workup and treatment can be delayed until after delivery. Rapidly growing tumors and medullary carcinomas should be removed on discovery regardless of gestational age. Short treatment delays to permit gestational advancement may be acceptable for some patients with medullary carcinomas, but as soon as fetal maturity can be demonstrated, labor should be induced or a cesarean section should be performed. Surgery is the only known effective therapy for medullary carcinomas and results in a 50% survival rate at 5 years. A prophylactic lymph node dissection on the site of the lesion is indicated. Fetal loss associated with surgery has been reported only with extensive neck exploration. **After tumor resection, suppressive doses of thyroid hormone should be administered, keeping in mind that thyroid hormone requirements may be higher in pregnancy.**

Radioactive iodine is contraindicated during pregnancy and lactation. Even though trace doses are used in these uptake studies, there is still a theoretic risk of a destructive effect on the fetal thyroid and a concern for teratogenesis within the fetus. A whole-body ^{131}I can be performed 3 months after discontinuation of lactation, and if necessary, ^{131}I ablation is recommended.

Undifferentiated Lesions

In the uncommon situation of an anaplastic carcinoma of the thyroid, the main concern is to keep the pregnant woman alive until the pregnancy has come to term because these tumors are almost uniformly lethal lesions. Between 90% and 95% of patients are dead within 1 year of diagnosis. The standard treatment in these patients is radical thyroidectomy followed by radiation therapy. This obviously presents a difficult situation for the patient in the first or second trimester, and one must carefully discuss the situation with the patient and the family. Treatment of pregnant patients who have progressive, local, unresectable, or metastatic thyroid carcinoma has to be individualized and tailored to the wishes of the patient. Surgical removal of these poorly differentiated lesions will achieve the best local control. The role of radiation therapy and chemotherapy remains investigational.

Prognosis Among Pregnant Women With Thyroid Cancer

Pregnancy does not negatively influence the prognosis of patients with well-differentiated thyroid carcinoma. For example, Moosa and Mazzaferri found no difference in the outcome between 61 pregnant women with thyroid cancer and a group of age-matched, nonpregnant control participants. In addition, pregnancy has not been shown to increase the recurrence rate of women previously treated for thyroid cancer. Hill and coworkers described 70 women who conceived after the diagnosis of thyroid cancer and compared them with 109 women who remained childless. There was no difference in the overall recurrence rate. The authors concluded that subsequent pregnancy did not alter the course of the disease. Rosvoll and Winship reviewed the cases of 60 women treated for thyroid carcinoma who subsequently became pregnant and concluded that a history of thyroid cancer is not an indication for avoidance of pregnancy or for therapeutic abortion. Friedman suggested that pregnancy was not contraindicated if the disease-free interval was at least 3 to 5 years. However, even in patients who

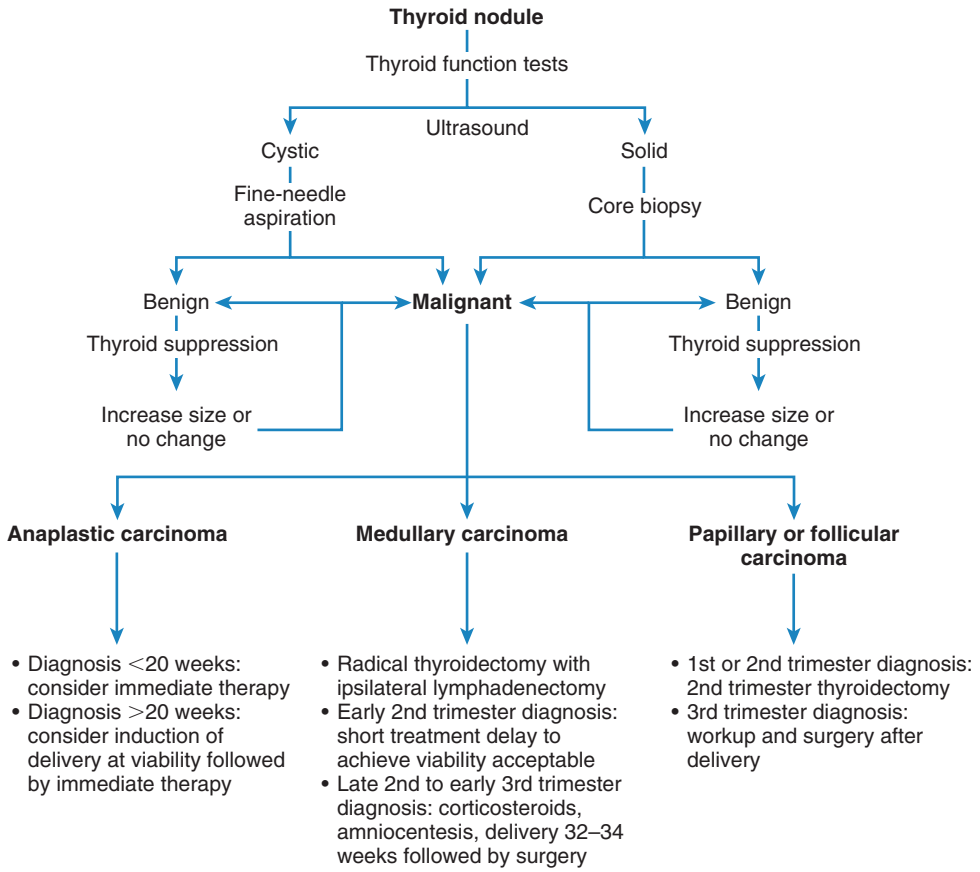

FIGURE 15.17 Management algorithm for the thyroid nodule and thyroid cancer in pregnancy.

had residual or recurrent disease, the prognosis did not appear to be altered by the pregnancy.

Thyroid cancer is among the fastest-rising types of cancer among women in North America. In 2010, Holt summarized the Endocrine Society Guidelines for the management of thyroid dysfunction during pregnancy and postpartum. With respect to thyroid nodules or thyroid cancer, the guidelines stipulate the following:

1. Thyroid nodules measuring 1 cm or larger should be evaluated by FNA biopsy.
2. Individuals with nodules that are malignant or show rapid growth should be offered surgery in the second trimester of pregnancy.
3. It may be appropriate for patients with follicular neoplasia or early-stage papillary thyroid cancers to wait until postpartum for thyroidectomy because these lesions are not expected to progress rapidly and the risk of surgery may outweigh the benefits of immediate intervention.
4. Patients with known thyroid cancer should maintain a low but measurable TSH and normal thyroxine (T_4) values on levothyroxine while pregnant.
5. RAI (radioactive iodine) therapy should not be provided to women who are breastfeeding.
6. After RAI therapy, women should wait 6 to 12 months before becoming pregnant.

Recently, the risk of complications of thyroid and parathyroid surgery during pregnancy was evaluated in a retrospective, US cross-sectional analysis of hospital discharge data from the Healthcare Utilization Project National Inpatient Sample (HCUP-NIS). A total of 201 pregnant and 31,155 age-matched nonpregnant women control participants who had undergone thyroid or parathyroid surgery were identified. Of the 201 pregnant women, 45.8% underwent surgery for thyroid cancer. Thyroidectomy during pregnancy was associated with a higher risk of complications from surgery for malignant (21% vs. 8%) or benign (27% vs. 14%) disease. After controlling for other risk factors associated with adverse outcomes, pregnant patients remained twice as likely to have surgical complications as their nonpregnant counterparts. Among the pregnant patients who had thyroid or parathyroid surgery, 5.5% had fetal complications (eg, fetal distress, abortion), and 4.5% had maternal complications (cesarean section, hysterectomy).

Rare Gynecologic Malignancies in Pregnancy

Vulvar Cancer

Fewer than 50 cases of invasive cancer of the vulva associated with pregnancy have been reported in the literature. Lutz and colleagues estimated an incidence of 1 case per 8000 deliveries at his institution; our experience has been less frequent, at about 1 per 20,000 deliveries. The most common of these are invasive epidermoid carcinomas followed by melanomas, sarcomas, and adenoid cystic adenocarcinomas. In recent years, reports of pregnancies complicated by recurrent vulvar carcinoma, metastatic vulvar melanoma, a rapidly enlarging myxoid leiomyosarcoma

of the vulva, and primary choriocarcinoma of the vulva have also appeared. The majority of patients have been between 25 and 35 years of age; the youngest patient was 17 years old. **With the increasing frequency of the diagnosis of CIS of the vulva, the occurrence of preinvasive disease with pregnancy is common today.** As is the practice with CIN, therapy for the vulvar counterpart is delayed until the postpartum period. Adequate biopsies of the most suspicious areas are essential to rule out invasive disease. The presence of intraepithelial neoplasia should not prohibit vaginal delivery but should prompt a careful colposcopic evaluation of the lower genital tract to exclude other preinvasive or invasive foci.

Historical series of vulvar cancer in pregnancy. Gitsch and colleagues presented a concise review of therapy and outcome for this group of patients, correctly noting that the reports have been inhomogeneous. In a review of the literature, Barclay found 31 women with vulvar cancers associated with pregnancy. The vulvar cancers were actually diagnosed and treated during pregnancy in only 12 of these women; another two were treated after termination of pregnancy. In 1974, Barclay furnished further details on nine patients, one of whom was treated with radiation therapy during pregnancy. Five patients were treated surgically before delivery, and three women underwent vulvectomy in the postpartum period. With extended follow-up, none of the patients experienced recurrent disease, although one woman developed a cervical carcinoma that was irradiated. Lutz and colleagues reported three cases diagnosed during pregnancy but treated postpartum. Although no one survived, details concerning the stage, treatment, and survival time were not provided.

Management of vulvar cancer in pregnancy. **Invasive vulvar malignant disease diagnosed during the first, second, and early third trimesters is usually treated as indicated in nonpregnant patients some time after the 18th week of pregnancy.** T1 lesions should be managed by radical wide excision with ipsilateral groin dissection if the depth of invasion is larger than 1 mm. Larger and more deeply invasive tumors require a radical vulvectomy and bilateral inguinofemoral lymphadenectomy. Patients with palpable inguinofemoral nodes undergoing surgery early in pregnancy present a unique challenge because skin bridge metastases are more likely to occur in patients with bulky positive nodes. Such patients are advised to have the groin dissected using an en bloc approach because of the need to delay radiation therapy for many months. When the diagnosis is made after 36 weeks of gestation, we recommend a wide local excision with definitive surgery postponed until the postpartum period. This avoids the greatly enhanced vascularity in vulvar tissues during the later months of gestation and into the immediate postpartum period. A short delay does not appear to seriously prejudice the course of the disease.

Women treated during pregnancy may be allowed to attempt vaginal delivery provided the vulvar wounds are well healed and there are no indications for additional therapy. Patients with high-risk surgicopathologic features warranting adjuvant radiation should undergo cesarean delivery as soon as fetal pulmonary maturation can be documented. After delivery of the baby, the ovaries should be transposed to the paracolic gutters, and pelvic or groin irradiation (or both) can be administered postpartum.

Because this disease occurs more frequently in women of lower socioeconomic groups, who often do not seek prenatal care, many of these cases are diagnosed at the time of delivery or later. In this group of patients, definitive therapy should be started within 1 week after delivery during the same hospitalization. The pregnant state does not appear to significantly alter the course of the malignant process; survival of these patients stage for stage is similar to that of nonpregnant patients.

Bakour and colleagues have carefully considered the subject of future pregnancies in this group of patients and have found no contraindications after surveying the literature. In fact, they believe that these young patients who have undergone such extensive surgery obtain a great boost psychologically when they realize this possibility. There have been several reports of patients treated for carcinoma of the vulva with radical vulvectomy and bilateral inguinal lymphadenectomy who subsequently became pregnant and had normal deliveries. Whether the patient should deliver vaginally or by cesarean section is a decision that rests with the obstetrician, but it is heavily influenced by the state of the postsurgical vulva. In most instances, the vulva is soft and does not impede a vaginal delivery. In other instances, there may be a high degree of vaginal stenosis or other fibrosis, which makes cesarean section the more appropriate means of delivery.

Primary Invasive Vaginal Tumors

Cancer of the vagina has been found mainly in women older than 50 years. The diagnosis of vaginal cancer during pregnancy is exceptionally uncommon, even with the clear cell adenocarcinoma of the vagina alleged to be associated with the diethylstilbestrol-exposed offspring. Although all these clear cell adenocarcinomas have occurred in women younger than 34 years, the incidence in association with pregnancy has fortunately been rare.

Senekjian and colleagues described 24 women who were pregnant when clear cell adenocarcinoma of the vagina or cervix was diagnosed; 14 were in the first trimester, six in the second, and four in the third. Among the stage I and stage II tumors, 16 (73%) were vaginal, and six (27%) were cervical. Thirteen long-term survivors were reported among the 16 early vaginal lesions. No significant differences were observed when the group of 24 patients with pregnancy-associated tumors and 408 never-pregnant (age-corrected) patients were compared with regard to maternal hormone history, symptoms, stage, location, predominant histologic or cell type, greatest tumor diameter, surface area, depth of invasion, grade, and number of mitoses. The overall 5- and 10-year actuarial survival rates (86% and 68%, respectively) for the group pregnant at diagnosis did not differ significantly from the rates for the never-pregnant group analyzed concomitantly (n = 408). Pregnancy did not seem to adversely affect the outcome of clear cell adenocarcinoma of the vagina and cervix. Jones and colleagues reported a diethylstilbestrol-related clear cell carcinoma of the vagina in a patient whose tumor, observed directly over an extended period, did not appear to be influenced by elevated plasma

estrogen levels during the period when the pregnancy was carried to term.

Primary SCC of the vagina discovered during pregnancy is exceedingly rare. In 1963, Collins and Barclay identified 10 patients from the literature and, although three responded well to radiation therapy, a rapidly progressive downhill course was described for four patients available for detailed analysis. In 1977, Lutz and colleagues reported a 24-year-old patient diagnosed at 24 weeks of gestation with a stage II SCC of the vagina, who despite immediate radiotherapy after preterm delivery, suffered a fatal recurrence 7 months later. Three additional cases have been reported by Palumbo and colleagues, Beck and Clayton, and Baruah and Sangupta, manifesting between 8 and 24 weeks of gestation and all resulting in maternal death within 18 months of diagnosis; in two of the cases, pregnancy termination had been performed so as to not delay radiotherapy.

Finally, Steed and colleagues reported a 28-year-old patient with antepartum bleeding at 20 weeks of gestation who was found to have a 6-cm diameter anterior vaginal wall SCC extending to the right lateral fornix. This patient opted to continue the pregnancy and received corticosteroids followed by cesarean delivery at 32 weeks of gestation. Before delivery, gold seeds were placed transvaginally to demarcate the tumor edges. Amazingly, although the patient was debulked of multiple, enlarged, positive pelvic lymph nodes, after treatment with chemoirradiation and brachytherapy, she had remained disease-free for 3 years at the time of publication. This report brings the total to 15 cases of primary invasive SCC of the vulva complicating pregnancy, with an overall survivorship rate of 38%, similar to what is observed in nonpregnant patients.

Both cervical cancer and vaginal cancer are staged clinically, and the management principles to be discussed in detail when cervical carcinoma complicates pregnancy also may be applied to vaginal tumors. Treatment of clear cell adenocarcinoma of the cervix and upper vagina is surgically similar to that of SCCs. Specifically, very early lesions involving the upper vagina may be treated by radical abdominal hysterectomy with pelvic lymphadenectomy, but all others are best managed radiotherapeutically. The pregnancy should be disregarded if the diagnosis is made in the first or early second trimester. If the pregnancy is further along, the decision for appropriate time of intervention depends on the preferences of the patient and the oncologist. Patients early in pregnancy who resist termination should be given corticosteroids and delivered as soon as fetal pulmonary maturation is demonstrable. The impact of a delay in therapy on the prognosis is impossible to predict. When there is extensive involvement of the vagina by any lesion, one should seriously consider evacuation of the uterus by a hysterotomy or cesarean section and institution of appropriate radiation therapy.

A few scattered reports of sarcoma botryoides of the cervix and vagina in pregnancy were recorded in the 1960s by Roddick and Honig and Schwartz and colleagues. When these sarcomatous lesions occur in the upper half of the vagina with or without cervical involvement, the most appropriate therapy has been a radical abdominal hysterectomy, upper vaginectomy, and bilateral pelvic lymphadenectomy followed by postoperative adjuvant chemotherapy. In 2003, the first primary vaginal leiomyosarcoma diagnosed during pregnancy was reported by Behzatoglu and colleagues in a 21-year-old woman who presented during the third trimester with a 1.5-cm firm, fleshy, pedunculated mass arising from a short stalk on the right vaginal wall. Previously, female genital tract leiomyosarcomas that have been associated with pregnancy had originated from the uterus or vulva ($n = 10$). Finally, some malignancies have been reported in pregnancy to involve the vagina secondarily by direct extension (eg, tumors of the cervix), via lymphatic spread (eg, endometrial carcinoma), or through hematogenous dissemination (eg, gestational choriocarcinoma and placental site trophoblastic tumor). **In fact, secondary involvement from an extravaginal site is more common than the development of a primary vaginal neoplasm, irrespective of pregnancy.** Although pregnancy-associated vaginal cancer is rare, the entity must remain part of the differential diagnosis of bleeding in pregnancy. Steed and colleagues emphasize that visualization of the entire vagina and cervix is necessary during speculum examination, and the procedure should be performed in every pelvic examination and for all investigations carried out for antepartum bleeding.

Endometrial Cancer

Endometrial carcinoma in conjunction with pregnancy is extremely rare. Most of the reported cases have been diagnosed at examination of uterine contents obtained by curettage for elective pregnancy termination or spontaneous abortion. Leiomyosarcoma (including a myxoid leiomyosarcoma), endometrial stromal sarcoma, and carcinosarcoma have also been reported during pregnancy. They are usually incidental findings noted in surgical specimens. The recommended therapy for endometrioid adenocarcinomas associated with pregnancy is total hysterectomy with bilateral salpingo-oophorectomy and adjuvant radiotherapy when indicated.

In 1972, Karlen and associates reviewed the literature since 1900, summarized five acceptable cases, and added a sixth. In 2004, Itoh and colleagues collected a total of 29 patients (including one of their own), 11 of whom were older than 35 years. Twenty-one of the 29 cases had no or minimal myometrial invasion, 18 of which were histologically FIGO grade I, and three were FIGO grade II. This group includes a 28-year-old patient who received conservative treatment with high-dose medroxyprogesterone acetate after a uterine curettage that had revealed diffuse complex hyperplasia with atypia and a focus of well-differentiated adenocarcinoma showing stromal invasion. This patient subsequently conceived, and after delivery at term, she underwent a total abdominal hysterectomy. Pathologic examination of the uterus revealed a persistent well-differentiated endometrioid adenocarcinoma limited to the endometrium. This case serves to illustrate a very important point: **As more women opt for conservative management of invasive cancers in an effort to preserve fertility, we may anticipate a larger number of referrals than what was seen previously for patients with persistent or even recurrent malignancy during pregnancy.**

All 21 patients with favorable histopathologic features were alive at the time of their report, ranging from 3 months to 10 years after treatment. **Therefore, most cases of endometrial carcinoma associated with pregnancy are characterized by well-differentiated tumors, an endometrioid histology with no or minimal myometrial invasion, and favorable outcome, consistent with the typical clinicopathologic features of type I endometrial carcinoma that develops in obese women.** It has been hypothesized that the elevated serum progesterone level during pregnancy inhibits the growth of endometrial carcinoma cells, and this may contribute to the good outcomes observed among these 21 patients. This has prompted several authorities to argue that adenocarcinoma in pregnancy does not occur and that the reported cases were misdiagnosed Arias–Stella reactions.

However, the remaining eight of the 29 reported patients have had well-documented deep myometrial invasion or extrauterine extension. The FIGO grade distribution included grade I ($n = 3$), grade II ($n = 2$), and grade III ($n = 3$, including one serous papillary carcinoma), and the FIGO stage ranged from Ic to IV. Two of these eight patients died of disease, and it is notable that the patient submitted by Itoh and colleagues had deep myometrial invasion and negative expression of ER and PR. Of note, higher grade tumors or nonendometrioid adenocarcinomas are often negative for ER or PR expression, and this group of endometrial carcinomas associated with pregnancy is characterized by high-grade histology, including nonendometrioid type, deep myometrial invasion, advanced stage, and poor outcome consistent with the type II carcinoma manifesting in nonobese patients. Thus, not all endometrial carcinomas associated with pregnancy have a favorable prognosis.

Fallopian Tube Cancer

The fallopian tube can become secondarily involved by malignancy through direct extension of an ovarian tumor or from an endometrial carcinoma. Primary fallopian tube carcinoma was described by Starr and colleagues as a disease of recent vintage, having been first reported in 1847 by Raymond and later, in 1861, by Rokitansky. The disease is the least common gynecologic tumor. The mean age ranges from 50 to 55 years. Thus, the possibility of its presence in pregnancy is extremely remote. Cases have been reported to be associated with pregnancy; in these instances, the neoplasm is usually unilateral and most often adenocarcinoma.

The clinical presentation of carcinoma of the tube is variable and nonspecific even without an associated pregnancy. **The usual watery, blood-tinged vaginal discharge would be obviated in pregnancy because at 12 weeks of gestation, the communication between the uterine cavity and the fallopian tube is blocked.** In most instances, the diagnosis is established at laparotomy, and the treatment is total abdominal hysterectomy with bilateral salpingo-oophorectomy and postoperative radiotherapy or chemotherapy, depending on the operative findings and the residual disease after surgery. Several instances are reported in the literature of incidental findings of CIS of the tube noted in specimens submitted after postpartum tubal ligation. In these instances, a total abdominal hysterectomy with bilateral salpingo-oophorectomy has been recommended; however, simple removal of the fallopian tubes may be a reasonable alternative.

Adolph and colleagues reported the first case of a recurrent fallopian tube carcinoma associated with pregnancy in 2001. The patient originally underwent a limited surgical procedure to preserve fertility followed by chemotherapy and subsequently experienced an intraperitoneal recurrence 1 year later during her 16th week of pregnancy. After a cesarean section at term, she underwent optimal cytoreductive surgery and was alive with stable disease 6 months after salvage chemotherapy when the paper was published. This case is included with some detail to emphasize a point made earlier, in that as fertility-preserving oncologic procedures become more widely accepted for certain early-stage malignancies, the probabilities increase for having to manage recurrent disease in pregnancy. The criteria through which surgeons determine candidacy for fertility preservation must be carefully devised and rigorously adhered to.

Trophoblastic Tumors of the Fallopian Tube: "Ectopic" Pregnancy

Although choriocarcinoma most frequently arises in the uterus, a primary choriocarcinoma of the fallopian tube may be associated with ectopic pregnancy. In these scenarios, the biologic behavior is very aggressive, with distant metastases manifesting in 75% of cases. A review of the world literature of 93 reported cases by Ober and Maier in 1981 yielded 58 acceptable cases, to which the authors added 18 from the files of the Armed Forces Institute of Pathology. Since that time, there have been approximately 15 additional reports, bringing the total to 91 cases of primary choriocarcinoma of the fallopian tube. **The mean age is 33 years, with 66% of patients presenting with acute symptoms consistent with a ruptured ectopic pregnancy.** The remainder typically have presented with a gradually expanding adnexal mass clinically indistinguishable from an ovarian tumor. Endovaginal ultrasonography may offer an image compatible with an extrauterine pregnancy in the left appendages, and the quantitative serum β-hCG is elevated. Grossly, the tumor appears as a hemorrhagic friable mass, occasionally containing spongy tissue resembling the placenta. Smaller tubal choriocarcinomas are difficult to distinguish on gross inspection from the common ectopic pregnancy. Histopathologic features and the distribution of metastases are similar to gestational choriocarcinoma arising in the uterus.

The surgical approach has not been uniform, with some women undergoing unilateral salpingectomy only or unilateral adnexectomy or total abdominal hysterectomy with bilateral salpingo-oophorectomy. Most patients have gone on to receive polychemotherapy. In the review by Ober and Maier, it was noted that of 47 acceptable cases treated before modern chemotherapy, the mortality rate was 87% ($n = 41$). Of 16 cases treated with modern chemotherapy, the salvage rate was 94% ($n = 15$). Fewer than 10 patients have been cured by unilateral salpingectomy or unilateral salpingo-oophorectomy alone. Whenever possible, a histologic examination of the tubes should be performed in all cases of ectopic pregnancies. Serial measurements

of the β-hCG is an essential component of the surveillance of all patients treated for ectopic pregnancy and especially for those treated with methotrexate or by salpingotomy alone.

Primary choriocarcinoma of the fallopian tube coexistent with a viable intrauterine pregnancy was first reported by Lee and colleagues in 2005, and a heterotopic pregnancy of a primary placental site trophoblastic tumor of the fallopian tube and an intrauterine pregnancy was first reported by Su and colleagues in 1999.

Placental and Fetal Tumors

The placenta may be the site of origin of gestational trophoblastic neoplasia (GTN) or can be secondarily involved by other malignancies. The disease spectrum of GTN encompasses molar pregnancies (eg, complete, partial, invasive), nonmetastatic GTN, gestational choriocarcinoma (ie, metastatic GTN), and placental site trophoblastic tumors. These entities are discussed in a separate chapter. The occurrence of gestational choriocarcinoma and placental site trophoblastic tumors in the fallopian tube has been addressed earlier in this chapter under the section concerning tumors of the fallopian tube in pregnancy. The following sections have as their focus the occurrence of a twin pregnancy complicated by a complete mole and a normal fetus, placental and fetal metastases, and primary fetal cancers that may manifest in utero.

Complete Hydatidiform Mole With Coexistent Fetus

Ultrasonography depicting the combination of a live fetus and a molar-appearing placenta suggests three distinct possibilities:

1. A singleton pregnancy consisting of a partial mole with a live fetus
2. A twin pregnancy comprising one placenta exhibiting a complete mole (no fetus) and the other placenta sustaining a normal twin
3. A twin pregnancy with a partial mole and fetus in one sac and a normal twin in the other sac

The first possibility involves a triploid fetus that usually dies during the first trimester. The third possibility is easily eliminated by the presence of two fetuses.

The incidence of complete hydatidiform mole with coexistent fetus (CMCF) ranges from 1 in 10,000 to 1 in 100,000 pregnancies. The true incidence is difficult to establish, and the observed increased incidence of iatrogenic multiple gestations in recent years is expected to result in a higher incidence of CMCF. Vaisbuch and colleagues have conducted a comprehensive review of the literature, and after exclusion of duplicate publications they have identified 130 cases, some of which include higher-order gestations (eg, triplets and quadruplets). Fifty-three elected to terminate. Thirty-three live births (25%) occurred. The calculated incidences of specific complications included 30% preeclampsia, 33% persistent GTN, and 22% metastatic GTN.

Steller and colleagues discovered eight well-documented cases of twin pregnancy with CMCF. They compared the clinical features of these eight patients with 71 women with singleton complete hydatidiform mole. **Although the presenting symptoms were similar in both groups, a twin pregnancy with CMCF was diagnosed at a later gestational age (20.1 weeks vs. 13 weeks), had higher preevacuation β-hCG levels, and had a greater propensity to develop persistent GTN (55% vs. 14%).**

Bristow and colleagues reported 25 cases from the literature and one of their own, of whom 19 were evacuated before fetal viability and only seven resulted in a live-born infant. Although the previable and viable group were unremarkable with respect to mean age, gravidity, parity, uterine size, and presence of theca-lutein cysts, significant differences in gestational age at diagnosis (17.4 weeks vs. 29.4 weeks) and preevacuation serum hCG levels (>1,000,000 mIU/mL vs. 170,000 mIU/mL) were observed. In addition, previable cases were also associated with higher frequencies of preeclampsia (31.6% vs. 14.3%) and persistent GTN (68.4% vs. 28.6%). Clinical factors that required termination of the pregnancy might have been surrogates for aggressive trophoblastic growth and therefore persistent disease and the subsequent need for adjuvant systemic therapy. Bruchim and colleagues reported a 53.3% incidence of persistent GTN (including four patients with pulmonary metastasis) when they analyzed 15 cases of CMCF that had resulted in a live neonate delivered at a mean age of 34.3 weeks of gestation. Although CMCF is associated with a higher risk of persistent GTN compared with the risk attributable to a singleton complete hydatidiform mole, the issues regarding pregnancy termination are unclear. It does not appear that advanced gestational age is an independent risk factor for developing persistent GTN in the setting of a CMCF. **After fetal anomalies and an abnormal karyotype are excluded, with some degree of caution, the literature supports continuing the pregnancy provided there is no evidence of preeclampsia and the pregnant woman strongly wishes to do so.** A declination in serum levels of hCG may also be included in the criteria through which expectant management can be offered. Patients should be informed that only 25% of such pregnancies will result in a live birth and that there may be some serious consequences of premature delivery and prematurity.

The overall risk of developing persistent GTN ranges from 19% to 57% (Table 15.24)**, irrespective of whether the**

pregnancy is terminated or carried to viability or term. Therefore, the major obstacles to continuing the pregnancy are the development of a paraneoplastic medical complication, catastrophic vaginal hemorrhage, and formation of metastatic foci antenatally. In the exceedingly rare situation in which metastatic GTN coexists with a normal gestation, intravenous systemic chemotherapy is necessary during pregnancy unless the disease is discovered when the baby is of advanced gestational age, in which case delivery followed by immediate systemic therapy might be an option.

Presenting symptoms of a complete hydatidiform mole with coexisting fetus are similar to those seen with complete hydatidiform moles alone (ie, size greater than dates, abnormal vaginal bleeding). A twin pregnancy with a complete hydatiform mole and coexisting fetus may be diagnosed later in gestational age (eg, 20 weeks vs. 13 weeks), have a higher preevacuation β-hCG level, and have a greater propensity to develop persistent GTN necessitating chemotherapy.

After fetal anomalies and an abnormal karyotype are excluded, the literature supports continuing the pregnancy provided there is no evidence of preeclampsia and the mother strongly wishes to do so. In cases of twin pregnancy with a complete hydatidiform mole and coexisting live fetus, continuation of pregnancy is acceptable with a normal fetal karyotype, no anomalies, no early preeclampsia, and declination of hCG levels (Table 15.25); the risk of persistent trophoblastic disease may rise to 57%. The overall risk of developing persistent GTN is 33% irrespective of whether the pregnancy is terminated or carried to viability or term. The major obstacles to continuing the pregnancy are the development of a paraneoplastic medical complication, catastrophic vaginal hemorrhage, and formation of metastatic foci antenatally.

A series of 14 cases were recently reported by Massardier and colleagues. In 10 cases (71%) the diagnosis was made by ultrasonography, with the differential diagnoses including partial hydatidiform mole and mesenchymal dysplasia. Eight patients elected to terminate their pregnancies, and six chose to continue. Of the latter, there were three intrauterine deaths or spontaneous abortions and three (21%) normal live births. Only one patient delivered after 37 weeks of gestational age. Seven patients (50%) were diagnosed with GTN, and none of the 14 had a fatal evolution. Of note, vaginal bleeding, preeclampsia, and hyperthyroidism did not have an impact on the risk of persistent GTN, nor did continuation of the pregnancy increase that risk.

TABLE 15.25 Recommendations for Continuation of Pregnancy in the Setting of a Twin Pregnancy With Complete Hydatidiform Mole and Coexisting Fetus

Normal fetal karyotype
No anomalies
No early preeclampsia
No observance of decrease in levels of human chorionic gonadotropin

Placental and Fetal Metastases

Patients diagnosed with cancer in pregnancy commonly ask whether the disease can spread to their children. Although cancer during pregnancy is not uncommon, metastases to the placental tissue or the fetus rarely occur. Most malignancies, when matched stage for stage, portend the same prognosis for the woman whether she is pregnant or not. Exceptions include hepatocellular cancer, lymphoma, thyroid cancer, colon cancer, and nasopharyngeal cancer. **In addition to the primary cancer sites, metastatic disease to the products of conception predicts an ominous course for the mother.** Metastatic lesions to the fetus or placenta remain a poorly understood subject.

The first report of metastases to the placenta or fetus appeared in 1866. In this case, Friedreich observed a mother with disseminated "hepatic" carcinoma that spread to and killed the fetus. There have been no other reports of "hepatic" metastases to the products of conception, and we suspect that Friedreich's patient had a melanoma, which is most likely to behave in this clinical manner. **Indeed, melanoma is the most common cancer to metastasize to placentas and fetuses.** Rothman and associates reported 35 cases of disseminated maternal malignant disease with either placental or fetal involvement. In only two instances was tumor demonstrated on both the maternal and fetal sides of the placenta and in the fetus. It is rare for the fetus to be involved if there is invasion only of the maternal side of the placenta. Of six cases in the literature when the villus itself was invaded, there was only one case of demonstrable fetal disease. In another report by Potter and Schoeneman, 24 cases of maternal cancer metastasizing to the fetus or placenta were reviewed. Melanoma, by far the most common tumor to spread to fetuses or placentas, was found in 11 cases. Breast cancer was found in four cases. Eight infants were found to have cancer at birth, and six of them subsequently died of their malignant neoplasms. Two infants with metastatic melanoma were noted to have complete tumor regression and ultimately survived. Seven of eight occurrences of metastasis to the fetus were found in cases of maternal melanoma, and there was one case of lymphosarcoma. Finally, Holland reported a case in which maternal, placental, and fetal disease was documented.

Since Friedreich's initial report, there have been fewer than 90 cases of maternal malignancy metastatic to the gestation (Table 15.26). Because of its generous blood flow, large surface area, and favorable biologic environment for growth, one would consider a placenta to be an ideal site for metastases, and therefore the relative paucity of such events remains unclear. Why have the products of conception been privileged in this way? Perhaps immunologic rejection of tumor cells, uteroplacental circulatory mechanisms, or even a protective role of the trophoblast limits the establishment of metastatic foci. Cancers that have been reported to metastasize to the intervillous space or to the placenta proper include sarcomas, carcinomas, lymphomas, leukemias, and melanomas. **Of note, 30% of the cases are melanomas followed by breast cancer (18%) and then the hematopoietic malignancies (13%).**

Nearly half of the reports contain cases of known malignancy diagnosed before the onset of pregnancy. Unfortunately, 93% of such women died of their disease, sometimes within hours

TABLE 15.26 Most Common Cancers in Pregnancy to Affect Placentas or Fetuses

Cancer Type	Cases Reporting Placental Involvement	Cases Reporting Only Fetal Metastasis	Cases Reporting Both Placental and Fetal Metastasis	Total Cases Affecting Placenta and/or Fetus	Percentage of Total Cases
All cancers	72	10	6	88	100
Melanoma	21	3	3	27	31
Breast	15	0	0	15	17

of delivery. Gestational reactivation of malignancy has been reported in women who had been disease free for 5 years before becoming pregnant. **Contrasting with the unfavorable prognosis for mothers with placental metastases, the prognosis for the infant has been excellent, with 53 of the reported cases revealing no evidence of disease in the baby.** In addition, since 1966, no infant has succumbed to metastatic disease, although several reports contained fetal demises as a consequence of complications of prematurity. More recently, the first case of maternal pulmonary adenocarcinoma metastatic to the fetus has been reported; the involved scalp was widely excised, and skin graft coverage was applied at 3 months of life. At the time of publication, the child was 5 years old and disease free.

Another unusual scenario is that of GTN metastatic to the fetus, with 15 to 20 cases reported to date. It is interesting that widely metastatic disease in the delivered neonate can occur in the absence of metastatic GTN in the mother. There are also reports of acute leukemia developing postnatally in the child of a mother with acute leukemia. In one report by Cramblett and associates, the child developed acute leukemia 9 months after delivery; in another report by Bernard, disease manifestation occurred 5 months after delivery. Transplacental transmission of maternal B-cell lymphoma was reported by Maruko and colleagues when a 29-year-old mother developed the disease at 29 weeks and her infant developed malignant lymphoma at 8 months of life. Hypotheses relating to familial, hereditary, environmental, and viral factors can be advanced in these circumstances, but the weight of evidence suggests that acquisition of maternal malignant disease by fetuses is extremely unlikely.

Guidelines for the evaluation of children born to women with cancer are sparse in the literature. **Tolar and Neglia recommend that any child born to a mother with active or suspected malignancy should initially have a thorough physical examination with a complete blood count, comprehensive metabolic panel, liver function tests, coagulation battery, serum LDH level, uric acid levels, and a urinalysis. In addition, the placenta should be macroscopically and microscopically examined for tumor involvement. It has been the author's practice to also obtain imaging studies, including an MRI of the brain and CT scans of the chest, abdomen, and pelvis, when maternal breast cancer, hematopoietic malignancy, or melanoma is at issue or in the setting of confirmed placental metastases.** Continued surveillance should be ongoing during the first year of a child's life because some cases of maternal to fetal metastases have not presented until several months after birth. Because not all cases with documented placental involvement have corresponding fetal metastases, infants with an initially negative workup should not be prophylactically treated but should be closely observed with frequent physical examinations, laboratory tests, and imaging studies as clinically indicated.

Primary Fetal Tumors

Benign tumors such as teratomas or lymphangiomas may progress rapidly in utero, distorting the fetal anatomy and resulting in intrauterine fetal and obstetric complications and morbidity. In addition, several developmental tumors, including hamartomas and vaginal adenosis, are not malignant in utero but may undergo malignant degeneration after delivery. Benign and malignant tumors present diagnostic problems and therapeutic challenges. Both typically appear as heterogeneous masses with solid and cystic components when viewed by ultrasonography. The extent and tissue characteristics of these lesions may be further evaluated by MRI, and the diagnosis can occasionally be guided by a cytologic analysis of fluid aspirated from a cystic lesion. **Jauniaux and Ogle maintain that expectant management should be the rule in the initial phase, with serial ultrasound evaluations to detect rapid enlargement, metastasis, or secondary fetal complications such as nonimmune hydrops.**

The sacrococcygeal teratoma is a tumor arising from totipotential embryonic cells of the coccyx and has an incidence of 1 in 35,000 to 40,000 deliveries. There is a four to one female to male predominance, although the sex ratio in the incidence of malignant tumors is equal. With routine prenatal ultrasonography, these lesions are being diagnosed increasingly when views of the spine to rule out neural tube defects are obtained. The advent of antenatal ultrasonography has shifted the management focus from birth to the antenatal period, in which the fetal mortality rate ranges from 30% to 50%. The most common cause of perinatal loss is premature labor secondary to polyhydramnios, with one series reporting the combination of hydrops and placentomegaly as a very ominous sign with 100% mortality. On this basis, fetal surgery with tumor resection has been advocated in selected cases if the hydrops appears before 28

weeks and the tumor is deemed resectable. Because of the risk of dystocia and traumatic hemorrhage, cesarean section has been the rule for tumors larger than 5 cm. After birth, complete excision of the tumor should not be delayed, and those who survive surgery should have a favorable prognosis. Residual tumor, however, may lead to malignant change, and although the recurrence risk is extremely low, isolated cases have been reported.

Congenital neuroblastoma is a cancer of neuronal lineage that may occur along the sites of the sympathetic ganglia from the neck to the presacral region, including the adrenal medulla. They typically contain Schwann cells and are the most common malignant tumor of newborns, representing 30% to 40% of all congenital tumors. The genetic defect is characterized by the loss of locus p36 on chromosome 1. The clinical features are a function of the size, location, and humoral activity of the neuroblastoma, with catecholamine or vasoactive intestinal polypeptide characterizing their biologic behavior. Fetal neuroblastomas are well encapsulated and may displace the kidney inferiorly and laterally, with a predilection for the right side. The presence of calcification by ultrasonography has been associated with improved survival. Of note, neuroblastoma cells may infiltrate the placenta beyond the fetal capillaries and villous trophoblast, with metastasis to maternal tissue. Postpartum symptoms attributable to catecholamine production may be observed in the mother and include sweating, flushing, palpitations, and hypertension.

Concordance for neuroblastoma in monozygotic twins has been rarely reported, with the cause for the shared pathology unestablished. In 2001, Anderson and colleagues described a case of infant monozygotic twins developing neuroblastomas that were morphologically, clinically, and molecularly indistinguishable but with a delay of 6 months between times of presentation. Both tumors had metastasized and had amplification of MYCN and deletion at 1p36. The twin who developed neuroblastoma first had constitutional karyotype abnormalities in at least 5% of peripheral blood mononuclear cells. The second twin had a normal constitutional karyotype and lacked rearrangements or deletions. The authors proposed an acquired neuroblastoma predisposition specific for the first twin and in utero metastatic spread of tumor cells to the second twin (ie, twin-to-twin metastasis) via the shared placental circulation.

Acute congenital leukemia is the second most common fetal cancer, occurring at an incidence of 1 in 4.7 million live births per year. The diagnosis requires the proliferation of blast cells together with anemia, thrombocytopenia, and leukocytosis. Important congenital infections, including cytomegalovirus, rubella, and toxoplasmosis, must be excluded. In utero, hepatosplenomegaly and nonimmune hydrops are common at presentation.

Sporadic heritable retinoblastoma is a malignant tumor of the retina that is inherited in an autosomal-dominant manner. The mutant retinoblastoma gene is mainly derived from the father and may be related to exposure of paternal germ cells to carcinogens. Primary hepatic malignant tumors of the fetus may present with an abdominal mass, and in cases of hepatoblastoma, the serum levels of α-fetoprotein are markedly elevated and reflect the tumor burden. Finally, rhabdomyosarcoma is the most common soft tissue sarcoma in children and is commonly located at the level of the head and neck. It is associated with a loss of heterozygosity of the short arm of chromosome 11. Only a few cases have been described during pregnancy, during which time the tumors manifested as rapidly growing masses of irregular contour.

Complications of Disease and Therapy

Kemi M. Doll, MD, MSCR, Daniel L. Clarke-Pearson, MD

OUTLINE

Disease-oriented Complications
- Hemorrhage
- Urinary Tract Complications
- Gastrointestinal Complications
- Venous Thromboembolic Complications
- Biliary Obstruction

Treatment-related Complications
- Surgical
- Radiation Therapy

KEY POINTS

1. Women with gynecologic cancers can have significant complications from treatment.
2. Vaginal bleeding is usually controlled with packing.
3. Ureteral obstruction can be treated by diversion either with surgery or stent placement.
4. Bowel complications are treated with conservative management or surgery depending on the patient's disease status and overall condition.
5. Deep vein thrombosis always needs to be considered for prophylaxis and treatment if necessary.
6. Infectious complications always need to be considered and managed appropriately.
7. The risk of complications always needs to be considered and the patient counseled appropriately.

Women with gynecologic cancers often experience complications associated with their primary disease process or from the cancer-directed treatment modalities. In addition, many women have medical comorbidities, are obese, or are elderly, all of which further complicate therapy and treatment decisions. Minimizing these problems requires the clinician to astutely evaluate the patient, be proactive in prevention strategies, and provide early intervention.

Complications of disease are, in fact, commonly the primary presenting symptom (chief complaint) of a gynecologic cancer. Common symptoms of disease include hemorrhage (cervical and endometrial cancers), urinary tract obstruction or fistulae (cervical cancer), and intestinal obstruction or weight loss (ovarian cancer). Although some complications have been discussed previously in this text, it seems appropriate to devote a chapter exclusively to complications of disease and therapy. Not all possible complications can be covered, and readers are referred to texts that expand on them. However, the most common complications and management are discussed.

DISEASE–ORIENTED COMPLICATIONS

Symptoms caused by cancer, such as bleeding, urinary tract obstruction, fistula, and intestinal obstruction, are complications of the primary gynecologic cancer that usually need to be managed coincidentally with the cancer itself.

Hemorrhage

Bleeding from cervical or endometrial cancer is a common presenting symptom. Although bleeding is rarely severe, the acute management of hemorrhage may be required before cancer therapy can be undertaken. Patients who are bleeding should be initially assessed for hemodynamic stability. On rare occasions, the bleeding is so severe that the patient may be in hypovolemic shock. Immediate management should include venous access, blood volume replacement, and supportive care. When stabilized, the patient should be examined, and the source of the bleeding should be determined. Most commonly, massive hemorrhage results from an exophytic cervical cancer eroding into a small cervical or vaginal artery. Prolonged slow vaginal bleeding from an endometrial cancer or sarcoma may also result in a patient presenting with profound chronic anemia. Because the bleeding has been slow over a longer period, the patient has often adapted to the anemia and may be hemodynamically stable despite profound anemia. Biopsy should be performed to document the pathology, and the patient should be evaluated to make a clinical estimation of the extent (stage) of disease.

Control of an actively bleeding cervical lesion is usually accomplished with a vaginal pack applied firmly to the cervix, filling the entire vagina. Monsel's solution (ferric subsulfate) may be put on the portion of the pack abutting the tumor. Soaking of the entire pack with Monsel's solution should be avoided because it will desiccate the normal vaginal mucosa,

making removal of the pack and subsequent pelvic examinations difficult. **Application of acetone to the pack adjacent to the tumor has also been helpful,** although acetone is often difficult to acquire in today's medical environment. An indwelling Foley catheter should be placed in the bladder because pressure from the pack will usually obstruct the urethra. The pack should be removed slowly 24 to 48 hours later, and the patient should be observed. Removal of the pack under anesthesia may provide a level of safety if immediate cautery or repacking was necessary. This would also provide the opportunity to perform an examination under anesthesia and cystoscopy or proctoscopy if indicated. Suturing bleeding points in a cervical cancer is rarely successful because the suture will tear through the tumor.

Pelvic radiation therapy for a patient with locally advanced cervical cancer who is actively bleeding should be initiated immediately. Alternatively, if the patient's cancer is an operable lesion, surgery should be performed expeditiously. In either event, if the patient has received more than 4 units of packed red blood cells (PRBCs), it is prudent to assess coagulation factors because the patient may have developed a "dilutional" coagulopathy and require fresh-frozen plasma (FFP), cryoprecipitate, or platelets.

If bleeding cannot be controlled with packing, other measures must be considered. Consultation with an interventional radiologist should be obtained to **consider arteriographic embolization of the hypogastric or uterine arteries. Arteriographic evaluation will usually identify the specific bleeding vessel, and selective embolization can be accomplished.** Arterial access is usually obtained through the femoral artery, and the catheter is advanced to the aortic bifurcation. Using contrast injected into the artery, the arterial vascular supply of the pelvis can be investigated to identify the specific bleeding site. Both sides of the pelvis should be evaluated. Intravascular contrast can be nephrotoxic and therefore must be used cautiously in patients who have an element of renal failure or who have diabetes. Control of the bleeding site can be accomplished by continuous vasopressin infusion, by embolization using synthetic materials (Gelfoam) or Gianturco springs imbedded with Dacron or with a balloon catheter (Fig. 16.1). Embolization is usually the procedure primarily chosen because the vasopressin infusion and balloon catheters require that the artery remain cannulated for a longer duration.

Hypogastric (internal iliac) artery ligation is usually the procedure of last resort for bleeding from a primary gynecologic cancer and is most commonly performed to control intraoperative hemorrhage. Details of hypogastric artery ligation are discussed later in this chapter.

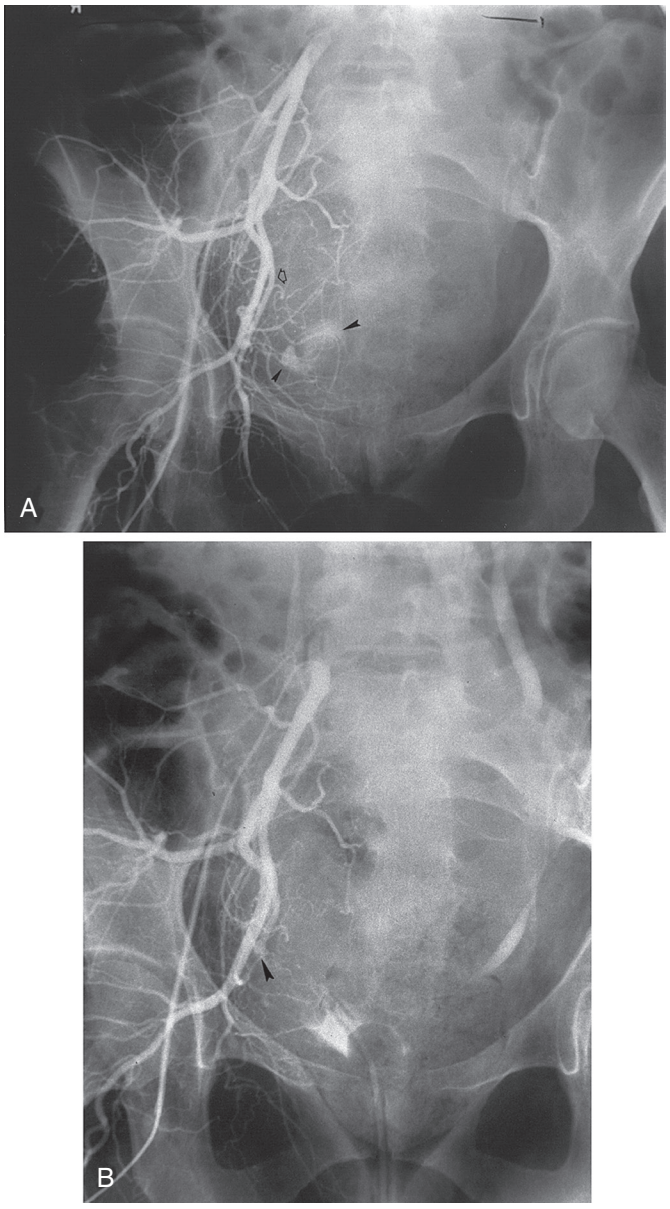

FIGURE 16.1 A patient who is postoperative from a vaginal hysterectomy with significant vaginal bleeding requiring multiple blood transfusions. The patient also has von Willebrand disease. *Arrowheads* represent areas of hemorrhage, resolved after embolization. **A,** Hemorrhage from the internal pudendal artery on the right. **B,** After embolization, no hemorrhage is seen from the internal pudendal artery. Dye in the pelvis is localized to the bladder, and the left ureter can be visualized. (Courtesy of Ivan Vujic, MD, and Keeling Warburton, MD, Medical University of South Carolina.)

Urinary Tract Complications

Ureteral Obstruction

Ureteral obstruction may be the primary presenting symptom of a locally advanced cervical cancer and less commonly other gynecologic cancers, including endometrial and ovarian cancers. **The most common evidence of ureteral obstruction is an elevated serum creatinine level** (rather than complaints of anuria or symptoms of uremia). Of course, acute renal failure may arise from a number of causes, which should be investigated (Table 16.1). **The ureters may be obstructed as a result of local extension of the cancer, by metastases to retroperitoneal lymph nodes, or by extrinsic compression of the ureter by large masses.** Uremia secondary to bilateral ureteral obstruction is rarely encountered today but warrants immediate recognition and treatment. Given evidence of an elevated creatinine, evaluation of the ureters should avoid the use of nephrotoxic

TABLE 16.1 Major Causes of Acute Renal Failure

Disorder	Example
PRERENAL FAILURE	
Hypovolemia	Skin, gastrointestinal, or renal volume loss; hemorrhage, sequestration of extracellular fluid (pancreatitis, peritonitis)
Cardiovascular failure	Impaired cardiac output (infarction, tamponade); vascular pooling (anaphylaxis, sepsis, drugs)
POSTRENAL FAILURE	
Extrarenal obstruction	Urethral occlusion; bladder, pelvic, or retroperitoneal neoplasms; surgical accident; calculi
Intrarenal obstruction	Crystals (uric acid, oxalic acid, sulfonamides, methotrexate)
Bladder rupture	Trauma
ACUTE TUBULAR NECROSIS	
Postischemic	All conditions listed above for prerenal failure
Pigment induced	Hemolysis (transfusion reaction); rhabdomyolysis (trauma, coma, heatstroke, severe exercise, potassium or phosphate depletion)
Toxin induced	Antibiotics; contrast material; anesthetic agents; heavy metals; organic solvents
Pregnancy related	Septic abortion; uterine hemorrhage; eclampsia

intravenous (IV) contrast dyes. A noncontrasted computed tomography (CT) scan of the abdomen and pelvis can demonstrate suspected hydronephrosis and provides the additional benefit of evaluating disease burden. Alternative imaging methods may include ultrasonography of the kidneys or a Lasix-renal scan to access if the kidney remains viable. If bilateral ureteral obstruction is diagnosed, the patient should be rapidly evaluated to determine the true extent of the cancer before any intervention is undertaken. If the cancer appears to be locally advanced and not widely metastatic, **relief of the ureteral obstruction should be attempted by cystoscopy and placement of retrograde ureteral stents. If stent placement is unsuccessful, then percutaneous nephrostomy (PCN) tubes should be inserted.** Dialysis may be necessary in extreme circumstances until the obstruction can be relieved. Postobstructive diuresis and correction of electrolytes should be carefully evaluated in the several days after relief of the ureteral obstruction.

Complications of PCN placement include a high frequency of urinary tract infections (UTIs) and pyelonephritis (70%), catheter occlusion (65%), and bleeding (28%). Seventy percent of the patients will have recovery of renal function after PCN placement (Dudley).

Comment needs to be made on two sets of circumstances in which the physician, patient, and family must seriously consider the possibility that relief of the obstruction may not be in the patient's best interest. These clinical situations include the following:

- A patient who presents with a widely metastatic malignancy for which there is little significant opportunity to provide effective therapy

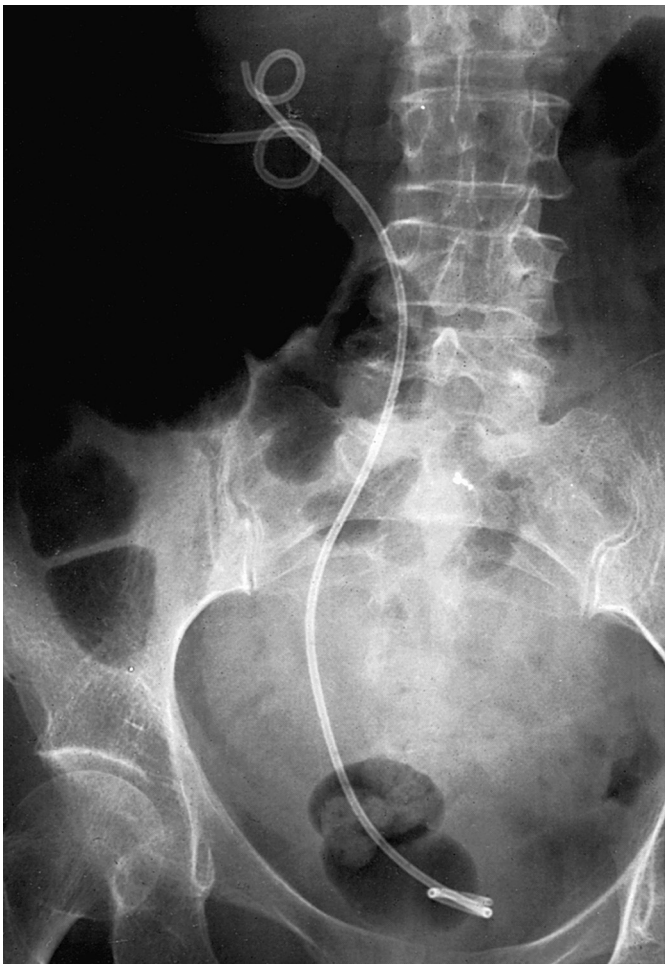

FIGURE 16.2 A double-J stent has been inserted into the right kidney, ureter, and bladder through a percutaneous nephrostomy.

- A patient who has previously been treated for cervical cancer and has bilateral obstruction secondary to recurrent pelvic disease. This is a situation in which there is no therapy available that would significantly prolong the patient's life. Careful evaluation should be made to be certain that the obstruction is not a result of retroperitoneal fibrosis caused by prior radiation therapy or from a lymphocyst.

Often, patients with bilateral ureteral obstruction are uremic and comatose. Decisions regarding intervention and care then fall to the next of kin, who must make the difficult decisions regarding intervention that may reverse the uremia but cause the patient to succumb from other complications of the cancer versus allowing the patient to expire peacefully in a uremic coma. Compassionate and knowledgeable consultation and advice with an experienced gynecologic oncologist are crucial in these difficult circumstances.

Unilateral ureteral obstruction at the time of initial presentation may not require stent or PCN placement if the patient's renal function is normal and therapy (eg, pelvic radiation therapy) is expected to control the cancer and relieve the obstruction. Placement of a PCN or stent in these circumstances must be balanced against the potential complications that might delay or interrupt therapy (Fig. 16.2). A Lasix renal scan

can aid in evaluating the function of the obstructed kidney. If the organ is still viable, placement of a stent to avoid loss of function while awaiting tumor shrinkage from therapy can be helpful.

Urinary outlet obstruction (obstruction of the urethra) by a cancer that has invaded the anterior vaginal wall (vaginal, vulvar, or cervical cancers) may usually be corrected by placement of a Foley catheter. If a Foley catheter cannot be placed, either a suprapubic catheter or PCNs should be considered.

Urinary Tract Fistulas

Vesicovaginal fistula caused by a primary gynecologic cancer is relatively rare and is more commonly caused by therapy. Nonetheless, some patients will present with tumor that has eroded into the bladder, and subsequent loss of integrity between the bladder and vagina results in urinary leakage. Correction of the fistula caused by a cancer cannot be considered until the cancer has been eradicated. In the interim, while cancer therapy is initiated, the patient may be very uncomfortable from the continued loss of urine. Attempts to diminish the leakage should be undertaken. Placement of a Foley catheter will often partially divert urine from the fistula into the catheter. Modified menstrual cups or external appliances to collect urine have been used on occasion with success. Urinary diversion (ileal or transverse colon conduit) may be the only complete solution to profuse vaginal urinary leakage. Performing this major surgery should be weighed against the delay in primary cancer therapy, which would be required while the patient recovers from surgical diversion.

Gastrointestinal Complications

Gastrointestinal Obstruction

Intestinal obstruction as a presenting symptom of a gynecologic cancer is most commonly caused by advanced ovarian cancer. In cases of small intestinal obstruction, initial therapy should include correction of fluid volume and electrolytes, nutritional assessment, and bowel rest. If nausea and emesis continue despite antiemetics, a nasogastric (NG) tube decompression should be placed. Alternatively, an NG tube may be placed immediately if there is significant stomach distention requiring decompression. Assessment of intestinal patency a CT scan with oral contrast should be performed to have a better understanding of the location and extent of obstruction. The colon should also be evaluated to exclude the possibility of colonic obstruction, which would need to be relieved at the same surgical procedure. **In most cases, surgical exploration is necessary to establish and stage the cancer diagnosis, debulk the tumor, and relieve the obstruction.** Small bowel or colonic resection performed to relieve obstruction and to debulk the primary tumor is commonly done. Although patients presenting with gastrointestinal (GI) obstruction may be severely malnourished, the role of preoperative total parental nutrition is debatable. The highest quality evidence suggests that at least 10 days of total parenteral nutrition (TPN) administration is necessary to provide a benefit of reduced postoperative complications.

Short bowel syndrome may result from extensive resection of the small bowel, colon, or both. The syndrome is characterized by frequent diarrhea, fluid and electrolyte depletion, malabsorption, and weight loss. Depending on the extent and location of the intestinal segment(s) resected, malabsorption of nutrients may include copper, zinc, chromium, selenium, essential fatty acids, vitamins A and E, biotin, thiamine, and vitamin B_{12}. Over time, the remaining small bowel often adapts, and fluid and nutrient absorption is improved. However, in the interim, attempts to relieve short bowel syndrome should be directed at decreasing transit time by the use of an "elemental" diet and Imodium or Lomotil, cholestyramine (to decrease irritation of bile salts on the colonic mucosa), and somatostatin (to decrease intestinal digestive fluid production). In extreme cases, support with IV fluids and TPN may be necessary for several months.

On occasion, the preoperative assessment (usually with a CT scan) discovers far advanced disease (extensive carcinomatosis), which would be unlikely to be successfully debulked. In these patients, neoadjuvant chemotherapy, rather than surgical intervention, may be the best option. If this therapeutic strategy is taken, GI decompression (NG tube or gastrostomy) and parenteral nutritional support (TPN) will be required for several weeks while the neoadjuvant chemotherapy has the opportunity to result in a tumor response and relief of the intestinal obstruction. Fortunately, many patients with ovarian cancer will regain intestinal function after two or three cycles of chemotherapy.

Even in the setting of neoadjuvant treatment route, correction of a colonic obstruction is necessary to prevent colonic perforation, peritonitis, sepsis, and death. Management options include placement of an intraluminal stent or surgical intervention. In a recently published experience with gynecologic oncology patients, rates of technical success of stent placement ranged from 75% to 88%; however, clinical success was lower, with more than one-third (33%–38%) of patients with stent placements requiring further intervention for either stent complication or failure. Advantages of stents include the avoidance of major surgery and a stoma. Systematic review of large patient populations beyond gynecologic oncology demonstrate median placement success rates of 96%, with associated risks of perforation (4.5%), stent migration (11%), and reobstruction (12%). In a palliative population, the median duration of patency was 106 days. Alternatively, surgical correction of the colonic obstruction may be considered, with colostomy as a frequent outcome given the disease burden in a neoadjuvant patient. If the patient has an excellent response to subsequent chemotherapy, colostomy take-down in the future is reasonable to consider.

Intestinal obstruction often occurs late in the course of progressive ovarian cancer. In these situations, superb clinical judgment is required to obtain an optimal palliative outcome because not all patients with recurrent ovarian cancer and intestinal obstruction benefit from surgical intervention. It does seem intuitive that patients with colonic obstruction should be either offered a self-expanding stent or undergo surgery to create colostomy, ileostomy, or cecostomy. A patient with a small bowel obstruction requires careful thought and triage. Initially, conservative management with IV fluid and electrolyte replacement and NG tube decompression should be instituted. Some patients may reestablish bowel function with a few days

of "bowel rest." However, if the obstruction persists, the decision to place a gastrostomy tube (which can often be placed percutaneously) or to attempt to surgically relieve the intestinal obstruction must be made. (Of course, a patient who has a small bowel obstruction caused by adhesions should undergo surgery in all cases.) The problem in decision making comes when it is clear that the patient has recurrent ovarian cancer. Many investigators have attempted to identify factors that would predict successful outcome (often defined as surviving 30 days or being discharged from the hospital and able to take oral fluids) or postoperative complications and death. These factors include presence of ascites, poor nutritional status, amount of prior chemotherapy regimens, availability of therapy with some potential for response, prior use of radiation therapy, length of time since prior therapy, and potential for being "platin sensitive." If surgical intervention is deemed appropriate, surgical procedures might include bypass of involved segments of small bowel (entero-enterostomy), bowel resection with anastomosis, or ileostomy. Unfortunately, in every investigator's experience, there are patients who undergo laparotomy only to find such extensive carcinomatosis that they are deemed inoperable. The decision to operate, then, should be based on a clear communication between the surgeon and patient regarding expectations and definitions of "success." In the authors' experience, which is reasonably representative of the general literature, the median survival time after small bowel obstruction surgery was 88 days, and only 14% of patients were alive at 12 months. In addition, 49% of patients had at least one significant postoperative complication, including wound infections, enterocutaneous fistula, sepsis, and recurrent obstruction.

If the decision is made not to operate, further decisions regarding management are also complex, including methods to palliate vomiting (percutaneous gastrostomy is recommended) and whether to continue IV fluids or even consider TPN in a hospice setting.

Gastrointestinal Fistulas

Rectovaginal fistula may be discovered at the time of primary diagnosis of cervical, vaginal, or vulvar cancers. Involuntary loss of feces, flatus, and mucous discharge are the most common symptoms. If the patient has vulvar pain and excoriation, a fistula from the small intestine must be suspected. In this instance, a fistulogram can be helpful if definitive diagnosis of a fistulae is in question, and a CT scan with oral contrast should be performed to define the exact anatomic structures involved. **If a rectovaginal fistula is found, diversion with a loop colostomy or end-colostomy is suggested to divert the fecal stream and allow prompt treatment of the cancer (usually radiation therapy).** If vulvar cancer is so advanced as to cause a rectovaginal fistula, some surgeons manage the cancer and the fistula in the same surgical procedure (eg, a posterior pelvic exenteration and modified radical vulvectomy). Others have had excellent results treating locally advanced vulvar cancer with radiation therapy and concurrent radiosensitizing chemotherapy, thereby preserving the rectal sphincter. Colostomy diversion is still suggested for patient comfort and hygiene. If the cancer treatment is successful, attempts to close the fistula are reasonable, and if successful, the colostomy may ultimately be reversed.

Enterovaginal fistulas are rare to complicate the initial cancer diagnosis and more often occur as a result of complications of therapy (radiation) or at the time of cancer recurrence. **The flow of intestinal contents out of the vagina is usually liquid and caustic to vulvar skin.** Thorough evaluation of the upper and lower GI tracts and the urinary tract is mandatory because many of these fistula are "complex," involving more than one viscus and more than one defect. Surgical intervention is necessary in most cases to either resect or isolate the involved bowel. If resection is not possible, the fistualized bowel will need to be isolated and excluded from the intestinal stream. Because the isolated bowel will continue to create succus entericus and subsequent continued vaginal drainage, resection is generally preferred.

Venous Thromboembolic Complications

Venous thromboembolic complications may precede the diagnosis of gynecologic cancer or may be the result of cancer treatments, especially surgery and chemotherapy. Most women with gynecologic cancers have several risk factors that increase the probability of developing a venous thromboembolic event during their course of therapy.

Risk Factors

The causal factors of venous thrombosis were first proposed by Virchow in 1858 and include a **hypercoagulable state, venous stasis, and vessel endothelial injury.** In addition to the increased risk of venous thromboembolism (VTE) resulting from cancer, other clinical risk factors include advanced age; major surgery; nonwhite race; a history of deep vein thrombosis (DVT) or pulmonary embolism; lower extremity edema or venous stasis changes; presence of varicose veins; being overweight; a history of radiation therapy; and hypercoagulable states, such as factor V Leiden, pregnancy, or use of oral contraceptives, estrogens, or tamoxifen. Intraoperative factors associated with postoperative DVT included increased anesthesia time, increased blood loss, and the need for transfusion in the operating room. It is important to recognize these risk factors in order to provide the appropriate level of venous thrombosis prophylaxis. The modified Caprini risk assessment model for VTE has been widely adopted as a predictive tool for surgical patients. This tool has limited use in the gynecologic oncology population, however. Importantly, nearly all gynecologic oncology patients, by virtue of having a malignancy, being older than 40 years old, with an operative time of more than 45 minutes are in the highest risk group, with a VTE risk of 6% in the absence of prophylaxis.

Prophylactic Methods

Deep vein thrombosis and pulmonary embolism, although largely preventable, are significant complications in women with **gynecologic cancers and especially those who are postoperative.** The magnitude of this problem is relevant to gynecologic oncologists because **40% of all deaths after gynecologic surgery are directly attributed to pulmonary emboli,**

which is also the most common cause of postoperative death in patients with uterine or cervical carcinoma.

A number of prophylactic methods have been shown to significantly reduce the incidence of DVT in women with gynecologic cancers, and a few studies have included a large enough patient population to demonstrate a reduction in fatal pulmonary emboli. The ideal prophylactic method would be effective, free of significant side effects, well accepted by the patient and nursing staff, widely applicable to most patients, and inexpensive. Available prophylactic methods may be divided into pharmacologic agents that reduce hypercoagulable states and mechanical methods that reduce stasis and may also enhance fibrinolysis. A key to the successful use of prophylactic methods is the understanding that women with gynecologic cancers are at very high risk and that more intense prophylactic measures are necessary to achieve maximal success. Based on the American College of Chest Physician Guidelines, all high-risk patients should receive either pharmacologic anticoagulation or combination pharmacologic anticoagulation and mechanical device prophylaxis. In addition, extended prophylaxis after surgery is recommended for patients undergoing major abdominal or pelvic surgery for cancer.

Low-dose heparin. The use of small doses of subcutaneously administered heparin for the prevention of DVT and pulmonary embolism is the most widely studied of all prophylactic methods. More than 25 controlled trials have demonstrated that **heparin given subcutaneously 2 hours preoperatively and every 8 to 12 hours postoperatively is effective in reducing the incidence of DVT.** The value of low-dose heparin in preventing fatal pulmonary emboli was established by a randomized, controlled, multicenter international trial, which demonstrated a significant reduction in fatal postoperative pulmonary emboli in general surgery patients receiving low-dose heparin every 8 hours postoperatively. In gynecologic oncology patients, a randomized trial of heparin given either in a regimen of 5000 units subcutaneously 2 hours preoperatively and every 8 hours postoperatively or 5000 units subcutaneously every 8 hours preoperatively (a minimum of three preoperative doses) and every 8 hours postoperatively was performed. Both of these prophylaxis regimens were effective in significantly reducing the incidence of postoperative DVT in patients with gynecologic cancers. The authors conclude that **in women undergoing surgery for gynecologic malignancy, a regimen of low-dose heparin 5000 units every 8 hours is necessary to provide effective prophylaxis.**

The benefits of unfractionated heparin (UFH) are its rapid onset of action and ability for quick reversal; ability for frequent monitoring with activated partial thromboplastin time (aPTT) levels; and lack of renal metabolism, making it ideal in cases of renal insufficiency or renal failure. The most serious adverse risk of UFH use is the occurrence of heparin-induced thrombocytopenia (HIT). HIT has been found to be associated with low-dose heparin use in 6% of patients after gynecologic surgery, although its overall postoperative risk is considered to be around 1%. If patients remain on low-dose heparin for more than 4 days, it is reasonable to check a daily platelet count for 14 days or until heparin is stopped, whichever comes first. Low-dose heparin is also limited by a narrow therapeutic range, requiring frequent monitoring.

Low-molecular-weight heparins. Low-molecular-weight heparins (LMWHs) are the preferred choice in perioperative pharmacologic prophylaxis. LMWHs are fragments of heparin that vary in size from 4500 to 6500 daltons. When compared with UFH, LMWHs have more anti-Xa and less antithrombin activity, leading to less effect on partial thromboplastin time (PTT) and possibly to fewer bleeding complications. An increased half-life of 4 hours results in increased bioavailability when compared with UFH. The increase in half-life of LMWHs also allows the convenience of once or twice-a-day dosing at 30 to 40 mg/day and can be used in the outpatient setting.

Randomized controlled trials (RCTs) have compared LMWH with UFH in patients undergoing gynecologic surgery. In all studies, there was a similar incidence of DVT. Bleeding complications were similar between the UFH and LMWH groups, and meta-analysis of all studies comparing the incidence of HIT confirmed that HIT is significantly less common with LMWH. A meta-analysis of general surgery and gynecologic surgery patients from 32 trials likewise indicated that daily LMWH administration is as effective as UFH in DVT prophylaxis without any difference in hemorrhagic complications, and these results have been confirmed in cancer surgery populations. Finally, prolonged prophylaxis for 4 weeks postoperatively has resulted in improved outcomes in high-risk surgical populations. In one randomized study of 1113 patients, 4 weeks of treatment after abdominal or pelvic cancer surgery reduced VTE rate from 4.6% to 0.8%, without increased bleeding complications. This extended prophylaxis has been adopted as the standard of care by the American College of Chest Physicians (ACCP), the National Comprehensive Cancer Network, and the American Society of Clinical Oncology.

Oral agents. Investigations into the use of oral agents, specifically vitamin K antagonist warfarin, and a host of newly developed factor Xa inhibitors is ongoing. High-quality randomized trials and investigations in cancer populations have been limited to date, so the agents are not recommended in perioperative VTE prophylaxis at this time.

Mechanical Methods

Stasis in the veins of the legs has been clearly demonstrated while the patient is undergoing surgery and continues postoperatively for varying lengths of time. Stasis occurring in the capacitance veins of the calf during surgery plus the hypercoagulable state induced by cancer and surgery are the primary factors contributing to the development of acute postoperative DVT. Prospective studies of the natural history of postoperative venous thrombosis have shown that the calf veins are the predominant site of thrombi and that most thrombi develop within 24 hours of surgery.

Although probably of only modest benefit, reduction of stasis by short preoperative hospital stays and early postoperative ambulation should be encouraged for all patients. Elevation of the foot of the bed, raising the calf above heart level, allows gravity to drain the calf veins and should further reduce stasis.

Graduated compression stockings. Controlled studies of graduated pressure stockings are limited but do suggest modest benefit when they are carefully fitted. **Poorly fitted stockings may be hazardous to some obese patients who develop a tourniquet effect at the knee or midthigh.** Variations in human anatomy do not allow perfect fit of all patients to available stocking sizes. There is no therapeutic advantage of thigh-length stockings as compared with calf-length stocking. The simplicity of elastic stockings and the absence of significant side effects are probably the two most important reasons that they are often included in routine postoperative care.

External pneumatic compression. The largest body of literature dealing with the reduction of postoperative venous stasis deals with intermittent external compression of the leg by pneumatically inflated sleeves placed around the calf or leg during intraoperative and postoperative periods. **Calf compression during and after gynecologic surgery significantly reduces the incidence of DVT on a level similar to that of low-dose heparin.** In addition to increasing venous flow and pulsatile emptying of the calf veins, external pneumatic compression (EPC) also appears to augment endogenous fibrinolysis, which may result in lysis of very early thrombi before they become clinically significant.

The duration of postoperative EPC has differed in various trials.

External pneumatic compression used in patients undergoing major surgery for gynecologic malignancy has been found to reduce the incidence of postoperative venous thromboembolic complications by nearly threefold but only if calf compression is applied intraoperatively and for the first 5 postoperative days. Patients with gynecologic malignancies may remain at risk because of stasis and hypercoagulable states for a longer period than general surgical patients and therefore appear to benefit from longer use of EPC.

External pneumatic leg compression has no significant side effects or risks and is considered slightly more cost effective compared with pharmacologic methods of prophylaxis. Of course, compliance to wearing the leg compression while in bed is of utmost importance, and the patient and nursing staff should be educated to the proper regimen for maximum benefit. We have investigated the risk factors associated with the failure of external compression to prevent DVT in a retrospective analysis of 1862 consecutive gynecologic surgery patients who received postoperative intermittent pneumatic compression. **A history of prior VTE, diagnosis of cancer, and age older than 60 years were factors independently associated with the development of VTE despite EPC prophylaxis** ($P < 0.05$). Patients having two or more of these factors had a 16-fold increased risk of postoperative VTE despite prophylaxis. In these extremely high-risk patients, of which the majority of gynecologic oncology patients would be categorized, combined methods of prophylaxis (eg, EPC plus low-dose UFH or LMWH) is recommended by the guidelines written by the ACCP. Although there have be no randomized trials on ECP alone versus combination prophylaxis specifically within gynecologic oncology populations, high-quality data from other cancer surgical populations have led to consensus recommendations that we follow. **Mechanical prophylaxis alone should be reserved for perioperative gynecologic oncology patients with unacceptably high bleeding risk.**

Postoperative Prophylaxis

Patients undergoing abdominal or pelvic surgery for malignancy remain at increased risk for development of VTE for an extended period of time after surgery. The administration of LMWH for 4 weeks postoperatively has been consistently shown to decrease development of VTE in this high-risk population. **For all patients undergoing laparotomy for gynecologic cancer surgery, we recommend extended (4 weeks) chemoprophylaxis with LMWH.** Evidence for extended treatment for patients undergoing minimally invasive procedures is less clear. Minimally invasive approaches to hysterectomy are associated with a threefold decreased incidence of VTE. In several retrospective reviews of large ($n \geq 400$) institutional studies, rate of VTE after laparoscopic or robotic hysterectomy has been reported at 0.5% to 1.2%, on par with the risk associated with open benign hysterectomy (0.6%). This suggests extended prophylaxis may not be required for this patient population. Importantly, in one study of 573 cases in which the VTE rate was highest (1.2%), the authors identified a high-risk group of women with a body mass index (BMI) greater than 40 and operative time longer than 180 minutes, who had a VTE rate of 9.5% (4 of 42) compared with 0.6% (3 of 531) of the remaining population. At this time, the authors recommend extended prophylaxis after minimally invasive surgery only for patients with other conferring risk factors (ie, limited mobility, super morbid obesity, history of VTE).

Management of Deep Vein Thrombosis and Pulmonary Embolism

Diagnosis of deep vein thrombosis. Because pulmonary embolism is the leading cause of death after gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic VTE regimens is an essential part of management. In addition, the early recognition of DVT and pulmonary embolism and immediate treatment are critical. **Most pulmonary emboli arise from the deep venous system of the leg, although after gynecologic surgery the pelvic veins are a known source of fatal pulmonary emboli also.**

The signs and symptoms of DVT of the lower extremities include pain, edema, erythema, and prominent vascular pattern of the superficial veins. These signs and symptoms are relatively nonspecific; 50% to 80% of patients with these symptoms do not actually have DVT. Conversely, approximately 80% of patients with symptomatic pulmonary emboli have no signs or symptoms of thrombosis in the lower extremities. Because of the lack of specificity when signs and symptoms are recognized, additional diagnostic tests should be performed to establish the diagnosis of DVT.

Doppler ultrasonography. **B-mode duplex Doppler imaging is currently the most common technique for the diagnosis of symptomatic venous thrombosis, especially when it arises in the proximal lower extremity.** With duplex Doppler imaging, the femoral vein can be visualized, and clots may be

seen directly. Compression of the vein with the ultrasound probe tip allows assessment of venous collapsibility and the presence of a thrombus diminishes vein wall collapsibility. Abnormal Doppler color flow is an additional sign of DVT. It should be recognized that Doppler imaging does not detect isolated iliac vein or proximal femoral thrombosis. In addition, 2% of patients with initially negative studies will develop DVT in the next 7 days. Repeat testing is warranted on any patient where a high suspicion or risk of DVT is present.

Venography. Although contrast venography has been the "gold standard" for diagnosis of DVT, other diagnostic studies have nearly equivalent accuracy when performed by a skilled technologist and, in most patients, may replace the need for this study. Venography is moderately uncomfortable, requires the injection of a contrast material that may cause allergic reaction or renal injury, and may result in phlebitis in approximately 5% of patients. However, if noninvasive imaging is normal or inconclusive and the clinician remains concerned given clinical symptoms, venography should be obtained to obtain a definitive answer.

Magnetic resonance venography. Magnetic resonance venography (MRV) has a sensitivity and specificity comparable to those of venography. In addition, MRV may detect thrombi in pelvic veins that are not imaged by venography. The primary drawback to MRV is the time involved in examining the lower extremity and pelvis and the expense of this technology.

Impedance plethysmography. Impedance plethysmography measures the change in blood volume in the calf from the impedance of a blood pressure cuff after rapid deflation. The measurements are determined by electrodes placed on the calf. When performed appropriately, it has high sensitivity (91%) and specificity (96%) for proximal vein thromboses. However, patients must lie still for 2 minutes for accurate measurements, and skilled personnel are required for performance of the test. For these reasons, this method is not routinely used.

Treatment of deep vein thrombosis. **The treatment of postoperative DVT requires the immediate institution of anticoagulant therapy.** Untreated, symptomatic DVT is associated with a 50% risk of pulmonary embolism, and untreated pulmonary embolism carries a 30% risk of mortality. Treatment may be with either UFH or LMWHs followed by 6 months of oral or subcutaneous anticoagulant therapy. Prolonged anticoagulation (lifetime) is recommended for women who continue to have active cancer (ie, those not in remission after treatment) because they remain at very high risk to rethrombose.

Low-molecular-weight heparin. Low-molecular-weight heparins (eg, enoxaparin, dalteparin) have been shown to be effective in the treatment of VTE and have a cost-effectiveness advantage over IV heparin in that they may be administered in the outpatient setting. The dosages used in treatment of thromboembolism are unique and weight adjusted according to each LMWH preparation. Because LMWH have a minimal effect on activated PTT, serial laboratory monitoring of PTT levels is not necessary. Similarly, monitoring of anti-Xa activity (except in difficult cases or those with renal impairment) has not been shown to be of significant benefit in a dose adjustment of LMWH. The increased bioavailability associated with LMWH allows for twice-a-day dosing, potentially making outpatient management for a subset of patients an option. A metaanalysis involving more than 1000 patients from 19 trials suggests that **LMWH is more effective, safer, and less costly compared with UFH in preventing recurrent thromboembolism.**

Unfractionated heparin. Unfractionated heparin may be the initial treatment of choice in a recent postoperative patient or other clinical settings in which a significant bleeding risk is appreciated and the need for immediate reversal may be evident. An initial bolus is given intravenously followed by a continuous infusion adjusted to therapeutic aPTT levels. Weight-based nomograms to aid in appropriate dosing are widely available and often embedded in hospital pharmacy administration processes.

Long-term anticoagulation. Traditionally, oral anticoagulation with warfarin was used in the long-term treatment of DVT in cancer patients. Warfarin may be a difficult drug to administer to some patients, however, especially if their nutrition is inadequate, their oral intake is variable, or they require prolonged use of antibiotics or other drugs that might alter the metabolism of warfarin. This is particularly common in women with advanced ovarian cancer. Given the wide variation in the international normalized ratio (INR) in many of these patients who are then predisposed to either bleeding complications or rethrombosis, we have found that it is safer to use subcutaneous LMWH (at therapeutic doses) for prolonged therapy. This clinical experience has been confirmed in a number of large, high-quality, RCTs that have demonstrated the superiority of LMWH over warfarin in the clinical setting. In each study, LMWH resulted in equal or reduced risk of recurrent DVT, with no increase in bleeding events, major or minor. In addition, two trials demonstrated a mortality benefit with LMWH over warfarin. Meta-analyses including these studies have supported these results, including one study with seven RCTs and 1908 cancer patients that demonstrated a hazards ratio of 0.47 (95% confidence interval [CI] 0.3–0.7) for reduction of recurrent DVT. **The authors therefore recommend LMWH as the first-line therapy for long-term treatment of DVT in gynecologic cancer patients.**

Oral anticoagulants. If oral anticoagulation must be used (eg, patient refuses daily injections, previous history of HIT), a vitamin K antagonist such as warfarin is preferred over no therapy. The conversion from parenteral heparin or LMWH to oral warfarin may start on the initial day of therapy. The change in INR resulting from warfarin administration often precedes the anticoagulant effect by approximately 2 days, during which time low protein C levels are associated with a transient hypercoagulable state. Therefore, both heparin and warfarin are given, and the heparin is discontinued when the warfarin has reached a therapeutic INR of 2 to 3 for 2 consecutive days. Patients should be cautioned to avoid the use of drugs and dietary products that might alter the metabolism or absorption of warfarin.

New agents such as direct thrombin or factor Xa inhibitors that have been approved for the treatment of acute DVT have not been well tested in cancer populations. Given the significant impact of surgery, chemotherapy, and radiation on a patient's

nutrition, performance status, and comorbid conditions, the authors do not believe there is sufficient data to support the use of the medications over warfarin. Their use is best restricted to scenarios when co-management with a hematologic specialists is available.

Inferior vena cava filter. In the gynecologic oncology population, acute DVT may often be diagnosed in the immediate pre- or postoperative setting, when pharmacologic anticoagulation is contraindicated because of bleeding risks. In these cases, placement of a retrievable (ie, temporary) inferior vena cava (IVC) filter is an alternative strategy to reducing the risks associated with DVT. The filter can remain in place until bleeding risks decrease, at which time the patient should be started on an appropriate anticoagulation regimen. Filter retrieval is associated with a high technical success rate (85%) and should be pursued given that long-term filter placement is associated with IVC thrombosis, increased recurrent DVT, and the potential for filter migration.

Diagnosis of pulmonary embolism. Many of the signs and symptoms of pulmonary embolism are associated with other, more commonly occurring pulmonary complications after surgery. The classic findings of pleuritic chest pain, hemoptysis, shortness of breath, tachycardia, and tachypnea should alert the physician to the possibility of a pulmonary embolism. Many times, however, the signs are much more subtle and may be suggested only by a persistent tachycardia or a slight elevation in the respiratory rate. Several diagnostic algorithms have been devised to aid in estimating the likelihood of pulmonary embolism before definitive imaging, such as the Wells or Geneva scoring systems. Interestingly, these algorithms have been compared against physician clinical estimations in a meta-analysis of 52 studies including 55,268 patients. Clinical acumen indeed has comparable sensitivity (0.85 vs. 0.84–0.91) to structured diagnostic algorithms when both are combined with D-dimer testing. Patients with suspected pulmonary embolism can be evaluated initially by chest radiography, electrocardiography, and arterial blood gas assessment. However, a high clinical suspicion or high likelihood based on diagnostic algorithms should prompt immediate spiral CT scan of the chest for definitive diagnosis. **Any evidence of abnormality should be further evaluated by spiral CT scan of the chest if renal function permits. Ventilation-perfusion lung scan is an option in the setting of renal insufficiency or failure,** although, a high percentage of lung scans may be interpreted as "indeterminate." In this setting, careful clinical evaluation and judgment are required to decide whether pulmonary arteriography should be obtained to document or exclude the presence of a pulmonary embolism.

The treatment of pulmonary embolism is similar to that of acute DVT in the hemodynamically stable patient. UFH, LMWH, or fondaparinux are all initial parental anticoagulation treatment options. Recommendations from the ACCP currently favor LMWH or fondaparinux for initial treatment, although UFH may be more prudent for the gynecologic oncology patient for whom a perioperative status or high disease burden often confers a bleeding risk requiring easy reversal of anticoagulation method. Hemodynamically unstable patients require immediate care in an intensive care unit (ICU) and assessment for thrombolytic therapy (eg, recombinant tissue type plasminogen activator, streptokinase) or embolectomy if thrombolysis is contraindicated.

Superior vena cava syndrome. **Superior vena cava syndrome is caused by advanced cancers arising in or invading the mediastinum, subsequently obstructing the venous drainage of the head, neck, and upper thoracic regions.** Primary tumors are most commonly the cause of this syndrome (bronchogenic carcinomas), although metastasis to the mediastinum from gynecologic cancers can also present in this manner. **The vena cava has a low intravascular pressure and is easily compressed by adjacent masses.** Most commonly, the symptoms caused by venous obstruction are dramatic swelling and plethora of the head, neck, upper extremities, and chest. Pleural and pericardial effusions can occur with decreased venous return to the heart and a resultant decrease in cardiac output. Patients also commonly complain of a severe headache. A similar clinical syndrome is also seen associated with thrombosis of the subclavian vein and superior vena cava, which is induced by central venous catheters. The diagnosis of the cause of superior vena cava syndrome is critical to selecting proper management. **If a localized primary or metastatic neoplasm is identified, immediate radiation therapy is usually the most effective method to achieve resolution.** Radiation therapy to the mediastinum in doses of 400 cGy for 3 days and then 150 to 180 cGy per day for a total dose of 3000 to 5000 cGy has been successful in relieving the vascular obstruction. **Responses are commonly recognized in 3 to 4 days.** Chemotherapy may also play a role, although the resolution of symptoms is usually much slower. Expandable wire stents across the constricted portion of the vena cava have also been used successfully.

In patients in whom thrombosis is the etiology of venous obstruction, immediate anticoagulant therapy should be instituted (Fig. 16.3). The edema and plethora will usually diminish in 1 to 3 days. In many instances, the central venous catheter may be left in place and used. However, if the condition persists or recurs, the catheter should be removed.

Biliary Obstruction

Obstruction of the biliary tree by gynecologic cancers is rare and is usually associated with far advanced cancers and limited life expectancy. Nonetheless, the resulting jaundice and pruritus caused by the obstruction is distressing to the patient and her family. Surgical relief of the obstruction is usually impossible because of the extent of cancer involvement in the region. However, **endoscopic placement of a stent in the common duct often will resolve the symptoms and provide a better quality of life.** If a stent cannot be placed as a result of extreme compression or other technical reasons, percutaneous placement of a drainage tube into the dilated biliary tree will also resolve symptoms.

Metastatic adenopathy high in the paraaortic chain resulting in biliary obstruction can commonly obstruct the duodenum, leading to gastric outlet obstruction. Although surgical intervention (gastrojejunostomy) or self-expanding metal stents may correct the anatomic problem, careful consideration should

FIGURE 16.3 Extensive thrombosis of large vessels in the thorax. Multiple collaterals are present. The subclavian catheter is evident *(arrow)*.

be given to the patient's life expectancy. These are similar considerations to those made in women with small intestinal obstructions and recurrent ovarian cancer discussed previously. In women with just days or weeks to live, placement of a gastrostomy tube may be more prudent.

TREATMENT-RELATED COMPLICATIONS

Surgical

Intraoperative and Postoperative Hemorrhage

Intraoperative management of vascular complications. Surgery for gynecologic cancer often requires extensive dissection in the retroperitoneal space, which may be distorted by cancer metastatic to lymph nodes or invading adjacent structures. It is not surprising, then, that injury to pelvic veins and arteries is common and may result in significant intraoperative blood loss and hemorrhage. Surgeons must be prepared for this eventuality and have in their armamentarium the tools and skills to bring a stop to the bleeding.

Before attempting to bring final control to a significant bleeding area, a few basic principles should be used. First, the patient's blood volume and coagulation factors must be maintained at all times. Poor communication between the surgeon and the anesthesiologist can lead to significant hypovolemia and cardiovascular instability. Frequent serial laboratory assessments are critical in this setting. Loss of coagulation factors during intraoperative hemorrhage results in continued bleeding that cannot be controlled by surgical means. The surgeon should pack the involved area to allow replacement of blood volume (PRBCs), coagulation factors (FFP, platelets, and cryoprecipitate), and acquisition of appropriate assistance. When the patient is stable and the team is fully prepared, the packed area should be exposed a small area at a time to identify the specific bleeding site.

Before attempting to control the bleeding point, the adjacent anatomy should be identified and protected. In particular, the ureter, adjacent vessels, and viscera must be recognized to avoid further injury. **In most cases of arterial bleeding, the artery can be isolated and controlled with sutures. Small arteries may be best controlled by vascular clips, but larger arteries may require sutures with 4-0 or 5-0 vascular suture** (Prolene). This holds for injury to the aorta and common and external iliac arteries. Injury to the internal iliac (hypogastric) artery may be controlled with total ligation of the artery. Patency of distal arteries should be confirmed throughout the remainder of the procedure and postoperatively. In rare instances, arterial injuries must be managed by vascular grafting.

Venous bleeding in the pelvis is probably more common given the fragility of the thin vein wall and the extensive network of pelvic venous plexus. **Often a specific bleeding point cannot be identified but, after several minutes of direct pressure on the bleeding area, a clot will form over the low-pressure veins, and the bleeding will resolve. If it does not, control will have to be achieved with vascular clips, clamps, and suture ligature.** Slow but persistent oozing from unidentified vessels can often be controlled by products that either serve as a matrix for clotting (Avitene, Surgicel, Gelfoam) or supply clotting factors that complete the clotting cascade (CoSeal, TISSEEL, FLOSEAL). After application of any of these products, pressure should be applied to the site for 5 minutes and then the site should be reevaluated. If bleeding has not been controlled, it may be necessary to place a pack and transfer the patient to an ICU. In all cases, **it should be emphasized that prompt replacement of clotting factors provided by transfusion of FFP and platelets is critical to achieve hemostasis in the face of hemorrhage.**

Replacement of platelets and clotting factors in patients with massive transfusion and microvascular bleeding is dependent on clinical and surgical assessments. Guidelines have been provided by the American Society of Anesthesiologists task force regarding replacement of these products. In general, platelet transfusion is rarely indicated for counts greater than 100,000/μL and usually indicated for counts less than 50,000/μL (with intermediate platelet counts 50,000/μL to 100,000/μL, transfusion should be based on the risk of bleeding). FFP therapy is indicated in massively transfused patients with microvascular bleeding or hemorrhage if the prothrombin time (PT) or aPTT values exceed 1.5 times the normal values. In cases of massive intraoperative blood loss, it may be prudent to administer FFP empirically. This strategy is aimed at preventing the patient from becoming hypocoagulable while awaiting the laboratory results (PT and PTT), which may take nearly an hour and another hour to thaw the FFP before it is available to be administered. Cryoprecipitate transfusions are recommended for correction of microvascular bleeding in massively transfused patients with fibrinogen concentrations less than 80 to 100 mg/dL. **For trauma patients with massive blood loss, on the order of 30% to 40% of their blood volume, a transfusion ratio of 1:1:1 for PRBCs, FFP, and platelets has been consistently reported to be associated with decrease in death**

caused by hemorrhage. If surgical bleeding has taken on this level of severity, such a massive transfusion protocol should be initiated.

Bleeding from the sacrum is usually not encountered except in the course of performing a total pelvic exenteration or rectosigmoid resection or during a sacral-colpopexy. **If bleeding from the sacrum cannot be controlled by suture ligatures or vascular clips, placement of sterile thumbtacks pushed into the sacral bone will usually compress veins exiting the sacrum and achieve hemostasis.**

Hypogastric (internal iliac) artery ligation. When the usual steps to control hemorrhage have failed, hypogastric artery ligation should be performed. Although the arterial blood supply to the pelvis is rich with anastomosis, ligation of the hypogastric arteries will usually decrease the arterial and venous pressure to the point at which (in a patient who is not hypocoagulable) venous bleeding will slow and can either be controlled by ligature or will clot with prolonged packing.

To safely perform hypogastric artery ligation, the vascular anatomy must be exposed, and adjacent structures, especially the ureter, must be identified. A retroperitoneal approach should be taken. The peritoneum overlying the psoas muscle (lateral to the external iliac artery) should be incised parallel to the artery. As the peritoneum is mobilized medially, the external iliac artery will first be identified. Dissection cephalad along the external iliac artery will identify the common iliac artery and the bifurcation of the internal iliac artery. **Invariably, the ureter crosses the pelvic brim at the bifurcation of the common iliac artery.** At this location, the ureter will be identified attached to the medial peritoneum. Further opening of the retroperitoneal space keeping the iliac vessels lateral and the ureter medial will create the pararectal space and further expose the internal iliac artery. Be aware that the common external and internal iliac veins lie just beneath their respective arteries. Without clear identification of these veins, injury can occur, which will further complicate the procedure. The hypogastric artery bifurcates into an anterior and posterior branch 2 to 3 cm from its origin from the common iliac artery. Because most bleeding arises from the blood supply from the anterior division, the anterior branch should be ligated if at all possible. (Ligation of the posterior branch increases the risk of buttock pain and potential necrosis of the gluteus.) A right angle clamp should be carefully passed from lateral to medial beneath the hypogastric artery. A heavy suture (eg, 0-silk) should be used to ligate the artery (Fig. 16.4). There is no reason to transect the artery between two ligatures. It is usually best to perform bilateral hypogastric artery ligation as the collateral blood supply crosses over the midline.

Finally, if all methods to control hemorrhage have been unsuccessful, the bleeding site should be packed firmly, and the abdomen should be closed. The patient should be taken to the surgical ICU and stabilized. Central monitoring and blood product replacement should be the primary focus of management. After the patient is stabilized, attempts at angiographic embolization should be considered. Ultimately, after 24 to 48 hours, the patient should be returned to the operating room and reexplored and the pack removed carefully. Surprisingly, many times the bleeding will have stopped as a result of compression of the injured veins and correction of the hypocoagulable state.

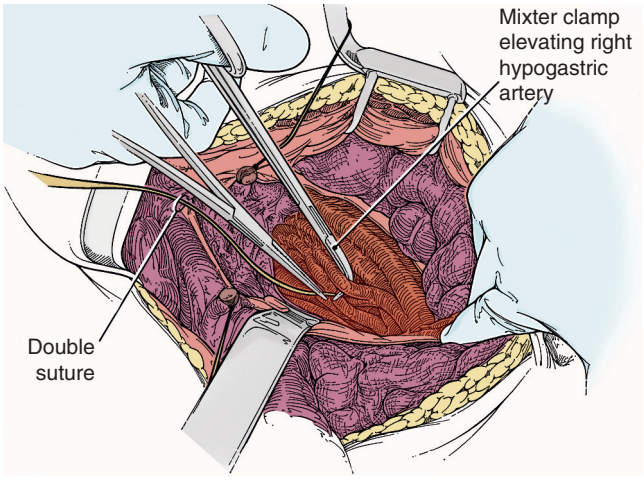

FIGURE 16.4 Technique for intraoperative ligation of the hypogastric artery. The ligature is placed 2 to 3 cm below the bifurcation so that the posterior branch will not be ligated. The clamp is passed lateral to medial to prevent trauma to the internal iliac vein. (From Nichols DH, Clarke-Pearson DL, eds. *Gynecologic, Obstetric and Related Surgery*, 2nd ed. St. Louis, 2000, Mosby.)

Management of shock. During and after gynecologic surgery, blood-volume deficit that results from intraoperative blood loss or postoperative hemorrhage is the most common cause of shock. **This shock usually is manifested by arterial hypotension, tachycardia, a weak pulse, anxiety, skin pallor, diminished urinary output, and peripheral vasoconstriction.** In addition to hemorrhage (hypovolemic shock), the differential diagnosis of shock must include many other causes, such as cardiogenic (myocardial infarction) and cardiac compressive conditions (cardiac tamponade or pneumothorax), sepsis, drug overdose, and pulmonary embolism. Appropriate studies are dictated by the patient's signs and symptoms.

Consideration should be given to obtaining arterial blood gas analysis, an electrocardiogram, a chest radiograph, blood chemistry studies, and blood cultures. The patient should be prepared for blood transfusion. The degree and duration of postoperative shock determine the need for resuscitation, central venous pressure monitoring, and Swan-Ganz pulmonary artery catheterization.

Resuscitation of a hemorrhaging patient during or after gynecologic surgery involves stabilization of the hemodynamic status and correction of the cause of the blood loss. When the hemorrhage is massive, fluid, electrolyte, and hemodynamic shifts are likewise massive. Central to stabilization efforts are the replacement and maintenance of adequate intravascular volume.

Central monitoring. Invasive cardiovascular monitoring may be lifesaving for patients with massive hemorrhage or patients who are at additional risk because of preexisting cardiopulmonary disorders. The monitoring allows the rational use of fluids and cardioactive medications while avoiding their complications.

In patients with marked hemodynamic instability, peripheral artery cannulation allows continuous monitoring of systemic arterial pressure and ready access to obtain repeated analysis of arterial blood gases. The radial artery is usually chosen because of accessibility and has good collateral circulation, although the brachial and femoral arteries may be used. The complications of arterial cannulation include catheter-related septicemia (4% in one large study), local infection (as high as 18%), and arterial embolization (0.2%–0.6%).

In patients without cardiopulmonary disease, monitoring of central venous pressure along with monitoring of the vital signs, urine output, and other clinical signs usually provide sufficient information for appropriate fluid resuscitation. In addition, central venous pressure monitoring avoids several of the complications of a pulmonary artery (Swan-Ganz) catheter.

A central venous catheter may be introduced into the great intrathoracic veins by way of the antecubital, external or internal jugular, or subclavian veins. Cannulation of the right internal jugular vein, which provides a straight course to the right atrium, has the lowest overall complication rate. In all cases, a chest radiograph should be obtained immediately after catheter insertion to confirm proper location and to assess for possible pneumothorax.

The usefulness of the Swan-Ganz catheter in critically ill patients (even those without heart disease) who do not respond to therapy based on an initial noninvasive assessment is primarily limited to its use as a diagnostic monitoring tool. Several randomized trials, including those of high-risk surgical patients, have confirmed that there is no mortality benefit to use of the Swan-Ganz catheter. It does provide additional diagnostic information concerning unsuspected cardiac dysfunction, pulmonary artery embolization, or sepsis. Patients without primary myocardial insult but with hypotension and evidence of inadequate perfusion of vital organs (eg, oliguria, acidosis, mental obtundation) can be managed with more information (Table 16.2).

In patients with cardiac or pulmonary disease, cardiac output and resistance measurements allow the proper use of pressors, afterload and preload reducers, and fluids. In addition, if sepsis is part of the clinical picture, careful monitoring of pulmonary capillary wedge pressures may be necessary to prevent pulmonary edema, which is seen with even mild increases in left atrial pressures as a result of the increased permeability of the pulmonary vascular bed. This increased permeability also may be seen in patients in hypovolemic shock, again leading to pulmonary edema at relatively normal wedge pressures. Finally, invasive monitoring not only provides a direct measurement of cardiac function but also provides information within minutes about the effects of therapy.

These catheters may be placed from the antecubital fossa, although the percutaneous subclavian or internal or external jugular vein approaches are more commonly used. Complications of pulmonary artery catheters include pulmonary infarction distal to the catheter (1%–2% of cases), pulmonary artery rupture (0.2% of cases), balloon rupture (3% of cases), and sepsis (2% of cases), all of which are made more likely by prolonged use of the catheter.

TABLE 16.2 Hemodynamic Calculations*

Parameter	Formula	Normal Range
MAP	⅓ (SBP – DBP) + DBP	0.70–105 mm Hg
CO	Heart rate × Stroke volume	1.4–8 L/min
Cardiac index	CO/body surface area (m^2)	2.5–4 L/min/m^2
SVR	MAP – (Right arterial pressure/CO)	0.10–20 U
Pulmonary vascular resistance	PAP† – (PCWP/CO)	1.1–3 U

*Stroke volume can be derived from cardiac output (CO) and heart rate. Resistance is derived from a relative change in pressure on each side of the circuit from which resistance is to be measured.
†PAP = (2 [Pulmonary SBP] + Pulmonary DBP)/3.
DBP, Diastolic blood pressure; *MAP,* mean arterial pressure; *PAP,* mean pulmonary artery pressure; *PCWP,* pulmonary capillary wedge pressure; *SBP,* systolic blood pressure; *SVR,* systemic vascular resistance.

Intraoperative Genitourinary Injuries

Given the close anatomic relationships of the gynecologic organs and the urinary tract, ureteral and bladder injury are to be anticipated, even in the hands of the most skilled surgeon. Prevention of urinary tract injury is predicated on the identification of the key urinary tract structures before embarking on radical or extended surgery for gynecologic cancers. Retroperitoneal exploration by opening the lateral retroperitoneal spaces (pararectal and paravesical spaces) allows for identification of the ureter and lateral bladder (and key vascular structures). If the medial pelvic peritoneum requires resection, the ureter must be detached from the peritoneum and mobilized laterally (ureterolysis). The ureter may be dissected throughout its entire pelvic course to the bladder, although between the uterine artery crossing the ureter and the insertion of the ureter into the bladder, techniques similar to those required for a type II or III radical hysterectomy will need to be used. Identification of the bladder is usually not a problem; however, because of anatomic distortion by advanced cancer, radiation therapy, or extensive adhesions from prior surgery, the bladder sometimes is not easily recognized. One simple method to identify the bladder is to fill it retrograde through the indwelling Foley catheter. With the bladder distended, dissection of the uterus or tumor from the bladder may be facilitated. Opening the retropubic space (space of Retzius) and the paravesical space also facilitates identification and protection of the bladder.

Injury to the bladder is usually easily corrected at the time of surgery. Incisions in the dome of the bladder should be closed in two layers with 3-0 or 2-0 delayed absorbable suture. The bladder should be allowed to heal by leaving the Foley catheter to dependent drainage for approximately 5 days. Cystotomies at the base of the bladder have a higher risk of fistula formation and ureteral occlusion. Furthermore, they may be more difficult to recognize. **Whenever there is concern about potential bladder injury, the bladder should be filled in a retrograde fashion with either sterile infant formula or indigo carmine–dyed saline.** The authors prefer infant formula because the formula does not stain tissues and potentially

obscure the site of injury. After the cystotomy in the base of the bladder is identified, it is important to assess the location of the ureteral orifices. This may be accomplished by cystoscopy or by opening the dome of the bladder and directly visualizing the orifices. The administration of IV indigo carmine may aid in the identification of the orifices. Closure of the cystotomy should again be accomplished using two layers of delayed absorbable suture. **If the cystotomy is near the ureteral orifice, retrograde placement of a stent is prudent to ensure that there is no occlusion or narrowing of the ureter.** If the pelvis has been previously radiated, the authors recommend placement of an omental J-flap between the bladder and the vaginal cuff to bring a new, nonirradiated blood supply into this area. The Foley catheter should be left to drain for several weeks, and a cystogram should be obtained before the decision to remove the catheter.

Injury to the ureter as it passes through the pelvis may be managed by several methods depending on the location and extent of the injury. Ureteral injury above the pelvic brim is usually best managed by end-to-end anastomosis over a ureteral stent (Fig. 16.5). Injury below the pelvic brim may be best corrected by a ureteroneocystostomy with psoas hitch or a Boari flap (Fig. 16.6). In either method of repair placement, a closed suction drain in the pelvis is advised to prevent a urinoma from a leak of the anastomosis.

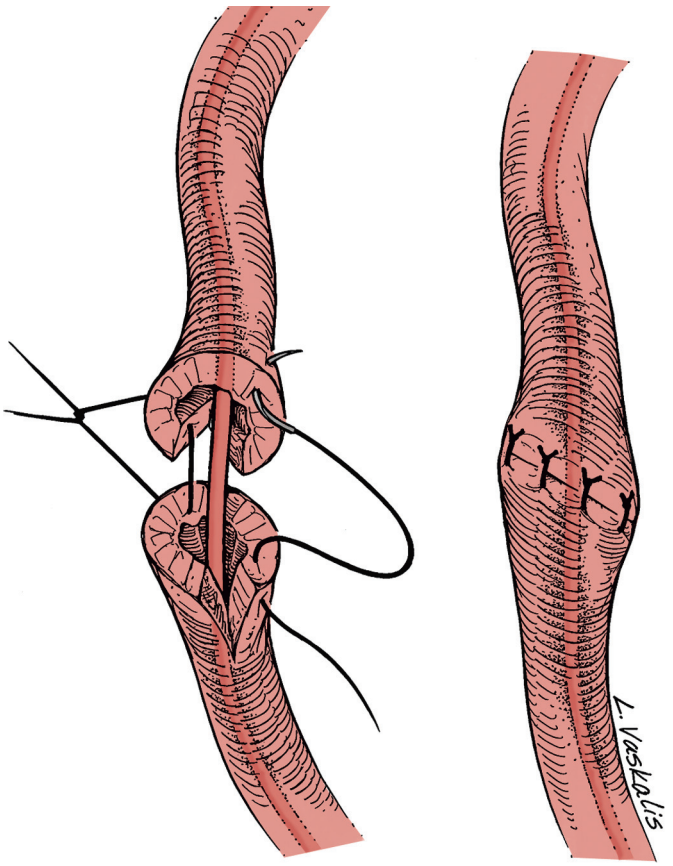

FIGURE 16.5 Ureteral injury at the pelvic brim repaired with an ureteroureterostomy using interrupted 4-0 delayed absorbance sutures. The ureter is spatulated to achieve a larger lumen at the anastomosis. The anastomosis is done over a ureteral stent, and the area is drained with a suction drain. (From Nichols DH, Clarke-Pearson DL, eds. *Gynecologic, Obstetric and Related Surgery*, 2nd ed. St. Louis, 2000, Mosby.)

In cases of suspected injury to the ureter, IV indigo carmine should be injected, and the pelvis should be inspected for spill of dye-colored urine. If the extent of ureteral injury is a clamp crush or ligature, placement of a ureteral double-J stent left in place for 6 weeks will usually allow the injured ureter to recover and at the same time prevent ureteral stricture.

Postoperative Urinary Tract Injury

Unless bilateral ureteral obstruction has been caused by surgery, most patients with postoperative anuria or severe oliguria will have these findings secondary to prerenal hypovolemia, which will resolve with hydration and diuresis. **However, unilateral ureteral injury may not be recognized until several days postoperatively, manifest by flank pain, pyelonephritis, or a slight rise in serum creatinine.** The volume of urinary output is rarely altered. When postoperative ureteral obstruction is suspected, evaluation may include intravenous pyelography (IVP) or CT scan with contrast (when the serum creatinine level is normal) or with a renal ultrasound or Lasix renal scan. **If ureteral obstruction is discovered, initial management should include cystoscopy with retrograde stent placement.** If successful, the obstruction is likely a result of tethering from nearby sutures or extrinsic compression from a mass (hematoma, lymphocyst, tumor). Leaving the stent in place for 6 weeks and then reevaluating with follow-up IVP is recommended. If a stent cannot be placed, however, consideration should be given to reexploration to correct the obstruction. If reoperation is not reasonable, a PCN tube should be placed.

Urinary tract fistulae are recognized complications of radical hysterectomy for the primary treatment of cervical cancer, with recent estimates at just over 1% incidence. It is thought that the extensive dissection of the distal ureter and base of the bladder may lead to ischemic necrosis and the development of a vesicovaginal or ureterovaginal fistula. In contemporary reports, these fistulas occur in only 1% to 3% of cases. The risk of fistula is increased when surgery is performed after prior pelvic radiation therapy.

Vaginal leakage of fluid during the first 10 weeks postoperatively is an ominous finding and requires evaluation for a urinary tract fistula. Confirming the presence of a fistula and, if present, identifying the location are the next priorities. Clinic-based examinations include retrograde filling of the bladder with dyed (eg, indigo carmine) saline and inspection of the vaginal vault for vesicovaginal fistula and administration of IV indigo carmine or oral pyridium with vaginal inspection for ureterovaginal fistula. Both of these methods do carry false-negative risks, and even if negative, in cases of continued vaginal leakage, a definitive CT scan with IV contrast (CT urogram or CT of the abdomen and pelvis with delayed phase contrast) should be obtained. Acute vesicovaginal fistula should be managed by decompression of the bladder by placement of an indwelling Foley catheter to allow continuous drainage. This management often allows the fistula to close spontaneously. If a ureterovaginal fistula is discovered, a ureteral stent should be

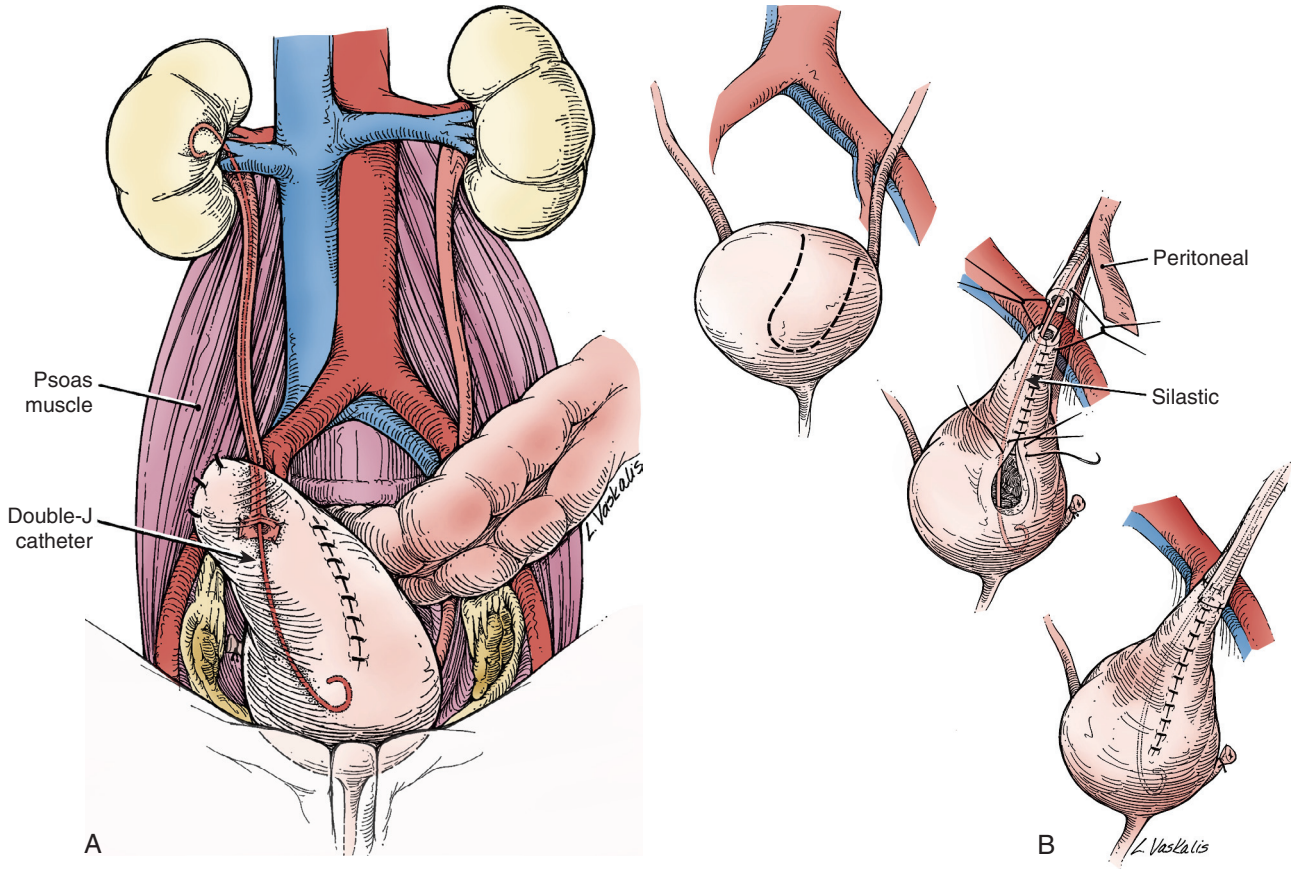

FIGURE 16.6 **A,** Ureteroneocystostomy with psoas hitch. The bladder is mobilized and sutured to the psoas muscle at the pelvic brim near the site of planned ureterovesical anastomosis. **B,** Boari flap. A flap from the dome of the bladder is created and "rolled" into a tube to substitute for the absent distal ureter and to reach the proximal ureter, which is reanastomosed. In either procedure, the area should be drained by closed suction. (From Nichols DH, Clarke-Pearson DL, eds. *Gynecologic, Obstetric and Related Surgery*, 2nd ed. St. Louis, 2000, Mosby.)

placed across the section of ureter that is fistualized. The stent may be placed retrograde at the time of cystoscopy or antegrade via a PCN. This usually allows the ureteral injury to heal "over" the stent. Throughout attempts at conservative management, prevention of UTI is an important priority. If after 6 weeks of conservative management the vesicovaginal or ureteral fistula has not resolved, surgical correction will be required.

Bladder Dysfunction After Radical Surgery

Voiding dysfunction after radical hysterectomy is commonly recognized and should be discussed in the preoperative informed consent. The exact frequency of occurrence depends on how the problem is diagnosed (patient report vs. prospective urodynamic testing) but occurs to a greater or lesser degree in nearly all patients. It is clear that a less radical hysterectomy (type I or II) is associated with a significantly lower incidence of bladder dysfunction as compared with the traditional radical (type III) hysterectomy.

Serial cystometric studies of patients undergoing radical hysterectomy have defined the natural history of bladder function in the perioperative period. **There is a nearly uniform development of detrusor hypertonia characterized by low capacity, high resting tone, and high filling pressure in the immediate postoperative phase.** Bladder insensitivity to filling is also present. The patient often has difficulty initiating her stream and may have overflow incontinence when the capacity is exceeded. **Hypertonia generally subsides within 3 to 6 months,** but other abnormalities often persist for years. The duration of bladder dysfunction is also variable, with extremes recognized as full recovery of bladder function to the rare patient who will require lifetime intermittent self-catheterization to achieve adequate bladder drainage. Many patients have persistent decrease in bladder sensation or prolonged urinary hesitancy.

The pathophysiologic mechanism of voiding dysfunction after radical hysterectomy is still not clearly understood. Some investigators have proposed that incomplete innervation of the bladder produced a temporary parasympathomimetic predominance that usually resolves with nerve regeneration. The use of parasympatholytic drugs, however, has been ineffective in altering the detrusor muscle function in this circumstance. Forney and colleagues have suggested that disruption of the sympathetic fibers that travel through the paracervical web results in loss of inhibition for the detrusor and trigone, leaving

an uncoordinated parasympathetic dominance. This is supported by the observation that incomplete division of the cardinal ligament results in decreased postoperative detrusor hypertonia compared with complete division.

It also seems clear that overdistention of the bladder aggravates bladder dysfunction. Therefore, a variety of techniques have been proposed to avoid overdistention, including short- or long-term use of a urethral Foley catheter, suprapubic catheter, or intermittent self-catheterization. All techniques have their proponents and varying degrees of success, but none has been proven to be superior.

Intraoperative Gastrointestinal Injuries

A mechanical bowel preparation with preoperative oral antibiotics (eg, erythromycin and neomycin) should be planned for all patients undergoing major abdominal surgery for which bowel surgery is anticipated. Several retrospective and prospective cohort studies of patients undergoing colorectal resection for colon cancer consistently demonstrate decreases in surgical site infection, anastomotic leak, and ileus in patients receiving both mechanical and antibiotic preparation. In a prospective cohort study of over 1500 patients, mechanical preparation plus oral antibiotics resulted in lower infection (4.6% vs. 12.4%; $P < 0.001$) and lower rate of ileus (3.8% vs. 8.9%; $P = 0.006$) compared with mechanical preparation alone. Additionally, researchers using a national surgical quality database of more than 8000 patients found that surgical site infection (6.1% vs. 12.0% vs. 14.3%), anastomotic leak (2.0% vs. 3.6% vs. 4.5%), postoperative ileus (9.1% vs. 12.1% vs. 15.1%), and 30-day mortality rate (0.4% vs. 0.6% vs. 1.5%) were all reduced in the dual prep method versus mechanical preparation alone versus no preparation. It should be noted that all patients in these studies also received parenteral antibiotics, confirming the additional benefit of the dual preparation. Bowel preparation may also reduce the risk of intraoperative intestinal injury, and if injury does occur, spill of GI contents can be minimized. Mechanical methods to prepare the bowel include the use of cathartics such as magnesium citrate or the ingestion of 4 L of polyethylene glycol (GoLYTELY).

Prior abdominal surgery and radiation therapy increase the probability of intraoperative injury to the small intestine. Adhesions to the anterior abdominal wall or small intestines adherent to the pelvic peritoneum increase the risk of entry into the intestines as adhesions are lysed. Interruption of the serosal and superficial muscular layers should be repaired with interrupted 2-0 or 3-0 sutures. Care should be taken to avoid narrowing of the intestinal caliber (Fig. 16.7). If the entire thickness of the intestine is entered, the segment of bowel must be assessed to decide whether primary closure should be undertaken or whether bowel resection and anastomosis should be performed. Primary closure is usually safely accomplished if the closure can reapproximate well-perfused bowel under no tension on the suture line and the bowel lumen is not narrowed. If these conditions cannot be met, resection and anastomosis will be necessary.

Primary closure of an enterotomy should be in two layers, the first being an interrupted layer of 2-0 or 3-0 polyglycolic acid suture incorporating the mucosa and muscularis, with the knot tied into the intestinal lumen. A second imbricating layer may be of either absorbable or nonabsorbable suture and incorporates the serosa and superficial muscularis (Fig. 16.8). Attention to the direction of closure of the enterotomy should ensure that the lumen is not narrowed.

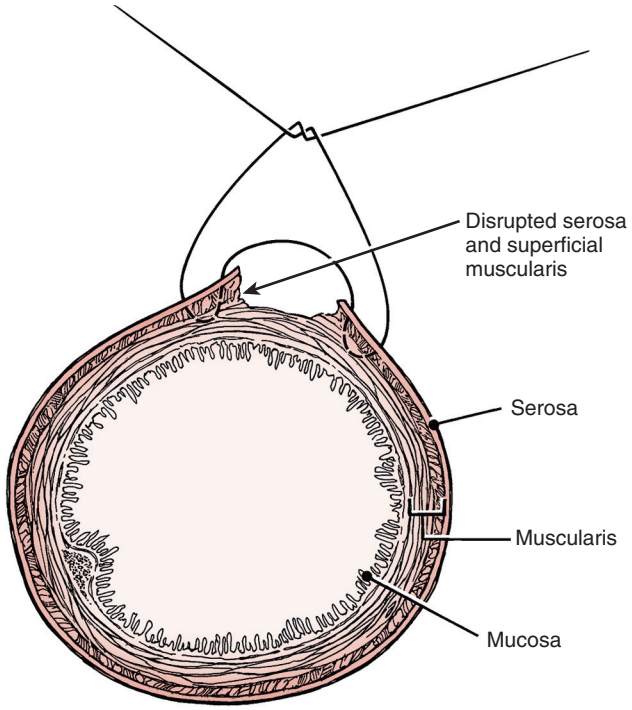

FIGURE 16.7 Repair of seromuscular injury of small or larger bowel. Interrupted imbricating sutures are used to reapproximate the injured seromuscular layer. (From Nichols DH, Clarke-Pearson DL, eds. *Gynecologic, Obstetric and Related Surgery*, 2nd ed. St. Louis, 2000, Mosby.)

Injury to the colon most commonly occurs in the pelvis, and the risk is increased in the face of prior pelvic surgery, cancer involving the colon, or prior radiation therapy. If colonic injury occurs, the decision must be made as to whether a primary closure is sufficiently safe or whether the fecal stream should be temporarily diverted by performing a transverse loop colostomy or ileostomy. **In most cases, primary closure without diversion may be performed; especially if the patient has had a mechanical bowel preparation.** The principles for closure require viable tissue and no tension on the closure. In patients who have had prior pelvic radiation, the risk of perforation of the colostomy closure is significantly increased, and diversion is usually advised. After a two-layered closure of a rectosigmoid injury, the authors routinely perform proctoscopy and a "bubble test" (Fig. 16.9). If either test suggests a defect in the reanastomosis, a diverting ostomy is again recommended.

Postoperative Gastrointestinal Complications

Ileus. After abdominal or pelvic surgery, most patients experience some degree of intestinal ileus. The exact mechanism by which this arrest and disorganization of GI motility occurs

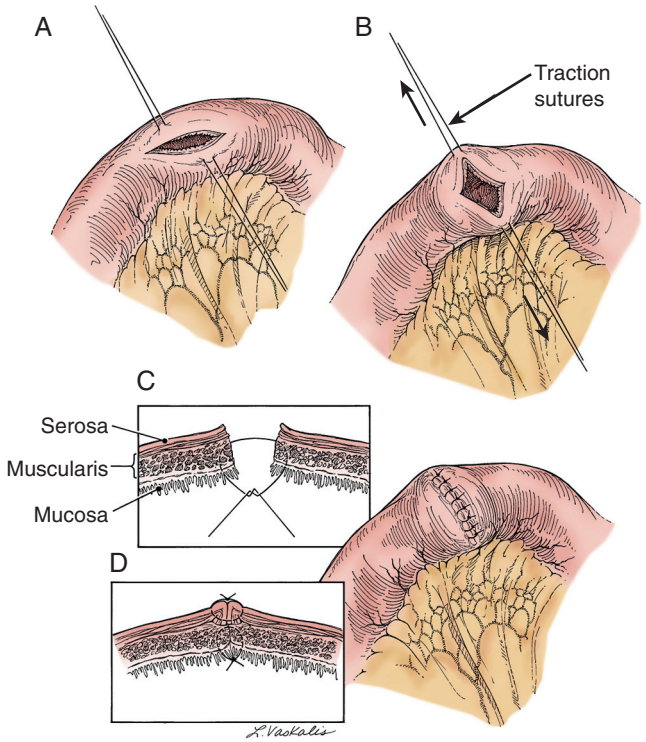

FIGURE 16.8 Repair of enterotomy. **A** and **B,** The repair should be performed so that the closure is perpendicular to the axis of the small bowel. **C** and **D,** Two-layer closure incorporating the mucosa and muscularis in the inner layer and the serosa and muscularis on the outer layer. (From Nichols DH, Clarke-Pearson DL, eds. *Gynecologic, Obstetric and Related Surgery*, 2nd ed. St. Louis, 2000, Mosby.)

is unknown, but it appears to be associated with the opening of the peritoneal cavity and is aggravated by manipulation of the intestinal tract and prolonged surgical procedures. (Ileus is much less commonly associated with minimally invasive surgical procedures. If ileus were to occur after laparoscopy or robotic surgery, the surgeon should strongly consider a more serious bowel injury and evaluate the patient accordingly.) Infection, peritonitis, postoperative hypervolemia causing bowel wall edema, and electrolyte disturbances may also result in ileus. For most patients undergoing gynecologic cancer operations, the degree of ileus is minimal and GI function returns relatively rapidly, allowing the resumption of oral intake within a few days of surgery. Patients who have persistently diminished bowel sounds, abdominal distention, and nausea and vomiting require further evaluation and more aggressive management.

Ileus is usually manifest by abdominal distention and should be evaluated initially by physical examination assessing the quality of bowel sounds and searching for tenderness or rebound on palpation. The possibility that the patient's signs and symptoms may be associated with a more serious intestinal obstruction or other intestinal complication must be considered. Pelvic examination should be performed to evaluate the possibility of a pelvic abscess or hematoma that may contribute to the ileus. Abdominal radiography to evaluate the abdomen in the supine position and in the upright position usually will aid in the diagnosis of an ileus. The most common radiographic findings include dilated loops of small and large bowel and air–fluid levels in the upright position. In postoperative patients, especially in the upright position, the flat plate of the abdomen may also show evidence of free air. This is a common finding

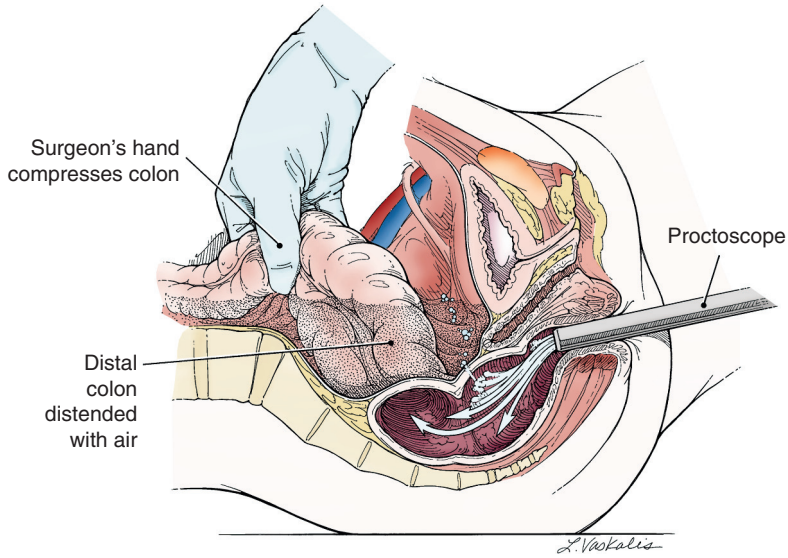

FIGURE 16.9 "Bubble test" to evaluate for rectosigmoid injury and to ensure a "watertight" closure of a colostomy or rectosigmoid anastomosis. The pelvis is filled with saline, and the proximal sigmoid or descending colon is occluded above the segment to be tested. Insert a proctoscope into the anus and inflate with air. Distend the occluded rectosigmoid colon with air and observe for bubbles, which would indicate a bowel defect. (From Nichols DH, Clarke-Pearson DL, eds. *Gynecologic, Obstetric and Related Surgery*, 2nd ed. St. Louis, 2000, Mosby.)

after surgery; it lasts 7 to 10 days in some instances and is not indicative of a perforated viscus in most patients. The remote possibility of distal colonic obstruction or pseudoobstruction (Ogilvie syndrome) suggested by a dilated cecum should be excluded by rectal examination, proctosigmoidoscopy, or barium enema.

The initial management of a postoperative ileus is aimed at GI tract decompression and maintenance of appropriate IV replacement fluids and electrolytes.

1. If a patient has moderate to severe vomiting, not improved with bowel rest and antiemetics, an NG tube should be placed to evacuate the stomach of its fluid and gaseous contents. Prolonged NG suction continues to remove swallowed air, which is the most common source of air in the small bowel.
2. Fluid and electrolyte replacement must be adequate to keep the patient well perfused. Significant amounts of third-space fluid loss occur in the bowel wall, the bowel lumen, and the peritoneal cavity during the acute episode. GI fluid losses from the stomach may also lead to a metabolic alkalosis and depletion of other electrolytes. Careful monitoring of serum chemistries and appropriate replacement are necessary.
3. Most cases of severe ileus begin to improve over a period of several days. In general, this is recognized by reduction in the abdominal distention, return of normal bowel sounds, and passage of flatus or stool. Follow-up abdominal radiographs should be obtained as necessary for further monitoring.
   - When the GI tract function appears to have returned to normal, the NG tube may be removed, and a liquid diet may be instituted.
   - If a patient shows no evidence of improvement during the first 48 to 72 hours of medical management, other causes of ileus should be sought. Such cases may include ureteral injury, peritonitis from pelvic infection, unrecognized GI tract injury with peritoneal spill, or fluid and electrolyte abnormalities such as hypokalemia. In the evaluation of persistent ileus, the use of water-soluble upper GI contrast studies may assist in the resolution of the ileus, the recognition of a small bowel obstruction, or injury (leak) of the GI tract.

Small bowel obstruction. Obstruction of the small bowel after abdominal surgery occurs in approximately 1% to 2% of patients, but it may be more common after radical gynecologic oncology procedures as a result of the extensive dissection and manipulation of the small bowel. (Again, this complication is less common in patients who have undergone minimally invasive surgery.) **The most common cause of small bowel obstruction is adhesions to the operative site.** If the small bowel becomes adherent in a twisted position, partial or complete obstruction may result from distention, ileus, or bowel wall edema. Less common causes of postoperative small bowel obstruction include entrapment of the small bowel into an incisional hernia and an unrecognized defect in the small bowel or large bowel mesentery. Early in its clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. **Initial conservative management as outlined for the treatment of ileus is appropriate.** Because of the potential for mesenteric vascular occlusion and resulting ischemia or perforation, worsening symptoms of abdominal pain, progressive distention, fever, leukocytosis, or acidosis should be evaluated carefully because immediate surgery may be required.

However, in most cases of postoperative small bowel obstruction, the obstruction is only partial, and the problem usually resolves with conservative management.

- After several days of conservative management (NG tube drainage, fluid and electrolyte replacement), further investigation may be necessary. Evaluation of the GI tract with barium enema and an upper GI series with small bowel follow-through is appropriate. Alternatively, an abdominal and pelvic CT scan with GI contrast may be useful in identifying the location of obstruction ("transition point") and evaluates for the presence of an abscess, lymphocele, or ureteral injury. In most cases, complete obstruction is not documented, although a narrowing or tethering of the segment of small bowel may indicate the site of the problem.
- Further conservative management with NG decompression and IV fluid replacement may allow time for bowel wall edema or torsion of the mesentery to resolve.
- If resolution is prolonged and the patient's nutritional status is marginal, the use of TPN may be necessary.

4. Conservative medical management of postoperative small bowel obstruction usually results in complete resolution. However, if persistent evidence of small bowel obstruction remains after full evaluation and an adequate trial of medical management, exploratory laparotomy may be necessary to surgically evaluate and manage the obstruction. In most cases, lysis of adhesions is all that is required, although a segment of small bowel that is badly damaged or extensively sclerosed from adhesions may require resection and reanastomosis.

Colonic obstruction. Postoperative colonic obstruction after gynecologic oncology surgery is exceedingly rare. Advanced ovarian carcinoma is the most common cause of colonic obstruction in postoperative gynecologic surgery patients and is caused by extrinsic impingement on the colon by the pelvic malignancy. Occult intrinsic colonic lesions (eg, colon cancer) also may cause obstruction. When colonic obstruction is manifest by abdominal distention and abdominal radiographs reveal a dilated colon and enlarging cecum, further evaluation of the large bowel is required by barium enema or colonoscopy. **Dilation of the cecum to more than 10 cm to 12 cm in diameter as viewed by abdominal radiography requires immediate evaluation because there is a higher probability of colonic perforation.** When there is no logical cause for a mechanical obstruction, Ogilvie syndrome should be considered. Colonoscopy should be performed, and the colonic gas should be evacuated. If a true mechanical obstruction is documented, surgical decompression by performing a colectomy, colostomy, or cecostomy may be required on an urgent basis. In some circumstances, an intraluminal stent may be placed endoscopically. Surgery should be performed as soon as the obstruction is documented. **Conservative management of colonic**

obstruction is not appropriate because the complication of colonic perforation has an exceedingly high mortality rate.

Diarrhea. Episodes of diarrhea often occur after abdominal and pelvic surgery as the GI tract returns to its normal function and motility. However, **prolonged and multiple episodes may represent a pathologic process such as impending small bowel obstruction, colonic obstruction, or pseudomembranous colitis.** Excessive amounts of diarrhea should be evaluated by abdominal radiographs and stool samples tested for the presence of ova and parasites, bacterial culture, and *Clostridium difficile* toxin. Proctoscopy and colonoscopy may also be advisable in severe cases. Evidence of intestinal obstruction should be managed as outlined previously. Infectious causes of diarrhea should be managed with the appropriate antibiotics and fluid and electrolyte replacement. ***C. difficile*–associated pseudomembranous colitis may result from recent exposure to any antibiotic.** Discontinuation of these antibiotics (unless they are needed for another severe infection) is advisable, along with the institution of appropriate therapy. **Because of the expense of vancomycin, the authors usually institute therapy with oral metronidazole for mild to moderate cases. Because of rising resistance to oral metronidazole, initiation of treatment with oral vancomycin may be necessary because clinical success (resolution of diarrhea) is lower (73% vs. 81%; $P = 0.02$) with metronidazole.** Therapy should be continued until the diarrhea abates, and several weeks of oral therapy may be required to obtain complete resolution of the pseudomembranous colitis.

Fistula. Gastrointestinal fistulas are relatively rare after gynecologic surgery. They are most often associated with malignancy, prior radiation therapy, or surgical injury to the large or small bowel that was unrecognized or a leak from an anastomosis. Signs and symptoms of GI fistula are often similar to those of small bowel obstruction or ileus except that a fever is usually a more prominent component of the patient's symptoms. When fever is associated with GI dysfunction postoperatively, evaluation should include early assessment of the GI tract for its continuity. When fistula is suspected, the use of water-soluble GI contrast material is advised to avoid the complication of barium peritonitis. Evaluation with abdominal pelvic CT scan may also assist in identification of a fistula and associated abscess. **Recognition of an intraperitoneal GI leak or fistula formation usually requires immediate surgery unless the fistula has drained spontaneously through the abdominal wall or vaginal cuff.**

An enterocutaneous fistula arising from the small bowel and draining spontaneously through the abdominal incision may be managed successfully with medical therapy. Therapy should include NG decompression, replacement of IV fluids, TPN, and appropriate antibiotics to treat an associated mixed bacterial infection. If the infection is under control and there are no other signs of peritonitis, the surgeon may consider allowing potential resolution of the fistula over a period of up to 6 weeks. **Some authors have suggested the use of somatostatin to decrease intestinal tract secretion and allow earlier healing of the fistula.** In many cases, especially if the bowel was not radiated, the fistula will close spontaneously with this mode of management. **If the enterocutaneous fistula does not close with conservative medical management, surgical correction with resection, bypass, or reanastomosis will be necessary in most cases.**

A rectovaginal fistula that occurs after gynecologic surgery is usually the result of surgical trauma that may have been aggravated by the presence of extensive adhesions or tumor involvement of the rectosigmoid colon and cul de sac. Low rectal anastomoses are also at risk to breakdown and lead to a rectovaginal fistula. Perforation of a colonic diverticulum is another possible cause for a colovaginal fistula. A small rectovaginal fistula may be managed with a conservative medical approach in the hope that decreasing the fecal stream will allow closure of the fistula. A small fistula that allows continence except for an occasional leak of flatus may be managed conservatively until the inflammatory process in the pelvis resolves. At that point, usually several months later, correction of the fistula is appropriate. **Larger rectovaginal fistulas that have no hope of closing spontaneously are best managed by performing an initial diverting colostomy followed by repair of the fistula after inflammation has resolved. After the fistula closure is healed and deemed successful, the colostomy may be taken down and closed.**

Lymphedema

Lower extremity lymphedema can occur after pelvic, paraaortic, or inguinal lymph node dissections that are commonly part of comprehensive surgical staging for gynecologic cancers. In addition to swelling, patients may report sensations of heaviness, numbness, aching, and pain. When defined as early accumulation of fluid that resides with limb elevation, the rate of lymphedema has been reported as high as 35%, although symptomatic rate of occurrence may be lower (5%–15%). This discrepancy is secondary to both a lack of a consensus definition of lymphedema and a paucity of studies. Patients presenting with lymphedema postoperatively should have early referral to physical therapy services specializing in lymphedema to reduce long-term swelling and improve quality of life.

Lymphocysts

The occurrence of lymphocysts after pelvic and paraaortic lymphadenectomy occurs in approximately 20% of cases, but it symptomatic in as few as 2% to 6%. It has been suggested that prevention requires the ligation of the ascending lymphatics at the time of lymphadenectomy. Furthermore, there is evidence that the use of low-dose heparin increases lymphatic drainage and lymphocyst formation. In years past, the parietal peritoneum was closed after lymphadenectomy, and a closed-suction drain was placed in the retroperitoneal space to aspirate any lymphatic fluid. Certainly, a suction drain is reasonable and likely does prevent lymphocysts whenever the retroperitoneum is closed. Currently, most gynecologic oncologists do not close the peritoneum, allowing the lymphatic fluid to drain into the peritoneal cavity and be reabsorbed. Retrospective reports indicate that there is no increase in lymphocyst formation using this strategy. However, the problem of lymphocyst formation has not been entirely eliminated.

Lymphocysts may be recognized clinically by palpation of a mass along the pelvic sidewall or in the iliac fossa on abdominal examination. **Most will be asymptomatic.** However, when a lymphocyst is found, investigation should be undertaken to evaluate for the possibility of ureteral or venous obstruction. **If hydroureter is found, the lymphocyst should be drained.** This may usually be accomplished by an interventional radiologist who can place a percutaneous drain in the lymphocyst. Suction drainage will collapse the lymphocyst and allow the cyst walls to sclerose together. If percutaneous drainage is not feasible or is unsuccessful, surgical exploration may be required to excise a wall of the lymphocyst and allow the lymphatic fluid to drain into the peritoneal cavity. There are reports of successfully performing this surgery laparoscopically. Placing an omental J flap into the cavity of the lymphocyst has been suggested to provide additional routes of lymphatic drainage. When extrinsic venous compression is discovered to be associated with a lymphocyst, the patient should be evaluated for the possibility of a venous thrombosis. If a venous thrombosis is found, the authors advise anticoagulation in order to stop propagation and allow stabilization of the thrombus. Thereafter the lymphocyst should be drained. Drainage of the lymphocyst before anticoagulation may result in venous decompression and subsequent embolization of the thrombus. Rarely, lymphocysts will become infected and require drainage and antibiotic therapy.

Lymphocysts can also occur in the inguinal region after inguinofemoral lymphadenectomy performed as part of the staging and treatment of vulvar carcinoma. **Small, asymptomatic lymphocysts may be managed by observation.** However, larger lymphocysts usually cause pain or lymphedema and require drainage with placement of a closed-suction drain. If repeated aspiration is required, sclerotherapy should be considered.

Postoperative Infections

Infections are a major source of morbidity in the postoperative period. Risk factors for infectious morbidity in gynecologic oncology patients include a lack of perioperative antibiotic prophylaxis, contamination of the surgical field from infected tissues or from spillage of large bowel contents, an immunocompromised host, diabetes, poor nutrition, chronic and debilitating severe illness, poor surgical technique, and preexisting focal or systemic infection. Sources of postoperative infection can include the lung, urinary tract, surgical site, pelvic sidewall, vaginal cuff, abdominal wound, and sites of indwelling IV catheters. Early identification and treatment of any infections will result in the best outcome from these potentially serious complications.

Although infectious morbidity is an inevitable complication of surgery, the incidence of infections can be decreased by the appropriate use of simple preventive measures. In cases that involve transection of the large bowel, spillage of fecal contents also inevitably occurs. Preoperative mechanical preparation in combination with oral and systemic antibiotic prophylaxis will help decrease the incidence of postoperative pelvic and abdominal infections in these patients. The surgeon can further decrease the risk of postoperative infections by using meticulous surgical technique. Blood and necrotic tissue are excellent media for the growth of aerobic and anaerobic organisms. When there is higher-than-usual potential for serum and blood to collect in spaces that have been contaminated by bacterial spill, closed-suction drainage may reduce the risk of infection. Elective surgical procedures should be postponed in patients who have an infection preoperatively.

Historically, the standard definition of febrile morbidity for surgical patients has been the presence of a temperature of 100.4°F (38°C) or higher on two occasions at least 4 hours apart in the postoperative period, excluding the first 24 hours. However, other sources have defined fever as two consecutive temperature elevations greater than 101.0°F (38.3°C). Febrile morbidity has been estimated to occur in as many as half of patients; however, it is often self-limited, resolves without therapy, and is usually noninfectious in origin.

The assessment of febrile surgical patients should include a review of the patient's history with regard to risk factors. Both the history and the physical examination should focus on the potential sites of infection. The examination should include inspection of the pharynx, a thorough pulmonary examination, percussion of the kidneys to assess for costovertebral angle tenderness, inspection and palpation of the abdominal incision, examination of sites of IV catheters, and an examination of the extremities for evidence of DVT or thrombophlebitis. In gynecologic surgery patients, an appropriate workup may also include inspection and palpation of the vaginal cuff for signs of induration, tenderness, or purulent drainage. **A pelvic examination should also be performed to identify a mass suggesting a pelvic hematoma or abscess and to recognize signs of pelvic cellulitis.**

Patients with a fever in the early postoperative period should have an aggressive pulmonary toilet, including incentive spirometry. If the fever persists beyond 72 hours postoperatively, additional laboratory and radiologic data may be obtained. The evaluation may include complete and differential white blood cell counts and a urinalysis. A routine urine culture has a yield of only 9%; therefore, one should not be sent unless indicated by the urinalysis results or symptoms. Routine chest radiographs have a yield of 6% to 12.5% and should be obtained in patients with and without signs and symptoms localizing to the lung. Blood cultures can also be obtained but will most likely be of little benefit unless the patient has a high fever (102°F). In patients with costovertebral angle tenderness, CT scan, renal ultrasonography, or IVP may be indicated to rule out the presence of ureteral damage or obstruction from surgery, particularly in the absence of laboratory evidence of UTI. Patients who have persistent fevers without a clear localizing source should undergo CT scanning of the abdomen and pelvis to rule out the presence of an intraabdominal abscess. Finally, in patients who have had GI surgery, a CT scan with oral contrast, a barium enema, or an upper GI series with small bowel follow-through may be indicated late in the course of the first postoperative week if fever persists to rule out an anastomotic leak or fistula.

Urinary tract infections. Historically, the urinary tract has been the most common site of infection in surgical patients.

However, the incidence reported in the more recent gynecologic literature has been less than 4%. This decrease in UTIs is most likely the result of increased perioperative use of prophylactic antibiotics.

Symptoms of a UTI may include urinary frequency, urgency, and dysuria. In patients with pyelonephritis, other symptoms include flank pain, headache, malaise, nausea, and vomiting. A UTI is diagnosed on the basis of microbiology and has been defined as the growth of 10^5 organisms/mL urine cultured. Most infections are caused by coliform bacteria, with *Escherichia coli* being the most common pathogen. Other pathogens include *Klebsiella*, *Proteus*, and *Enterobacter* spp. *Staphylococcus* organisms are the causative bacteria in fewer than 10% of cases.

Despite the high incidence of UTIs in the postoperative period, few of these infections are serious. Most are confined to the lower urinary tract, and pyelonephritis is a rare complication. Catheterization of the urinary tract, either intermittently or continuously with the use of an indwelling catheter, has been implicated as a main cause of urinary tract contamination.

The treatment of UTI includes hydration and antibiotic therapy. Commonly prescribed and effective antibiotics include sulfonamide, cephalosporins, fluoroquinolones, and nitrofurantoin. The choice of antibiotic should be based on knowledge of the susceptibility of organisms cultured at a particular institution. In some institutions, for example, more than 40% of *E. coli* strains are resistant to ampicillin. For uncomplicated UTIs, an antibiotic that has good activity against *E. coli* should be given in the interim while awaiting the urine culture and sensitivity data.

Patients who have a history of recurrent UTIs, those with chronic indwelling catheters (Foley catheters or ureteral stents), and those who have urinary conduits should be treated with antibiotics that will be effective against the less common urinary pathogens such as *Klebsiella* and *Pseudomonas* spp. Chronic use of the fluoroquinolones for prophylaxis is not advised because these agents are notorious for inducing antibiotic-resistant strains of bacteria.

Pulmonary infections. The respiratory tract is a relatively common site for complications after surgery for gynecologic cancer. Risk factors include extensive or prolonged atelectasis, preexistent chronic obstructive pulmonary disease, severe or debilitating illness, central neurologic disease causing an inability to clear oropharyngeal secretions effectively, and NG suction. In surgical patients, early ambulation and aggressive management of atelectasis are the most important preventive measures.

A significant proportion (40%–50%) of hospital-acquired pneumonias are caused by Gram-negative organisms. These organisms gain access to the respiratory tract from the oral pharynx. Gram-negative colonization of the oral pharynx has been shown to be increased in patients in acute care facilities and has been associated with the presence of NG tubes, preexisting respiratory disease, mechanical ventilation, tracheal intubation, and paralytic ileus (which is associated with microbial overgrowth in the stomach).

A thorough lung examination should be included in the assessment of all febrile surgical patients. In the absence of significant lung findings, chest radiography should nonetheless be obtained in patients at high risk for pulmonary complications. A sputum sample should also be obtained for Gram stain and culture. The treatment should include postural drainage, aggressive pulmonary toilet, and antibiotics. The antibiotic chosen should be effective against both Gram-positive and Gram-negative organisms, and in patients who are receiving assisted ventilation, the antibiotic spectrum should include drugs that are active against *Pseudomonas* organisms.

Wound infections. The results of a prospective study of more than 62,000 wounds are revealing in regard to the epidemiology of wound infections. The wound infection rate varied markedly, depending on the extent of contamination of the surgical field. The wound infection rate for clean surgical cases (infection not present in the surgical field, no break in aseptic technique, no viscus entered) was lower than 2%, but the incidence of wound infections with dirty, infected cases was 40% or higher. Preoperative showers with hexachlorophene slightly lowered the infection rate for clean wounds, but preoperative shaving of the wound site with a razor (but not clippers) increased the infection rate. A 5-minute wound preparation immediately before surgery was as effective as preparation 10 minutes before surgery. The wound infection rate increased with the duration of the preoperative hospital stay and with the duration of the surgical procedure. (Prophylactic antibiotics should be readministered if the surgical procedure lasts longer than 4 hours.) In addition, incidental appendectomy increased the risk of wound infection in patients undergoing clean surgical procedures. The study concluded that the incidence of wound infections could be decreased by short preoperative hospital stays, hexachlorophene showers before surgery, clipping hair (not shaving) of the wound site immediately before incision, use of meticulous surgical technique, decreasing operative time as much as possible, bringing drains out through sites other than the wound, and dissemination of information to surgeons regarding their wound infection rates. A program instituting these conclusions led to a fall in the clean wound infection rate from 2.5% to 0.6% over an 8-year period. Although the wound infection rate in most gynecologic services has been lower than 5%, reflective of the "clean" nature of most gynecologic operations, it is higher in gynecologic oncology patients.

The symptoms of wound infection often occur late in the postoperative period, usually after the fourth postoperative day, and may include the presence of fever, erythema, tenderness, induration, and purulent wound drainage. Wound infections that occur on postoperative days 1 through 3 are generally caused by streptococcal and clostridial infections. The management of wound infections is mostly mechanical and involves opening the infected portion of the wound above the fascia, with cleansing and débridement of the wound edges as necessary. Wound care, consisting of débridement and dressing changes two to three times daily with mesh gauze, will promote growth of granulation tissue, with gradual filling in of the wound defect by secondary intention. **The application of a Wound-Vac (negative pressure wound therapy) to larger wounds speeds recovery and minimizes dressing changes.**

In a gynecologic oncology population, the median number of days of wound vac therapy was 32 days (range, 3–88 days) with a 96% reduction in the median size of the wounds. Clean, granulating wounds can often be secondarily closed with good success, shortening the time required for complete wound healing.

The technique of delayed primary wound closure can be used in contaminated surgical cases to reduce the incidence of wound infection. Briefly, this technique involves leaving the wound open above the fascia at the time of the initial surgical procedure. Vertical interrupted mattress sutures though the skin and subcutaneous layers are placed 3 cm apart but are not tied. Wound care is instituted immediately after surgery and continued until the wound is noted to be granulating well. Sutures may then be tied, and the skin edges can be further approximated using sutures or staples. Using this technique of delayed primary wound closure, the overall wound infection rate has been shown to be decreased from 23% to 2.1% in high-risk patients.

Vaginal cuff infection after hysterectomy is characterized by erythema, induration, and tenderness at the vaginal cuff. Occasionally, a purulent discharge from the apex of the vagina may also be present. The cellulitis is often self-limited and does not require any treatment. Fever, leukocytosis, and pain localized to the pelvis may accompany severe cuff cellulitis and most often signifies extension of the cellulitis to adjacent pelvic tissues. In such cases, broad-spectrum antibiotic therapy should be instituted with coverage for Gram-negative, Gram-positive, and anaerobic organisms. If purulence at the vaginal cuff is excessive or if there is a fluctuant mass noted at the vaginal cuff, the vaginal cuff should be gently probed and opened with a blunt instrument. The cuff can then be left open for dependent drainage.

Intraabdominal and pelvic abscess. The development of an abscess in the surgical field or elsewhere in the abdominal cavity is most likely to occur in contaminated cases in which the surgical site is not adequately drained or as a secondary complication of hematoma that becomes infected. The causative pathogens in patients who have intraabdominal abscess are usually polymicrobial in nature. The aerobes most commonly identified include *E. coli* and *Klebsiella, Streptococcus, Proteus,* and *Enterobacter* spp. Anaerobic isolates are also common, usually from the *Bacteroides* group. These pathogens are mainly from the vagina but also can be derived from the GI tract, particularly when the colon has been entered at the time of surgery.

An intraabdominal abscess is sometimes difficult to diagnose. The evolving clinical picture is often one of persistent febrile episodes with a rising white blood cell count. Findings on abdominal examination may be equivocal. If an abscess is located deep in the pelvis, it may be palpable by pelvic or rectal examination. For abscesses above the pelvis, diagnosis will depend on radiologic confirmation.

Ultrasonography can occasionally delineate fluid collections in the upper abdomen and the pelvis. However, bowel gas interference makes visualization of fluid collections or abscesses in the mid-abdomen difficult to distinguish. CT scanning with oral and IV contrast is much more sensitive and specific for diagnosing intraabdominal abscesses and is the radiologic procedure of choice.

Standard therapy for an intraabdominal abscess is drainage combined with appropriate parenteral administration of antibiotics. Abscesses located low in the pelvis, particularly in the area of the vaginal cuff, can often be reached through a vaginal approach. In many patients, the ability to drain an abscess by placement of a drain percutaneously under CT guidance has obviated the need for surgical exploration. With CT guidance, a pigtail catheter is placed into an abscess cavity via percutaneous, transperineal, transrectal, or transvaginal approaches. The catheter is left in place and irrigated daily until drainage decreases. Transperineal and transrectal drainage of deep pelvic abscesses has been successful in 90% to 93% of patients, obviating the need for surgical management. However, for patients in whom radiologic drainage is not successful, surgical exploration and evacuation are indicated. The gold standard of initial antibiotic therapy has been the combination of ampicillin, gentamycin, and clindamycin. Adequate treatment can also be achieved with currently available broad-spectrum single agents (including the broad-spectrum penicillin), second- and third-generation cephalosporins, levofloxacin and metronidazole, and the sulbactam/clavulanic acid–containing preparations.

Necrotizing fasciitis. Necrotizing fasciitis is an uncommon infectious disorder; approximately 1000 cases occur annually in the United States. **The disorder is characterized by a rapidly progressive bacterial infection involving the subcutaneous tissues and fascia while characteristically sparing underlying muscle.** Systemic toxicity is a common feature of this disease, as manifested by the presence of dehydration, septic shock, disseminated intravascular coagulation, and multiorgan system failure.

The pathogenesis of necrotizing fasciitis involves a polymicrobial infection of the dermis and subcutaneous tissue. Historically, hemolytic streptococcus was believed to be the primary pathogen responsible for necrotizing fasciitis. However, it is now evident that numerous other organisms are present in addition to streptococcus, including other Gram-positive organisms, coliforms, and anaerobes. Bacterial enzymes such as hyaluronidase and lipase released in the subcutaneous space destroy the fascia and adipose tissue and induce a liquefactive necrosis. In addition, noninflammatory intravascular coagulation or thrombosis subsequently occurs. Intravascular coagulation results in ischemia and necrosis of the subcutaneous tissues and skin. Late in the course of the infection, destruction of the superficial nerves produces anesthesia in the involved skin. The release of bacteria and bacterial toxins into the systemic circulation results in septic shock, acid–base disturbances, and multiorgan impairment.

The diagnostic criteria for necrotizing fasciitis include extensive necrosis of the superficial fascia and subcutaneous tissue with peripheral undermining of the normal skin, a moderate to severe systemic toxic reaction, the absence of muscle involvement, the absence of clostridia in wound and blood culture, the absence of major vascular occlusion, intensive leukocytic infiltration, and necrosis of subcutaneous tissue.

Most patients with necrotizing fasciitis suffer pain, which in the early stages of the disease is often disproportionately greater than that expected from the degree of cellulitis present. Late in the course of the infection, the involved skin may actually be anesthetized secondary to necrosis of superficial nerves. Temperature abnormalities, both hyperthermia and hypothermia, are concomitant with the release of bacterial toxins and with bacterial sepsis, which is present in up to 40% of patients. The involved skin is initially tender, erythematous, and warm. Edema develops, and the erythema spreads diffusely, fading into normal skin, characteristically without distinct margins or induration. Subcutaneous microvascular thrombosis induces ischemia in the skin, which becomes cyanotic and blistered. **As necrosis progresses, the skin becomes gangrenous and may slough spontaneously.** Most patients will have leukocytosis and acid–base abnormalities. **Finally, subcutaneous gas may develop, which can be identified by palpation (crepitus) and by radiograph.** The finding of subcutaneous gas by radiograph is often indicative of clostridial infection, although it is not a specific finding and may be caused by other organisms. These organisms include *Enterobacter* spp., *Pseudomonas* spp., anaerobic streptococci, and *Bacteroides* spp., which, unlike clostridial infections, spare the muscles underlying the affected area. A tissue biopsy specimen for Gram stain and aerobic and anaerobic culture should be obtained from the necrotic center of the lesion to identify the causative organisms.

Predisposing risk factors for necrotizing fasciitis include diabetes mellitus, alcoholism, an immunocompromised state, hypertension, peripheral vascular disease, IV drug abuse, and obesity. Increased age, delay in diagnosis, inadequate debridement during initial surgery, extent of disease on initial presentation, and the presence of diabetes mellitus are all factors that have been associated with an increased likelihood of mortality from necrotizing fasciitis.

Early diagnosis and aggressive management of this lethal disease have led to improved survival. In an earlier series, the mortality rate was consistently higher than 30%, but in more recent series, the mortality rate has decreased to less than 10%.

Successful management of necrotizing fasciitis involves early recognition, immediate initiation of resuscitative measures (including correction of fluid, acid–base, electrolyte, and hematologic abnormalities), **aggressive surgical debridement (and redebridement as necessary), and broad-spectrum antibiotic therapy.** Many patients benefit from central venous monitoring and high caloric nutritional support.

During surgery, the incision should be made through the infected tissue down to the fascia. An ability to undermine the skin and subcutaneous tissues with digital palpation often confirms the diagnosis. Multiple incisions can be made sequentially toward the periphery of the affected tissue until well-vascularized, healthy, resistant tissue is reached at all margins. The remaining affected tissue must be excised. The wound can then be packed and sequentially debrided on a daily basis as necessary until healthy tissue is displayed at all margins.

Hyperbaric oxygen therapy historically was considered to benefit, particularly in patients for whom culture results are positive for anaerobic organisms. Retrospective studies demonstrated that the addition of hyperbaric oxygen therapy to surgical debridement and antimicrobial therapy appears to significantly decrease both wound morbidity and overall mortality in patients with necrotizing fasciitis. However, more contemporary, large-scale studies have failed to show a benefit of this treatment. **Given the technical difficulty with its administration, hyperbaric oxygen treatment should only be considered in hemodynamically stable patients for whom the treatment will not delay surgical management.**

After the initial resuscitative efforts and surgical debridement, the primary concern is the management of the open wound. Allograft and xenograft skin can be used to cover open wounds, thus decreasing heat and evaporative water loss. Interestingly, temporary biologic closure of open wounds also seems to decrease bacterial growth. Application of a wound vacuum-assisted closure (VAC) device will also promote wound healing. When spontaneous closure is not likely, the VAC device may allow for the development of a suitable granulation bed and prepare the tissue for graft placement, thereby increasing the probability of graft survival. Finally, skin flaps can be mobilized to help cover open wounds after the wound infections have resolved and granulation has begun.

Special Populations

Obesity

Incidence and definition. Obesity (BMI ≥30) is an epidemic in the United States and is commonly encountered as a risk factor for complications associated with gynecologic oncology surgery. Centers for Disease Control and Prevention statistics from the year 2014 indicate that 34.9% of US adults (and 36.1% of women) older than age 20 years are obese. Current American Gastroenterology Association Guidelines use BMI to define classes of obesity (overweight, 25–29.9; class I, 30–34.9; class II, 35–39.9; and class III, >40.0). Of importance to the gynecologic oncologists are the further classes of morbid obesity (BMI >40) and super morbid obesity (BMI >50).

Postoperative complications and management. Obese patients are at much higher risk for postoperative complications because of the more common occurrence of comorbidities, including diabetes, hypertension, coronary artery disease, sleep apnea, obesity hypoventilation syndrome (OHS), and osteoarthritis of the knees and hips. These underlying alterations in physiology result in increased surgical risks and complications, including respiratory failure, cardiac failure, DVT and pulmonary embolism, aspiration, wound infection and dehiscence, postoperative asphyxia, and misdiagnosed intraabdominal catastrophe.

Control of the airway is critical in the immediate postoperative period. Extubation may not be prudent or possible at the end of the case as a result of tracheal edema resulting from a difficult intubation. Alternatively, the patient may not have the physical capacity to adequately ventilate as a result of suppression of the respiratory drive from anesthetics and excess chest wall weight. Many obese patients have OHS, which increases their baseline hypercarbia and may also delay extubation. It is may be necessary to plan immediate postoperative admission

to a surgical ICU with mechanical ventilation and serial arterial blood sampling to aid in the proper timing for extubation.

After extubation, ventilation of the obese patient during sleep may be aided by the use of noninvasive positive-pressure ventilation units, particularly if the patient has a history of sleep apnea and uses a continuous positive airway pressure (CPAP) machine at home. Respiratory therapists can be of assistance in patient instruction and management of CPAP machinery in addition to other respiratory toilet. Monitoring with continuous pulse oximetry assists in the detection of impending respiratory failure.

There is a higher risk of aspiration in obese patients due to increased gastric residual volumes, a higher rate of gastroesophageal reflux disease (GERD), and increased intraabdominal pressure from mass effect. Neutralization of the stomach contents with a proton pump inhibitor can minimize the chemical burn potential of aspirated stomach contents. GI motility agents such as metoclopramide may decrease residual volume by increasing intestinal transit. It is also prudent to raise the head of the bed to prevent aspiration.

Prophylaxis for postoperative venous thrombosis and pulmonary embolism (as detailed earlier) should be ordered for obese patients because they are at higher risk for these complications.

Venous access poses another problem. Extreme obesity obliterates anatomic landmarks and makes insertion of peripheral lines and central lines problematic. Adjunctive visualization technology such as Doppler ultrasonography or fluoroscopy should increase the accuracy and safety of line placement. Arterial line placement facilitates monitoring of pressures and blood gas parameters. Ideally, central venous lines and arterial lines should be placed intraoperatively by the anesthesia team to ensure adequate access in the postoperative period. The intraoperative placement of central lines should be verified for position postoperatively by chest radiography in the postanesthesia care unit.

Medication administration must consider the concepts of total body weight and ideal body weight. Certain medications are dosed on ideal body weight (corticosteroids, penicillin, cephalosporins, beta-blockers). Others are dosed on total body weight (heparin), and still others are based on a calculated "dosing weight" (aminoglycosides, fluoroquinolones, vancomycin). An inpatient pharmacist should be consulted for assistance with proper dosing and monitoring of pharmacotherapy.

Minimally invasive surgical techniques decrease the morbidity of surgery in obese patients. In particular, wound complications are greatly reduced, and patients are able to ambulate sooner and have a faster return to full levels of activity. This is particularly important in the endometrial cancer population, for whom obesity is such a strong driver of disease. Concerns regarding longer operating times and the feasibility of steep Trendelenburg positioning were initially raised in this population. A recent multi-institution retrospective cohort study of 1032 obese (BMI >30) patients who all underwent robotic endometrial cancer staging reported a pulmonary complication rate of just 3% ($n = 33$) and overall complication rate of 14% ($n = 146$), both significantly less than that of laparotomy. Several more large studies have consistently reported decreased complication rates with equal or improved comprehensive surgical staging rates for obese patients undergoing minimally invasive surgery. Minimally invasive surgery has been endorsed by the Society of Gynecologic Oncology as the preferred surgical approach for all, including obese, patients with endometrial cancer.

Elderly patients. The life expectancy of American women continues to increase. In addition, as the baby boomer generation ages, we will see an increasingly larger population of older women who will develop gynecologic cancers. **Elderly women are at higher risk of developing gynecologic cancer in that 57% of vulvar cancers, 55% of epithelial ovarian cancers, 41% of endometrial cancers, and 20% of cervical cancers occur in women older than 65 years of age.** Although many of these cancers are managed with radical surgery, careful consideration must be given in selection of surgical procedures in women who may be at high risk for surgical complications. In addition to patient's chronological age, preoperative evaluations that include measurements of frailty, performance status, quality of life, and geriatric assessments can aid greatly in appropriate patient selection for radical surgery. In fact, complications of radiation therapy and chemotherapy are more likely to occur in older patients, so selection of any therapy requires consideration of patient tolerance. In past years, radical surgery was avoided in elderly women. We now know that surgery can be safely and successfully accomplished, despite a patient's age, if the patient is fully evaluated and determined to be a surgical candidate. There is no doubt that **older patients present with more advanced disease and have poorer preoperative performance status and more comorbid conditions than younger patients.** Retrospective review of elderly patients with gynecologic cancers demonstrates that 90% of women older than age 65 years can undergo radical surgery as definitive therapy for their gynecologic cancers. Compared with women younger than 65 years, the postoperative mortality rate was 1.5%, and the minor complications and length of stay were similar in the two groups. In women older than 65 years of age who underwent radical hysterectomy for early-stage cervical cancer, there was no perioperative mortality or ureteral fistula. Transfusion requirements and lymphedema were also similar. Febrile morbidity was less common in the older patients, although postoperative small bowel obstruction, bladder dysfunction, and pulmonary emboli were more commonly encountered in the older patients. In a population-based evaluation of 28,651 women undergoing cytoreductive surgery for ovarian cancer across the country, age was significantly associated with increased complication rate (<50 years, 17%; >70 years, ≥30%), including surgical site, medical, and infectious complications. With regard to minimally invasive surgery, in contrast, there is minimal increase in morbidity associated with age. Elderly cohorts of patients undergoing robotic surgery for endometrial cancer have been reported to have equivalent outcomes of blood transfusions, surgical complications, and length of hospital stay while preserving surgical comprehensive staging.

Perioperative management is the key to success when managing elderly women. Cardiac and pulmonary complications

are the two most common serious problems encountered postoperatively. Careful preoperative assessment of cardiac status should include assessment for underlying coronary artery disease, valvular heart disease, and chronic congestive heart failure. Several risk-assessment algorithms may be applied to estimate cardiac risk of major noncardiac surgery. Because more than 40% of elderly women have hypertension, optimal blood pressure control should be achieved preoperatively; intraoperative hypotension is one of the most common causes of myocardial ischemia and infarction. Pulmonary complications occur in nearly 40% of elderly women after major abdominal surgery. Because physiologic changes of aging diminish vital capacity, lung compliance, reduced expiratory flow rates, and increased residual volume, elderly patients are more likely to have pulmonary complications after general anesthesia. These women may be at even higher risk if they have chronic obstructive pulmonary disease or asthma. Preoperative assessment may include assessment of pulmonary function by performing spirometry and obtaining an arterial blood gas measurement. Patients with underlying pulmonary disease should have their medical regimen maximized preoperatively, including the use of bronchodilators and corticosteroids. Conduction anesthesia should be considered in consultation with an anesthesiologist to avoid the pulmonary complications more often encountered with general anesthesia.

Avoiding perioperative hypothermia and hypoxemia are extremely important to avoid additional cardiac oxygen consumption. Invasive monitoring and planned ICU admission should be considered in any circumstance when there is an increased risk of cardiac or pulmonary complications. Care must also be taken when ordering pharmacologic agents because elderly patients may have altered GI absorption and decreased renal or hepatic clearance of specific drugs. Consultation with a clinical pharmacist is advised to establish the correct dose of drug for patients with altered renal or hepatic function.

Radiation complications in elderly patients are also increased. **Thin, hypertensive patients appear to be at greater risk for radiation therapy complications to both the GI and genitourinary tracts.** It appears that elderly women tolerate initial therapy poorly and often require delays in treatment or discontinuation of treatment because of acute toxicity such as diarrhea, dehydration, or neutropenia. This observation, then, requires carefully planned treatment decisions as to whether the patient would be best treated with surgery or radiation therapy. Neither is without risk, and it cannot be assumed that radiation therapy is necessarily less toxic.

Radiation Therapy

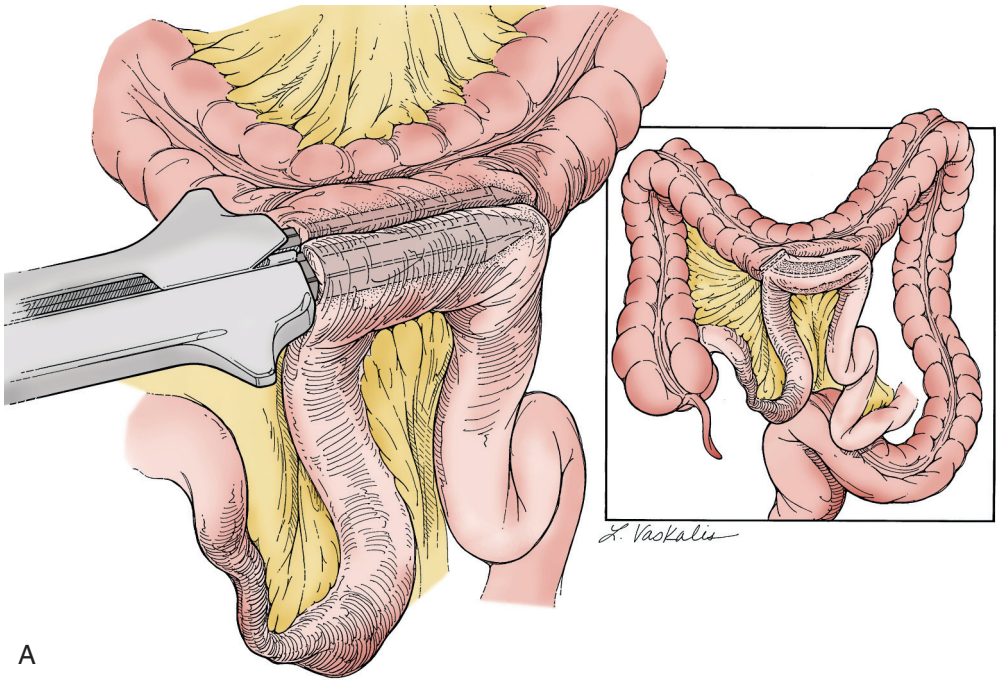
Radiation therapy serves as a primary treatment modality for cervical and vaginal cancers (and occasionally advanced vulvar cancers) and as an adjuvant therapy for patients with high-risk endometrial cancers. Furthermore, individualized radiation therapy may be used in nearly all gynecologic cancers to achieve palliation under specific circumstances. Morbidity resulting from properly conducted radiation therapy in patients with carcinoma of the cervix and vagina is usually minimal. However, there are unfortunate misconceptions about the magnitude of radiation morbidity because of issues regarding failure to distinguish between adverse effects from poor techniques, failure to recognize that poorer outcomes of patients with inoperable extensive tumors, and lack of recognition that morbidity attributed to irradiation may actually result from uncontrolled tumor (ie, rectovaginal and vesicovaginal fistulas). As in the case of surgery, the treatment-related morbidity can be minimized by good application, but it cannot be eliminated.

Because the small bowel, bladder, and rectum are adjacent to the female genital tract, most of the side effects and complications of radiation involve these adjacent organs. Radiation complications are related to the dose, field size, and type of radiation equipment used. **The larger the field, the greater the risk of problems if the dose remains constant. Usually, as the fields enlarge, the dose must be decreased.** Conversely, as the fields become smaller, a larger dose can be tolerated. The use of brachytherapy also increases the risk of local complications. Finally, the use of combined chemoradiation therapy seems to increase slightly some complications during therapy (eg, neutropenia) but does not seem to lead to serious long-term sequelae.

The pathogenesis of radiation-induced injury may be divided into acute and delayed complications. **Complications during therapy are caused by ionizing radiation injury to cells that are mitotically active such as the GI epithelium.** Damage of the mucosal cells results in mucosal thinning and denudation followed by malabsorption and fluid and electrolyte loss (resulting from diarrhea). The GI mucosal stem cells generally recover totally, and the acute symptoms resolve. **Late complications involve a different mechanism of tissue injury based on vascular endothelial damage.** Radiation results in an endarteritis and the gradual occlusion of small vessels. Subsequent tissue hypoxia leads to fibrosis of the affected tissue. These changes are progressive and may be aggravated further by other vascular compromise such as diabetes, hypertension, and aging. In severe cases, ulceration, stricture, perforation, and fistula formation may occur.

Gastrointestinal Complications

Acute complications. **Nearly all patients receiving external radiation to the pelvis will develop radiation proctitis or enteritis with associated diarrhea.** This problem commonly begins after 2 weeks of radiation therapy and is **usually easily managed by dietary modification and antidiarrheal medications (diphenoxylate; Lomotil). As a rule, the diarrhea resolves within 7 to 10 days of completing radiation.** Some of the transitory symptoms are tenesmus and the passage of mucus and even blood per the rectum. **Diarrhea and abdominal cramping characterize small intestinal irritation (radiation enteritis). This problem is more common and more severe when a portion of the small intestine is fixed in the pelvis as a result of adhesions or other pathologic conditions.** Anorexia may also occur during radiation therapy. If nausea and vomiting occur, the patient should be evaluated for dehydration. This is more common when concurrent chemotherapy is being given along with the radiation. IV hydration and correction of electrolytes is occasionally required. If dehydration is severe,



radiation should be interrupted until these acute side effects are corrected.

The patient should have a complete blood count weekly during radiation therapy. If the hemoglobin decreases below 10 g/dL, PRBC transfusion is advised to achieve improved tumor kill. Occasionally, radiation of the pelvic bone marrow will result in neutropenia or thrombocytopenia. In severe cases, radiation will need to be temporarily interrupted. **In nearly all cases, the acute side effects of radiation therapy will resolve after the radiation course is completed.**

Chronic conditions. Radiation injury to the small intestine may manifest itself at any time after therapy and may vary from chronic diarrhea to small bowel obstruction or fistula. A typical patient with small bowel injury will initially present with postprandial abdominal cramps and pain, anorexia, and diarrhea. About half of small bowel injuries occur within 1 year after radiation, and three-fourths occur within 2 years. These symptoms are more common in patients who have had a prior laparotomy. Initial conservative management focuses on dietary modification (avoiding green leafy vegetables, milk products, and fried foods). Antidiarrheal drugs and oral cholestyramine (which binds bile salts) are often useful in managing symptoms.

As small bowel injury progresses, fibrosis of the injured bowel wall develops, leading to stricture and partial or complete obstruction. Patients usually present with worsening abdominal pain, cramps, diarrhea, and vomiting. Sometimes the intermittent obstruction goes unrecognized until a significant weight loss is recorded. If medical management of a partial small bowel obstruction fails, surgical intervention is the course of last resort. The decision to proceed with surgical intervention in cases of intermittent obstruction is a difficult one and should be undertaken with proper preoperative preparation. Often, patients have developed a significant degree of malnutrition and should have their nutritional status corrected with preoperative TPN. Mechanical bowel preparation is mandatory, although sometimes it must be limited to enemas because the patient's small bowel obstruction will not allow the ingestion of oral cathartics. Dilated loops of bowel should be decompressed preoperatively with NG suction. Surgical correction depends on the situation encountered at the time of surgical exploration. **The obstruction is usually found to be bowel adherent in the pelvis that has been radiated.** The bowel usually is thickened, edematous, and fibrotic. **The two primary surgical options are resection of the obstructed loops with either reanastomosis or small bowel bypass. In either event, it is preferable to make anastomoses to intestinal segments that have not been radiated in order to have maximum opportunity for healing.** Care should be taken to have adequate perfusion and no tension on the anastomosis. Perforation or fistula, if present, must be isolated and diverted; more extensive surgery (resection and anastomosis) must be done only if it is technically feasible (Fig. 16.10).

Radiation injury to the rectum is more common after treatment for cervical cancer because of the high rectal doses from the intracavitary brachytherapy. **Injury to the rectum may manifest as proctitis, rectal ulcer, stricture, or fistula.** Complete colonic obstruction from radiation injury is extremely rare. The symptoms of radiation proctitis may develop after an asymptomatic interval of many months to years after radiation

A

FIGURE 16.10 A, Small bowel obstruction that has been managed with a bypass ileotransverse enteroenterostomy.

Continued

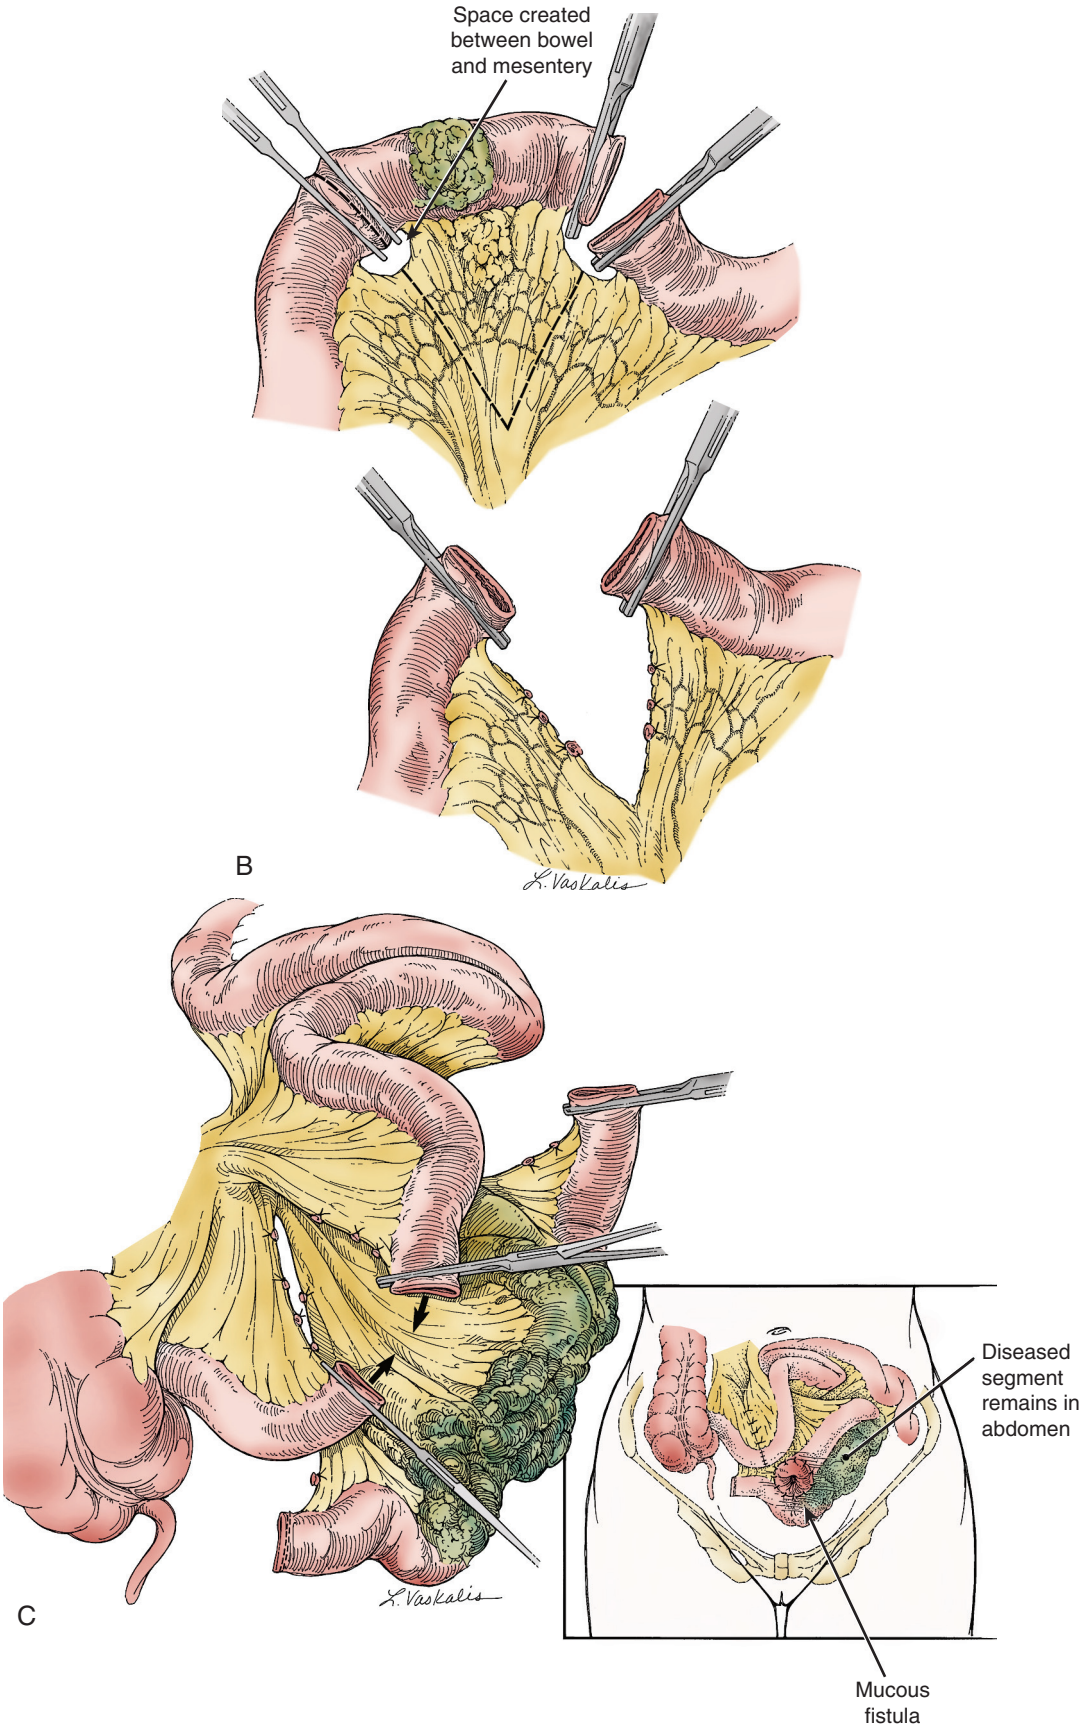


FIGURE 16.10, cont'd **B,** Resection of the involved bowel has been done with reanastomosis of the small bowel. Sufficient terminal ileum must be present for this procedure to be accomplished. **C,** The obstructed bowel has been isolated with formation of a mucous fistula. An end-to-side anastomosis has also been done. (From Nichols DH, Clarke-Pearson DL, eds. *Gynecologic, Obstetric and Related Surgery*, 2nd ed. St. Louis, 2000, Mosby.)

therapy is completed. Diarrhea with or without rectal bleeding is the most common presenting symptom. Cramping abdominal pain may be associated with the diarrhea. The injury is most often located on the anterior rectal wall that received the maximal dose from the brachytherapy application and range from thickened, fragile mucosa to thin, atrophic mucosa or mucosal ulceration. These changes usually heal with conservative measures, including low-residue diet, anticholinergic drugs, stool softeners, and corticosteroid enemas. Hyperbaric oxygen treatments also appear to enhance healing of a rectal ulcer. If there is excessive bleeding from the rectal ulcer or proctitis, diversion of the fecal stream (colostomy) may be necessary to allow healing. Obviously, when bleeding is encountered, full evaluation of the rectosigmoid colon with flexible sigmoidoscopy is mandatory to exclude recurrent cancer, rectal cancer, polyps, diverticula, or hemorrhoids as the cause of bleeding.

Rectovaginal fistula is the most common significant radiation injury to the large bowel and is often preceded by radiation proctitis and rectal ulceration. All patients with rectovaginal fistulas should have a diverting colostomy. It is rare that diversion will result in spontaneous healing of radiated colon, and it is often necessary to decide as to whether repair of the fistula may be subsequently undertaken. Whenever surgical correction is considered, endovascular flaps are used to bring a new blood supply to the repair (Fig. 16.11). **Only after the fistula repair has completely healed and absence of obstruction of the bowel has been documented should the colostomy be reversed.**

Radiation-induced strictures or obstruction of the rectosigmoid colon appear at approximately 24 months from the completion of the radiation therapy. Again, the initial step in management is a diverting colostomy. Correction requires a

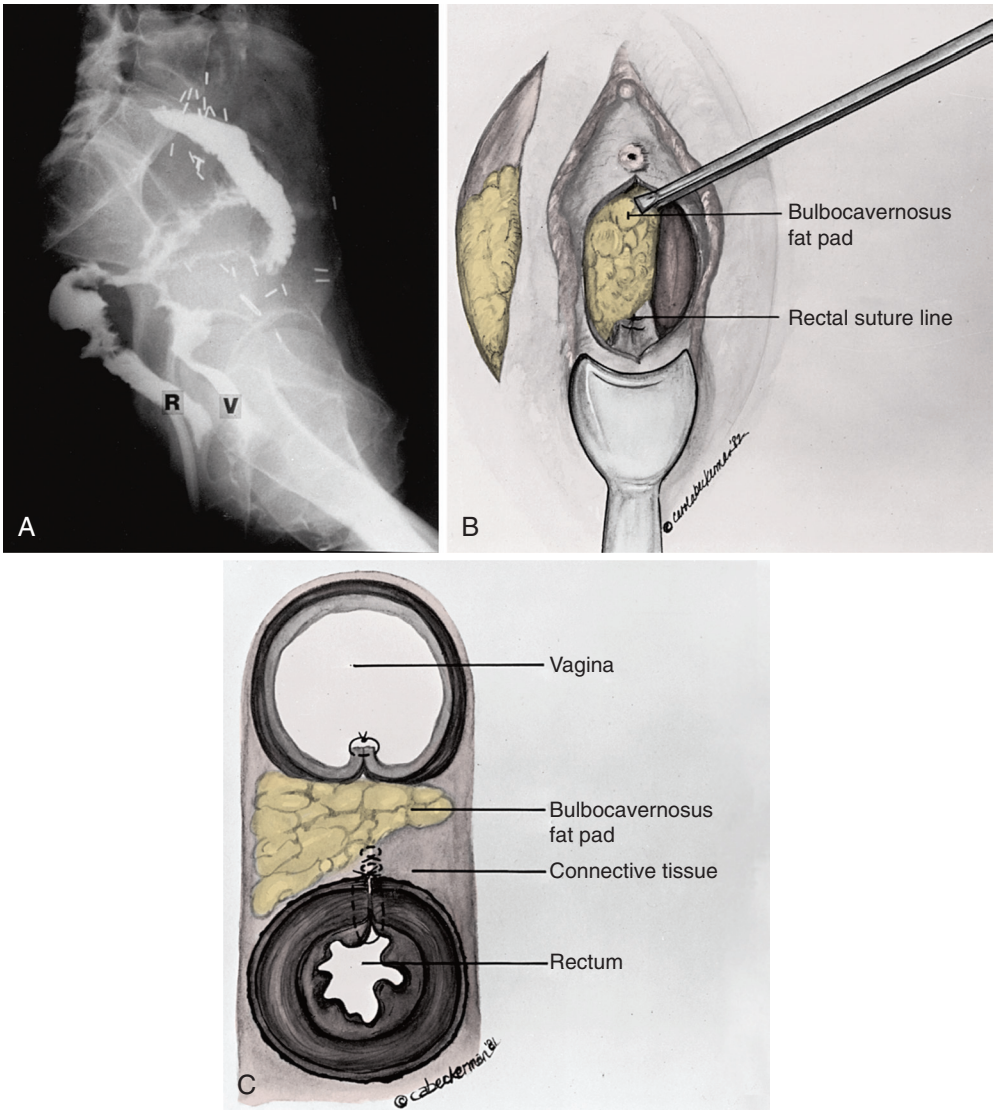

FIGURE 16.11 A, Barium enema demonstrating a rectovaginal fistula after irradiation. B, Repair of the rectovaginal fistula has been strengthened by interposition of the bulbocavernosus fat pad. C, The cross-section shows placement of the neovascular fat pad.

rectosigmoid resection with low rectal anastomosis. Harris and Wheeless reported their experience with the end-to-end stapler device in low colorectal anastomosis associated with rectal injury. This was accomplished in 49 patients, 17 of whom had prior radiation therapy. All five postoperative complications (two strictures, two anastomosis breakdowns, and one fecal incontinence after colostomy closure) occurred in the patients who had prior radiation. In a more recent series by Mirhashemi et al., prior pelvic radiation remained a significant risk factor for anastomotic breakdown and fistula (35% vs. 7.5%, N = 77).

Complex fistulas may include a variety of communications between the small bowel, colon, vagina, bladder, and skin. Thorough evaluation of the anatomy involved is mandatory and should include all organ systems that are possibly involved. The evaluation may include barium enema, proctosigmoidoscopy, upper GI series with small bowel follow-through, IVP, cystography, cystoscopy, and a "fistulogram" (injection of contrast directly into the fistula and imaging the retrograde flow of the contrast dye). These complex fistulas are often very difficult to repair, and the patients should be in optimal medical condition before surgery is performed. This usually includes antibiotics to control infection, TPN, and mechanical bowel preparation. If a fistula can be resected, it should be; however, many times the fistula must be isolated and the intestinal stream diverted around the lesion.

Prior pelvic radiation to the ileum (or resection or bypass surgery of the ileum) may lead to the malabsorption of vitamin B_{12} and result in a megaloblastic anemia. Because the liver usually has significant stores of vitamin B_{12}, it may be several years after radiation or surgery before the anemia is recognized. It is therefore advised that patients have annual complete blood counts indefinitely. A Shilling test can differentiate between vitamin B_{12} and folic acid deficiency. Treatment of vitamin B_{12} deficiency requires weekly vitamin B_{12} injections until the hemoglobin level returns to normal (usually 4–6 weeks) and then monthly injections to prevent recurrent anemia.

Urologic Complications

Acute radiation cystitis is occasionally encountered during radiation therapy or in the period immediately after completion of therapy. Typical symptoms of cystitis are usually present, but urine cultures show no significant bacterial growth. Management includes increased oral liquid intake and urinary analgesics and anticholinergics to relieve symptoms. Chronic radiation cystitis commonly presents with symptoms of urinary frequency, suprapubic pain, and hematuria. The patient should have an immediate urine culture because a UTI further aggravates bladder mucosa damaged by radiation therapy. **Gross hematuria (rather than microscopic hematuria) usually can be relieved by continuous bladder irrigation using 0.5% or 1% acetic acid, a 1:1000 potassium permanganate, or an alum solution.** Clots may need to be evacuated by cystoscopic irrigation to relieve bladder spasms. Cystoscopy may also be needed to identify bleeding points that may be fulgurated. An experienced urologist should be consulted because **excessive fulguration or unnecessary biopsies may lead to an iatrogenic vesicovaginal fistula. As a last resort, the bladder may be sclerosed with formaldehyde irrigation.** In the most extreme cases, cystectomy and urinary diversion may be required to control bleeding.

Vesicovaginal fistulas are more common when the patient has had intensive radiation therapy and are increased by brachytherapy. Improper placement of the tandem and ovoids may result in an excessive dose to the base of the bladder and speaks to the importance of careful placement of intracavitary devices and attention to bladder doses delivered. Surgery after radiation therapy, such as a "completion" hysterectomy for bulky stage IB2 or "barrel" lesions of the cervix, further increases the risk of vesicovaginal fistula. In many cases, upper vaginal radiation necrosis is recognized months before the occurrence of the fistula. **Treatment of the necrosis may prevent the progression to a fistula. Therapy includes half-strength hydrogen peroxide douches, intravaginal estrogen, and hyperbaric oxygen therapy.**

Evaluation of an apparent vesicovaginal fistula should include a complete evaluation of the bladder and the upper tracts. **It is common to discover an associated ureterovaginal fistula or ureteral stricture or stenosis, which must be addressed at the time of fistula repair.** Furthermore, given the proximity of the upper vagina to the bladder and rectum, proctosigmoidoscopy is advised because the rectosigmoid colon may also communicate with the fistula.

Repair of a radiation-induced vesicovaginal fistula is difficult and less successful than fistula repair in nonirradiated areas. **The primary complicating matter is diminished blood supply to the radiated tissues. Therefore, techniques of repair often use the mobilization of a nonirradiated tissue with a good blood supply into the surgical repair.** If an intraabdominal, transvesical approach is taken to repair the vesicovaginal fistula, the omentum and its blood supply may be mobilized and used to cover the repair of the fistula, often being interposed between the closed bladder and vagina. Vaginal approaches to vesicovaginal fistula repair may include repair combined with colpocleisis or the use of the bulbocavernosus labial flap (Martius flap), which is mobilized and interposed between the repaired bladder and vagina (Figs. 16.12 and 16.13). Ureteral injury after radiation therapy may require reimplantation of the distal ureter into the bladder (ureteroneocystostomy) or permanent diversion (urinary conduit).

Sexual Function and Vaginal Stenosis

Vaginal stenosis results from fibrosis and narrowing of the upper vagina after vaginal brachytherapy in both cervical and endometrial cancer treatment. Given the dose-rate response, vaginal toxicity is more common in definitive chemoradiation management of cervical cancer (89%) than adjuvant pelvic or vaginal radiation for endometrial cancer (widely ranging from 1% to 55% in published reports). Vaginal dilator use can significantly prevent the severity of vaginal stenosis and should be encouraged both during and after therapy. One recent study examined risk factors for vaginal stenosis after adjuvant brachytherapy in endometrial cancer patients. Of 101 patients examined, 33 (33%) had either mild or severe vaginal stenosis, and multivariate analysis revealed that factors of having more than

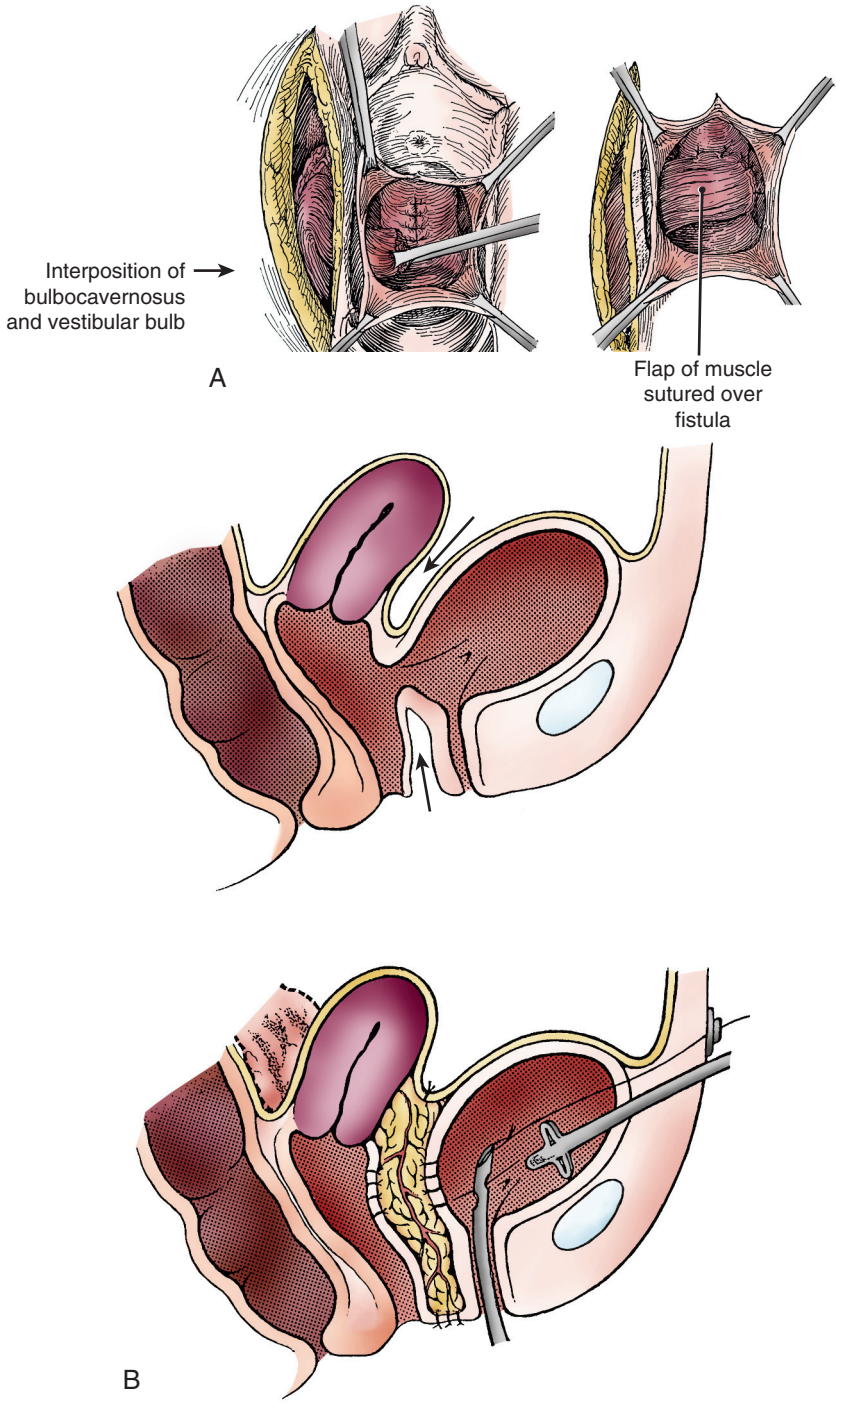

FIGURE 16.12 A, Vesicovaginal fistula repair using the bulbocavernosus fat pad as a source of neovascularization. B, Repair using an omental J flap for neovascularization. (From Nichols DH, Clarke-Pearson DL, eds. *Gynecologic, Obstetric and Related Surgery*, 2nd ed. St. Louis, 2000, Mosby.)

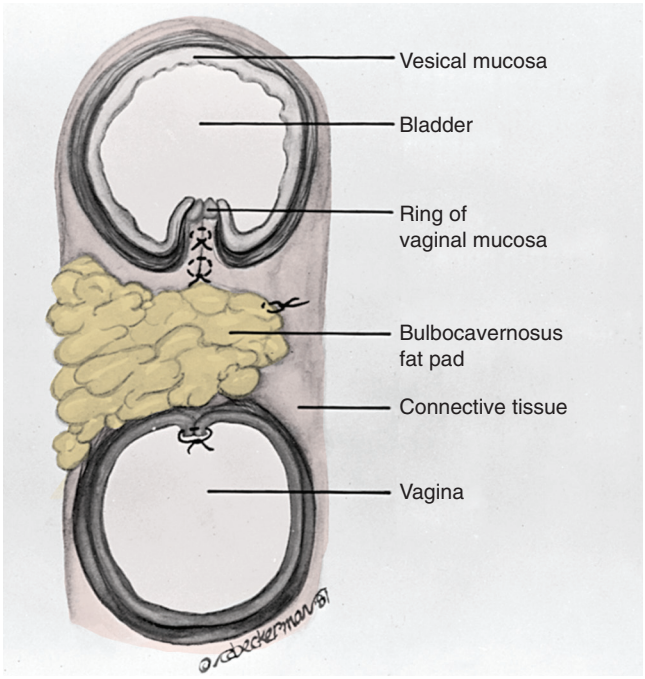

FIGURE 16.13 Cross-section of the vesicovaginal repair using the bulbocavernosus fat pad as a source of neovascularization.

60% of the vagina treated and a total dose larger than 14 Gy were significantly associated with greater odds of vaginal stenosis. It should be noted that the Common Terminology Criteria for Adverse Events (CTCAE), version 4.03 criteria for vaginal stricture was used to grade vaginal stenosis, and 26 of the 33 women with stenosis had grade 1 severity.

Basic Principles of Chemotherapy

Christina S. Chu, MD, Stephen C. Rubin, MD

OUTLINE

Historical Overview
General Principles
Cell Cycle Control and Growth Kinetics
Dynamics of Chemotherapy
Pharmacologic Principles
- Drug Interactions
- Drug Resistance
- Calculation of Dosage

Categories of Drugs in Current Use
- Alkylating Agents
- Antimetabolites
- Antitumor Antibodies
- Agents Derived From Plants
- Hormonal Agents
- Targeted Therapies and Immunotherapy

Drug Toxicity
- Hematologic Toxicity
- Gastrointestinal Toxicity
- Skin Reactions
- Hypersensitivity
- Hepatic Toxicity
- Pulmonary Toxicity
- Cardiac Toxicity
- Renal Toxicity
- Genitourinary Toxicity
- Neurologic Toxicity
- Gonadal Dysfunction
- Supportive Care

Evaluation of New Agents
- Phase I
- Phase II
- Phase III

KEY POINTS

1. In malignant tumors, unregulated growth appears to result from a combination of loss of normal cell cycle controls and a failure of normal apoptotic mechanisms. Despite uncontrolled growth, malignant cell division does not appear to be more rapid than normal cell division.
2. In general, as tumors grow, they display gompertzian growth characteristics: As the tumor mass increases in size, the time necessary to double its size also becomes progressively longer. Metastases generally have a shorter doubling time than the primary lesion.
3. In late stages of tumor growth, only a few doublings in tumor mass may make a dramatic impact on the size of the tumor and the status of the patient.
4. Chemotherapeutic agents work by first-order kinetics—that is, they kill a constant fraction of cells rather than a constant number.
5. The effectiveness of any cancer treatment is limited by drug resistance, which may be intrinsic or acquired and may develop to one drug or to multiple drugs.
6. Alkylating agents, such as the platinum compounds and cyclophosphamide, prevent cell division primarily by cross-linking strands of DNA.
7. Antimetabolites, such as 5-flurouracil and methotrexate, act by inhibiting essential metabolic processes that are required for synthesis of purines, pyrimidines, and nucleic acids. These agents are typically S phase specific.
8. Antitumor antibiotics, such as bleomycin and doxorubicin, generally work via DNA intercalation.
9. Several chemotherapeutic agents, such as the taxanes, work via inhibition of normal microtubule function.
10. Antiangiogenesis therapies, such as bevacizumab, are among the most common targeted agents.
11. Hematologic toxicity and nausea and vomiting are the most frequently observed side effects in patients undergoing chemotherapy.
12. Common antiemetic regimens include use of a 5-HT3 receptor antagonist with dexamethasone or aprepitant, a substance P/NK1 antagonist.
13. The taxanes and platinum compounds are the most likely to cause hypersensitivity.
14. Unlike reactions to taxanes, which typically occur within minutes of starting the initial dose, reactions to platinum agents typically do not manifest until several cycles have already been administered.

HISTORICAL OVERVIEW

The era of modern chemotherapy began in the 1940s with the Nobel Prize–winning work of Huggins and Hodges on the antitumor effect of estrogens in prostate cancer. This observation was followed in the mid-1940s by the investigation of nitrogen mustard, a byproduct of nitrogen gas used in World War I, for its effects against lymphomas and solid tumors. Between 1945 and 1965, a wide variety of chemotherapeutic agents was identified and studied, including actinomycin D, cyclophosphamide, the vinca alkaloids, 5-fluorouracil (5-FU), and the progesterones. In the 1970s, cisplatin was noted to exert significant antitumor effects against ovarian and testicular cancers, and tamoxifen was found to have activity against breast cancer for both adjuvant therapy and treatment of advanced disease. In the same decade, bleomycin, etoposide, and doxorubicin came into clinical use, and derivative compounds such as carboplatin, vinorelbine, and idarubicin were developed for their ability to achieve similar antitumor effects but with less hematologic toxicity. The 1980s and 1990s led to the widespread use of a host of new drugs, such as the taxanes (paclitaxel and docetaxel), ifosfamide, the topoisomerase inhibitors (topotecan and irinotecan), and nucleoside analogs (gemcitabine and capecitabine).

The growing number of agents in the chemotherapeutic armamentarium has been accompanied by advances in alternative dosing regimens; differing formulations using liposomal or polymer-based encapsulation; and varying schedules, sequences, and routes of administration. Fortunately, supportive therapies for gastrointestinal (GI) and hematologic toxicities have also evolved to include routine usage of 5-HT3 receptor antagonists (eg, ondansetron and granisetron) for antiemetic prophylaxis and colony-stimulating factors (eg, sargramostim and filgrastim) to allow for greater chemotherapeutic dose intensity.

GENERAL PRINCIPLES

Chemotherapeutic agents are a crucial part of physicians' armamentarium in the ever-broadening fight against cancer. Physicians can, with use of these drugs, ameliorate and sometimes even cure diseases that were usually fatal in the past. Until recently, in most cases, chemotherapy has been reserved for relatively late stages of the disease, but its increasingly successful use, particularly in the treatment of hematologic malignancies, suggests that chemotherapy should be administered earlier. All physicians and surgeons must understand the nature and use of cancer chemotherapy so they can make rational decisions about when it may be indicated. The outcome of cancer chemotherapy is not fully predictable, but the chances of remission can be improved by judicious selection of patients, careful assessment of the tumor's growth pattern, and treatment of the neoplasm with the drug or drugs most likely to be effective. **The clinical response to chemotherapy may be assessed using standard Response Evaluation Criteria in Solid Tumors defined by the National Cancer Institute** (Table 17.1).

TABLE 17.1 National Cancer Institute Response Evaluation Criteria in Solid Tumors

Evaluation	
TARGET LESIONS	
Complete response	Disappearance of all target lesions
Partial response	At least a 30% decrease in the sum of the longest diameter of target lesions, taking as reference the baseline sum longest diameter
Progressive disease	At least a 20% increase in the sum of the longest diameter of target lesions, taking as reference the smallest sum longest diameter recorded since the treatment started or the appearance of one or more new lesions
Stable disease	Neither sufficient shrinkage to qualify for partial response nor sufficient increase to qualify for progressive disease, taking as reference the smallest sum longest diameter since the treatment started
NONTARGET LESIONS	
Complete response	Disappearance of all nontarget lesions and normalization of tumor marker level
Incomplete response or stable disease	Persistence of one or more nontarget lesion(s) or maintenance of tumor marker level above the normal limits
Progressive disease	Appearance of one or more new lesions or unequivocal progression of existing nontarget lesions*

*Although a clear progression of "nontarget" lesions only is exceptional, in such circumstances, the opinion of the treating physician should prevail, and the progression status should be confirmed later on by the review panel (or study chair).

Unfortunately, not all patients with cancer are amenable to chemotherapy. The suitability of a patient for treatment depends on at least three critical criteria:

1. The nature of the neoplasm
2. Its extent of spread or stage
3. The patient's clinical condition

Not all cancers are equally sensitive to drugs. Factors that determine a given tumor's susceptibility include how the drug is distributed to the tumor, drug transport into the cell, whether a drug-sensitive biochemical pathway is present in the tumor cell, and the relative rates of intracellular activation and inactivation of the drug. A thorough knowledge of the cell cycle and growth kinetics is fundamental to understanding of the appropriate uses of chemotherapy.

CELL CYCLE CONTROL AND GROWTH KINETICS

All living things have an inherent capacity to multiply, and they cease multiplication for various reasons. Control appears to be mediated by an unknown feedback mechanism, probably resulting from contact phenomena when cells are crowded together. Knowledge of growth patterns has aided in the derivation of chemotherapeutic principles. Strategies for therapy have evolved to take advantage of these differences in growth characteristics between normal and malignant tissues.

Normal tissues fall into three predominant categories: static, expanding, and renewing. Static populations of cells are generally well differentiated and after a period of proliferation in fetal life rarely undergo division during adult life. Examples of static tissues include neurons and skeletal muscle. Because of the rare incidence of cell division, these cells are unlikely to be injured by chemotherapies that target rapidly dividing cells. Expanding tissue populations are also usually inactive in adult life, but unlike static populations, they retain the ability to proliferate rapidly in response to stress or injury. Typical examples of expanding cells include hepatocytes and vascular endothelium. Last, the renewing cell populations are those that are constantly undergoing division, such as bone marrow and GI epithelium. Renewing tissues are most sensitive to injury by chemotherapeutic agents (Table 17.2).

In malignant growth, cells do not cease multiplying when they reach a critical mass. This unregulated growth appears to result from a combination of loss of normal cell cycle controls and a failure of normal apoptotic mechanisms. Despite uncontrolled growth, malignant cell division does not appear to be more rapid than normal cell division.

In general, as tumors grow, they display gompertzian growth characteristics (Fig. 17.1): As the tumor mass increases in size, the time necessary to double its size also becomes progressively longer. Thus, in the early phases of growth, tumor cells appear to grow exponentially, but as tumor mass increases, there is a progressive increase in the doubling time, although doubling times in humans may vary greatly. For example, whereas embryonal tumors and some lymphomas have relatively short doubling times (20–40 days), adenocarcinomas and squamous cell carcinomas have relatively long doubling times (50–150 days). Three explanations have been given for this prolonged volume-doubling time:

1. An increase in cell cycle time (the time from one mitosis to the next)
2. A decrease in the growth fraction (cells participating in cell division in the tumor)
3. An increase in cell loss from tumor cells with insufficient nutrients and vascular supply

The gompertzian model has several important implications for cancer progression. First, metastases generally have a shorter doubling time than the primary lesion. If it is assumed that an exponential growth occurs early in the malignancy's history and that the malignancy starts from a single cell, then a 1-mm mass will have undergone approximately 20 tumor doublings. A 5-mm mass (a size that is first recognizable on a radiograph) may have undergone 27 doublings. It follows that a 1-cm mass will have undergone 30 doublings, and a clinician will be pleased to have detected such an "early" lesion. Unfortunately, this "early" lesion has already undergone 30 doublings, with significant DNA change being possible. Using this rationale, clinical techniques that are currently available tend to recognize malignancies late in their growth, and metastatic disease may well have occurred long before there was obvious clinical manifestation of the primary lesion. **Another implication from this kinetic information is that in late stages of tumor growth, a few doublings in tumor mass make a dramatic impact on the size of the tumor and the status of the patient.** When a tumor becomes palpable (1 cm in diameter—30 doublings), only three more doublings will produce a very large tumor mass (8 cm in diameter).

The gompertzian model also has clinical implications that have guided a good deal of clinical chemotherapy research. **As a mass responds to treatment (ie, gets smaller), the doubling time has been assumed to decrease as a consequence of a greater number of cells moving into cycle. This larger percentage of metabolically active cells would therefore increase the sensitivity of the neoplastic population of cell cycle–specific agents. This has led to the sequential use of cell cycle–nonspecific agents (eg, cyclophosphamide) to bring down the mass to be followed by cell cycle–specific agents (eg, methotrexate).** Although these sequential combinations have been theoretically attractive, none has shown clear superiority in clinical trials. Another implication of the gompertzian growth concept is that metastases can be expected to be more sensitive to chemotherapy in general, and to cell cycle–specific agents in particular, than the primary tumor from which they arise. The smaller the size of the metastatic focus, the greater is the differential sensitivity. Therefore, the insensitivity of a primary tumor to a given drug regimen might not necessarily predict the response of metastasis to the same regimen.

TABLE 17.2 Classification of Normal Tissues by Rate of Proliferation

Renewing (Rapid Proliferation)	Expanding (Slow Proliferation)	Static (Rare Proliferation)
Bone marrow	Lung	Muscle
Gastrointestinal mucosa	Liver	Bone
Ovary	Kidney	Cartilage
Testis	Endocrine glands	Nerve
Hair follicles	Vascular endothelium	

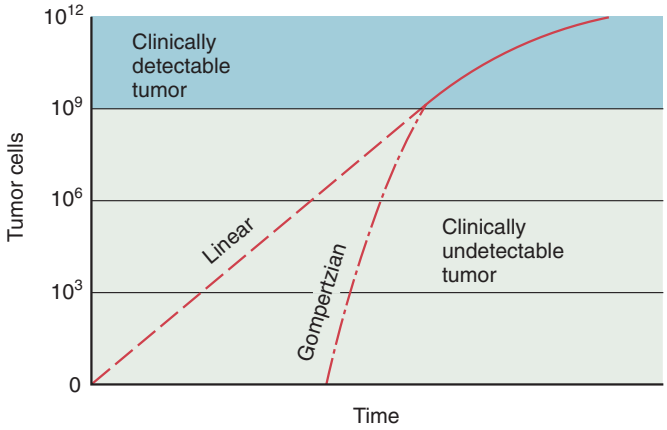

FIGURE 17.1 Tumor growth. As tumors grow, they display gompertzian characteristics. As tumor mass increases, doubling time becomes longer. However, a palpable tumor needs relatively few doublings to achieve a large mass.

Phase		Duration (hr)
Gap 1 (G_1)	Postmitotic	4–24 (variable)
DNA synthesis (S)		10–20
Gap 2 (G_2)		2–10
Mitosis (M)		0.5–1
Gap 0 (G_0)		Resting (variable)

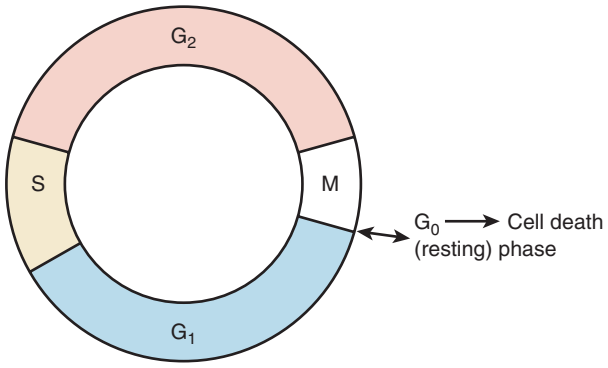

FIGURE 17.2 Cell generation time and sequence are similar for all mammalian cells. Tumor cells do not have faster generation times but do have more cells in the active phases of replication.

The rationale for the use of drugs in the treatment of cancer is to achieve the selective killing of tumor cells. Underlying this rationale are the basic principles of the "cell kill" hypothesis first described by Skipper and associates. The following four principles were worked out in the L1210 leukemia model.

1. The survival of an animal with cancer is inversely related to the number of cancer cells.
2. A single cell is capable of multiplying and eventually killing the host.
3. For most drugs, a clear relationship exists between the dose of the drug and its ability to eradicate tumor cells.
4. A given dose of a drug kills a constant fraction of cells, not a constant number, regardless of the cell numbers present.

This fourth and most important principle implies that chemotherapeutic agents work by first-order kinetics—that is, they kill a constant fraction of cells rather than a constant number. This concept has important implications in cancer treatment. A single exposure of tumor cells to an antineoplastic drug may be capable of producing two to four logs of cell kill. With a common tumor burden of 1012 cells (1 kg), a single dose of chemotherapy will destroy a large number of cells but not be curative. Thus, there is a need for intermittent courses of chemotherapy to achieve the magnitude of cell kill necessary to eradicate the lesion. Clinically, first-order cell kinetics dictate that to eradicate a tumor population effectively it is necessary to either:

- Increase the total dose of the drug or drugs to the maximal limits tolerated by the host, or
- Start treatment when the number of cells is small enough to allow the destruction of the tumor at total doses of the drug that are reasonably tolerated.

The logical conclusion derived from this hypothesis is that the maximal opportunity for achieving cure exists during the early stage of disease. In the past, chemotherapy was generally reserved for the treatment of disseminated cancer; surgery and radiotherapy were treatments of choice for localized disease. However, this concept of "log kill hypothesis" provides a rationale for the philosophy of adjuvant chemotherapy, which assumes the presence of undetectable cell masses of 101 to 104 cells after the initial surgical therapy that are capable of producing tumor relapse. This small tumor burden is particularly vulnerable to effective chemotherapy.

To better understand cell kinetics, it is imperative to visualize cell cycling. All dividing cells follow a predictable pattern for replication. The time that it takes a cell to complete one cycle of growth and division is termed its *generation time*. There are five basic phases (Fig. 17.2). The G1 phase (G stands for gap and uncertainty as to purpose) lasts for a variable amount of time—usually between 4 and 24 hours. If this phase is prolonged, the cell is usually referred to as being in the G0, or resting, phase. The S phase is the phase of DNA synthesis and usually lasts between 10 and 20 hours. The G2 phase is a premitotic phase that lasts from 2 to 10 hours, and the M phase, when actual mitosis takes place, lasts between 0.5 and 1 hours. Tumors do not have faster generation times but have more cells in the active phases of replication than normal tissues. Normal tissues have a large number of cells in the G0 phase, wherein the cell is not actively committed to division or is "out of cycle."

Some chemotherapeutic agents appear to act at several phases of the cell cycle (Fig. 17.3). Alkylating agents appear to act in all phases from G0 to mitosis. They are called cycle-nonspecific agents. Drugs such as hydroxyurea, doxorubicin (Adriamycin), and methotrexate appear to act primarily in the S phase. Bleomycin appears to act in the G2 phase, and vincristine appears to act in the M phase. These drugs are called cycle-specific agents (Table 17.3) because they act chemotherapeutically only on cells that are in a specific phase of a cell generation cycle. Steroids, 5-FU, and cisplatin have rather uniform activity around the cell generation cycle. **In theory, if certain cancer therapeutic agents attack only cells that are dividing and more tumor cells are dividing than normal tissue cells, then by properly spacing the chemotherapeutic agent and combining agents that act in different phases of the cell cycle, one should be able to kill tumor cells in much greater numbers than normal cells.** Kinetic studies in humans and animals suggest that tumors that have been cured by chemotherapy are those with large fractions of cells in the proliferative phase (eg, gestational choriocarcinoma and Burkitt

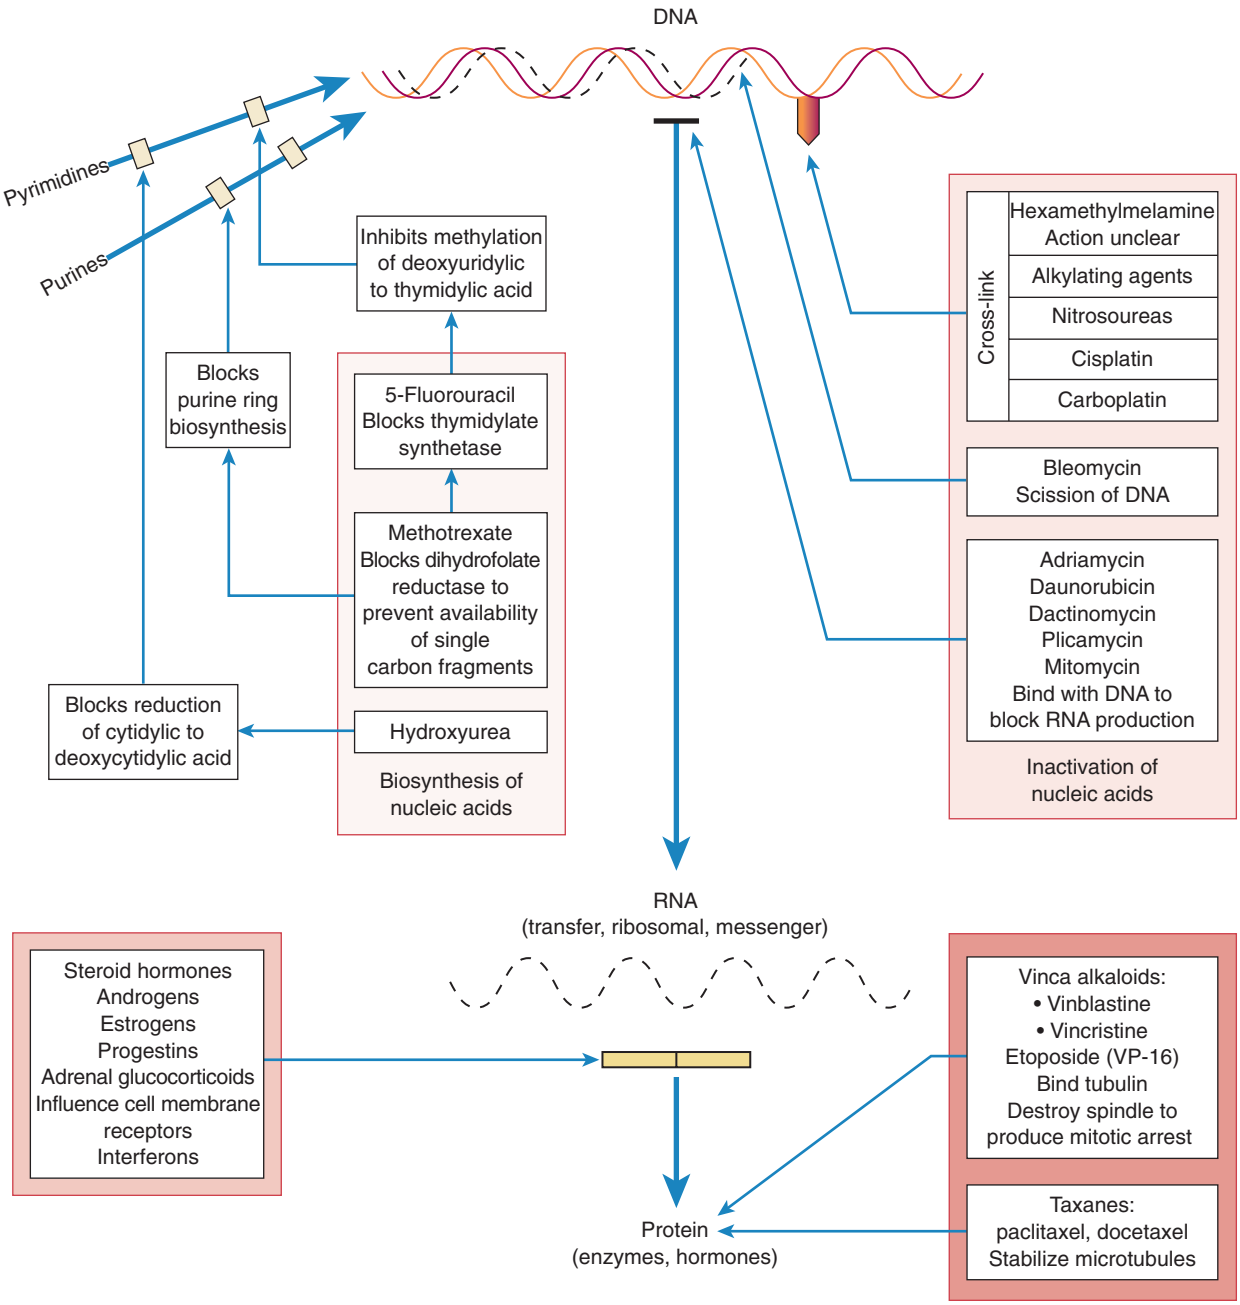

FIGURE 17.3 Cancer chemotherapeutic agents. (Modified from Krakoff IH. Cancer chemotherapeutic agents. *CA Cancer J Clin* 1987;37:93.)

lymphoma). The extent of the disease rather than the total mass of tumor is the most important factor when considering curative radiation or surgery, but in using chemotherapy, the total mass is most important. When tumor volume is reduced, the remaining tumor cells can begin to divide actively (they are propelled from the G0 phase into the more vulnerable cell generation cycle), thus rendering them susceptible to chemotherapy. These chemotherapeutic agents, as in radiation therapy, kill by first-order kinetics—that is, there is a reduction of the tumor population by a characteristic percentage, regardless of the actual number of tumor cells initially present (Fig. 17.4). If the tumor burden is small, fewer cycles of chemotherapy may be necessary. One milligram of tumor usually consists of 106 cells. One cubic centimeter of tumor usually consists of 109 cells. Patient death usually occurs at 1012 cells.

DYNAMICS OF CHEMOTHERAPY

The doubling time of a tumor depends on both generation time and cell death rate (Fig. 17.5)**.** One cannot assume a long generation time simply because a tumor enlarges slowly. Slow tumor growth can result from rapid generation time combined with a high cell death rate. For similar reasons, a small tumor discovered on radiographic or physical examination is not

TABLE 17.3 Cell Cycle (Phase)–Specific Drugs

Phase Dependence	Type	Drugs
S phase dependent	Antimetabolite	Cytarabine
		Doxorubicin
		5-Fluorouracil
		6-Mercaptopurine
		Methotrexate
		Hydroxyurea
		Prednisone
M phase dependent	Vinca alkaloids	Vincristine
		Vinblastine
	Taxanes	Paclitaxel
		Docetaxel
	Podophyllotoxins	Etoposide
		Teniposide
	Epothilones	Ixabepilone
G2 phase dependent	—	Bleomycin
G1 phase dependent	—	Corticosteroids

necessarily an early tumor; only serial studies to judge its growth rate will help establish its age. Bulky tumors (diameters >2–3 cm) enlarge more slowly than small ones because their cells, especially those of the inner core (farthest from the blood supply), have a long generation time. Competition for nutrients and other less-defined competitive pressures reduce the activity of the entire mass.

Successful chemotherapy of cancer requires a physiologic edge that can be exploited to differentially kill cancer cells but spare normal cells as much as possible. The more rapid growth rate of tumors and the increased synchronicity of tumor cells compared with normal tissues may be taken advantage of when designing therapeutic regimens. At any given time, comparatively large numbers of cancer cells will be in the DNA synthesis phase (S phase) of the cell cycle, the only time during which cycle-dependent agents (those inhibiting DNA synthesis) can act. Thus, short-term high-dose chemotherapy with agents affecting DNA synthesis, such as methotrexate, is most effective in killing rapidly dividing tumor cells with relative sparing of normal bone marrow elements. Unfortunately, bone marrow cells, the epithelial cells that line the GI tract, and hair follicles all have generation times comparable with those of tumors, and they are therefore vulnerable to compounds that inhibit DNA synthesis (see Table 17.2). However, compared with the more synchronously growing tumor cell population, only a few of the bone marrow cells are in their S phase at any given time, and this accounts for the selective toxicity of phase-dependent compounds. A course of therapy extending over a period of several days or even weeks may be required to kill a slow-growing tumor in which only a few cells are in the stage of DNA synthesis at any one time. Agents that do not depend on DNA synthesis for their effects (ie, cycle-nonspecific agents), such as alkylating agents, are most effective against bulky, slow-growing tumors. The cells remaining after treatment tend to divide more rapidly and are more susceptible to attack by cycle-specific agents. Thus, there is some flexibility in the interplay of chemotherapeutic agents.

The phenomenon of increased susceptibility of tumor cells during recovery from alkylating agents is the rationale for sequentially combining cycle-nonspecific and cycle-specific agents in many new regimens. If, in addition, drugs with different mechanisms of toxicity are combined, each drug can be given safely in the dose used when it is given alone. Each drug chosen for combination therapy should have antitumor activity when used alone. Whenever possible, intermittent courses of chemotherapy are used to allow restoration of normal cells if they were reduced in number by treatment. In cases in which an antidote to the chemotherapeutic agent is known—for example, leucovorin (citrovorum factor, folinic acid) for methotrexate—the antidote can also be given to hasten normal cell recovery. Of course, the danger of revitalizing sublethally injured tumor cells also exists and must be evaluated with each new treatment regimen. Although careful studies are needed to compare each new combination with the single agents concerned, the trend in chemotherapy is unquestionably toward exploitation of drug combinations used simultaneously and sequentially.

PHARMACOLOGIC PRINCIPLES

Several general pharmacologic factors significantly affect the appropriate use of chemotherapeutic agents, including drug absorption, distribution, transport, metabolism, and excretion. These principles not only impinge on drug effectiveness but also dictate drug dose and schedule and how drugs are selected for use in combination. The effectiveness of a given regimen depends on optimizing the *concentration x time* (also known as the area under the curve [AUC]) at the site of tumor. Drug absorption influences route of administration, which in turn affects the AUC. Whether a drug is given orally, intravenously, intraarterially, intramuscularly, or intraperitoneally is also determined by patient acceptance, feasibility, and toxicity. Drug distribution and delivery to the tumor site also affects AUC. Factors such as drug binding (to albumin or to plastic catheters), lipid solubility, and membrane transport are critical in determining effectiveness of a given agent. Certain sites in the body, such as the brain and testes, represent pharmacologic sanctuaries where drug delivery is limited. Similarly, poor tumor perfusion because of necrosis or hypoxia may also impair drug delivery and concentration. Understanding of membrane transport mechanisms is also key: Certain drugs, such as 5-FU and mitomycin C, may enter cells through passive diffusion, but others, such as cisplatin and melphalan, require active transport.

Drug metabolism is often necessary to convert an inactive prodrug into the active form. One example is cyclophosphamide, which requires cytochrome P-450 activation before antitumor effects are possible. Agents requiring hepatic metabolism to active forms are not amenable to intraperitoneal or intraarterial administration. Conversely, metabolism and excretion of the active drug also affects AUC. The liver and the kidneys are responsible for the majority of drug elimination,

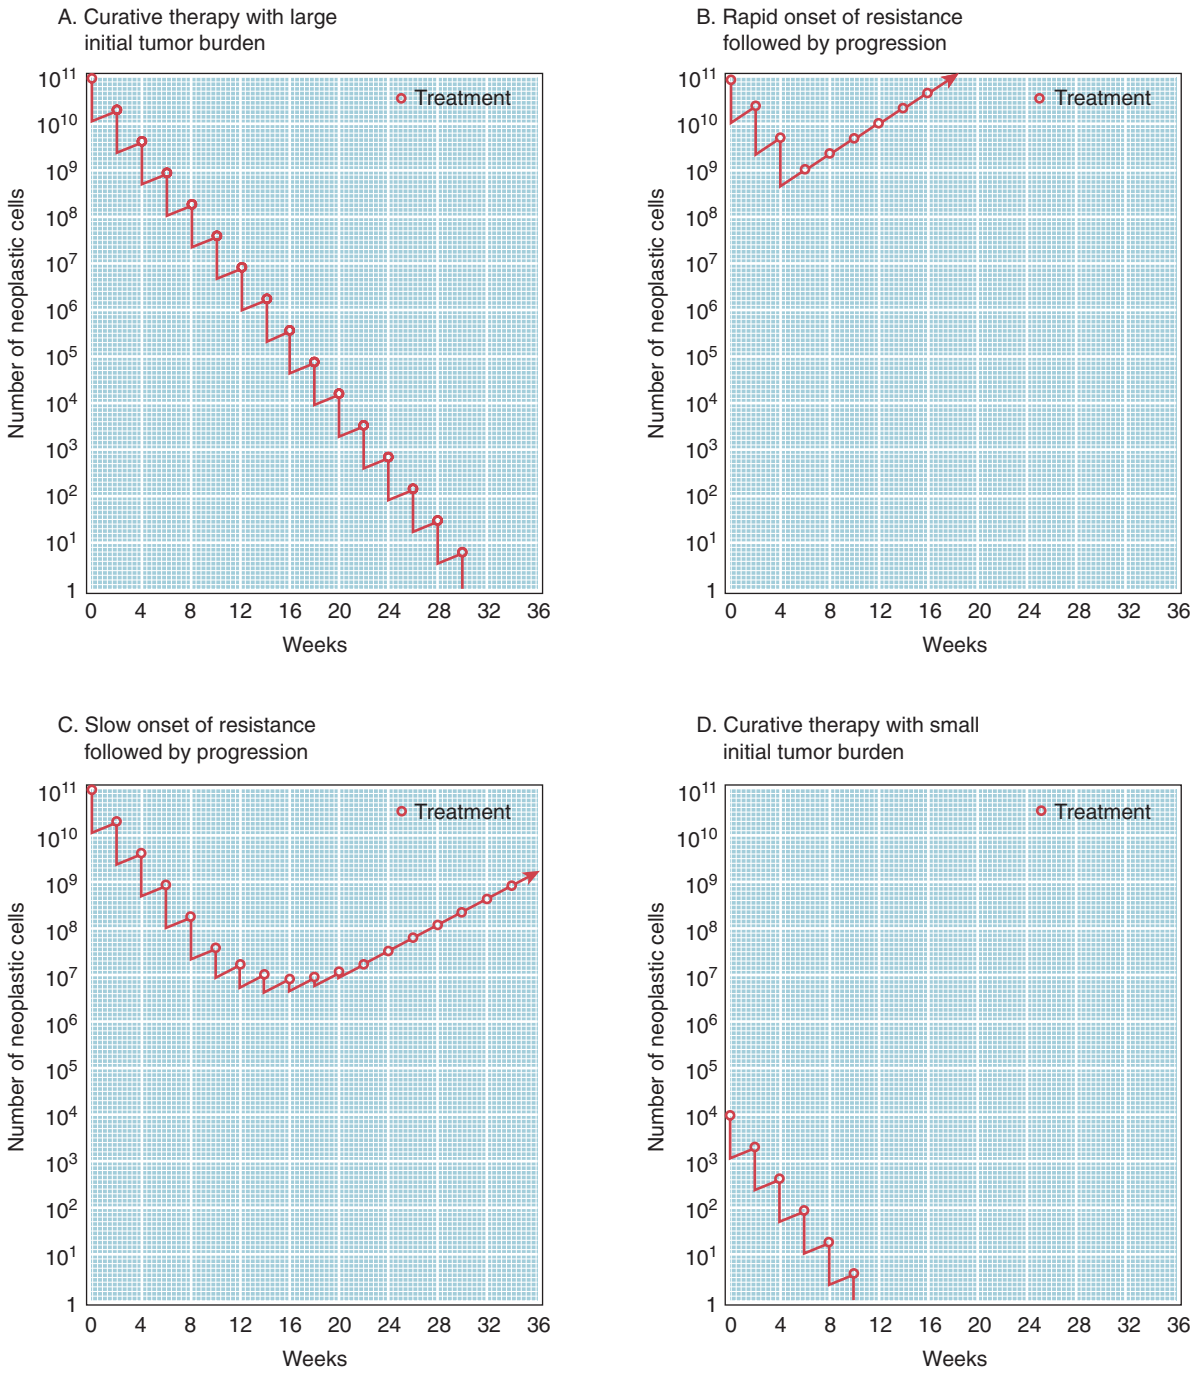

FIGURE 17.4 Efficacy of chemotherapy related to tumor kinetics. (Modified from Bodye GB Sr, Frei E III, Luce JK. The Systemic Approach to Cancer Therapy. *Hosp Pract* 1967;2(10):42.)

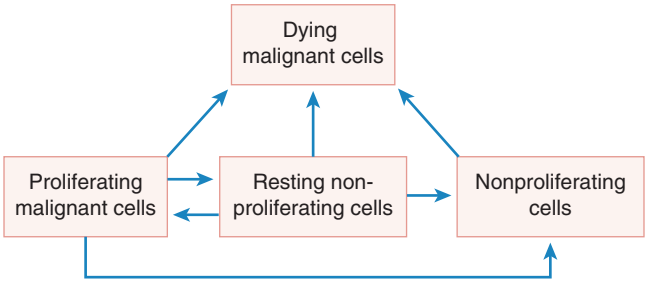

FIGURE 17.5 Dynamics of tumor growth, showing the interrelationship of cell compartments contributing to the clinical presence of tumor.

although excretion in bile, stool, and respiration may also contribute in some cases. Organ dysfunction may result in increased drug toxicity and may require dose modification.

Drug Interactions

Although patients undergoing chemotherapy treatment may also receive a variety of other drugs for treatment of acute side effects or chronic medical conditions, few drug interactions are clinically significant. **However, a few interactions are noteworthy. In particular, whereas doxorubicin and taxane agents are known to exert increased toxicity in the setting of impaired**

biliary excretion, the platinum compounds and methotrexate may cause increased toxicity in the setting of decreased renal function. Aspirin and sulfonamides are known to displace methotrexate from plasma proteins, and direct chemical interactions are noted between cisplatin and mannitol and mitoxantrone and heparin.

Drug Resistance

The effectiveness of any cancer treatment is limited by drug resistance, which may be intrinsic or acquired and may develop to one drug or to multiple drugs (pleiotropic resistance). It has been suggested that spontaneous mutation is a basis for drug resistance. This spontaneous mutation occurs rapidly in malignant tumors. **This concept, the Goldie–Coldman hypothesis, has been applied to the growth of malignant tumors and has important clinical implications.** The theory suggests that most malignant cells begin with intrinsic sensitivity to chemotherapeutic agents but develop spontaneous resistance at variable rates. Goldie and Coldman have developed a mathematic model that relates curability to the time of recurrence of the singly or doubly resistant cells. Assuming that there is a natural mutation rate, the model predicts a variation in the size of the resistant fraction in tumors of the same size and type, which depends on that mutation rate and the point at which the mutation develops. Thus, the proportion of resistant cells in any untreated tumor is likely to be small, and the initial response to treatment would not be influenced by the number of resistant cells. In clinical practice, this means that a complete remission could be obtained even if the resistant cell line were present. The failure to cure such a patient, however, would depend directly on the presence of these resistant cells. This model of spontaneous drug resistance implies that minimizing the emergence of drug-resistant clones requires that multiple effective drugs or therapies be applied as early as possible in the course of the patient's malignant disease process.

In cell lines and animal models, resistance to specific drugs likely occurs via a wide variety of mechanisms, although only a few have been confirmed to be of clinical significance in human cancers. These include increase in proficiency of DNA repair, decrease in drug uptake or increase in efflux by cells, increased levels of or alterations in target enzymes, alterations in drug activation or degradation, gene amplification, and defective drug metabolism. These mechanisms are reviewed in Table 17.4.

Multidrug resistance also occurs via various mechanisms. Some experimental evidence in murine tumors suggests that one form of multiple-drug resistance relates to the ability of drug-resistant tumor cells to limit drug accumulation of structurally unrelated agents. This cross-resistance is seen most often with natural products (eg, doxorubicin, etoposide, paclitaxel, and vinca alkaloids); resistance to a single drug may confer a cross-resistance to structurally dissimilar drugs with different modes of action. This is the best studied mechanism for multidrug resistance and has been characterized involving the p-170 glycoprotein and its gene *MDR1*. Ling initially demonstrated the appearance of a P-glycoprotein with a molecular weight of 170 kD on the cell membrane. The appearance of pleiotropic drug resistance is associated with permeability of the cell to accumulate and retain antineoplastic drugs. It has been demonstrated that this P-glycoprotein is directly related to the expression of resistance, and cells that revert to the drug-sensitive state lose this membrane glycoprotein. DNA can be transferred from resistant cells to the sensitive cells, producing a transfer of pleiotropic resistance to unexposed cells.

TABLE 17.4 Probable Mechanisms Associated With Resistance to Some Commonly Used Anticancer Drugs

Mechanism	Drugs
Increase in proficiency of repair of DNA	Alkylating agents, cisplatin
Decrease in cellular uptake or increase in efflux of drugs	Cisplatin, doxorubicin, etoposide, melphalan, 6-mercaptopurine, methotrexate, nitrogen mustard, vinblastine, vincristine
Increase in levels of "target" enzyme	Methotrexate
Alterations in target enzyme	5-Fluorouracil, 6-mercaptopurine, methotrexate, 6-thioguanine
Decrease in drug activation	Cytosine arabinoside, doxorubicin, 5-fluorouracil, 6-mercaptopurine, 6-thioguanine
Increase in drug degradation	Bleomycin, cytosine arabinoside, 6-mercaptopurine
Alternative biochemical pathways	Cytosine arabinoside
Inactivation of active metabolites by binding to	Alkylating agents, cisplatin, doxorubicin sulfhydryl compounds
Decreased activity of topoisomerase	Camptothecins, doxorubicin, etoposide
Alteration of tubulin-binding sites	Vincristine, paclitaxel, ixabepilone
Increased damage tolerance	Alkylating agents, cisplatin

Modified from Tannock IF, Hill RT, eds. *The Basic Science of Oncology*, 3rd ed. New York, 1988, McGraw-Hill. Reproduced by permission of The McGraw-Hill Companies.)

Although best characterized, *MDR1* is unlikely to be the most common mechanism for chemotherapy resistance among ovarian cancers, given that most do not express the *MDR1* gene. Another mechanism for the multiple-drug resistance phenotype is seen among alkylating agents, cisplatin, and irradiation. Resistance in this group of agents has been linked to elevations in intracellular glutathione levels and is not associated with an overall measurable decrease in drug accumulation. Other transport proteins, including multidrug resistance–associated protein, have been identified that do not involve the p-170 glycoprotein pump. Furthermore, alterations in genes controlling apoptosis and growth arrest have also been cited. Although the relative importance of these separate mechanisms in ovarian cancer remains to be established, it seems most likely that in clinical situations various combinations of mechanisms are at work.

Calculation of Dosage

Dosages of chemotherapeutic agents are usually discussed in terms of mg/kg of body weight or mg/m^2 of total body surface area (Table 17.5). Dosage based on surface area is preferable to

TABLE 17.5 Equations for Calculation of Body Surface Area

	Equation*
Mostellar (m^2)	$\sqrt{\text{Weight} \times \text{Height}/3600}$
DuBois and DuBois (m^2)	$(\text{Weight}^{0.425}) \times (\text{Height}^{0.725}) \times 71.84$
Haycock (m^2)	$(\text{Weight}^{0.5378}) \times (\text{Height}^{0.3964}) \times 0.024265$

*Weight in kilograms; height in centimeters.

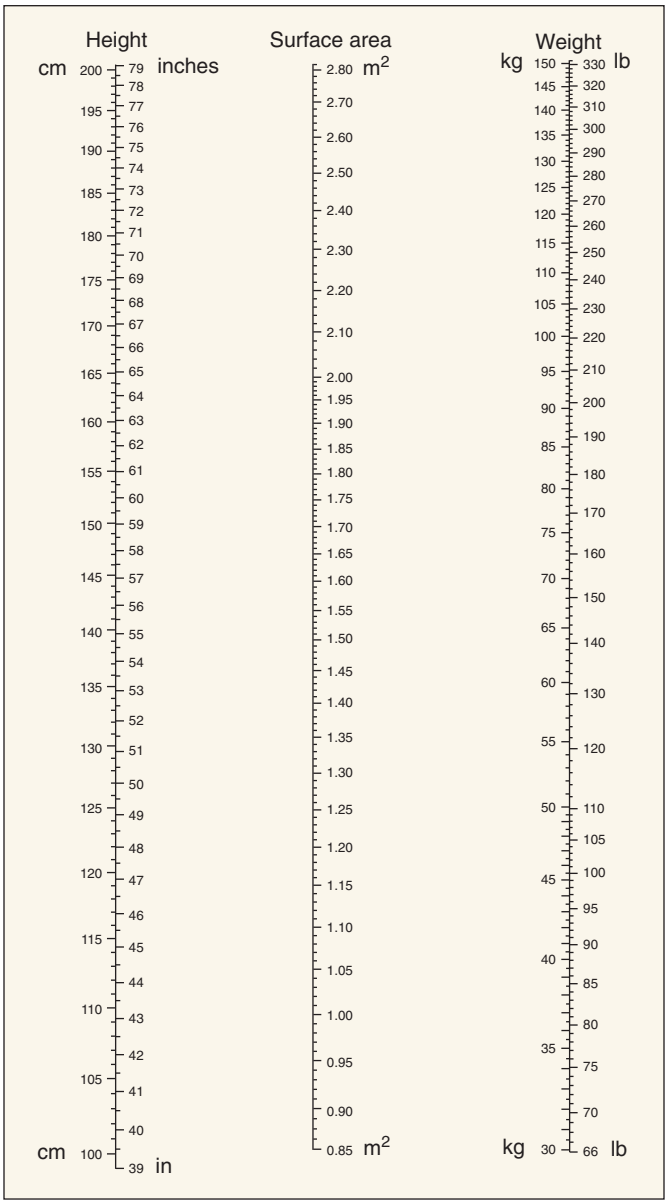

FIGURE 17.6 Nomogram for calculating the body surface area of adults.

that based on weight, because surface area changes much less during the course of therapy, allowing a more consistent absolute amount of drug to be given throughout therapy. Dosages per unit are also more comparable in adults and children (Figs. 17.6 and 17.7), and the variation in total dose between very obese and very thin people is minimized. Dosage in experimental animals expressed as mg/m^2 is more easily related to that in humans. In adults, mg/kg can be converted with reasonable accuracy to mg/m^2 by multiplying by 40.

Dose adjustments should be made for patients who are likely to have a compromised bone marrow reserve—that is, those older than 70 years of age, those who have received previous pelvic or abdominal irradiation, and those who have had previous chemotherapy. In these subsets of patients, the physician should consider beginning with a dose reduced by 35% to 50% and escalate up to a full dose with subsequent courses if initial doses are well tolerated. In a similar manner, any moderate to severe toxicity during the patient's course of therapy should direct a reduction in future doses. The adverse effects criteria table used by the Gynecologic Oncology Group is included as Appendix B.

Dose adjustments are often required in patients receiving anticancer agents that are eliminated by the kidneys. These adjustments reduce the likelihood of overly high plasma drug concentrations and the attendant risk of serious renal toxicity. Several techniques have been used to assess renal function (glomerular filtration rate [GFR]) in individuals with cancer. The calculated creatinine clearance (Cr Cl) using serum creatinine is the most commonly used. The elimination of creatinine is primarily via glomerular filtration, although a small amount may be secreted in the renal tubules. Several studies have compared the different methods of estimating Cr Cl using a serum creatinine value. These methods are based on correlations of Cr Cl with age, body weight, serum creatinine, and creatinine metabolism. The most utilized methods follow.

Jelliffe Method

The Jelliffe method was used originally as a simple estimate of Cr Cl using serum creatinine, making minor adjustments in the calculation for female patients. The current Jelliffe formula takes into consideration age and renal function, and is as follows:

$$\text{Cr Cl (mL/min)} = (98 - (0.8 \times (\text{age} - 20))/ (\text{serum creatinine in mg/dL})) \times \text{Patient's BSA}/1.73\ m^2$$

(For female patients, use 90% of predicted Cr Cl.)

Cockroft–Gault Method

This equation includes factors for lean body weight, which is especially important for obese patients, and correlation for female patients (the obtained value is multiplied by 0.85 for women). This method is similar to the Jelliffe calculation and is as follows:

$$\text{Cr Cl} = (140 - \text{Age}) \times (\text{Lean body weight [in kg]})/ (\text{Serum creatinine}) \times 72$$

Calvert Formula

The use of the Cr Cl has also been incorporated into the so-called Calvert formula. Based on good data, there is evidence showing that there is an inverse linear correlation between the GFR and the AUC of drugs such as carboplatin (Table 17.6).

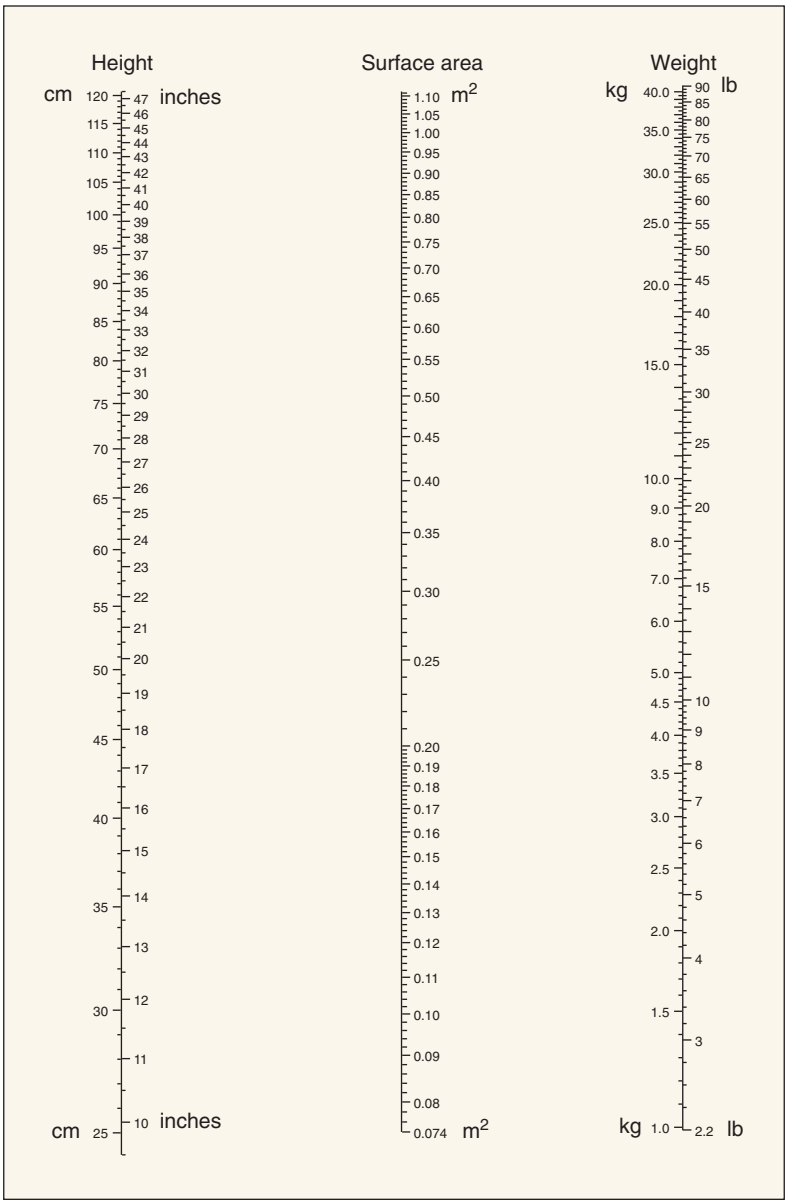

FIGURE 17.7 Nomogram for calculating the body surface area of children.

TABLE 17.6 Recommended Individualized Dosing of Carboplatin

Carboplatin dose (mg) = Target AUC × (GFR+ 25)*
AUC is selected for appropriate clinical situation:
AUC 6 in untreated patients, when used in combination with taxanes
AUC 5 in previously treated patients
AUC 7 in previously untreated patients

*Glomerular filtration rate (GFR) is equivalent to creatinine clearance, which can be measured or can be estimated from the patient's age, weight, and serum creatinine.
AUC, Area under the curve.

This finding suggests that to obtain the desired AUC, the dose must not only be decreased in patients with low renal function but also higher than standard doses may be required for patients with high renal clearance values. The Calvert formula is as follows:

$$\text{Dose (mg)} = \text{Target AUC} \times (\text{GFR} + 25)$$

The original Calvert calculations were derived from GFR as measured by the chromium-51–EDTA (ethylenediaminetetraacetic acid) method. Although calculated GFR is not the same as one that is measured and Cr Cl can exceed GFR by 10% to 40%, the majority of physicians calculate rather than measure the GFR by using formulas such as Jelliffe or Cockcroft–Gault formula and then insert these numbers into the Calvert formula.

CATEGORIES OF DRUGS IN CURRENT USE (TABLE 17.7)

Alkylating Agents

Alkylating agents prevent cell division primarily by cross-linking strands of DNA. Because of continued synthesis of other cell constituents, such as RNA and protein, growth is

TABLE 17.7 Chemotherapy Agents Used in the Treatment of Gynecologic Cancer

Drug	Dosage and Route of Administration	Acute Side Effects	Toxicity	Precautions	Major Indications
ALKYLATING AGENTS					
Cisplatin (CDDP or Platinol)	50–100 mg/m^2 IV every 3 wk; 40 mg/m^2 IV every week with radiation therapy; 75–100 mg/m^2 IP in 2 L over 30 min every 3 wk	Nausea and vomiting, often severe	Renal damage, moderate myelosuppression, neurotoxicity; severe renal damage can be minimized by not exceeding a total dose of 500 mg/ m^2 in any treatment course	Infuse at a rate not to exceed 1 mg/min and only after 10–12 hr of hydration; avoid nephrotoxic antibodies; watch renal function and discontinue if BUN exceeds 30 mg/dL or creatinine exceeds 2 mg/dL	Carcinoma of the ovary, endometrium, or cervix
Carboplatin (Paraplatin)	250–400 mg/m^2 IV bolus or by 24-hr continuous infusion every 2–4 wk (most authorities recommend dosing to AUC values of 5.0–8.0); may be given IP at AUC 6 every 3 wk	Mild nausea and vomiting	Bone marrow suppression, especially thrombocytopenia	Decreased dose in patients who have had previous chemotherapy	Carcinoma of the cervix, ovary, and endometrium
Cyclophosphamide (Cytoxan)	50–1500 mg/m^2 as a single dose IV or 1–5 mg/kg/day (usually 50 mg PO per day); dose decreased if severe leukopenia develops; 50 mg PO daily	Nausea and vomiting	Bone marrow depression, alopecia, cystitis	Maintain adequate fluid intake to avoid cystitis	Carcinoma of the cervix, ovary, endometrium, and fallopian tube
Chlorambucil (Leukeran)	0.1–0.2 mg/kg per day PO; dose decreased if severe bone marrow depression develops	Nausea, vomiting (with high doses)	Bone marrow depression	None	—
Ifosfamide (Ifex)	7–10 g/m^2 IV over 3–5 days every 3–4 wk	Nausea, vomiting	Bone marrow depression, alopecia, cystitis	Uroprotectant to prevent hemorrhagic cystitis	Carcinoma and sarcoma of ovary, cervix, and endometrium
Oxaliplatin	59–130 mg/m^2 IV as a 20-min or 2-hr infusion every 3 wk	Nausea, vomiting, diarrhea, mucositis	Mild to moderate myelosuppression; transaminase elevation; peripheral neuropathy	Should not be given to patient with significant renal or hepatic dysfunction	Ovarian carcinoma
Altretamine (Hexalen)	4–12 mg/kg per day PO in divided doses for 14–21 days, repeated every 6 wk	Nausea and vomiting	Bone marrow depression; neurotoxicity, both central and peripheral	None	Ovarian carcinoma
ANTIMETABOLITES					
5-Fluorouracil (5-FU)	12 mg/kg per day IV for 4 days; then alternate days at 6 mg/kg for 4 days or until toxicity; repeat course monthly or give weekly IV dose of 12–15 mg/kg; maximal dose, 1 g for either regimen; often used as one drug in combination regimens at a dose of 500 mg/m^2 IV	Bone marrow depression, diarrhea, stomatitis, alopecia	Occasional nausea and vomiting	Decrease dose in patients with diminished liver, renal, or bone marrow function or after adrenalectomy	Carcinoma of the ovary and endometrium
Methotrexate	Choriocarcinoma: 10–30 mg/day IV for 5 days; ovarian or cervical carcinoma: 200–2000 mg/m^2 IV with concomitant or sequential systematic antidote ("leucovorin rescue")	None	Bone marrow depression, megaloblastic anemia, diarrhea, stomatitis, vomiting; alopecia less common; occasional hepatic fibroids, vasculitis, pulmonary fibrosis	Adequate renal function must be present, and urine output must be maintained	Choriocarcinoma, carcinoma of the ovary and cervix

TABLE 17.7 Chemotherapy Agents Used in the Treatment of Gynecologic Cancer—cont'd

Drug	Dosage and Route of Administration	Acute Side Effects	Toxicity	Precautions	Major Indications
Gemcitabine (Gemzar)	800–1000 mg/m^2 IV days 1, 8, 15 every 28 days; 800–1000 mg/m^2 IV days 1, 8 every 21 days; 900 mg/m^2 IV days 1, 8 every 21 days for patients with leiomyosarcoma	Mild nausea, vomiting, malaise (usually mild), transient febrile episodes, maculopapular rash	Bone marrow suppression	None	Carcinoma of the breast and ovary; leiomyosarcoma of the uterus
Capecitabine (Xeloda)	1500–2000 mg/m^2 PO daily in two divided doses for 2 wk with a 1-week rest period; repeat every 3 wk	Hand and foot syndrome (palmar–plantar syndrome); nausea, vomiting, diarrhea; abdominal pain; constipation	Myelosuppression; hyperbilirubinemia	Should be taken in divided doses 12 hr apart, administered with water 30 min after a meal	Ovarian carcinoma
ANTITUMOR ANTIBIOTICS					
Dactinomycin (actinomycin D, Cosmegen)	15 μg/kg per day IV or 0.5 mg/day for 5 days	Pain on local infiltration with skin necrosis; nausea and vomiting in many patients 2 hr after the dose; occasional cramps and diarrhea	Bone marrow depression, stomatitis, diarrhea, erythema, hyperpigmentation with occasional desquamation in areas of previous irradiation	Administer through running IV infusion; use with care in patients with liver disease and in the presence of inadequate marrow function; prophylactic antiemetics are helpful	Embryonal rhabdomyosarcoma, choriocarcinoma, ovarian germ cell tumors
Bleomycin	10–20 mg/m^2 IV or IM one or two times a week	Fever, chills, nausea, vomiting; local pain and phlebitis less frequent	Skin: hyperpigmentation, thickening, nail changes, ulceration, rash, peeling, alopecia; pulmonary: pneumonitis with dyspnea, rales, infiltrate can progress to fibrosis; more common in patients older than 70 years of age and with more than a 400-mg total dose but unpredictable	Watch for hypersensitivity in lymphoma with first one or two doses; use with extreme caution in presence of renal or pulmonary disease; start in hospital under observation; do not exceed a total dose of 400 mg	Squamous cell carcinoma of the skin, vulva, and cervix; choriocarcinoma; germ cell and sex cord–stromal tumors
Doxorubicin (Adriamycin)	60–100 mg/m^2 IV every 3 wk	Nausea, vomiting, fever, local phlebitis, necrosis if extravasated, red urine (not blood)	Bone marrow depression, alopecia, cardiac toxicity related to the cumulative dose, stomatitis; atrophy of the myocardia can occur, especially if a total dose of 450–500 mg/m^2 is exceeded	Administer through running IV infusion; avoid giving to patients with significant heart disease; observe for ECG abnormalities and signs of heart failure	Adenocarcinoma of the endometrium, fallopian tube, ovary, and vagina; uterine sarcoma
Liposomal doxorubicin hydrochloride (Doxil)	40–50 mg/m^2 IV every 4 wk	Hand and foot syndrome (palmar–plantar erythrodysesthesia syndrome); mild nausea or vomiting, mucositis, stomatitis	Mild myelosuppression; cardiomyopathy is less common compared with standard doxorubicin	Hypersensitivity reported in approximately seven patients	Ovarian carcinoma
Vinca Alkaloids					
Vinblastine (Velban)	0.10–0.15 mg/kg per week IV	Severe, prolonged inflammation if extravasated; occasional nausea, vomiting, headache, and paresthesias	Bone marrow depression, particularly neutropenia; alopecia, muscle weakness, occasional mild peripheral neuropathy, mental depression 2–3 days after treatment, rarely stomatitis	Administer through running IV infusion or inject with great care to prevent extravasation; decrease dose in liver disease	Choriocarcinoma

Vincristine (Oncovin)	0.4–1.4 mg/m^2 IV weekly in adults; 2 mg/m^2 weekly in children	Local inflammation if extravasated	Paresthesias, weakness, loss of reflexes, constipation; abdominal, chest, and jaw pain; hoarseness, foot drop, mental depression; marrow toxicity generally mild, anemia and reticulocytopenia most prominent; alopecia	Administer through running IV infusion or inject with great care to prevent extravasation; decrease dose in patients with liver disease; patients with underlying neurologic problems may be more susceptible to neurotoxicity; alopecia may be prevented by use of a scalp tourniquet for 5 min during and after administration	Uterine sarcoma, germ cell tumor of the ovary
Vinorelbine (Navelbine)	30 mg/m^2 weekly IV	Mild nausea, 10% alopecia	Bone marrow depression, mild to moderate peripheral neuropathy	Local irritant, dose modification with hepatic dysfunction	Ovarian carcinoma
Epipodophyllotoxins					
Etoposide (VP-16)	100 mg/m^2 IV days 1, 3, and 5; repeat in 4 wk	Nausea and vomiting	Leukopenia, thrombocytopenia, alopecia, headache, fever, occasional hypotension	Reduce dose by 25%–50% for hematologic toxicity	Trophoblastic disease, germ cell tumors
Taxanes					
Paclitaxel(Taxol)	135-175 mg/m^2 IV over 3 hr every 3 wk; as part of **IP dosing** with a platinum, may give 135 mg/m^2 IV on day 1 with 60 mg/m^2 IP on day 8 every 3 wk; as part of **dose-dense therapy**, may give 80 mg/m^2 IV weekly with carboplatin AUC on 6 day 1 every 3 wk	Allergic reaction, nausea, vomiting	Bone marrow depression, severe allergic-like reactions with facial erythema, dyspnea, tachycardia, and hypotension cardiotoxicity with bradycardia, alopecia, stomatitis, fatigue	Cardiac monitoring may be necessary	Ovarian carcinoma; endometrial cancer; cervical cancer
Protein-bound paclitaxel (Abraxane)	80–200 mg/m^2 IV over 30 min weekly; 175–260 mg/m^2 IV over 30 min every 3 wk	Nausea, vomiting, diarrhea	Bone marrow depression, 1% hypersensitivity; abnormal ECG; neuropathy	Dose adjustment in hepatic impairment	Ovarian carcinoma
Docetaxel (Taxotere)	60–100 mg/m^2 IV over 1 h every 3 wk	Hypersensitivity	Myelosuppression; mucositis; alopecia; fluid retention	Requires premedication with steroids	Ovarian carcinoma
Epothilones					
Ixabepilone	20 mg/m^2 IV day 1, 8, 15 of 28-day cycle	Nausea, vomiting, diarrhea	Myelosuppression; neuropathy; fatigue; mucositis	Avoid concomitant use of CYP3A4 inhibitors; avoid grapefruit juice	Ovarian carcinoma
CAMPTOTHECIN ANALOGS					
Topotecan	1.5 mg/m^2 daily for 5 days; 4 mg/m^2 IV on day 1 and day 8; repeat every 21 days	Maculopapular pruritic exanthema	Bone marrow depression	Watch for neutropenic fever	Ovarian carcinoma, cervical carcinoma
Irinotecan (CPT-11)	300 mg/m^2 IV every 3 wk; 100 mg/m^2 IV weekly for 4 wk every 6 wk	Nausea and vomiting, diarrhea	Myelosuppression, alopecia, rash	None	Ovarian carcinoma
PARP INHIBITORS					
Olaparib (Lynparza)	400 mg PO BID	Abdominal pain, decreased appetite, nausea, diarrhea, fatigue, arthralgia, myalgia	Anemia, neutropenia, thrombocytopenia, creatinine elevation	Swallow capsules whole, do not chew, dissolve or open capsules; avoid concomitant use with CYP3A inhibitors	Ovarian cancer (germline or tumor *BRCA* mutation positive)

Continued

TABLE 17.7 Chemotherapy Agents Used in the Treatment of Gynecologic Cancer—cont'd

Drug	Dosage and Route of Administration	Acute Side Effects	Toxicity	Precautions	Major Indications
ANTIANGIOGENESIS AGENTS					
Bevacizumab (Avastin)	15 mg/kg IV every 3 wk; 10 mg/kg IV every 2 wk	Pain, abdominal pain, epistaxis, voice alteration, vomiting, constipation, anorexia	Hemorrhage, bowel perforation, delayed wound healing, wound dehiscence, hypertension, arterial and venous thromboembolism; proteinuria	Use with caution in patients with symptoms of bowel obstruction or ileus given risk of bowel perforation; discontinue at least 28 days before elective surgery because of risks of delayed wound healing and dehiscence	Ovarian cancer, cervical cancer
HORMONAL AGENTS					
Progestational Agents					
Medroxyprogesterone acetate	400–800 mg/wk IM or PO	None	Occasional liver function abnormalities, occasional alopecia and hypersensitivity reactions	Use with care when liver dysfunction present	Carcinoma of the endometrium
Hydroxyprogesterone caproate	1000 mg IM twice weekly				
Megestrol acetate (Megace)	20–80 mg PO twice a day				
Antiestrogens					
Tamoxifen	10–20 mg PO twice daily	Nausea, usually mild	Caused by antiestrogenic action (eg, hot flashes, pruritus vulvae, and occasionally vaginal bleeding)	None	Breast cancer, possibly useful in endometrial carcinoma (metastatic)
AROMATASE INHIBITORS					
Anastrozole (Arimidex)	1 mg PO daily	Hot flashes, asthenia, arthritis, arthralgia depression, nausea, vomiting, rash	Liver enzyme elevation, osteoporosis, fracture, depression	Estrogen-containing therapies and tamoxifen should not be used in conjunction with anastrozole	Breast cancer; ovarian and endometrial carcinoma
Letrozole (Femara)	2.5 mg PO daily	Arthralgia, arthritis, hot flashes, night sweats, fatigue, depression, headache	Bone effects, fracture, myocardial infarction, increase in cholesterol		Breast cancer; ovarian and endometrial carcinoma
Exemestane (Aromasin)	25 mg PO daily after a meal	Hot flashes, fatigue, arthralgia, headache, insomnia, increased sweating, nausea	Cardiac ischemic events, hypertension	Co-medications that induce CYP 3A4 may decrease exposure to exemestane	Breast cancer; ovarian and endometrial carcinoma
MISCELLANEOUS					
Hydroxyurea (Hydrea)	80 mg/kg PO every 3 days or 20–30 mg/kg per day	Anorexia and nausea	Bone marrow depression, megaloblastic anemia; stomatitis, diarrhea, and alopecia less common	Decrease dose in patients with marrow and renal dysfunction	Carcinoma of the cervix (with radiotherapy)

AUC, Area under the curve; *BID,* twice a day; *BUN,* blood urea nitrogen; *CDDP,* cisplatin; *ECG,* electrocardiogram; *IM,* intramuscular; *IP,* intraperitoneal; *IV,* intravenous; *PO,* oral.

unbalanced, and the cell dies. Activity of alkylating agents does not depend on DNA synthesis in the target cells. Cyclophosphamide, however, also inhibits DNA synthesis, which makes it distinctive among the alkylating agents in its mode and spectrum of activity. Alkylating agents now used in gynecologic oncology are as follows:

- Carboplatin
- Cisplatin
- Oxaliplatin
- Cyclophosphamide
- Ifosfamide
- Altretamine (hexamethylmelamine)

Antimetabolites

Antimetabolites act by inhibiting essential metabolic processes that are required for synthesis of purines, pyrimidines, and nucleic acids. These agents are typically S phase specific. The currently used drugs in this category are as follows:

- 5-FU
- Methotrexate
- Capecitabine
- Gemcitabine
- Pemetrexed

Antitumor Antibiotics

Antitumor antibiotics have generally been derived from fermentation products of various fungi, and **most work via DNA intercalation.** Several cytotoxic antibiotics have come into use for chemotherapy of certain neoplasms. Those used in gynecologic oncology are as follows:

- Dactinomycin (actinomycin D)
- Bleomycin
- Doxorubicin and liposomal doxorubicin hydrochloride

Agents Derived From Plants

Several chemotherapeutic agents have been developed from plants. **The vinca alkaloids, the epipodophyllotoxins, the epothilones, and the taxanes act to disturb the normal assembly, disassembly, and stabilization of microtubules. The camptothecin analogs serve to inhibit topoisomerase I,** thereby inducing single-stranded DNA breaks. Inhibitors of topoisomerase II include etoposide (VP16) and mitoxantrone. These drugs are as follows:

- Vinca alkaloids:
  - Vinblastine
  - Vincristine
  - Vinorelbine
- Taxanes:
  - Paclitaxel
  - Protein-bound paclitaxel
  - Docetaxel
- Epipodophyllotoxin:
  - Etoposide
- Camptothecin analogs:
  - Topotecan
  - Irinotecan
- Epothilone:
  - Ixabepilone

Hormonal Agents

These agents are often used in the treatment of endometrial, breast, and ovarian cancers and are classified in two broad categories: antiestrogens and progestational agents. Megestrol acetate may both downregulate estrogen-responsive genes and reduce the number of available cell surface estrogen receptors. Examples of these agents are as follows:

- Antiestrogen:
  - Tamoxifen
- Progestational agents:
  - Megestrol acetate
  - Medroxyprogesterone acetate
- Aromatase inhibitors:
  - Anastrazole
  - Letrozole
  - Exemestane

Targeted Therapies and Immunotherapy

To date, traditional chemotherapy has predominantly focused on killing rapidly dividing cells. Unfortunately, normal cells may also be affected, causing significant toxicity. Targeted therapies have attempted to focus anticancer treatment on particular pathways and mechanisms that cause cancer to both increase efficacy and decrease toxicity in comparison with traditional chemotherapies. These therapies may aim to affect pathways for angiogenesis, cell cycle, and apoptosis in tumor cells. Several broad categories of targeted therapies exist. Monoclonal antibodies target receptors on the surface of tumor cells. As part of anticancer therapy, monoclonal antibodies have been used in two fashions. First, infusion of the antibody has allowed binding to target cells, which in turn triggers normal effector mechanisms of the body. Second, monoclonal antibodies have been conjugated to a strongly radioactive atom, such as iodine-131, to aid in killing the target. Monoclonal antibodies, such as bevacizumab, directed against vascular endothelial growth factor (VEGF) to block angiogenesis are among the most common used in gynecologic cancer therapy.

Other targeted therapies focus on the internal components and function of the cancer cell, using small molecules to disrupt the function of the cells, triggering apoptosis. Poly(ADP-ribose) polymerase (PARP) inhibitors are a newer class of targeted agent available for treatment of breast and ovarian cancers. PARP is important in repair of single-strand DNA breaks (SSBs). Inhibition of PARP allow SSBs to persist, leading to eventual double-strand breaks (DSBs) as the replication fork progresses. Patients with mutations in BRCA are unable to repair these DSBs, resulting in cell death. Immunotherapies include vaccines (which may be dendritic cell, protein/peptide, DNA, or RNA based) and adoptive immunotherapy. Although many agents are in clinical trial, none are currently approved by the US Food and Drug Administration (FDA) except for bevacizumab and the PARP inhibitor olaparib. Some examples, along with their targets, are as follows:

- Monoclonal antibodies:
  - Oregovomab (CA-125)
  - Cetuximab (EGFR)
  - Bevacizumab (VEGF)
  - Trastuzumab (HER-2/neu)

- Small molecules:
  - Cediranib (VEGFR)
  - Gefitinib (EGFR)
  - Erlotinib (EGFR)
  - Bortezomib (proteosome)
  - Imatinib (Bcr-Abl protein tyrosine kinase, c-kit receptor tyrosine kinase)Pazopanib (VEGFR, platelet-derived growth factor receptor [PDGFR]-α, -β, ckit)
  - Sorafenib (Raf/Mek/Erk, VEGFR)
  - Sunitinib (VEGFR, PDGFR-α, -β)
- PARP inhibitors:
  - Olaparib
  - Rucaparib
  - Veliparib

DRUG TOXICITY

Unfortunately, traditional chemotherapeutic agents are indiscriminate in their effects: Both malignant and normal tissues are affected. Although their goal is to kill more cancerous than normal cells, many side effects, particularly those to organ systems with rapidly proliferating cell populations, are inevitable. Usually, the mechanism of toxicity is similar to the one producing the desired cytotoxic effect. Even organs with limited cell proliferation can be damaged by chemotherapeutic agents, especially if the agents are used at high doses. Chemotherapeutic agents must be used at doses that produce some degree of toxicity to normal tissue in order to be effective. The incidence of severe side effects of chemotherapeutic agents is greatly influenced by states such as severe disability, advancing age, poor nutrition, or direct organ involvement by primary or metastatic lesions. The physician must monitor these patients with extreme care, and appropriate dose modifications must be made (Table 17.8).

Hematologic Toxicity

Hematologic effects are the most frequently observed toxicity. Acute granulocytopenia occurs 6 to 12 days after the administration of most myelosuppressive chemotherapeutic agents. Recovery occurs in 10 to 14 days. The megakaryocyte series is affected later, such that platelet suppression usually occurs 4 or 5 days after granulocytopenia and recovers several days after the white blood cell count.

Most clinicians consider patients with absolute granulocyte counts less than 500/mm^3 for 5 days or longer to be at a higher risk for sepsis. The practice of using prophylactic broad-spectrum antibiotics in febrile granulocytopenic cancer patients has significantly decreased the incidence of life-threatening infections in this group of patients. Granulocytopenic patients should have their temperatures checked every 4 hours, and they should be examined frequently for evidence of infection. **Thrombocytopenic patients with platelet counts less than 20,000/mm^3 are at increased risk for spontaneous hemorrhage, particularly from the GI tract.** Routine platelet transfusions for platelets under 10,000 to 20,000/mm^3 have been used by some clinicians. Others wait and watch until patients manifest some evidence of bleeding. Repeat transfusions of platelets at 2- to 3-day intervals may be necessary in patients with severe thrombocytopenia. Patients with active peptic ulcer disease and patients needing surgical procedures need to be transfused with counts lower than 50,000/mm^3.

TABLE 17.8 Drug Dose Modification Based on Common Hematologic Toxicity

Count Before Next Course (per mm^3)	Dose Modification*
Leukocytes	
>4000	100% of dose
3000–3999	100% of nonmyelotoxic agents 50% of myelotoxic agents
2000–2999	100% of nonmyelotoxic agents 25% of myelotoxic agents
1000–1999	25% of myelotoxic agents
≤999	No drug
PLATELETS	
>100,000	100% of dose
50,000–100,000	100% of nonmyelotoxic agents
<50,000	No drug

*Based on myelosuppression.

Growth Factor Therapy

Granulocyte-stimulating therapy. The application of hematopoietic factors to supportive care has been dramatic. Rapid advances in unraveling the molecular biology and biochemistry of these glycoprotein hormones that regulate hematopoiesis have led to their routine clinical use. Since their emergence in 1989, their use has allowed amelioration of therapy-related myelosuppression, modulation of disease-related myelosuppression, and enhanced host defense to infection. This class of agents includes molecules such as granulocyte-colony stimulating factor (G-CSF) and granulocyte macrophage colony–stimulating factor (GM-CSF). The biologic activities of these proteins are complex and multifunctional, stimulating potent changes in the growth, differentiation, distribution, and functional status of mature cells and their precursors (Table 17.9).

Initial studies with G-CSF and GM-CSF focused on their administration via the intravenous (IV) route. Since then, numerous studies have shown that subcutaneous administration once or twice a day is even more myelostimulatory than 2- to 4-hour IV infusions. The recommended dose of GM-CSF is 250 μg/m^2 or 3to 5 μg/kg. It is interesting that, at least in some cases, a fairly low dose of GM-CSF may be more myelostimulatory than a higher dose. The enhancement of neutrophil function in terms of adherence, phagocytosis, and chemotaxis has also been noted in clinical studies, and GM-CSF may also function to activate lymphocytes. **Two types of G-CSF are available: filgrastim and a long-acting pegfilgrastim. The recommended dose of filgrastim is 5 μg/kg, given subcutaneously. Treatment should begin at least 24 hours after completion of chemotherapy and should continue daily until the absolute neutrophil count exceeds 10,000/mm^3. Subsequent chemotherapy should not begin until at least 48 hours have elapsed since the last dose. The recommended dose of pegfilgrastim is 6 mg. A**

TABLE 17.9 Characteristics of the Hematopoietic Growth Factor Family of Cytokines

Cytokine	Source	Function
Granulocyte-macrophage colony stimulating factor (GM-CSF)	T cells, endothelial cells, stromal cells	Stimulates hematopoiesis of granulocyte and macrophage lineage; activates granulocytes and macrophages
Granulocyte-colony stimulating factor (G-CSF)	Endothelial cells, monocytes, stromal cells	Stimulates hematopoiesis of granulocyte lineage; activates granulocytes
Erythropoietin	Kidney	Stimulates erythroid growth and development
Interleukin-1	Monocytes and macrophages, B and T cells, endothelial cells	Co-stimulates early stages of hematopoiesis; T- and B-cell activation
Interleukin-3	T cells	Stimulates early stages of hematopoiesis
Interleukin-6	T cells, monocytes and macrophages, fibroblasts	Co-stimulates early stages of hematopoiesis; T- and B-cell activation

Modified from Kouides PA. The hematopoietic growth factors. In Haskell CM, ed. *Principles of Cancer Treatment,* 4th ed. Philadelphia, 1995, Saunders.)

subcutaneous injection is recommended at least 24 hours after the completion of chemotherapy infusion and should not be given within 14 days of any subsequent chemotherapy. Bone pain is the most common side effect of G-CSF. Other rarer effects include:

- A cutaneous eruption of macules and papules
- Exacerbation of underlying autoimmune disease
- Anaphylaxis, which is rare
- Mild increased risk of thrombosis
- A theoretic possibility of the exacerbation of the underlying malignancy

Unquestionably, the administration of G-CSF or GM-CSF accelerates neutrophil recovery to a significant degree after standard-dose chemotherapy. G-CSF is indicated to decrease the incidence of febrile neutropenia with regimens associated with a significant incidence of neutropenia with fever.

Erythrocyte-stimulating therapy. The existence of a hormone that regulates erythropoiesis (Epo) has been proposed for 100 years. In 1985, two independent groups cloned the gene responsible for this growth factor. This gene was labeled the Epo gene. The kidney appears to be the major site of production of erythropoietin. Erythropoietin stimulates the division and differentiation of committed erythroid progenitors in the bone marrow. Epoetin alpha is a glycoprotein manufactured by recombinant DNA technology that contains the exact amino acid sequence of the natural Epo.

Epoetin has the potential to reduce the transfusion requirement in anemic patients and may enhance the overall quality of life. Administration may be indicated when hemoglobin levels have decreased below 10 mg/dL during chemotherapy treatment or when a significant chance for blood transfusion exists. However, iron deficiency must be corrected before starting epoetin. Epoetin injected at a dose of 150 U/kg subcutaneously three times a week for 12 weeks has been used by many clinicians. The dose may be increased up to 300 U/kg. Others use a daily dose of 60 U/kg, progressing to a maximum dose of 90 U/kg per day. Another commonly used approach is to inject 40,000 U/week, with escalation to 60,000 U for nonresponders. Darbepoetin alfa is a long-acting form that may be administered at doses of 3.0 μg/kg every 3 weeks. Adverse effects are uncommon but include worsening hypertension in patients with end-stage renal disease. Other effects include edema and diarrhea.

Erythropoiesis-stimulating agents must be used with caution. In 2007, the FDA issued a black box warning regarding the use of both epoetin alfa and darbepoetin alfa. Indeed, two large randomized trials have reported significantly worse tumor control and survival rates in patients receiving epoetin. Research also indicates that the erythropoietin receptor is expressed in several cancer cell lines, raising the concern of possible stimulation of tumor cell growth by these drugs. Epoetin has also been implicated in possible thromboembolic complications, possibly related to elevated hemoglobin levels. Currently, physicians who wish to use these agents for chemotherapy-related anemia must register with the Risk Evaluation and Mitigation Strategy (REMS) program. Manufacturers have implemented the Erythropoiesis Stimulating Agents (ESA) Assisting Providers and cancer Patients with Risk Information for the Safe use of ESAs (APPRISE) Oncology Program as part of a REMS designed for health care providers treating patients with cancer.

Platelet-stimulating Therapy

Oprelvekin is produced in *Escherichia coli* by recombinant DNA methods. The protein is very similar to interleukin (IL)-11, which is a thrombopoietic growth factor that directly stimulates the proliferation of hematopoietic stem cells and megakaryocyte maturation, which in turn increase platelet production. IL-11 is produced by bone marrow stromal cells and is part of the cytokine family. The usual dose is 50 μg/kg, which is given once daily subcutaneously as a single injection in the abdomen, thigh, or hip. Treatment should begin 6 to 24 hours after completion of chemotherapy and continued until the nadir platelet count is 50,000 cells/μL. Potential side effects include mild to moderate fluid retention, and IL-11 should be used with caution in patients with a history of atrial arrhythmia, transient mild visual blurring, and transient rashes at the injection site. Anaphylactic reactions have been reported.

Gastrointestinal Toxicity

Gastrointestinal toxicity is another frequent manifestation of chemotherapeutic agents. Mucositis may be caused by direct effects on the rapidly dividing epithelial mucosa. Concomitant granulocytopenia allows the injured mucosa to become infected and serve as a portal of entry for bacteria and fungi.

The onset of mucositis is frequently 3 to 5 days earlier than myelosuppression. The nasopharyngeal lesions are difficult to distinguish from viral lesions. Candidiasis is often seen and is difficult to distinguish from stomatitis secondary to chemotherapy; antifungal agents have been very effective in treating this condition. Necrotizing enterocolitis is another condition that is seen in patients receiving chemotherapy. Symptoms of this condition are watery or bloody diarrhea, abdominal pain, nausea, vomiting, and fever. Patients usually have abdominal tenderness and distention. They also have a history of broad-spectrum antibiotic use. Most necrotizing enterocolitis is caused by anaerobic bacteria such as *Clostridium difficile.* The treatment of choice for *C. difficile* infection is oral vancomycin, 125 mg four times daily for 10 to 14 days.

The most common side effect of chemotherapy that patients experience is nausea and vomiting. Although the exact mechanisms are not clearly defined, most agents appear to stimulate the chemoreceptor trigger zone in the area postrema of the brain to secrete neurotransmitters such as dopamine, serotonin, and histamine. These neurotransmitters may activate the neighboring vomiting center to induce nausea and emesis. Direct stimulation of serotonin receptors in the GI tract, direct cerebral action, and psychogenic effects may also play a role. Different patterns of emesis include acute emesis (within 24 hours of chemotherapy infusion), delayed emesis (typically beginning 16–24 hours after chemotherapy but persisting up to 72–96 hours), and anticipatory emesis. Common antiemetic regimens are detailed in Table 17.10. The choice of agents should be governed by knowledge of the emetogenic potential of the chemotherapies administered (Table 17.11).

Highly emetogenic chemotherapies include cisplatin (>50 mg/m^2) and high-dose cyclophosphamide (>1500 mg/m^2). Cisplatin may induce both acute and delayed vomiting. A premedication regimen should consist of a combination of antiemetics given 30 minutes before chemotherapy infusion. Common regimens include use of a 5-HT3 receptor antagonist with dexamethasone. Lorazepam and oral aprepitant may also be used. Moderately emetogenic chemotherapies include lower doses of cisplatin (<50 mg/m^2) and cyclophosphamide (750–1500 mg/m^2) and carboplatin, doxorubicin, methotrexate (>1000 mg/m^2), ifosfamide, and high-dose 5-FU. These agents may be premedicated with 5-HT3 receptor antagonists in combination with dexamethasone. Mildly emetogenic chemotherapies include methotrexate, paclitaxel, docetaxel, liposomal doxorubicin, gemcitabine, bleomycin, and etoposide. These agents may be premedicated with single-agent antiemetics.

Delayed emesis requires special consideration. Prophylaxis may include use of single-agent 5-HT3 receptor antagonist therapy or a brief pulse of dexamethasone in combination with metoclopramide, a 5-HT3 receptor antagonist, or aprepitant, a substance P/NK1 antagonist. Long-acting drugs such as palonosetron, a 5-HT3 receptor antagonist, and fosaprepitant, a substance P/NK1 antagonist, are now available and may be administered intravenously on the day of chemotherapy. These drugs are noninferior to standard 3-day oral dosing and may provide advantages in convenience for the patient.

TABLE 17.10 Common Antiemetic Regimens

	Drug	Dosage
	PREMEDICATION	
5-HT3 receptor antagonists	Ondansetron	8–24 mg IV/PO
	Granisetron	10 μg/kg IV; 2 mg PO
	Dolasetron	1.8 mg/kg IV; 100 mg IV; 100 mg PO
	Palonosetron (long acting)	0.25 mg IV
Substance P/NK1 receptor antagonist	Aprepitant	125 mg PO
	fosAprepitant (long acting)	150 mg IV
Motility agent	Metoclopramide	2–3 mg/kg IV; 20–40 mg PO
Phenothiazine	Prochlorperazine	10 mg IV/IM/PO; 25 mg PR; 15-mg spansule
Benzodiazepine	Lorazepam	0.5-2 mg IV, PO, or SL
Corticosteroid	Dexamethasone	8-20 mg IV or PO
Acute-phase emesis	Dexamethasone	20 mg IV
	Ondansetron	8–24 mg IV
	Metoclopramide	3 mg/kg IV (repeat every 2 hr prn)
	Diphenhydramine	25–50 mg IV (repeat every 2 hr prn)
	Lorazepam	1–2 mg IV
Prophylaxis of delayed emesis	Dexamethasone	8 mg PO bid × 2 days; then 4 mg PO bid × 2 days
	plus metoclopramide	40 mg PO qid × 2–3 days*
	or 5-HT3 antagonist	Ondansetron 8 mg PO bid or tid × 2–3 days or granisetron 1 mg PO bid or 2 mg PO qid × 2–3 days
	5-HT3 antagonist	PO × 2-3 days alone or plus aprepitant 80 mg PO and dexamethasone 8 mg PO qid × 3 days

*Patients should be advised to take 50 mg of diphenhydramine PO at the first sign of dystonic reaction.
Bid, Twice a day; *IM,* intramuscular; *IV,* intravenous; *PO,* oral; *prn,* as needed; *qid,* four times a day; *tid,* three times a day;

Skin Reactions

Skin reactions, including alopecia and allergic hypersensitivity reactions, are also often seen with chemotherapeutic agents. **Skin necrosis and sloughing at the site of IV extravasation is associated particularly with agents such as doxorubicin, actinomycin D, mitomycin C, vinblastine, vincristine, and nitrogen mustard.** The extent of the necrosis is determined by the amount of extravasated drug. **Management includes removal of the IV line and local infiltration of the area with corticosteroids and ice pack therapy four or five times a day for 3 days.** Long-term monitoring of these patients is essential. **Palmar–plantar erythrodysesthesia, or hand and foot**

TABLE 17.11 Emetogenic Potential of Cancer Chemotherapeutic Agents Used in Gynecologic Oncology

Emetogenic Potential (Frequency, %)	Agent
<10	Bleomycin
	Hydroxyurea
	Melphalan (PO)
	Methotrexate (<50 mg/m^2)
10–30	Docetaxel
	Doxorubicin (<20 mg/m^2)
	Etoposide
	Fluorouracil (<1000 mg/m^2)
	Gemcitabine
	Methotrexate (50–250 mg/m^2)
	Paclitaxel
	Topotecan
30–60	Cyclophosphamide (<750 mg/m^2)
	Dactinomycin (<1.5 mg/m^2)
	Doxorubicin (20–60 mg/m^2)
	Ifosfamide
	Methotrexate (250–1000 mg/m^2)
60–90	Carboplatin
	Cisplatin (<50 mg/m^2)
	Cyclophosphamide (750–1500 mg/m^2)
	Dactinomycin (>1.5 mg/m^2)
	Doxorubicin (>60 mg/m^2)
	Irinotecan
	Melphalan (IV)
	Methotrexate (>1000 mg/m^2)
>90	Cisplatin (>50 mg/m^2)
	Cyclophosphamide (>1500 mg/m^2)

Modified from Hesketh PJ, Kris MG, Grunberg SM, et al. Proposal for classifying the acute emetogenicity of cancer chemotherapy. *J Clin Oncol* 1997;15:103-109.

TABLE 17.12 Prophylaxis for Taxane Hypersensitivity

Agent	Prophylaxis Regimen
Docetaxel	Starting 1 day before infusion: dexamethasone 8 mg PO bid × 3 days
Paclitaxel	Night before and morning of infusion: dexamethasone 20 mg PO*
	30 min before infusion†: diphenhydramine 25–50 mg IV *plus* H2 antagonist IV (cimetidine 300 mg or ranitidine 50 mg)

*May be repeated orally or intravenously 30 minutes before infusion.
†If the first cycle of treatment is well tolerated, subsequent cycles may be premedicated using oral doses.
IV, Intravenous; *PO,* oral.

syndrome, may be a dose-limiting toxicity of liposomal doxorubicin and is characterized by painful edema and erythema. Alopecia is a common side effect of many chemotherapeutic agents. Therapies designed to reduce alopecia have not been successful. Hair growth resumes 10 to 20 days after treatment is completed.

Hypersensitivity

Many chemotherapeutic agents may be associated with hypersensitivity reactions, although only a few agents elicit these responses in more than 5% of patients. **Of the agents commonly used in gynecologic oncology, the taxanes and platinum compounds are the most likely culprits,** although occasional reactions may also be seen with bleomycin, doxorubicin, etoposide, cyclophosphamide, ifosfamide, and methotrexate.

In phase I trials, the incidence of severe hypersensitivity to paclitaxel was approximately 30%; however, with adequate prophylaxis (Table 17.12)**, the incidence is now less than 10%.** Although hypersensitivity associated with paclitaxel is often attributed to its formulation in Cremophor EL, a polyoxyethylated castor oil, docetaxel has also been associated with a similar incidence of hypersensitivity despite its formulation in Tween 80. With appropriate premedication, hypersensitivity to docetaxel has been reduced to 2% to 3%. The occurrence of hypersensitivity does not preclude further treatment with the drug. If additional diphenhydramine or corticosteroids do not allow the infusion to be completed after a delay, patients may undergo successful systematic desensitization.

The incidence of hypersensitivity to platinum analogs varies from 5% to 20%. Unlike reactions to taxanes, which typically occur within minutes of starting the initial dose, reactions to platinum agents typically do not manifest until several cycles have already been administered. In one series, a median of eight platinum courses was administered before hypersensitivity occurred. Routine premedication for hypersensitivity is not recommended, and patients who experience mild reactions may respond well to the addition of appropriate premedications. Patients with severe reactions may attempt systematic desensitization if indicated, although success is variable.

Hepatic Toxicity

Hepatic toxicity is uncommon. Mild elevations in transaminase, alkaline phosphatase, and bilirubin are seen with many agents, but rarely is the condition severe. Psoriasis and drug-induced hepatitis can affect the amount of the chemotherapeutic agent given, as can preexisting liver disease or exposure to other hepatic toxins.

Pulmonary Toxicity

Interstitial pneumonitis with pulmonary fibrosis is seen with certain chemotherapeutic agents. The agents most likely to produce this are doxorubicin, alkylating agents, and nitrosoureas. Treatment of patients with drug-induced interstitial pneumonitis involves discontinuation of the cytotoxic agent and supportive care. Steroids may be of some benefit.

Cardiac Toxicity

The risk of cardiac toxicity is seen primarily with doxorubicin. The risk increases dramatically when the cumulative dose

exceeds 500 mg/m^2 of ideal body surface area. In recent years, this limit has rarely been exceeded; thus, cardiomyopathy has diminished greatly in incidence. Acute arrhythmias may often be seen, but these disappear with a few days of supportive care. On rare occasions, cyclophosphamide has been reported to produce cardiotoxicity, particularly when it is used in massive doses. Mitomycin C has been reported to cause endocardial fibrosis and myocardial fibrosis, but again these events occur rarely.

Renal Toxicity

Nephrotoxicity may be dose limiting in up to 35% of patients receiving cisplatin. Proximal and distal tubule damage leads to electrolyte wasting and increase in serum creatinine with concomitant decrease in Cr Cl. Renal toxicity may be reduced with adequate IV hydration and mannitol- or furosemide-induced diuresis. Antibiotic therapy with aminoglycosides potentiates the nephrotoxicity of drugs such as cisplatin and should be avoided if possible.

Genitourinary Toxicity

Metabolites of cyclophosphamide are irritants to the bladder mucosa and can cause chronic hemorrhagic cystitis. The toxic metabolite of cyclophosphamide that causes bladder toxicity is known as acrolein. Vigorous hydration and diuresis during administration of cyclophosphamide are essential. Cisplatin produces renal tubular toxicity associated with azotemia and magnesium wasting. Again, this complication can be minimized with diuresis during administration of cisplatin. Other agents known to cause genitourinary toxicity are methotrexate, nitrosoureas, and mitomycin C. Mesna or N-acetylcysteine has been used in recent times in conjunction with cyclophosphamide to prevent bladder toxicity. This agent acts by inactivating the toxic metabolite acrolein.

Neurologic Toxicity

In general, most antineoplastic drugs are associated with mild neurologic side effects. There are some exceptions, however. Vinca alkaloids are commonly associated with peripheral motor sensory and autonomic neuropathies. Agents such as vincristine, vinblastine, paclitaxel, and vinorelbine can produce loss of deep tendon reflexes with distal paresthesias. Paclitaxel may also cause peripheral neuropathy. In most cases, these neurologic toxicities are reversible after cessation of the drug. Cisplatin produces ototoxicity and peripheral neuropathy and occasionally retrobulbar neuritis. **High doses of cisplatin, which are often used in ovarian cancer therapy, are particularly likely to produce progressive and somewhat delayed peripheral neuropathy.** 5-FU has been associated with acute cerebellar toxicity. Hexamethylmelamine is reported to produce peripheral neuropathy and encephalopathy. Ifosfamide has also been associated with encephalopathy, particularly in patients with low serum albumin levels.

Gonadal Dysfunction

Many chemotherapeutic agents have lasting effects on testicular and ovarian functions. This is particularly true of alkylating agents, which can cause azoospermia and amenorrhea. The onset of amenorrhea and ovarian failure is accompanied by an elevation of the serum follicle-stimulating hormone and a fall in serum estradiol. Indeed, these patients often end up with premature menopause. The younger the patient at the onset of therapy, the less likely it is that chemotherapy would eventuate in permanent gonadal dysfunction. **In women older than 30 years of age, most chemotherapeutic regimens are associated with a high incidence of premature ovarian failure.**

Supportive Care

Supportive social workers, chaplains, and psychiatrists in a concentrated total care setting are of great value in enabling a patient to cope with the emotionally and financially shattering experience of having cancer. Home health care services have improved in most areas of the United States, so that IV fluids, antibiotics, IV alimentation, and even chemotherapy can be administered in the home if the situation allows. Although treatment of many patients must be conducted at large medical centers where new agents and multidisciplinary facilities are available, continuing collaboration between the medical center and the patient's primary physician is essential. Problems caused by the disease or its treatment often arise when the patient returns to her community. An informed local physician can rapidly evaluate these crises and take appropriate action. The performance status of the patient should be watched carefully (Table 17.13).

EVALUATION OF NEW AGENTS

The development of new, promising agents is a long, complicated, and expensive process. After identification of potential drugs in in vitro and animal models, all anticancer therapeutic agents must undergo rigorous clinical testing. Several levels of clinical trials are necessary to demonstrate that a newly developed agent should be allowed in regular medical practice. Such trials have been defined as follows.

Phase I

These initial trials are designed to test new drugs at various doses to evaluate toxicity and determine the tolerance to a particular agent. The primary endpoint to these trials is safety evaluation. A dose escalation design is often used in order to define the maximum tolerated dose and to characterize the dose-limiting toxicities of the drug. Some therapeutic effects may be observed, even though the intent of these trials is not response measurement.

Phase II

Phase II studies attempt to determine the response rate of the particular agent at the dose and schedule defined by phase I trials. Secondary endpoints include determination of progression-free interval, determination of toxicity, and overall survival. Most phase II trials are single-arm nonrandomized studies.

TABLE 17.13 Performance Status

GOG/ECOG Group Score	Zubrod Description	Scale (%)	Karnofsky Description	Scale (%)
0	Fully active, able to carry on all predisease performance without restriction	90–100	Normal, no complaints, no evidence of disease	100
			Able to carry on normal activity; minor symptoms or signs of disease	90
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature (eg, light housework, office work)	70–80	Normal activity with effort; some signs and symptoms of disease	80
			Cares for self; unable to perform normal activity or to do active work	70
2	Ambulatory and capable of all self-care but unable to carry out any work activities; up and about more than 50% of waking hours	50–60	Requires occasional assistance but is able to care for most of own needs	60
			Requires considerable assistance and frequent medical care	60
3	Capable of only limited self-care; confined to bed or chair more than 50% of waking hours	30–40	Requires special care and assistance; disabled	40
			Severely disabled; hospitalization indicated, although death not imminent	30
4	Completely disabled; cannot carry on any self-care; totally confined to bed or chair	10–20	Very sick, hospitalization indicated	20
			Fatal processes progressing rapidly; moribund	10
5	Dead	0	Dead	0

ECOG, European Cooperative Oncology; *GOG,* Gynecologic Oncology Group.

Phase III

Phase III trials are designed to compare a drug identified as promising in phase II trials with current standard treatment regimens. Commonly, a new drug is tested against the accepted gold-standard drug therapy for a particular disease site and histology. These trials are typically large in order to provide sufficient power to detect a difference between the treatment arms. Whereas the primary endpoint in phase III trials is usually progression-free survival, secondary endpoints usually include response rate and overall survival.

Multipathway Targeted Agents
- Sorafenib
- Vandetanib
- Imatinib
- Dasatinib
- Cabozantinib (XL-184)

Other Targets of Interest
- Angiopoietin (Ang)/Tie-2
- Aurora Kinase
- Delta-Like 4/Notch
- Folate Receptor α
- Vintafolide (EC-145)
- Antimesothelin Antibodies
- Histone Acetyltransferases and Histone Deacetylases
- Platelet-derived Growth Factor
- P53
- Immune Therapy

Unique Toxicities of Targeted Therapy
- Hypertension
- Reverse Protein Leukoencephalopathy
- Cardiotoxicity
- Renal Toxicity
- Thromboembolic Events
- Gastrointestinal Perforation and Fistula
- Cutaneous Complications
- Metabolic Abnormalities

Special Considerations for Targeted Therapies
Conclusions

KEY POINTS

1. The development of new and effective therapies should be rooted in a clear understanding of tumor biology.
2. Bevacizumab, a humanized monoclonal antibody to human vascular endothelial growth factor, was the first US Food and Drug Administration–approved drug targeting angiogenesis
3. Reverse protein leukoencephalopathy is a rare complication of antiangiogenic agents, including bevacizumab, sorafenib, and sunitinib.
4. As knowledge regarding tumor biology and pathogenesis continues to expand, the number of targeted agents will no doubt increase exponentially. These agents have the potential to have a profound impact on the treatment of patients with gynecologic malignancies.

TARGETED THERAPY

The use of site-specific combinations of surgery, chemotherapy, and radiation therapy in gynecologic malignancies has led to marked initial improvements in patient survival. Unfortunately, over the past 30 years, there has been little improvement in disease-specific mortality rates from the three major gynecologic malignancies (Table 18.1). Furthermore, the incidence of these cancers has remained fairly stable since 1985, especially among endometrial cancers (Table 18.2). The addition of traditional cytotoxic chemotherapies to current treatment regimens is likely to offer only increased toxicities in the absence of further survival benefit. To critically affect patient outcome and improve quality of life, the therapeutic armamentarium of modern oncologists must be expanded. **The search for novel therapeutic options has led to an exploration of therapies targeting molecular pathways critical to the survival of cancer cells.**

FOUNDATION OF TARGETED THERAPY

The development of new and effective therapies should be rooted in a clear understanding of tumor biology. In a pair of seminal papers in 2000 and 2011, Hanahan and Weinberg described the key capabilities acquired by normal cells that lead to the development of cancer. Fig. 18.1 represents the 10 "hallmarks of cancer" implicated in the tumorigenic process. Sustained proliferative signaling and evading growth suppressors relate to the development of cellular autonomy, which is essential for uncontrolled proliferation. Enabling replicative immortality indicates that the cell is unencumbered by two typical processes of senescence: (1) the cessation of growth upon reaching a set number of cellular doublings and (2) crisis, which involves massive cellular death. Resisting cell death is a feature seen in most cancer types, allowing the cells to continue to grow and replicate in the setting of damage that would lead to attrition in a normal cell. The ability to activate invasion of tissues and metastasis is crucial to the continued expansion of tumor when space and nutrients become limited. Inducing sustained angiogenesis describes uncontrolled growth of new blood vessels, which supply oxygen and nutrients to the tumor. Evading immune destruction allows the tumor to avoid detection by immune cells and limit the extent of immunologic killing. Finally, the ability to reprogram energy metabolism allows adjustment of energy use and creation to prioritize tumor growth and survival. Two additional enabling characteristics allow the cancer to leverage the above mechanisms into cellular growth and survival. Genomic instability hampers the cell's ability to detect and repair DNA errors and damage. Thus, mutations accumulate, and genomic integrity is lost. The presence of rich immune infiltrates in the tumor microenvironment can support tumorigenesis by growth and prosurvival factors. Collectively, these steps enable tumor initiation, growth, and progression.

Acquisition of survival capabilities by cancer cells is theorized to be directly related to dysfunction of the normal molecular mechanisms and pathways within the cell and surrounding microenvironment. Because these pathways drive the progression of cancer, identifying and targeting the changes in the pathways to treat malignancy is a rational strategy. Thus, the field of targeted therapy has flourished in modern cancer treatment, especially among common gynecologic malignancies.

Cytotoxic chemotherapy typically acts primarily on any rapidly dividing cells. Although this may have the desired effects on tumor cells, these drugs do not discriminate between tumor cells and normal host cells, resulting in undesirable side effects in the gastrointestinal (GI) tract, bone marrow, and integumentary and other systems. Ideal targeted therapies provide a more

TABLE 18.1 Mortality Rates* of Major Gynecologic Malignancies Over 30 Years

	1975	1985	1995	2005	2008–2012
Cervical	5.55	3.82	3.24	2.42	2.3

directed approach by acting on targets selectively leveraged in tumor cells or in the tumor microenvironment. These targets are typically members of the pathways involved in tumorigenesis, supporting growth, proliferation, metastasis, and angiogenesis. By honing in on those pathways rather than broad-based activity, normal tissues could be spared, and adverse events are minimized.

These therapies hold the potential to reduce mortality rates from gynecologic malignancies while concurrently reducing the morbidity associated with cancer treatment by targeting abnormal rather than normal tissue. This chapter provides a broad overview of the pertinent molecular pathways in gynecologic cancer and the targeted agents that are currently being explored as treatment options. In addition, the unique toxicities of these targeted agents are reviewed. As our knowledge continues to expand, there will no doubt be myriad other pathways to exploit along with agents used to treat gynecologic malignancies.

TARGETED AGENTS

Targeting molecular pathways that drive tumor progression can be accomplished through a variety of mechanisms. The first is a humanized monoclonal antibody (mAb), which is created to bind cancer-associated antigens or molecules for cancer therapy. mAbs may be directed toward ligands or cell surface molecules that participate in pathways of tumorigenesis. Table 18.3 describes the standard nomenclature of the mAb classes. These agents are classified based on the origin of the antibody. By definition, mAbs have affinity for a single target, which allows for minimal non–tumor-related effects. These agents are administered systemically and have long clearance times, allowing biweekly to monthly administration. One such agent is bevacizumab, which is an mAb to vascular endothelial growth factor A (VEGF-A), a key active ligand in angiogenesis, to be discussed later in the chapter. Engineered antibodies are also being developed that can interact with more than one ligand or binding domain.

Small molecule inhibitors are primarily oral agents that inhibit the function of molecular receptors through the blockage tyrosine kinase activity. Tyrosine kinases are enzymes involved in an array of normal and abnormal cellular functions. Their activity causes the transfer of a phosphate group from adenosine triphosphate (ATP) to a downstream protein tyrosine residue, resulting in changes in protein conformation and association, affecting innumerable biologic processes. Two types of tyrosine kinases exist: receptor and nonreceptor tyrosine kinases. Fig. 18.2 demonstrates the typical structure of a receptor tyrosine kinase, exhibiting three major domains: extracellular ligand binding, transmembrane, and cytoplasmic. Currently, approximately 100 receptor tyrosine kinases have been identified and classified. Nonreceptor tyrosine kinases are typically present in the cytoplasm or nucleus and interact with

TABLE 18.3 Biologically Targeted Monoclonal Antibody Class and Nomenclature

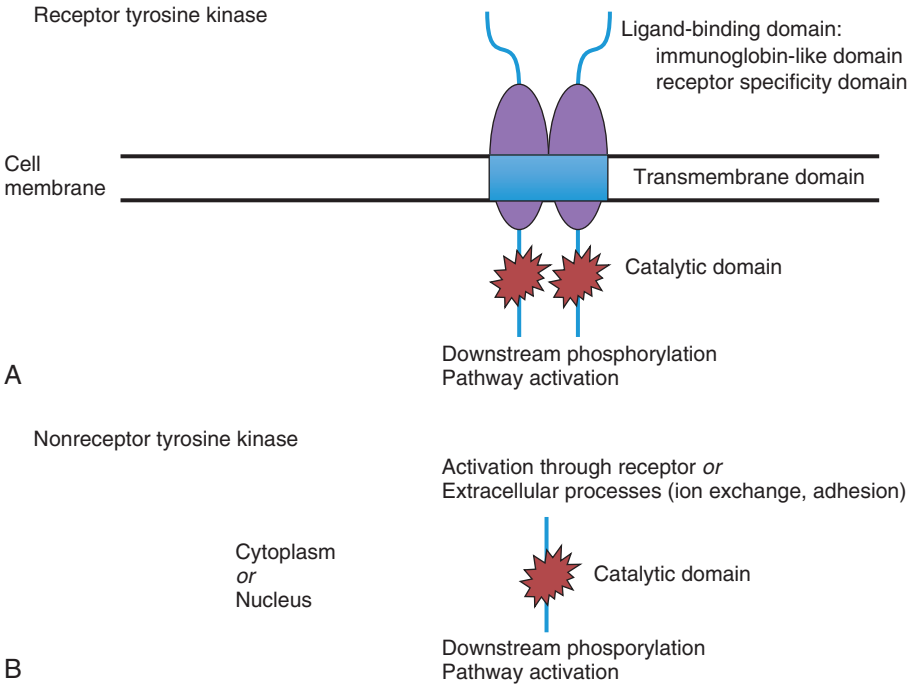

FIGURE 18.2 Schematic of two types of tyrosine kinases: receptor (A) and nonreceptor (B).

transmembrane receptors to phosphorylate downstream substrates. They may also be activated through signals derived from extracellular processes such as ion exchange. Erlotinib is one small molecule inhibitor that targets the epidermal growth factor receptor (EGFR) pathway affecting cellular division and proliferation.

Small molecule inhibitors typically block tyrosine kinase phosphorylation through interaction with the ATP-binding site on the intracellular domain of the tyrosine kinase. Binding to this site may be reversible or irreversible, depending on the agent. These molecules often have short half-lives, which necessitates frequent administration. Secondary to the high degree of homology found at the ATP-binding domain of the various tyrosine kinases, many of these molecules may inhibit one or more receptors within the cellular mechanism. Depending on the pathways affected, this can improve antitumor activity or lead to undesired adverse effects related to "off-target" inhibition.

To reduce off-target associations, unique structural features of a given target are being identified. Then agents that are chemically altered to maximize interaction with these specific components can be introduced. One example is the development of wrapping technology. This involves targeting a defect that is inherently specific to a given region in a protein called a dehydron. Dehydrons are hydrogen bonds of the protein that are poorly protected from water. Drugs designed to protect a given dehydron from water will selectively direct ligands to the receptor with that specific defect. Additional methods of introducing selectivity are being explored, including the disruption of protein–protein interactions.

The use of RNA interference technology has great promise for expanding targeted therapy through knockdown of expression of specific genes involved in tumorigenesis. RNA silencing pathways are mechanisms within the cell that directly control gene expression. In general, short interfering RNAs (siRNAs) are generated from double-stranded RNA (dsRNA) within the cell by an endonuclease called Dicer. The antisense strands of the siRNA then associate with an RNA-induced silencing complex (RISC) that targets a specific messenger RNA (mRNA) for cleavage by Argonaute 2. Cleavage of the mRNA can silence genes involved in cellular survival, proliferation, invasion, and metastasis. Of note, the level of expression of the components of RNA silencing pathways correlates with survival in a variety of cancers.

The delivery of siRNA in vivo has been challenging. However, local delivery (intranasal or intravitreal) approaches have been advanced into clinical trials in nonmalignant diseases such as macular degeneration. Recent methods of delivery using biodegradable lipids and polymers have shown safety and efficacy in cancer models. Furthermore, an ongoing first-in-human phase I trial has demonstrated successful delivery of siRNA through nanoparticles. Early results from this trial revealed induction of RNA interference mechanisms at specific targeted sites. Nanodelivery vehicles for selective delivery can further enhance tumor specificity. This approach to targeted therapy has the potential to greatly expand the possible targets while reducing undesirable adverse effects.

Other unique agents have also been explored as prospective biologic options to disrupt carcinogenic pathways. Decoy receptors that bind key ligands of carcinogenic pathways have been developed. An example of this is VEGF-Trap (aflibercept), which binds VEGF to negatively affect angiogenesis. Antibody–drug conjugates (ADCs) combine a highly toxic cytotoxic agent with a specific immunoglobulin meant to create a targeted therapy that spares normal tissues that lack expression of the selected target. Current ADCs in development use targets including CD30, mesothelin, and folate receptor α. There is no doubt that as our knowledge of cellular signaling mechanisms grows, so will the variety of agents for targeted therapy.

ANGIOGENESIS

Arguably, the most successful examples of targeted therapy in gynecologic cancer are found in the arena of angiogenesis. Angiogenesis is a key process for the supply of nutrients, oxygen, growth factors, and dissemination of a tumor. Thus, the development of new vasculature is an essential process for a tumor to grow beyond 1 mm in size. There are two primary mechanisms for the growth of new blood vessels in both the normal and tumor microenvironment. Sprouting, the dominant means of vessel formation, is the branching of a new vessel from an established blood vessel. The other major mechanism is nonsprouting, which occurs when an existing blood vessel enlarges and splits into two separate vessels. Aggressive tumor cells may also develop microvascular channels to support neovascularization in a process known as vasculogenic mimicry. Finally, existing vasculature in the host tissue may be coopted by the tumors to increase vascular supply.

In normal tissues, the vasculature is organized and uniform in size and shape. Angiogenesis in the tumor microenvironment results in vessels that are more irregular, appearing tortuous, dilated, and leaky. The regulation of angiogenic mechanisms is provided by a complex set of growth factors that stimulate and inhibit vascular growth in response to internal and external stimuli. In general, these factors act on the cells lining the blood vessel (the endothelial cells) to regulate activity within the cellular microenvironment. In the normal cellular microenvironment, the endothelial cells are stable, dividing rarely. Pathologic angiogenesis secondary to an increase in proangiogenic factors results in endothelial cells that demonstrate unregulated division and growth. In fact, high expression of proangiogenic molecules and increased microvessel density (a marker of increased tumor vascularization) are poor prognostic factors in many solid malignancies.

VASCULAR ENDOTHELIAL GROWTH FACTORS AND VASCULAR ENDOTHELIAL GROWTH FACTOR RECEPTORS

Fig. 18.3 demonstrates a schematic of the VEGF pathway, a key contributor to the regulation of angiogenesis. Activation of this pathway promotes the proliferation, survival, and migration of endothelial cells leading to vascular growth. In addition, VEGF

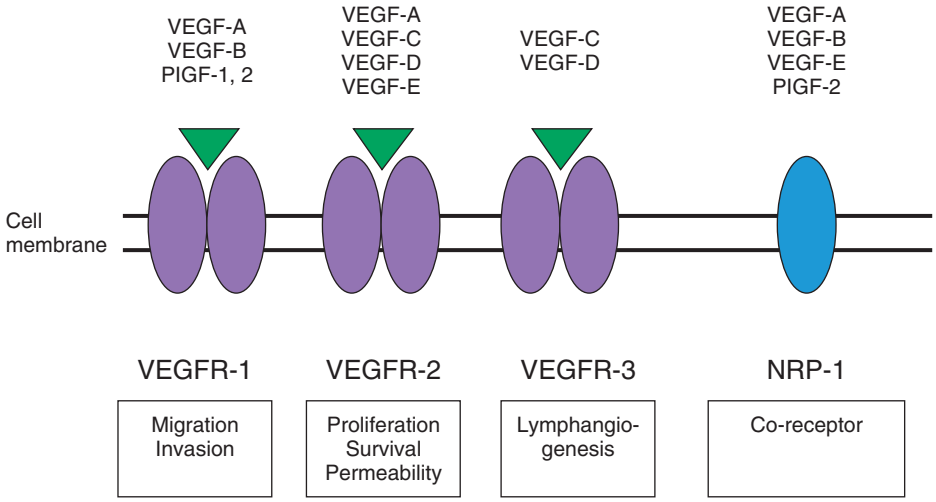

FIGURE 18.3 Vascular endothelial growth factor (VEGF) ligands and receptors. *PIGF,* placental growth factor; *VEGFR,* vascular endothelial growth factor receptor.

stimulation increases cell fenestration and vascular permeability, which has been associated with the development of malignant effusions in the lungs and peritoneal cavity. VEGF overexpression has been found in a majority of solid tumors, including all three major gynecologic cancers, and is associated with poor prognosis and tumor progression.

As demonstrated in Fig. 18.3, the VEGF pathway includes seven different ligands: VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, placental growth factor (PlGF)-1, and PlGF-2. The mediation of the angiogenic effects for each VEGF ligand is accomplished through one of three receptors (VEGFRs), including VEGFR-1, VEGFR-2, and VEGFR-3. These receptors belong to the class III family of tyrosine kinase receptors and are typically expressed on the vascular and lymphatic endothelium. However, these receptors may also be expressed by tumor tissue. The overexpression of VEGF in tumor cells is associated with increased tumor growth and metastasis in several solid malignancies, including ovarian and endometrial cancer. Recent studies revealed that ovarian cancers expressing VEGF receptors have higher mortality rates compared with tumors lacking VEGF receptor expression. In cervical cancer, human papilloma virus infection can lead to degradation of p53 and subsequent upregulation of hypoxia inducible factor (HIF-1). This factor can lead to increased neovascularization, supporting the rationale for antiangiogenic therapy in cervical cancer.

Activation of a given VEGFR results in subsequent downstream activation of a variety of known survival, proliferation, and migration pathways in the cell. These downstream pathways include phosphoinositide-3-kinase/akt (PI3K-AKT), Ras and Raf superfamily-MAPK (Ras-Raf-MAPK), focal adhesion kinase (FAK), and v-src sarcoma viral oncogene homolog (SRC). The activity of the VEGFR2 appears to be potentiated by the binding of co-receptors, neuropilin-1 (NRP-1) on arteries, and NRP-2 on venous and lymphatic vessels. NRP-1 and NRP-2 may have intrinsic activity through the binding of small G proteins and regulation of the cytoskeleton also.

Given the importance of the VEGF pathway, the majority of angiogenesis-related targeted therapies are focused on the VEGF family of ligands and receptors. Current options for therapy include drugs that directly target VEGF and its receptors and vascular disrupting agents that damage existing tumor related blood vessels.

Agents Targeting the Vascular Endothelial Growth Factor Pathway

Bevacizumab

Ovarian cancer. Bevacizumab, a humanized mAb to human VEGF, was the first US Food and Drug Administration (FDA)–approved drug targeting angiogenesis. In ovarian cancer, bevacizumab has been evaluated both as a single agent and in combination therapy for primary and recurrent disease. After encouraging preclinical studies and multiple case studies, the Gynecologic Oncology Group (GOG) instituted a phase II trial of single-agent bevacizumab (15 mg/kg every 3 weeks) in persistent or recurrent refractory epithelial ovarian cancer. Despite a heavily pretreated cohort, the authors reported 13 of 62 patients (21%) experienced a clinical response, including 11 patients with partial response and two patients with a complete response. The median number of cycles was seven, and 25 patients (40.3%) had a progression-free survival (PFS) time of at least 6 months. Overall, toxicity was low, and there were no reports of bowel perforation. Another phase II trial of bevacizumab (15 mg/kg every 3 weeks) in 44 patients with ovarian cancer receiving third- or fourth-line chemotherapy demonstrated a partial response rate of 16%. The median PFS time was 4.4 months, and the median overall survival (OS) period was 10.7 months at study closure. This study was terminated early secondary to five patients (11.4%) experiencing spontaneous bowel perforation. The risk of bowel perforation appeared to be higher in patients with a higher median number of prior treatments and in whom impending bowel obstruction was suspected. Further studies are ongoing to elucidate a clear list of risk factors for perforation in the setting of bevacizumab therapy.

In the setting of relapsed disease, bevacizumab has been evaluated in combination with both cytotoxic and biologic

therapies. A phase II study of bevacizumab (10 mg/kg every 2 weeks) combined with oral cyclophosphamide (50 mg/day) demonstrated a partial response rate of 24% (17 of 70 patients) at a median follow-up period of 23.2 months. The probability of being progression free at 6 months was 56% in this study. Overall toxicity was acceptable in this study. This combination has also been evaluated retrospectively at several institutions with similar encouraging results (objective response rates, 44%–53.3%). A phase II trial combining bevacizumab (15 mg/kg every 21 days) and oral erlotinib (150 mg/day) in 13 patients with recurrent Müllerian cancer showed an objective response rate of 15% and a stable disease (SD) rate of 54%. However, this trial was stopped early secondary to lack of clear benefit of the combination over single-agent bevacizumab and a higher than expected rate of bowel perforation (15%).

Success in the platinum-resistant recurrent setting as well as in several phase II trials in the upfront setting led to five major phase III trials in ovarian cancer. In the upfront setting, GOG 218 and International Collaborative Ovarian Neoplasm (ICON) 7 both include bevacizumab in combination with standard cytotoxics followed by maintenance bevacizumab. Key characteristics of these studies are summarized in Table 18.4. Preliminary data from GOG 218 revealed a PFS benefit of 3 months in the arm that included bevacizumab treatment up front and continued as single-agent maintenance (14.1 vs. 11.2 months; hazards ratio [HR], 0.72; P <0.001). It is interesting that there was no PFS benefit in the patients who only received adjuvant bevacizumab compared with standard therapy alone. No OS benefit was noted in the arms containing bevacizumab, although this was not a primary endpoint of the study. Although different in design, ICON7 reached similar conclusions. In the arm receiving paclitaxel, carboplatin, and bevacizumab followed by bevacizumab maintenance, the PFS time was improved by 1.7 months (24.1 vs. 22.4 months; HR, 0.87; $P = 0.04$). OS, albeit immature, was similar between the arms.

More promising results for bevacizumab have been observed in the phase III trials in the recurrent setting. GOG 213 is a bifactorial randomized study to evaluate the effect of the addition of bevacizumab to standard carboplatin and paclitaxel or gemcitabine on OS in platinum-sensitive patients (Fig. 18.4). Preliminary results of this study demonstrated a significant improvement in PFS as well as a trend toward improved OS in the arm containing bevacizumab. This study is also addressing the benefit of secondary cytoreductive surgery by randomly assigning a subset of patients who meet criteria for cytoreduction to surgery versus no surgery before initiation of chemotherapy.

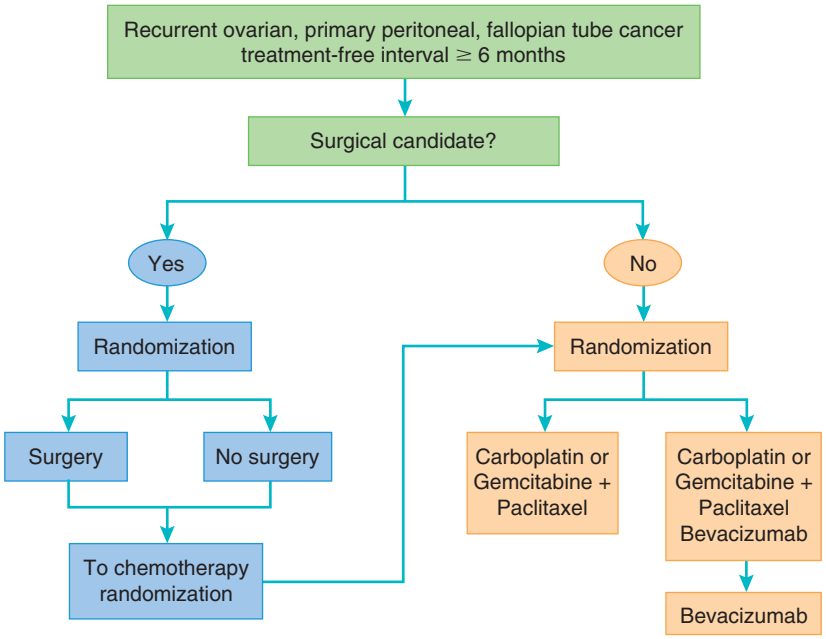

FIGURE 18.4 Gynecologic Oncology Group 213 schema.

In the OCEANS trial, patients with platinum-sensitive ovarian cancer were treated with gemcitabine and carboplatin with or without bevacizumab. This trial aimed to evaluate PFS and potential GI toxicity of this combination. Similar to GOG 213, the arm containing bevacizumab demonstrated a significant improvement in PFS of 4 months. This did not, however, yield a difference in OS. In the platinum-resistant setting, the AURELIA trial compared bevacizumab with a physician choice standard agent, including paclitaxel, liposomal doxorubicin, or topotecan, with the standard agent alone. Bevacizumab provided a statistically significant improvement in response rate and PFS when added to standard chemotherapy. Interestingly, when a subanalysis stratified by each chemotherapy cohort was performed, the greatest PFS benefit (6 months) was found in the cohort that combined weekly paclitaxel with bevacizumab. The high crossover to bevacizumab after trial participation likely influenced the lack of OS difference noted in this trial. The results of this trial yielded an FDA approval for bevacizumab in combination with chemotherapy in platinum-resistant ovarian cancer receiving one or two prior regimens.

Bevacizumab has also shown promise in nonepithelial ovarian cancer. A retrospective review of eight patients with recurrent granulosa cell tumors demonstrated a partial response rate of 38% and SD rate of 25%. This study has encouraged the development of a phase II trial by the GOG evaluating bevacizumab for women with recurrent ovarian sex cord–stromal tumors. Among 36 patients treated, 16.7% had a partial response, and 77.8% achieved SD. Certainly, these results are promising in this notoriously chemoresistant disease.

Uterine cancer. Vascular endothelial growth factor expression has been correlated with adverse outcomes in endometrial cancer, and bevacizumab has demonstrated encouraging results in early phase clinical settings. The GOG initiated a phase II study of single-agent bevacizumab (15 mg/kg every 21 days) for advanced endometrial cancer demonstrating a 13.5% response rate and 40.4% surviving progression free at 6 months. The median OS time was 10.5 months in this trial. A subsequent trial attempted to maximize this benefit by combining bevacizumab with temsirolimus, an mTORC1 inhibitor described later in this chapter. The combination was deemed active based on reasonable response rate (24.5%) and 47% of patients surviving progression free at 6 months; however, its development has been limited by increased toxicity. In the upfront setting, the addition of bevacizumab to Intensity Modulated Radiation Therapy (IMRT) with cisplatin was evaluated in high-risk endometrial cancer. Overall, toxicity was reasonable, and the OS rate for the cohort was 96.7% at 2 years.

Cervical cancer. Bevacizumab is the first targeted agent that has demonstrated activity in recurrent cervical cancer. A phase II trial of single-agent bevacizumab (15 mg/kg every 21 days) had promising results in a cohort of patients with fewer than three prior regimens, achieving a median OS period of 7.29 months and acceptable toxicity. Five patients (10.9%) had a partial response, and an additional 11 patients were progression free for a minimum of 6 months. Furthermore, an analysis of six patients treated with bevacizumab in combination with 5-fluorouracil or capecitabine demonstrated a clinical benefit rate of 67%. There are several trials with bevacizumab in cervical cancer actively accruing or completed in the upfront and recurrent settings. GOG 240 combined bevacizumab with standard chemotherapy in four regimens, described in Fig. 18.5. **This study found a significantly significant improvement in OS among the arms that received bevacizumab (17.0 vs. 13.3 months, 0,71; $P = 0.004$), which led to an FDA approval for bevacizumab in combination with chemotherapy for advanced and recurrent cervical cancer.**

VEGF-Trap (Aflibercept)

Aflibercept is a manufactured protein that acts as a decoy receptor for all VEGF-A isoforms and placental growth factor. This agent was engineered through fusion of the ligand-binding domains from two VEGF receptors with the constant region of IgG1, resulting in high-affinity VEGF binding and prevention of VEGF pathway activation. In the in vivo setting, aflibercept was found to improve ascites and reduce tumor growth.

Initial phase I trials of aflibercept for advanced solid malignancy demonstrated acceptable toxicity with clinical benefit approaching 50%. Several partial responses were observed in ovarian cancer. This led to a randomized phase II trial of aflibercept (2 mg/kg vs. 4 mg/kg) in platinum-resistant recurrent ovarian cancer. A response rate of 11% was reported with five partial responses and no mention of SD. Aflibercept has

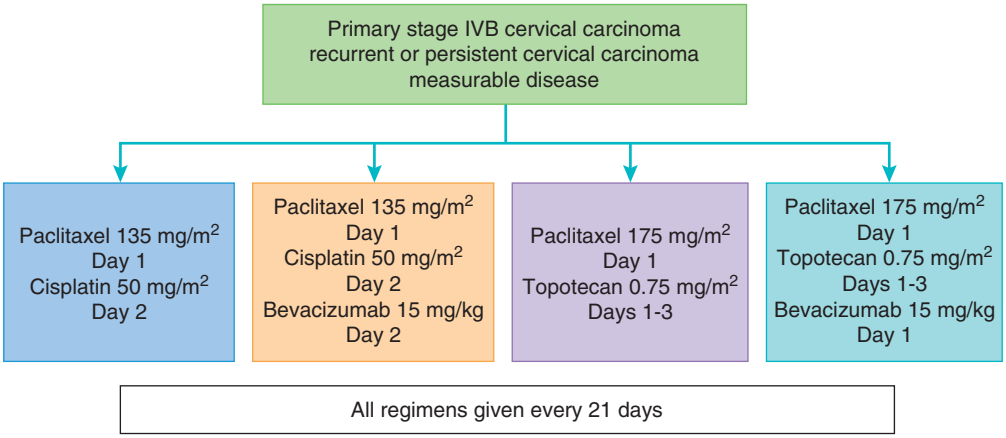

FIGURE 18.5 Gynecologic Oncology Group 240 schema.

also been studied for the treatment of malignant ascites in ovarian cancer. Colombo and colleagues treated 12 patients with aflibercept (4 mg/kg) every 2 weeks and found successful prolongation in time to repeat paracentesis with minimal adverse advents. A phase I/II, multi-institutional trial reported the activity and toxicity of aflibercept in combination with docetaxel in women with recurrent ovarian cancer. Overall response in the phase II component was 54%, including 11 of 25 responders being complete. Median PFS and OS periods were 6.4 and 26.6 month, respectively. As expected, the most frequent aflibercept-associated toxicity was hypertension (11% grade 1 or 2). In endometrial cancer, the GOG performed a phase II study of aflibercept in the recurrent setting. This agent achieved a 7% response rate, and 23% of patients survived progression free for 6 months.

Agents Targeting Vascular Endothelial Growth Factor Receptors

AZD2171 (Cediranib)

Cediranib is a small molecule inhibitor of VEGFR-2, platelet-derived growth factor receptor (PDGFR), and c-kit, which has shown promise in several phase II trials. In a study of 46 patients with recurrent ovarian cancer, the clinical benefit rate of single-agent cediranib was 30%. Eight patients achieved partial response, and six patients had SD, and median PFS for the group was 5.2 months. Hirte and colleagues reported a response rate of 41% in platinum-sensitive and 29% in platinum-resistant ovarian malignancy. Toxicities in both studies included diarrhea, hypertension, mucositis, fatigue, and anorexia. Cediranib was evaluated in the upfront setting in combination with standard paclitaxel and carboplatin as part of ICON6 (Fig. 18.6). Toxicity of the combination was well tolerated and yielded a PFS benefit of 3 months. Importantly, the use of cediranib in the maintenance setting was not associated with a significant improvement in OS. This combination of paclitaxel and carboplatin with cediranib was studied in cervical cancer as well, yielding 2 months of increased PFS at the expense of increased toxicity. Single-agent cediranib in endometrial cancer had promising activity, with a 12% response rate and 30% of patients progression free at 6 months, leading to the development of an ongoing combination trial with standard of care chemotherapy.

IMC-1121B (Ramucirumab)

IMC-1121B is the most developed fully humanized mAb to VEGFR-2. A phase I trial in 12 patients with advanced solid malignancies demonstrated a clinical benefit in nine patients (two partial responses, seven with SD). These promising results led to a phase II trial of ramucirumab in recurrent ovarian cancer. This study revealed that single-agent ramucirumab (8 mg/kg) only achieved a response rate of 6% with 56.7% of patients having SD. Thus, there has been minimal effort to explore this agent further in gynecologic malignancies. Several other mAbs to VEGF receptors are still in development, including IMC-18F1 and IMC-1C11.

Agents Targeting Multiple Vascular Endothelial Growth Factor–Related Molecules

Sunitinib

Sunitinib is an oral receptor tyrosine kinase inhibitor whose targets include VEGFR, PDGFR, epidermal growth factor (EGF), and the stem cell factor (KIT) receptor. This drug has been evaluated in the treatment of recurrent ovarian cancer in several phase II trials and one phase III trial. A phase II trial of sunitinib (50 mg/day intermittent dosing, 4 of 6 weeks vs. 37.5 mg/day) in recurrent platinum-sensitive and platinum-resistant ovarian cancer demonstrated a 66% clinical benefit with partial response in one patient, CA125 responses in three patients, and SD in 16 patients. Of note, responses were only seen in patients in the intermittent cohort. Common side effects were hand and foot reaction, fatigue, hypertension, and mucositis. Mackay and colleagues reported the results from a phase II trial of sunitinib (50 mg/day) in 19 patients with advanced or metastatic cervical cancer. Although they achieved no objective responses, 16 patients achieved SD with a median duration of 4.4 months. There are several ongoing active phase II trials of single-agent sunitinib in endometrial and cervical cancer and clear cell ovarian cancer (GOG 254).

Pazopanib

Pazopanib inhibits all of the VEGF receptors (VEGFR1, VEGFR2, and VEGFR3) and PDGFR-α and -β and the KIT receptor. This small molecule inhibitor (800 mg/day) has been evaluated in a phase II study of 36 patients with recurrent ovarian cancer by CA-125 and nonbulky disease. This study

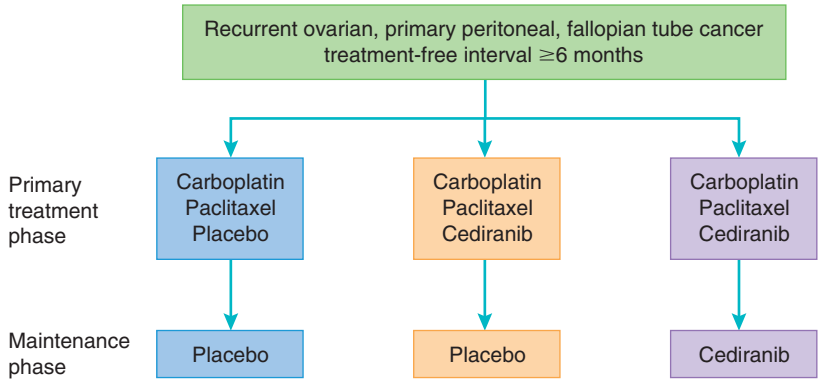

FIGURE 18.6 International Collaborative Ovarian Neoplasm 6 schema. Randomization is 2:3:3 in this trial.

revealed a 31% response by CA-125 level and a 56% SD rate. Among the 17 patients with measurable disease, 18% had a partial response. Ongoing ovarian cancer studies of pazopanib include combination with liposomal doxorubicin in the recurrent setting and in combination with paclitaxel and carboplatin in the upfront setting. A phase III, placebo-controlled study of pazopanib for consolidation after completion of primary chemotherapy in ovarian cancer was recently published. Use of pazopanib as maintenance therapy prolonged PFS by 5.6 months when compared to placebo. Adverse events were increased in the pazopanib arm, with 33% of patients terminating this agent early. Interim results did not yield a subsequent benefit in OS. Interestingly, a subset analysis of East Asian women included in this study revealed a negative impact of pazopanib on PFS among this cohort. Further studies are ongoing to understand the mechanism underlying this difference. Pazopanib has also been combined with chemotherapy in the recurrent ovarian cancer setting. One randomized phase II trial comparing weekly paclitaxel with or without pazopanib revealed a 3-month PFS benefit in the setting of moderately increased adverse events, including neutropenia and fatigue. However, another placebo-controlled trial failed to demonstrate a benefit with the addition of pazopanib to weekly paclitaxel in recurrent ovarian cancer. In cervical cancer, pazopanib was explored alone and in combination with lapatinib (a small molecule EGFR inhibitor to be discussed later) in the treatment of advanced and recurrent disease (Fig. 18.7). The combination pazopanib and lapatinib arm was closed early after a futility analysis, leaving the randomized phase II trial to compare pazopanib with single-agent lapatinib. Both progression-free (HR, 0.66; 90% CI 0.48–0.91) and OS (HR, 0.67; 90% CI 0.49–0.99) were superior in the monotherapy pazopanib arm. Median OS was 50.7 weeks versus 39.1 weeks for pazopanib and lapatinib, respectively.

Brivanib

Brivanib alaninate is a prodrug of brivanib, a dual inhibitor of VEGFR2 and FGFR. This compound has demonstrated acceptable toxicity and activity when given alone or in combination, in multiple solid tumors, including hepatocellular carcinoma refractory to other antiangiogenic therapies. Brivanib was evaluated in a phase II study for recurrent or persistent endometrial cancer and found worthy to pursue further based on a response rate of 19% (one complete response and seven partial responses) and 30% of patients surviving progression free at 6 months. Similar favorable activity was found in the first stage of a phase II trial of brivanib in recurrent cervical cancer; however, the trial was closed early because of drug availability.

Nintedanib

Nintedanib is a multikinase inhibitor targeting three key angiogenic receptors: VEGFR, PDGFR, and FGFR. A phase I trial of this agent in patients with gynecologic malignancies revealed a promising response rate, with five of seven patients with measurable disease demonstrating response and two achieving SD. Nintedanib (250 mg/day) was evaluated as a maintenance therapy compared with placebo in recurrent ovarian cancer after response to standard therapy. Although the trial was not powered to compare the two arms, PFS was less in the placebo arm (2.8 months) compared with the nintedanib arm (4.8 months). A randomized phase III placebo-controlled trial compared standard paclitaxel and carboplatin with or without nintedanib in previously untreated primary ovarian cancer patients. The combination arm was associated with significantly prolonged PFS, although clinically, this was a median increase of approximately 2 weeks. Furthermore, there was significant toxicity in the combination arm, including GI and hematologic adverse events. A phase II study of this agent in recurrent endometrial cancer did not provide sufficient activity to warrant further study as a single agent.

Vascular Disrupting Agents

This broad group of antiangiogenic drugs acts to occlude preexisting vasculature in the tumor rather than prevent neovascularization. The disturbance of existing vessels leads to ischemia; hemorrhagic necrosis; and ultimately, cellular death.

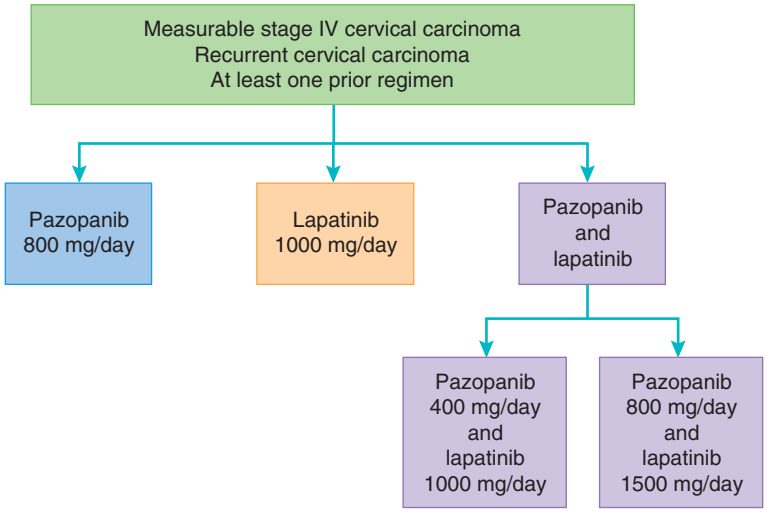

FIGURE 18.7 Schema of trial of pazopanib and lapatinib for advanced cervical cancer.

Of note, these agents are able to selectively target tumor blood vessels by taking advantage of the differences between normal and tumor endothelial cells. Two major types of vascular disrupting agents exist: small molecule based and ligand based. The majority of vascular disrupting agents under evaluation in gynecologic cancers target small molecules.

Vadimezan (ASA404/DMXAA)

Vadimezan, 5,6-dimethylxanthenone-4-acetic acid, is a flavone acetic acid analog that increases production and release of tumor necrosis factor α. This leads to endothelial cell apoptosis and decreased perfusion of the tumor. Gabra and colleagues evaluated this drug in combination with paclitaxel and carboplatin for the treatment of recurrent ovarian cancer. **The arm that received vadimezan conferred significant improvement in response rate compared with the control arm (64% vs. 49%) without additional adverse effects.**

Fosbretabulin (Combretastatin A4); Ombrabulin (AVE8062)

Fosbretablin is a tubulin-binding agent that causes vascular congestion and decreased tumor blood flow by changing endothelial cell shape. This effect is very rapid, occurring within 1 hour of drug administration. This agent has been evaluated primarily for the treatment of platinum-resistant ovarian cancer. Treatment with combretastatin A4 (63 mg/m^2) in addition to paclitaxel (175 mg/m^2) and carboplatin (area under the curve [AUC] 5) resulted in a 13.5% response rate by Response Evaluation Criteria for Solid Tumors (RECIST) and a 34% response rate by Gynecologic Cancer Inter Group (GCIG) criteria without additional observed toxicity. A randomized phase II trial of bevacizumab with or without fosbretabulin demonstrated higher response rate as well as improved PFS in the combination arm among patients with platinum-resistant ovarian cancer. OS data from this study have not yet been presented. Ombrabulin is a combrestatin derivative that has shown excellent efficacy in preclinical ovarian cancer models. This agent appears to have a similar toxicity profile to combretastatin A4 and is undergoing evaluation in a phase II trial in combination with paclitaxel and carboplatin in platinum-sensitive recurrent ovarian cancer (OPSALIN).

Other Antiangiogenic Agents

Thalidomide

Thalidomide is a legacy agent that has found recent renewed interest as an antiangiogenic agent. Thalidomide inhibits FGF-2 by interacting with the FGF-2 receptor. In addition, this agent acts as an immune modulator by inducing production of interferon-γ, interleukin-2 (IL-2), and IL-10. Thalidomide (200 mg/day) added 4 months to OS when added to topotecan (1.25 mg/m^2) for the treatment of recurrent ovarian cancer. A phase II of thalidomide (200–1000 mg/day) in persistent or recurrent endometrial cancer demonstrated a 25% clinical benefit with two partial responses and four patients with disease stabilization. The GOG reported randomized phase III trial results comparing thalidomide (200 mg/day) with tamoxifen (20 mg/day) for biochemically recurrent ovarian carcinoma. In this study, there was essentially no difference in PFS, with thalidomide achieving 3.2 months compared with 4.5 months for tamoxifen. Patients on the thalidomide arm had an increased risk of death (HR, 1.76; 95% CI 1.16–2.68). Furthermore, patients receiving thalidomide had a higher incidence of grade III and IV toxicity. Common toxicities of thalidomide include hematologic, GI, and cardiovascular complications. Lenalidomide (Revlimid) is a thalidomide derivative that demonstrated modest activity in platinum resistant ovarian cancer, yielding a clinical benefit rate of 38% at 4 months, including four partial responses by RECIST.

PHOSPHATIDYLINOSITOL-3-KINASE/AKT PATHWAY

The PI3K/AKT pathway plays a central role in cell survival, growth, and avoidance of apoptosis. Fig. 18.8 demonstrates a simple schematic of this complex pathway that is known to interact with many other cellular growth and survival pathways. This pathway may be activated by a large number of receptor tyrosine kinases, including the EGFR family and the insulin-like growth factor receptors (IGFRs). Thus a variety of mitogenic substances are involved in its activation.

Activation of the pathway starts with the PI3K family, which consists lipid and serine/threonine kinases composed of heterodimers, including a catalytic and regulatory subunit. Activation of PI3K leads to phosphorylation of phosphatidylionositol-4,5-bisphospate (PIP2) to phosphatidylinositol-3,4,5-triphosphate (PIP3). PIP3 acts as a second messenger to bind a variety of targets and recruit them to the plasma membrane, leading to their activation. One critical downstream mediator of PIP3 is AKT, which on activation acts on a number of different targets that directly affect cellular survival, proliferation through activation of transcription and translation, evasion of apoptosis, and resistance to chemotherapy. One key downstream target of AKT is the mammalian target of rapamycin (mTOR), a serine/threonine kinase. The upregulation of mTOR by AKT leads to activation of downstream regulator protein S6 kinase, which directly affects protein translation and the progression of growth through the cell cycle.

The PI3K/AKT pathway is known to be activated in a variety of cancers, especially in gynecologic malignancies. The phosphatase and tensin homolog on chromosome 10 (PTEN) is a tumor suppressor that encodes for a serine/threonine kinase, which acts directly to dephosphorylate PIP3 to PIP2. In patients with PTEN mutation and loss of function, there is an overaccumulation of PIP3, leading to constitutive activation of the AKT pathway. The PI3K/AKT pathway is also frequently activated through mutations in PIK3CA, which encodes for the activating subunit (110α) of PI3K or through mutations in AKT.

As described in Chapter 19, the aforementioned mutations are commonly found in endometrial cancer and less frequently in the other gynecologic malignancies. Furthermore, this pathway is thought to be targeted more frequently in cancer than any other pathway aside from p53. Thus, PI3K/AKT signaling provides a promising target for the treatment of malignancy and is under active exploration. Currently, the drugs

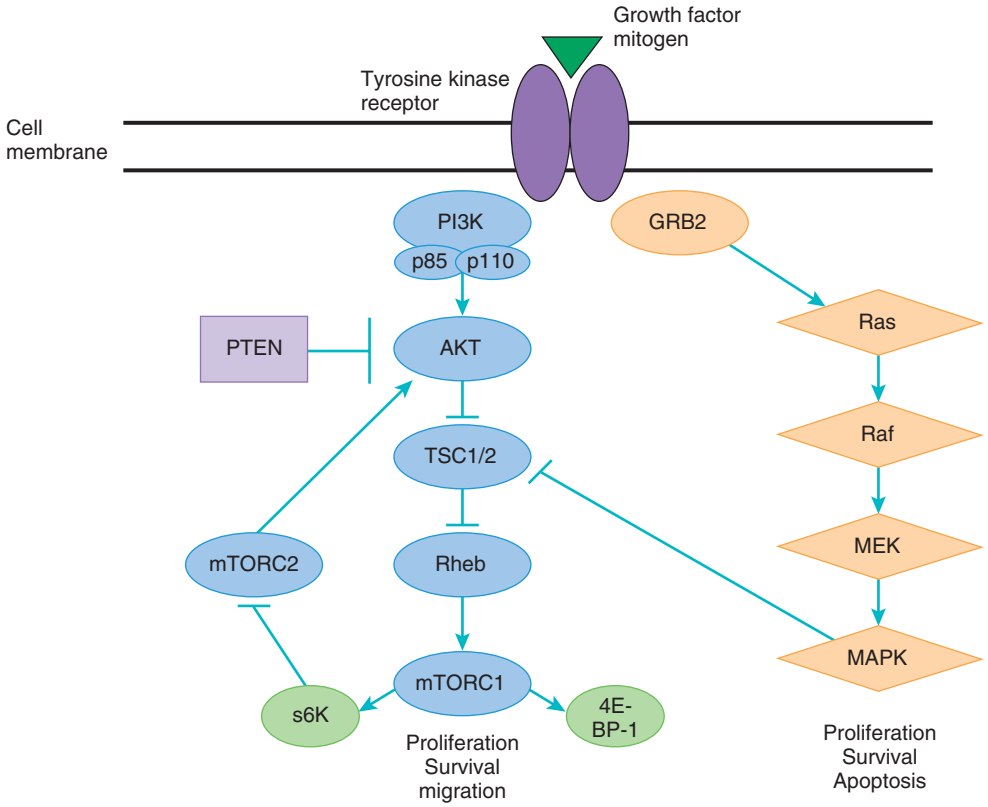

FIGURE 18.8 PI3K/AKT signaling pathway. *PTEN,* phosphatase and tensin homolog; *mTORC,* mammalian target of rapamycin complex; *PI3K,* Phosphatidylinositol-3-kinase; *AKT,* protein kinase B; *TSC,* tuberous sclerosis complex; *Rheb,* Ras homolog enriched in brain; *GRB,* growth factor receptor-bound protein; *Ras,* human rat sarcoma protein; *Raf,* Rapidly accelerated fibrosarcoma protein; *MEK,* mitogen-activated protein kinase kinase.

targeting this pathway consist primarily of small molecule inhibitors of key pathway components. The inhibition of only one member of the pathway may not be sufficient to affect tumor growth given the significant pathway cross-talk and feedback loops. For example, mTOR is known to regulate cellular growth and proliferation through activation of several downstream proteins. These proteins also participate in a feedback loop that can lead to subsequent upregulation of AKT phosphorylation. Thus, the exploration of combination therapies in this pathway is paramount.

Agents Targeting mTOR

mTOR is a key downstream protein of the PI3K/AKT pathway, consisting of two major complexes (mTORC1 and mTORC2). Initial attempts at targeting this pathway node were directed at mTORC1 (rapalogs). Overall, trials in gynecologic cancer with rapalogs have demonstrated only modest success. Thus, there are newer agents in development that compete with ATP on the mTOR catalytic site and inhibit mTORC1 and mTORC2.

Temsirolimus (CC1-779)

Temsirolimus (25 mg intravenously weekly), a water-soluble ester of rapamycin, had a favorable response rate in a phase II trial of patients with recurrent or metastatic endometrial cancer treated with a maximum of one prior regimen. Among the chemotherapy naïve cohort, 14% of 29 evaluable patients had a partial response, and an additional 69% achieved SD. However, among patients treated with prior chemotherapy, only 4% had partial responses, and 48% had SD of median 4 months' duration. A study of temsirolimus in 54 heavily pretreated patients with recurrent endometrial cancer yielded 9% partial responses and 24% progression free at 6 months. Temkin and colleagues reported on a phase I trial of temsirolimus combined with topotecan to treat a variety of advanced and recurrent gynecologic malignancies. The drug combination was well tolerated in patients without a history of radiotherapy and achieved SD in 9 of 11 patients at 8 weeks. Trials incorporating temsirolimus have shown manageable toxicities, including hypertriglyceridemia, hyperglycemia, electrolyte abnormalities, and rash.

This agent has been combined with a variety of combination chemotherapies and targeted therapies in endometrial cancer. As noted earlier, the combination of temsirolimus with bevacizumab did not yield a significant increase in response or PFS at 6 months to warrant further exploration. Results of this combination in ovarian cancer were similar as well. To improve on the current standard of care for advanced and recurrent chemotherapy-naïve endometrial cancer, the GOG performed a randomized phase II trial with three arms: (1) temsirolimus in combination with paclitaxel and carboplatin; (2) bevacizumab, paclitaxel, carboplatin; and (3) ixabepilone, paclitaxel, and carboplatin. This trial did not demonstrate a significant increase in PFS in any of the arms compared to historical

controls. Interestingly, the secondary endpoint of OS was increased in the bevacizumab arm (HR, 0.71; 92% CI 0.55–0.91 compared with historical controls). In recurrent cervical cancer, single-agent temsirolimus had similar modest effects, achieving only one (3%) partial response and a 6-month PFS rate of 28%. A phase II trial combining temsirolimus with carboplatin and paclitaxel was recently completed in advanced clear cell carcinoma of the ovary; results are anticipated soon.

Everolimus (RAD001)

Everolimus is an orally bioavailable ester that is a potent inhibitor of mTOR. Two phase II studies of everolimus (10 mg/day) as a single agent in recurrent endometrial cancer have been reported, with only modest activity. Slomovitz and colleagues demonstrate a short- and long-term clinical benefit rate with 43% and 21% of patients achieving SD at 8 weeks and 20 weeks, respectively. The ENDORAD study of 54 metastatic endometrial cancer patients reported five partial responders and a median PFS period of only 2.8 months. Given these results, attempts have been made to maximize the success of this drug in combination with other targeted agents, traditional cytotoxic chemotherapy, and hormones. The latter combination has gained keen interest in breast and endometrial cancers because endocrine resistance may be mediated by activation of the PI3K pathway. **A phase II study of the combination of everolimus and letrozole markedly improved on the single-agent efficacy, with confirmed objective response rate of 32%, including nine complete responders. Furthermore, the clinical benefit rate was 40%, and the combination was well tolerated.**

Ridaforolimus (AP23573; MK-8669)

Ridaforolimus, previously known as deforolimus, is an mTOR inhibitor that may be given orally or intravenously. In a phase II study of ridaforolimus (12.5 mg intravenously daily for 5 days every other week) for patients with advanced or recurrent endometrial cancer, 13 of 45 patients achieved clinical benefit, including five with partial response. The oral formulation (40 mg orally daily for 5 days every 3 weeks) was evaluated in recurrent endometrial cancer as well. Similar to the intravenous (IV) formulation, ridaforolimus yielded a response rate of 8.8% and disease stabilization of 53%. Final results of a multi-institutional randomized phase II trial of ridaforolimus (40 mg orally for 5 days every 28 days) in women with recurrent, previously treated endometrial cancer were reported in 2015. The control arm of the trial was the physician's choice of either hormones or chemotherapy. Overall, 130 patients (114 evaluable) were enrolled—64 to ridaforolimus, 52 to hormonal therapy, and 13 to chemotherapy. The response rates in each arm were similar (0% vs. 4% for ridaforolimus and control participant, respectively). However, PFS was significantly longer in the ridaforolimus arm (1.7 months) when assessed by either the investigators or by independent radiologic review. OS has not been reported.

Agents Targeting AKT

Given the modest activity of targeting downstream regulators of the PI3K/AKT pathway, there is interest in targeting higher level nodes of the pathway. There are several AKT-inhibiting agents in development and the majority are undergoing evaluation in phase I trials. MK-2206 is a highly selective non-ATP competitive allosteric Akt inhibitor that is equally potent against Akt1 and Akt2 and demonstrated efficacy in vitro and in vivo in several tumor models. A phase I dose escalation study in patients with solid tumors has been completed to identify tolerance of the compound at 60 mg orally every other day. Dose-limiting toxicities were skin rash, mucosal inflammation, and hyperglycemia. Three ovarian cancer patients treated in this study had reducing CA-125 values. A single-agent study of MK-2206 in recurrent endometrial cancer stratified by presence of PI3KCA mutation had only modest response rates (6%) and little overall clinical benefit.

Agents Targeting PI3K

Although several companies are exploring the inhibition of PI3Kinase in solid tumors, there are only two PI3K inhibitors in phase II trials. Pilaralisib is a highly selective oral inhibitor of PI3K and successfully inhibits tumor growth in vivo. A phase I trial revealed acceptable toxicity and durable clinical benefit. A phase I trial combining pilaralisib with carboplatin and paclitaxel incorporated a dose expansion for ovarian and endometrial cancer patients secondary to favorable responses in those tumor types, although final results have not yet been reported. In recurrent endometrial cancer, pilaralisib as a single agent yielded only a 6% response, and the rate of PFS at 6 months was only 12%.

Enzastaurin is an oral multikinase inhibitor that primarily acts to suppress tumor growth through the inhibition of PI3K. A phase I study of enzastaurin combined with bevacizumab revealed promising responses in advanced solid tumors, especially among ovarian cancer (29% partial response or complete response). Furthermore, 51% of 21 ovarian cancer patients remained in the study for greater than 6 months. A phase II study of enzastaurin alone in recurrent ovarian cancer had limited activity, with a response rate of only 7.4% (D. Armstrong, personal communication). These results led to the development of several phase II trials of enzastaurin in combination with standard chemotherapy for advanced ovarian cancer. Vergote and colleagues reported that the combination was well tolerated, however, did not yield a statistically significant improvement in progression free survival.

Combination Agents

In addition to the agents targeting specific aspects of the PI3K/AKT pathway noted previously, there are a large number of combination drugs in development and in early clinical trials. These include combination PI3K/mTOR, PI3K/AKT, and PI3K/MEK inhibitors. Given the extensive cross-talk and feedback loops involved in this pathway, the inhibition of two major nodes in one or more pathways is rational and may lead to improved outcomes. Unfortunately, early reports from single-agent studies of PI3K/mTOR inhibitors have not yielded increased efficacy over the single node agents reported earlier. Furthermore, the majority of published studies combining PI3K/AKT pathway inhibitors with MEK inhibitors have reported limited activity

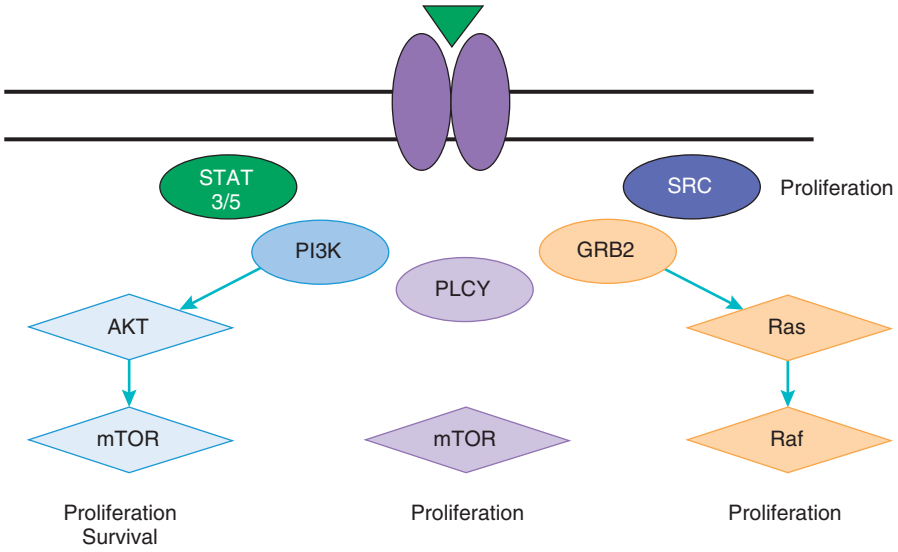

FIGURE 18.9 Epidermal growth factor receptor downstream signaling. *STAT,* signal transducer and activator of transcription; *AKT,* protein kinase B; *PI3K,* Phosphatidylinositol-3-kinase; *mTORC,* mammalian target of rapamycin complex; *PLCY,* phospholipace C gamma; *GRB2,* growth factor receptor-bound protein 2; *SRC,* proto-oncogene tyrosine-protein kinase; *Ras,* human rat sarcoma protein; *Raf,* Rapidly accelerated fibrosarcoma protein.

secondary to significant toxicities found with the combinations. A large study of the combination of SAR245409 (PI3K/mTOR inhibitor) with pimasertib (MEK inhibitor) is ongoing in low-grade serous ovarian cancer.

RAS/RAF PATHWAY

The Ras/Raf pathway is an essential regulator of tumorigenesis, including regulation of cell growth, survival, death, and motility (Fig. 18.9). This pathway is tightly linked to the PI3K/AKT pathway, creating series of feedback loops that can lead to chemotherapy and targeted therapy resistance. Furthermore, this pathway is often activated in tandem with the PI3K/AKT pathway because it shares activating mitogens and receptors, including the EGFR family. Ras is a GTPase that is activated by cell surface signaling and subsequently phosphorylates downstream extracellular signal-related kinases (ERKs). Two essential pathway kinases are Raf and MEK, which ultimately serve to activate numerous downstream regulators and drive tumorigenic processes. Activation of the Ras/Raf pathway can occur through activating mutations in *KRAS, HRAS, BRAF*, and *MEK*. Ras mutations are the most common across solid tumors; however, targeting these proteins has been difficult. Thus, agents directed at downstream targets such as MEK and ERK are the most well developed.

Agents Targeting MEK

The highest rates of Ras/Raf pathway aberrations are found in low-grade serous and mucinous ovarian cancer as well as endometrial cancer. The rarity of mucinous cancer has limited the exploration of targeted agents for this indication. However, MEK inhibitors have been quite successful for the treatment of low-grade ovarian cancer. Selumetinib was explored in a phase II trial by the GOG, yielding a 15% objective response rate and a 65% SD rate in this notoriously chemo-insensitive disease. Based on the results of this trial, two large phase III studies are ongoing to compare MEK inhibition therapy with physician choice chemotherapy in recurrent low-grade serous ovarian cancer. In recurrent endometrial cancer, single-agent results for MEK inhibition have been limited. A phase II GOG trial of selumetinib reported a 6% objective response ($n = 3$) and an event-free survival rate at 6 months of 12%. As noted earlier, these modest results have led to exploration of MEK inhibitor combinations for endometrial cancer.

POLY-ADP-RIBOSE POLYMERASE PATHWAY

DNA damage can be repaired through a variety of pathways in the cell, including base excision, direct repair, mismatch repair, and nucleotide excision repair. High activity of DNA damage repair pathways is a known mechanism of resistance to cytotoxic chemotherapy. Poly-ADP-ribose polymerase (PARP) is a nuclear enzyme that contributes to the repair of single-stranded breaks in DNA along the base excision repair pathway (Fig. 18.10). There are several key mechanisms of action of this therapy. When PARP is inhibited, accumulation of single-stranded breaks can lead to double-stranded breaks and ultimately, cellular death. The use of PARP inhibitors in carriers of *BRCA* mutations is effective because tumor cells in these patients have dysfunctional homologous recombination repair, a primary double-stranded break repair mechanism. Furthermore, PARP inhibitors also stimulate a separate DNA repair mechanism, the nonhomologous end joining (NHEJ) pathway, which is error prone and yields cell death. Finally, PARP inhibitors appear to gain antitumor function through PARP "trapping" in which the PARP protein is trapped on the DNA complex, interfering with further DNA repair and replication. Of note, some *BRCA* mutation carriers appear resistant

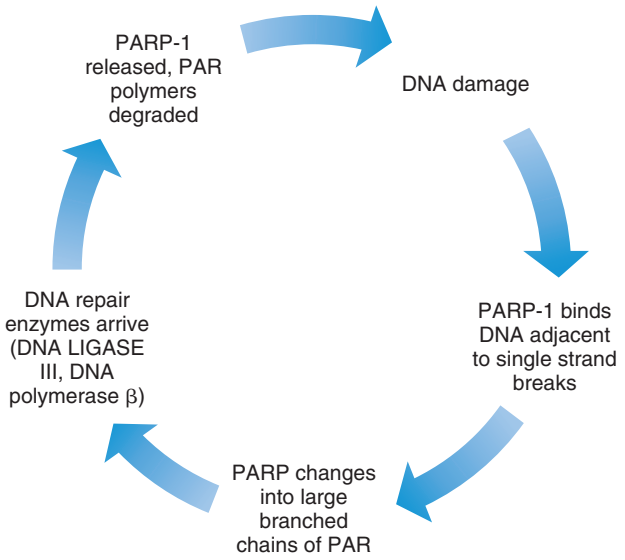

FIGURE 18.10 Single-stranded DNA repair. *PAR,* Poly-ADP-ribose; *PARP,* poly-ADP-ribose polymerase.

to PARP inhibition. Proposed mechanisms of PARP inhibitor resistance include the presence of secondary *BRCA2* mutations that restore *BRCA* function, activation of Rad51, loss of 53BP1 leading to suppression of the NHEJ pathway, and increased activity of drug efflux pumps. A better understanding of these mechanisms will no doubt lead to expansion of the use of PARP inhibitors alone and in combination for the treatment of gynecologic malignancies.

PARP inhibitors have been primarily explored in ovarian cancer given the strong correlation between *BRCA* mutations and this disease. The potential indication of PARP inhibitor use is actively expanding to tumors with homologous recombination deficiency, including those with *BRCA1* promotor methylation, aberrations in ataxia telangiectasia mutated (ATM), ataxia telangiectasia and Rad3-related (ATR) and the Fanconi anemia pathway. Certainly, preclinical data supporting the consideration of PARP inhibition in other gynecologic malignancies exist, including the similar genomic landscape found in a subset of endometrial cancers based on molecular data generated from The Cancer Genome Atlas, indicating genomic instability and homologous recombination deficiency. In addition, the presence of PTEN alterations in endometrial cancer may increase sensitivity to PARP inhibition, based on work in cell lines as well as a case report. Similarly, preclinical data have supported potential synergy between PARPs in combination with chemotherapy or with radiation in cervical cancer cell lines. Thus, early-stage trials to evaluate PARP inhibition in both of these tumor types have been initiated.

Olaparib

Olaparib is the most studied PARP inhibitor to date in ovarian cancer. Preclinically, this orally active PARP inhibitor induces synthetic lethality in cells deficient in *BRCA*. In a study of two doses of olaparib in *BRCA*-mutant patients with advanced ovarian cancer, both doses were well tolerated and demonstrated modest effect. Olaparib at 100 mg twice a day (bid) achieved a response rate of 12.5% and a clinical benefit rate of 16.7% among 24 patients. The 400-mg bid dose had higher levels of response and clinical benefit among 33 patients, 33% and 57.6%, respectively. Additional phase II studies of olaparib in recurrent high serous ovarian cancer have confirmed favorable response in patients with and without *BRCA* mutations. Olaparib also appears to reintroduce chemosensitivity to carboplatin and paclitaxel in heavily pretreated patients.

Although olaparib has been well tolerated as a single agent with primarily adverse events consisting of fatigue, nausea, and vomiting, early studies have indicated that there may be increased toxicity in combination with cytotoxic chemotherapy, necessitating dose reduction. Oza and colleagues compared the combination of olaparib with paclitaxel and carboplatin versus paclitaxel and carboplatin alone in platinum-sensitive recurrent ovarian cancer. This study included a maintenance arm of olaparib alone. Although there was no significant difference in response rate, there was improvement in PFS in the olaparib arm, which became clear during the maintenance phase of the trial. An additional study confirmed that olaparib monotherapy as maintenance after platinum-based chemotherapy for platinum-sensitive recurrence significantly increased PFS, especially in women with *BRCA* mutations.

Whether this class of compounds outperforms chemotherapy in selected germline *BRCA* mutation carries is unclear. A randomized phase II trial compared olaparib (200 mg bid and 400 mg bid) with pegylated liposomal doxorubicin (50 mg/m^2) in *BRCA* patients progressing within 12 months of platinum. The primary endpoint was PFS. Although response rates were numerically higher for the olaparib arms, PFS was no different between the arms. This may be due to higher than expected efficacy of liposomal doxorubicin in *BRCA*-mutant ovarian cancer patients.

Activity as a single agent in a platinum-resistant setting led to the FDA approval of olaparib in a tight niche, including those treated for ovarian cancer with more than three prior chemotherapies for recurrent disease. The approval of olaparib for *BRCA*-related ovarian cancer marks the first therapy approved for gynecologic malignancies with an associated biomarker. Olaparib has also achieved registration in Europe as a maintenance therapy after response to platinum-therapy after platinum-sensitive recurrence. Additional phase III trials to evaluate the role of olaparib as maintenance therapy in *BRCA*-mutant ovarian cancer in the upfront or platinum-sensitive recurrent setting have either completed accrual or are ongoing.

Veliparib

Veliparib, an oral inhibitor of PARP-1 and PARP-2, has also demonstrated encouraging activity in recurrent ovarian cancer. A phase 2 study of veliparib as a single agent yielded a response rate of 26% in women with *BRCA*-mutant ovarian cancer. Adverse events were modest and expected, consisting primarily of hematologic toxicities. Thus far, compared with other PARP inhibitors, this agent has been the most successfully combined with cytotoxic agents. However, it is unclear what benefit the addition of veliparib may add to cytotoxic chemotherapy. A randomized phase II trial of oral cyclophosphamide with

veliparib did not find additional benefit in terms of response rate when compared with cyclophosphamide alone. A subsequent large scale phase 1 trial identified a tolerable recommended phase II dose of veliparib in combination with paclitaxel, carboplatin, and bevacizumab therapy in upfront advanced ovarian cancer. The combination including maintenance veliparib is now under study as part of a phase III clinical trial of the NRG Oncology group (GOG 3005).

Rucaparib

Preclinical studies of rucaparib have revealed that this agent is a potent inhibitor of PARP-1 and -2 with significant activity in ovarian cancer. The phase 1 trial of the single agent discovered a phase II dose that is well tolerated, with toxicities primarily including neutropenia, anemia, and elevated liver enzymes. A subset analysis of four patients with ovarian and primary peritoneal cancer reported 80% with objective response leading to the ongoing ARIEL2 study in women with platinum-sensitive recurrent ovarian cancer. An objective of this trial is to evaluate a genomic signature to predict response to PARP inhibition in pretreatment tumor tissue. *BRCA*-mutant tumors had impressive overall response rate of 69% and median PFS of 9.4 months. Conversely, BRCA negative tumors had the lowest evidence of activity with response rate and median PFS of 13% and 3.7 months, respectively. BRCA-like tumors included those with evidence of genome-wide loss of heterozygosity in the absence of BRCA mutation. Interestingly, these tumors had evidence of efficacy with response rates of 30% and median PFS of 7.1 months. Rucaparib is currently under evaluation as a switch maintenance therapy in the platinum-sensitive recurrent setting after response to chemotherapy in the ARIEL3 trial.

Niraparib

Similar to the aforementioned agents, niraparib inhibits PARP-1 and PARP-2 across a variety of advanced solid tumors. The phase 1 trial identified a recommended phase II dose of 300 mg/day, with the most common adverse events including myelosuppression, fatigue, and GI toxicity. The trials included *BRCA*-mutant and proficient tumors, achieving objective response rates of 40% and 16%, respectively. After these promising results, niraparib is undergoing evaluation in similar setting to rucaparib (ARIEL3) and olaparib (SOLO-2). A single-agent study of niraparib (QUADRA) in women who have received at least three prior lines of chemotherapy is ongoing for *BRCA*-mutant ovarian cancer. This agent is also under evaluation in the maintenance setting as well as in combination with immune therapies.

EPIDERMAL GROWTH FACTOR RECEPTOR PATHWAY

The EGFR pathway was identified as an anticancer therapy target secondary to myriad genetic alterations found in a variety of solid tumor types, including ovarian, endometrial, and cervical carcinomas. The pathway consists of four tyrosine kinase cell-surface receptors, including EGFR (ErbB-1), HER2/neu (ErbB-2), Her-3 (ErbB-3), and Her-4 (ErbB-4).

TABLE 18.5 Epidermal Growth Factor Ligands and Receptor

EGF Receptor	Ligands
EGFR (ErbB-1)	EGF
	Transforming growth factor α
	Amphiregulin
	Epigen
	Betacellulin
	Heparin-binding growth factor
	Epiregulin
HER2/neu (ErbB-2)	None
HER-3 (ErbB-3)	Neuregulin 1
	Neuregulin 2
HER-4 (ErbB-4)	Betacellulin
	Heparin-binding growth factor
	Epiregulin
	Neuregulin 1
	Neuregulin 2
	Neuregulin 3
	Neuregulin 4
	Tomoregulin

EGF, Epidermal growth factor; *EGFR,* epidermal growth factor receptor.

Each receptor is specific for a variety of ligands, including EGF, transforming growth factor α (TGF-α), and neuregulins (NRGs) (Table 18.5). Although the receptors are activated through a traditional tyrosine kinase receptor mechanism, they also require the union between two identical receptors (homodimerization) or two different receptors within the same family (heterodimerization) for downstream activation.

Upon activation, the EGFRs induce activation of a variety of cell survival pathways, including the Ras/Raf/MEK and PI3K pathways (see Fig. 18.9). In addition, EGFRs are known to negatively affect apoptosis and induce invasion. EGFRs are also present on endothelial cells within the tumor microenvironment. EGF ligands demonstrate a direct effect on the endothelial cells, leading to increase in endothelial cell proliferation and angiogenesis. Thus, targeting this pathway has been an area of significant research for the treatment of gynecologic malignancies. Unfortunately, recent studies of drugs affecting the EGFR pathway have only demonstrated modest success in gynecologic cancer. This may be explained, in part, by research that demonstrates that EGFR has a role in glucose transport in cancer cells. EGFR associates with the sodium/glucose cotransporter (SGLT1) to promote the uptake of glucose into cancer cells. Of note, the action appears to be kinase independent. Thus, the blockage of kinase activity with antibodies or small molecules may not be sufficient to make a significant impact on tumorigenesis. Furthermore, based on data in multiple tumor types, response to EGFR inhibitors appears to be correlated with mutation status rather than expression. The rate of EGFR mutations in gynecologic malignancies is quite low; thus, the potential for success of these compounds as a single agent is unclear.

Small Molecule Inhibitors Targeting Epidermal Growth Factor Receptor

Gefitinib

Gefitinib is a small molecule inhibitor that prevents EGFR activation through binding the ATP-binding site of the receptor. This agent has been evaluated extensively in ovarian cancer with unsatisfactory results. Gefitinib (500 mg/day) was evaluated in a phase II trial in 30 patients with recurrent or persistent ovarian cancer treated with up to two prior regimens. Of 27 evaluable patients, four had SD for more than 6 months, and only one patient had an objective response. Of note, patients with EGFR expression in their tumors had longer median PFS periods, and the one objective response was found in a patient with a mutation in EGFR. This suggests that the use of mutation status to guide targeted therapies may provide better response rates.

Gefitinib (500 mg/day) has also been evaluated in combination with carboplatin (AUC 5) and paclitaxel (175 mg/m^2) for platinum-sensitive and platinum-resistant recurrent ovarian cancer. Nineteen percent of platinum-resistant and 62% of platinum-sensitive patients had responses to this combination therapy. OS was also acceptable, reaching 17 months for the resistant group and 26 months for the sensitive group. However, there appeared to be more hematologic toxicity compared with the standard regimen. The combination of gefitinib (500 mg/day) with tamoxifen (40 mg/day) in recurrent ovarian cancer required dose reduction secondary to diarrhea in 10 of 56 patients and resulted in no objective responses. However, 16 patients achieved SD, and the median survival period was 253 days.

The only published trial of gefitinib (500 mg/day) in cervical cancer reported minimal activity. Of 28 evaluable patients, there were no objective responses, and 20% achieved SD for a median duration of 112 days. It is interesting that disease control was not associated with the expression of EGFR in tumor specimens. Similarly, a study of gefitinib as a single agent in recurrent endometrial cancer achieved only one responder (4%), and four patients were progression free at 6 months (15%). EGFR mutation, EGFR expression, and hormonal expression were not associated with survival in this study.

Erlotinib

Erlotinib (150 mg/day) is reversible inhibitor of EGFR, acting to block autophosphorylation of the tyrosine kinase portion of the receptor. Based on overexpression of EGFR and preclinical results that indicated that the combination of EGFR-directed therapies and chemotherapy would potentially be synergistic, a phase II trial of erlotinib in combination with standard paclitaxel (175 mg/m^2) and carboplatin (AUC 6) for first-line treatment in ovarian cancer was performed. The primary endpoint was pathologic complete response rate with a plan to compare with historical control participants. Of a total of 56 patients treated, erlotinib in combination with standard chemotherapy achieved a pathologic complete response rate in 11 patients, which was not a significant improvement over historical control participants. Erlotinib was also explored as a maintenance therapy in patients with no sign of progression after frontline treatment for ovarian cancer in a large randomized control trial. After 2 years of therapy, there was no difference in PFS or OS between the erlotinib and observation arms.

In the setting of recurrent ovarian cancer, erlotinib has been primarily evaluated in combination with other therapies, although a solo trial is ongoing. Erlotinib in combination with carboplatin (AUC 5) achieved a response rate of 57% in the platinum-sensitive arm and 7% in the platinum-resistant arm with no unexpected toxicities. As noted previously, a trial of erlotinib with bevacizumab (15 mg/kg) was terminated early secondary to a high level of bowel perforation. The use of erlotinib as a single agent in chemotherapy-naïve endometrial cancer was well tolerated, and four of 32 patients had an objective response. In addition, 15 patients had SD lasting a median of 4 months. EGFR mutations were evaluated and did not correlate with response.

Schilder and colleagues reported disappointing results of erlotinib as a single agent in cervical cancer, with only one of 25 patients achieving objective response and four with SD. Only one patient in this trial had PFS period longer than 6 months. The combination of erlotinib with cisplatin (40 mg/m^2 weekly) with radiotherapy in locally advanced cervical cancer was found to be feasible, with acceptable toxicity and a complete response rate of 91%.

Monoclonal Antibodies Targeting Epidermal Growth Factor Receptor

Cetuximab

Cetuximab (250 mg/m^2) is a chimerized mAb to the ligand-binding domain EGFR, which has been evaluated as a treatment for primary and recurrent ovarian cancer as a single agent and in combination with traditional cytotoxics. As a single agent in 25 patients, cetuximab achieved only one partial response and nine patients with SD. The median PFS period was only 2.1 months. Cetuximab in combination with carboplatin (AUC 6) in 28 patients with recurrent platinum-sensitive ovarian cancer also had disappointing results, with only nine objective responses and eight patients with SD. Although cetuximab in combination with paclitaxel (175 mg/m^2) and carboplatin (AUC 6) was well tolerated, it offered no increased benefit in terms of PFS compared with traditional cytotoxic agents alone.

Cetuximab was given as a single agent in a phase II trial of cervical cancer performed by the GOG. There were no clinical responses, and only five patients (14%) were progression free at 6 months. The combination of cetuximab with topotecan (0.75 mg/m^2) and cisplatin (50 mg/m^2) for advanced cervical cancer induced a high rate of serious adverse events, including myelosuppression, infection, and skin reaction. Furthermore, five patients died, with three deaths attributable to toxicity. Cetuximab and cisplatin (30 mg/m^2) for recurrent cervical cancer was better tolerated but did not show any additional benefit compared with historical rates of cisplatin alone. A recent study of single-agent cetuximab for recurrent endometrial cancer has completed accrual, and preliminary results are pending.

Trastuzumab

The overexpression of HER2 in gynecologic cancers has been associated with prognosis in endometrial cancer and other

gynecologic malignancies. Trastuzumab is a humanized mAb to the extracellular domain of HER2, which prevents ligand binding. Although this drug has found great success in the treatment of Her-2/neu–positive breast cancer, its use in gynecologic oncology has been limited. Bookman and colleagues performed a phase II trial of trastuzumab in HER-2–positive recurrent ovarian cancer. Of 837 patients screened, only 11.4% were found to have high expression of HER-2. The low prevalence of this abnormality combined with a modest objective response rate of 7.3% has limited further exploration of this agent in ovarian cancer. Similarly, a phase II trial of trastuzumab (2 mg/kg) for patients with advanced or recurrent HER-2–positive endometrial cancer demonstrated no responses. Of 30 patients, 12 had SD, and the trial was closed early secondary to poor accrual. Recent data have supported the selection of only uterine serous tumors; thus, a phase II randomized trial is ongoing examining standard chemotherapy with or without trastuzumab.

Pertuzumab

The humanized mAb pertuzumab prevents the linkage of HER2 to other receptors by binding a protein site in the dimerization domain. To date, pertuzumab has only been evaluated in recurrent ovarian cancer. In a trial of two dosing regimens of pertuzumab (840 mg loading with 420 mg every 21 days vs. 1050 mg every 21 days), five patients achieved partial response, and eight patients had SD. This study found a trend toward improved median PFS and expression of phospho-HER2. The GOG evaluated pertuzumab as a monotherapy in recurrent ovarian cancer and achieved an overall response rate of 4.3%. An additional 6.8% of patients had SD for longer than 6 months. A large randomized trial comparing gemcitabine (800 mg/m^2) alone with gemcitabine with pertuzumab (420 mg every 21 days) found that the addition of pertuzumab resulted in improved response rates (4.6% vs. 13.8%, respectively) and a trend toward improved PFS. The greatest treatment benefit was found in patients with low HER3 mRNA expression.

Seribantumab

HER3 has also been identified as a potential target of interest in gynecologic malignancies, specifically ovarian cancer. Seribantumab is a mAb that targets HER3 to block heregulin-mediated ErbB3 signaling and chemotherapy resistance. After identification of a recommended phase II dose, seribantumab has been primarily evaluated in combination with cytotoxic and targeted therapies to treat advanced solid tumors. A randomized phase II trial of seribantumab in combination with paclitaxel revealed no difference in PFS compared with paclitaxel alone in recurrent ovarian cancer. A specific panel of biomarkers, including heregulin mRNA expression and low HER2, were associated with benefit from the addition of seribantumab to paclitaxel.

Combination Agents

Lapatinib

Lapatinib is an oral tyrosine kinase inhibitor of EGFR and HER2. It acts through binding of the ATP-binding domain and prevents pathway activation downstream. A single-agent study in recurrent ovarian cancer conducted by the GOG revealed no objective responses and only two patients progression free at 6 months (8%). As a combination, lapatinib (1000 mg/day) with metronomic carboplatin (AUC 2 weekly) and paclitaxel (60 mg/m^2 weekly) achieved response rates of 50% and SD in 30% of patients with recurrent ovarian cancer. These results were encouraging given the high number of median prior therapies in this group of patients. Other combinations with lapatinib including carboplatin and topotecan have not been as successful and have demonstrated unacceptable toxicity.

The use of lapatinib in combination with pazopanib in cervical cancer was discussed earlier in the chapter. The GOG also performed a phase II trial of lapatinib as monotherapy in recurrent or advanced endometrial cancer. Similar to the results in ovarian cancer, there was only one objective response, and seven patients achieved a best response of SD.

MULTIPATHWAY TARGETED AGENTS

Sorafenib

Sorafenib is an interesting small molecule inhibitor that effectively blocks several angiogenesis-related receptors (VEGFR, PDGFR, and KIT) and Raf, a key component of the Raf-MAPK kinase (MEK)-MAPK proliferation pathway. Sorafenib is of considerable interest in ovarian cancer that has been shown to harbor alterations in this pathway. Consequently, several trials are ongoing to evaluate the efficacy of sorafenib in the upfront, recurrent, and consolidation setting. Matei and colleagues reported the results of a phase II trial of sorafenib (400 mg bid) in recurrent ovarian cancer treated with fewer than two prior therapies. Of 73 patients, 22 achieved partial response or SD with toxicities, including rash and metabolic abnormalities. Of note, among the 59 patients with measurable disease, 12 were progression free for at least 6 months. The combination of sorafenib (200 mg twice daily) with bevacizumab (5 mg/kg) for the treatment of solid tumors was explored in a phase I study. Although the combination appeared to have significant activity in 13 patients with ovarian cancer (43% response rate), toxicity was common, leading to sorafenib dose reductions in 74% of patients. The most prevalent toxicities were diarrhea, elevated liver transaminases, hypertension, hand and foot syndrome, and fatigue.

In combination with traditional cytotoxic chemotherapy, including topotecan and gemcitabine, sorafenib has shown similar clinical benefit rates in recurrent ovarian cancer with minimal additional toxicity. A current phase III trial in newly diagnosed ovarian cancer after cytoreductive surgery seeks to determine if the addition of sorafenib (400 mg bid) to standard paclitaxel (175 mg/m^2) and carboplatin (AUC 6) provides any additional PFS benefit. Sorafenib is also being explored as a maintenance agent in ovarian cancer and an additional chemosensitizer in the upfront treatment of advanced cervical cancer with radiotherapy.

Vandetanib

Vandetanib inhibits the tyrosine kinase activity of two parallel pathways through action on VEGFR-2 and EGFR. This leads to

suppression of angiogenesis, cell proliferation, migration, and survival mechanisms. A phase II trial of vandetanib alone to treat recurrent ovarian cancer was terminated after the first stage of accrual because no patients achieved response or SD. Of note, molecular testing in this study revealed evidence of blockage of the EGFR pathway but no activity against VEGFR. Although single-agent activity has been disappointing, this agent underwent exploration in combination with docetaxel and liposomal doxorubicin for the treatment of ovarian cancer. A randomized phase I/II study of liposomal doxorubicin alone or in combination with vandetanib was limited by significant toxicity, which led to cessation in a high number of patients treated with the combination. Conversely, in a separate randomized phase II study, vandetanib in combination with docetaxel was tolerable; however, there was no improvement in PFS compared with docetaxel alone.

Imatinib

Imatinib mesylate is an example of a small molecule that inhibits multiple pathways, including c-kit, bcr-abl, and PDGFR. Although imatinib has been quite successful for the treatment of chronic myelogenous leukemia, in which the tyrosine kinase bcr-abl is constitutively activated, the success in gynecologic malignancies as a single agent has been limited. This may result in part from the impact of the PDGF axis on pericytes, which are mesenchymal cells that support endothelial cells and newly developing blood vessels. PDGF activity recruits pericytes, which produce VEGF to stimulate angiogenesis and survival. Research on pericytes has indicated that blocking the PDGF axis in addition to the VEGF axis may be necessary to achieve improved response rates. Thus far, imatinib has only been explored as a single agent or in combination with cytotoxic chemotherapy for gynecologic malignancies.

Several phase II trials for recurrent ovarian cancer, both high and low grade, have been performed using imatinib (400 mg/day) as a single agent. Unfortunately, rates of response have been low, with only one objective responder among all trials. Rates of SD ranged from 9% to 33%. Similar disappointing results have been seen in cervical cancer. In a trial of 12 patients with recurrent cervical cancer treated with imatinib, there were no responses and only one patient with SD. In all trials, expression of drug-related targets has not been associated with response. The use of imatinib in combination with docetaxel (30 mg/m^2 weekly) in 23 patients with recurrent ovarian cancer achieved five responses, including one complete response. Three additional patients had SD lasting longer than 4 months. Further evaluations of this drug in combination with other cytotoxic chemotherapy for recurrent ovarian cancer have yielded minimal success.

Dasatinib

Dasatinib is a strong inhibitor of the Src family of kinases, which participate in the regulation of cellular growth, adhesion, invasion, and migration. At higher concentrations, dasatinib has effects on a variety of different targets relevant to tumor progression, including bcr-abl, c-kit, and PDGF. In addition, dasatinib targets the EphA2 receptor, which modulates cell migration, survival, proliferation, and angiogenesis. EphA2 overexpression correlates with poor outcome in ovarian cancer. Dasatinib (150 mg/day) has been explored in multiple solid tumors in early-phase trials with promising response rates. A phase I trial of this agent in combination with paclitaxel (175 mg/m^2) and carboplatin (AUC 6) was tolerable with reasonable activity. This combination has also been evaluated in advanced endometrial cancer with results pending.

Cabozantinib (XL-184)

Exploration into mechanisms of resistance to anti-VEGF therapies has suggested pathways responsive to the observed upregulation of HIF-1α. One pathway of interest is c-Met, which is also implicated in tumor growth, survival, and metastases. Cabozantinib is a small molecule inhibitor of VEGFR-2 and c-Met, which has been evaluated in a number of solid tumors including, recently, ovarian cancer. In a phase II randomized discontinuation trial, cabozantinib was administered to 68 platinum-sensitive and -resistant patients. Overall response was 24% with 35% of patients also exhibiting prolonged SD. Response rates were similar between the platinum-sensitive and -resistant cohorts. Because of better-than-expected results, the trial was terminated early. A subsequent GOG study compared this agent with weekly paclitaxel in recurrent ovarian cancer. Cabozantinib failed to meet prespecified endpoints of interest, demonstrating lower levels of response than weekly paclitaxel.

OTHER TARGETS OF INTEREST

Angiopoietin (Ang)/Tie-2

In addition to the classic VEGF pathways of angiogenesis, other pathways involved in later stages of neovascularization hold promise for targeted therapy. Ang-1 and Ang-2 bind the receptor Tie-2 to activate pathways that stimulate endothelial cell proliferation, motility, and survival. In addition, the angiopoietins recruit pericytes to support vascular maturation. Trebananib (AMG-386) is a peptibody, a peptide fusion protein, that selectively binds Ang-1 and Ang-2, preventing interaction with Tie-2. In phase I studies of solid tumors, this compound was well tolerated, without many of the classic toxicities associated with antiangiogenic agents. A phase II study comparing two different dose levels of trebananib (3 mg/kg, 10 mg/kg) versus placebo in combination with weekly paclitaxel (80 mg/m^2) demonstrated a trend toward improved PFS in patients who achieved higher steady-state concentrations of trebananib. These results lead to the dose selection for TRINOVA-1, a study comparing trebananib versus placebo plus weekly paclitaxel in recurrent ovarian cancer. The addition of trebananib yielded a significant improvement in PFS period of 2 months. A phase Ib study of trebananib in combination with paclitaxel and carboplatin was found to be tolerable in women with advanced ovarian cancer. This led to development of TRINOVA-3, a randomized phase III study in upfront ovarian cancer. Results have not yet been reported. AMG-386 (10 mg/kg) has been explored in combination with liposomal doxorubicin (50 mg/m^2) or topotecan (4 mg/m^2) for recurrent ovarian cancer in a

phase Ib trial. Interim results have demonstrated acceptable toxicity; however, efficacy data are not yet mature. In recurrent endometrial cancer, trebananib as a single agent did not have sufficient efficacy to pursue further evaluation, with only one objective response of 32 patients treated.

Aurora Kinase

Three members of the aurora kinase family (Aurora kinase, A, B, and C) play large roles in the phases of mitosis. These proteins are serine/threonine kinases that act to control cell division through regulation of spindle assembly, chromosome separation, and centrosome maturation. Overexpression of Aurora A and Aurora B is associated with tumorigenesis in multiple solid tumor types. Currently, there are 14 agents targeting Aurora kinase activity, which are under investigation in phase I and II trials. One agent targeting Aurora kinase A, alisertib (MLN8237), demonstrated significant activity in recurrent ovarian cancer and was evaluated as a single agent in a phase II study. Ten percent of patients treated with alisertib achieved a partial response, and 20% had SD for more than 3 months. A subsequent randomized phase II study of weekly paclitaxel alone or in combination with alisertib yielded improved PFS in the combination arm (6.7 vs. 4.7 months; HR, 0.75; 95% CI 0.58–0.96). Objective responses by RECIST were higher as well in the combination arm. An interesting new Aurora kinase A inhibitor, ENMD-2076, has additional activity against VEGFR, Flt-3, and FGFR3 kinases and has demonstrated activity in a phase I expansion cohort study of refractory ovarian cancer patients. Based on RECIST (defined later) or GCIG CA-125 response criteria, two of 20 patients and six of 20 patients, respectively, responded to single-agent therapy. This encouraged pursuit of additional phase II studies in ovarian cancer patients, which are ongoing.

Delta-Like 4 (Dll4)/Notch

The Notch signaling pathway participates in the regulation of angiogenesis, proliferation, and apoptosis, making it an attractive potential target for anticancer therapy. One major avenue of Notch activation is through one of its ligands, Dll4, which creates a negative feedback loop to block cellular proliferation stimulated through VEGFR2. In addition, Notch signaling through Dll4 appears to activate cell cycle arrest through a variety of mechanisms. Notch overexpression has been demonstrated in multiple tumor types, including ovarian carcinoma. Two major therapeutic avenues exist that block signaling through the Notch pathway. The gamma secretase complex acts as a mediator of Notch signaling. Gamma secretase inhibitors are nonspecific agents that are currently in multiple phase I trials for solid tumors. Their lack of specificity has led to significant toxicity in the GI tract. Thus, antibodies that target the Dll4 ligand have been developed to reduce toxicity. These compounds have demonstrated significant activity in in vivo models and are undergoing evaluation in early-phase clinical trials. Demcizumab, an anti-Dll4 antibody, achieved reasonable dose levels with adverse events, including hypertension, fatigue, anemia, and headache. This agent is undergoing evaluation in combination with weekly paclitaxel in recurrent ovarian cancer. Other agents, including tarextumab, MK-0752, R04929097, and PF63084014, are under study in early-phase clinical trials.

Folate Receptor α

Folate receptor α binds folic acid with high affinity and is involved in folate transport. This is quite relevant in gynecologic malignancy because this receptor is overexpressed in more than 90% of ovarian cancers. Furthermore, there is minimal expression of this target in normal tissues, making this an attractive target for anticancer therapy. Farletuzumab (MORAb-003), a humanized mAb to folate receptor α, demonstrated inhibition of cellular proliferation and stimulation of cell death in preclinical models. A phase II trial of this agent (100 mg/m^2) in platinum-sensitive ovarian cancer was designed as a single-agent study with subsequent addition of traditional chemotherapy (carboplatin and paclitaxel) at the time of disease progression. In the single-agent arm, 24 of 28 patients remained on therapy at least 9 weeks. With combination therapy, 80% of patients achieved normalization of their CA-125, and 75% had complete or partial response. Unfortunately, farletuzumab in combination with carboplatin and paclitaxel did not yield superior outcomes compared with chemotherapy alone. Of note, a planned subset analysis found that lower pretreatment CA125 and higher exposure to farletuzumab yielded improved PFS compared with placebo.

Mirvetuximab soravtansine (IMGN853) is an antibody–drug conjugate targeting folate receptor α. The folate receptor antibody is attached to maytansinoid, a highly toxic agent that targets microtubules to induce cellular death. This agent is quite potent against cells that are folate receptor positive and even to nearby folate receptor–negative cells. A phase I trial of mirvetuximab soravtansine revealed that the agent was well tolerated, and in a small expansion cohort of ovarian cancer (n = 17), 53% had an objective response despite platinum-resistant disease. This agent may undergo further development, alone and in combination with bevacizumab, in ovarian and endometrial cancer.

Vintafolide (EC-145)

Another agent leveraging the folate receptor α is vintafolide. This novel ligand drug conjugate combines folic acid with desacetylvinblastine hydrazide, a chemotherapeutic agent difficult to deliver systemically. In a randomized phase II trial, vintafolide combined with pegylated liposomal doxorubicin (PLD) was associated with a significantly longer PFS than PLD alone (5 vs. 2.7 months; HR, 0.63; P = 0.031). Of interest, and in support of the target selectivity, there were few differences in the observed toxicities between the two arms. Furthermore, patients with global tumor expression of folate receptor α as measured by EC-20, a tracer conjugated to folic acid, had a PFS that was similar to that of the overall population but substantially better than the control arm, suggesting that high receptor expression is associated with poor prognosis. Unfortunately, a subsequent phase III trial was stopped early because of futility, although final results have not yet been reported.

Antimesothelin Antibodies

Mesothelin is an antigen that is highly expressed in several advanced solid tumors, including ovarian cancer. Growing data indicate that this protein may have a role in the peritoneal spread of ovarian cancer. Thus, a number of antibody–drug conjugates containing an antimesothelin antibody are in development. DMOT4039A was studied in the phase I setting for unresectable pancreatic and platinum-resistant ovarian cancer. Toxicities included GI and constitutional, and many were cumulative over time. Objective activity was seen, and this agent is under further evaluation. There are several other agents in development, although no results have been reported.

Histone Acetyltransferases and Histone Deacetylases

The epigenetic modulation of gene expression is a promising target for the treatment of gynecologic malignancies. The post-translational modification of histones is a key mechanism to regulate the expression of certain genes and has been implicated in tumorigenesis. Histones may be modified through acetylation, methylation, phosphorylation, and ubiquitination. Two enzymes, histone acetyltransferase and histone deacetylases (HDAC), mediate the addition and removal of acetyl groups, respectively. HDAC activity leads to a change in the histone structure, which leads to a change in transcription activity. Through activation of oncogenes or inactivation of tumor suppressors, cell growth, proliferation, and evasion of apoptosis may occur. HDAC inhibitors have been explored in a variety of solid tumor types. Suberoylanilide hydroxamic acid (Vorinostat) is FDA approved for the treatment of refractory cutaneous T-cell lymphoma and has been explored in recurrent ovarian cancer. A phase II study of single-agent vorinostat (400 mg/day) in 27 patients had limited success with only one partial response (4%) and two patients with SD for 6 months (7%). The HDAC inhibitor belinostat was evaluated as a single agent in platinum resistant ovary and micropapillary low malignant potential tumors. This study of 32 patients demonstrated modest activity with only one partial response and 19 patients with SD. There is evidence to suggest that the combination of HDAC inhibitors with traditional cytotoxic chemotherapy may yield improved results; thus, these agents have been explored in combination with traditional chemotherapy regimens. The combination of vorinostat with gemcitabine and carboplatin was quite toxic, although some activity was achieved. The study was terminated early secondary to overall poor tolerance. Conversely, belinostat was successfully combined with carboplatin as well as with carboplatin and paclitaxel. Although both combinations were tolerable, only belinostat in combination with carboplatin and paclitaxel yielded response rates worthy of further study.

Platelet-derived Growth Factor

In addition to the combination agents noted previously, there are agents in development that solely target the PDGFR. This is supported by recent research indicating that the v-sis oncogene is derived from the PDGF gene. Furthermore, the PDGF pathway is involved not only in angiogenesis but also in stimulation of cancer growth and regulation of fibroblasts. The use of a mAb to target this pathway promises to improve efficacy and reduce off-target effects. Olaratumab (IMG-3G3) is a mAb to PDGF-α that has demonstrated significant antitumor activity in preclinical studies in ovarian cancer cell lines. Phase I trials in advanced solid malignancy toxicity have led to the development of a current phase II study of this agent (20 mg/kg) in combination with liposomal doxorubicin (40 mg/m^2) for platinum-resistant recurrent ovarian cancer. As noted previously, as a result of the effects on pericytes, the use of this agent in combination with other therapies promises to improve efficacy over it as a single agent.

P53

Given its high prevalence across a number of gynecologic malignancies and advanced solid tumors, there is great interest to leverage targeted agents against p53 mutations. **By far, Wee1 inhibitors are the furthest developed against this important target. Tumors with mutations in p53 are dependent on the G2 cell cycle checkpoint, which is regulated by Wee1, to repair damaged DNA.** Inhibition of Wee1 creates a situation of synthetic lethality among p53 mutant tumors. AZD1775 is a Wee1 inhibitor that has been combined with carboplatin and paclitaxel in the platinum-sensitive recurrent setting of ovarian cancer. The combination of chemotherapy with a Wee1 inhibitor yielded an improved response rate and PFS compared with chemotherapy alone. This agent is now under evaluation alone and in combination with several targeted agents for ovarian cancer. In addition to Wee1 inhibitors, several molecules are in early development that appear to restore the function of p53 across a number of p53 mutant tumors in the preclinical setting.

Immune Therapy

As noted earlier, immune escape is an essential contribution to successful tumorigenesis. Over the past 5 years, the number of successful immune therapy agents has skyrocketed. Early studies have focused on notoriously immune-driven cancers, including melanoma and non–small cell lung cancer. Single-agent studies of agents targeting PD-1 and PD-L1, including avelumab, nivolumab, and pembrolizumab, have been less successful in ovarian cancer, yielding modest response rates approaching 15% in an unselected platinum-resistant setting, primarily among patients with clear cell histology. Responses among high-grade serous ovarian cancer have been limited. However, growing data indicate that activity of immune therapy may be related to common features of gynecologic malignancies, such as mutations in *BRCA*, POLE, or the presence of microsatellite instability. This has led to development of immune therapy trials in ovarian, endometrial, and cervical cancer both alone and in combination with chemotherapy or targeted therapy. In addition to the checkpoint inhibitor trials described earlier, the use of tumor-directed T cells (adoptive T-cell therapy) has been explored in cervical malignancies. A small study of this therapy in nine women with metastatic cervical cancer yielded three objective responses, including two durable complete responses. Certainly, these therapies are promising and results from larger clinical trials are eagerly anticipated. In addition, approaches to enhance cytotoxic T lymphocytes (CTL) entry into tumor islets

will be important for improving the efficacy of immune therapies.

UNIQUE TOXICITIES OF TARGETED THERAPY

In addition to survival benefit, a major goal of targeting tumor-specific pathways is to reduce the incidence of adverse events caused by "nonspecific" cytotoxic agents. Targeted agents may have similar toxicities to the traditional agents such as myelosuppression, fatigue, and diarrhea. As our experience with novel targeted agents grows, it is apparent that there exist toxicities unique to these compounds. Side effects may be secondary to the inherent mechanism of the agent or unintended "off-target" effects. This section of the chapter serves as a brief review of the most commonly encountered toxicities and methods of prevention and treatment.

Hypertension

Hypertension is one of the most commonly experienced side effects related to targeted agents, with a prevalence that approaches 40%. This adverse event is most commonly related to the use of antiangiogenic agents, including bevacizumab, and combination agents such as sorafenib. The mechanism of hypertension is currently hypothesized to be twofold. First, the inhibition of VEGF results in the reduction of production of nitric oxide by endothelial cells. Resultant vasoconstriction and endothelial cell dysfunction are compounded by the occurrence of microvascular rarefaction. Microvascular rarefaction is a process found in a majority of patients with hypertension, regardless of etiology, and consists of the loss of the arterioles and capillaries that make up the microcirculation. Vasoconstriction from loss of nitric oxide serves to exacerbate nonperfusion and elevate peripheral vascular resistance, which can result in permanent microvessel extinction.

Hypertension appears to be dose dependent for several of the antiangiogenic agents. Bevacizumab at the typical doses given for gynecologic malignancies (10–15 mg/kg) has an incidence of hypertension between 18% and 36% compared with an incidence of 3% to 30% in patients treated with low-dose bevacizumab (3–7.5 mg/kg). This incidence may be further increased when bevacizumab is combined with cytotoxic agents known to have antiangiogenic activity such as topotecan or paclitaxel. Agents affecting the HIF-1α pathway reduce nitric acid synthesis and metabolism, leading to exacerbation of antiangiogenic drug-induced hypertension. Of note, small molecular inhibitors to VEGF have reduced incidence and severity of hypertension compared with mAbs targeting the receptor.

Hypertension induced by antiangiogenic agents is most commonly found in patients with preexisting hypertension. Thus, active management of blood pressure and cardiac risk factors such as elevated lipids is paramount. The use of several antihypertensive agents is often necessary to control hypertension in this setting. Acceptable treatments for angiogenesis inhibitor–induced hypertension include angiotensin-converting enzyme inhibitors, beta-blockers, and dihydropyridine calcium channel blockers (amlodipine, felodipine). Nondihydropyridine calcium channel blockers should be avoided given their inhibition of the P450 CYP3A4, which can affect the metabolism of tyrosine kinase inhibitors. Nifedipine is also not an optimal therapeutic choice secondary to the increase in VEGF levels associated with chronic use.

Reverse Protein Leukoencephalopathy

Reverse protein leukoencephalopathy (RPLS) is a rare complication of antiangiogenic agents, including bevacizumab, sorafenib, and sunitinib. Occurring in fewer than 1% of all patients treated with these agents, this syndrome is characterized by finding of diffuse, hyperintense T2-weighted signaling secondary to leaking of the capillaries in the brain. Symptoms of RPLS include change in mental status, headache, seizures, and lethargy. Aggressive antihypertensive management and supportive care typically lead to full recovery; however, in rare cases, this syndrome may be fatal. Typically, further use of anti-VEGF therapy in these patients is contraindicated.

Cardiotoxicity

Other effects of targeted agents on the cardiovascular system can include left ventricular dysfunction, congestive heart failure, and myocardial infarction. Uncontrolled hypertension can lead to left ventricular hypertrophy and cardiac musculature that outgrows its vascular supply. This results in traumatic cardiovascular events, which may be seen in any of the anti-VEGF agents. Furthermore, any tyrosine kinase inhibitor may have off-target effects that damage cardiac muscle cells and impair their survival. For example, sorafenib and sunitinib have been associated with decreased left ventricular ejection fraction in up to 30% of patients. Of note, this damage appears to be reversible secondary to mitochondrial dysfunction rather than the permanent free radical–induced cardiac damage found after anthracycline cardiac toxicity.

Thus far, prediction of the development of cardiac toxicity from targeted agents has been difficult. It does appear more common in patients with preexisting cardiac disease and prior treatment with anthracyclines. Again, aggressive medical management of preexisting conditions and careful monitoring of cardiac function are essential to maximize outcomes.

Renal Toxicity

Renal adverse effects may be found in response to a variety of targeted agents as a result of the expression of key targets along the nephron. The most common toxicity is proteinuria, especially among the antiangiogenic agents. This is thought to originate secondary to damage of endothelial cells, which depend on VEGF for integrity and regulation of permeability. In addition, thrombotic microangiopathy that leads to further damage of the glomerular capillaries may compound the loss of protein from the vasculature. Proteinuria is typically low grade, is asymptomatic, and may be monitored through assessment of albumin levels by urine dipstick. If protein readings exceed 2+ protein, collection of 24-hour urine protein is indicated for treatment decision making. Urine protein levels exceeding 2 g require treatment interruption and possible dose reduction depending on protocol requirements. Spot urine protein to creatinine ratios may also be used to monitor renal effect of targeted agents. Renal failure caused by targeted agents is rare and appears to be primarily related to glomerulonephritis,

interstitial nephritis, and acute tubular necrosis. Prevention and management of renal toxicity is based on thorough assessment of renal risk factors before therapy institution and optimization of any preexisting conditions.

Thromboembolic Events

The risk of venous thromboembolism (VTE) is increased at baseline among patients with active malignancy receiving chemotherapy. Antiangiogenic agents also appear to increase the propensity for thrombosis, especially arterial thromboembolism (ATE), including myocardial, cardiovascular, cerebral, and peripheral vascular events. In a large meta-analysis of patients treated as part of a randomized trial for a variety of solid tumors, patients treated with bevacizumab in addition to chemotherapy had two times greater incidence of ATE. Multivariate analysis revealed that bevacizumab remained a significant risk factor for ATE, in addition to age 65 years or older and prior history of ATE. Of note, the rate of thromboembolic complications appears low for VEGF-Trap and VEGF tyrosine kinase inhibitors. This may be secondary to formation of complexes by anti-VEGF antibodies that create a nidus for the formation of thromboses in the vasculature. Further study of this complication in large randomized controlled trials is necessary to determine the true incidence rates. At this point, patients with a history of VTE warrant the careful assessment and aggressive use of anticoagulation therapy. Anti-VEGF therapy should be avoided in patients with a history of prior ATE. Support for the use of routine thromboprophylaxis has not been established.

Gastrointestinal Perforation and Fistula

Gastrointestinal toxicity is a life-threatening complication that has been primarily associated with anti-VEGF therapy. Risk of intestinal perforation or fistula in any tumor type is associated with prior GI surgery, acute diverticulitis or active abdominal infection, obstruction, carcinomatosis, or history of prior radiotherapy. Rates of bowel perforation are highest among patients with ovarian cancer, ranging as high as 11% in one study of bevacizumab in the recurrent setting. In this study, a higher risk of perforation was associated with a history of more than two prior chemotherapy regimens. Furthermore, the high perforation rate in a trial combining bevacizumab and erlotinib in ovarian cancer led to early closure. Of note, frontline treatment does not appear to lead to increased GI toxicities, as evidenced by equivalent rates of perforation in the control and experimental arms of GOG 218 (reviewed in Table 18.4). Proposed mechanisms for bowel injury include the negative effect on wound healing secondary to damage of normal endothelial cells. Anti-VEGF therapies may induce microangiopathic events in the intestinal lining that cause edema and hemorrhage, making the wall more susceptible to bacterial dissemination and infection. In addition, rapid tumor shrinkage may cause the bowel wall to become weak, leading to perforation.

The management of anti-VEGF therapy-induced GI perforation must be individualized based on patient history, amount of disease, and status. In general, surgical exploration with intestinal diversion is the standard of care for patients with acceptable performance status; however, consideration should be made for risk of further poor wound healing. If a patient cannot undergo surgical exploration, conservative management with decompression, bowel rest, drainage, antibiotics, and nutritional support may be indicated.

Diarrhea and mucositis are common among patients treated with a majority of the small molecule inhibitors regardless of target. These adverse events may be the dose-limiting toxicity for a patient, requiring admission for IV hydration and drug discontinuation. Prevention with antimotility agents or neutralizing mouthwashes may be helpful to reduce incidence of these off-target effects. Esophagitis or gastritis may be an issue in patients treated with sorafenib or sunitinib; therefore, prevention with a proton pump inhibitor is reasonable.

Cutaneous Complications

Skin toxicities are quite common in patients treated with anti-EGFR agents (50%–100%), are dose dependent, and appear to be indicative of drug efficacy. Typically, an acneiform rash consisting of pruritic papules and pustules presents within 3 weeks of treatment on skin areas that have sebaceous glands. A similar rash may be seen in patients treated with mTOR inhibitors. The mechanism is thought to be related to follicular hyperkeratosis that causes glands blockage and inflammatory eruption.

This rash may be managed with topical antiseptics and antiinflammatory agents. Oral antibiotics such as doxycycline or minocycline may be used daily for a short course to improve rash severity and symptoms. In addition to this rash, patients may experience significant xerosis, which may be managed with over-the-counter emollients. Changes to the nail bed may be seen, including fragility, paronychia (inflammation of nail folds), and fissures. The hair may also be affected by the use of these agents. Most commonly, hypertrichosis, including growth of the eyelashes and scalp hair, has been reported.

Hand and foot skin reaction or acral erythema is a classic skin toxicity of sorafenib and sunitinib. Occurring in 20% to 25% of patients, it may consist of erythema, hyperkeratosis, xerosis, and dysesthesias and paresthesia in the bilateral hands, feet, or both. Patients can develop callous-like blisters and desquamation in both pressure- and non–pressure-bearing areas. Treatment for hand and foot skin reaction is primarily supportive, consisting of elevation, compresses, avoidance of trauma, and topical application of corticosteroid cream. Symptoms usually resolve during the course of therapy, but some patients may require dose reduction or complete cessation of therapy. In addition to hand and foot skin reaction, patients treated with sorafenib or sunitinib can develop stomatitis, scalp dysesthesias, perianal rash, and a skin rash that resembles seborrheic dermatitis.

Metabolic Abnormalities

The nonspecific nature of some of the targeted agents has led to a variety of unique metabolic side effects, requiring careful monitoring and action. Endocrine effects of tyrosine kinase inhibitors may include altered thyroid function, glucose metabolism, and bone metabolism. For example, sunitinib and sorafenib have been associated with onset of hypothyroidism in previous euthyroid patients. mTOR inhibitors, including temsirolimus and everolimus, have been associated with incidence of any hyperglycemia as high as 50%. Of note, alterations in

glucose metabolism can occur in either direction in patients treated with sunitinib or imatinib. Glucose levels must be monitored closely because these changes may necessitate change in dosing of antihyperglycemic agents among patients with diabetes. Glycemic control should be maximized before treatment with these agents. Lipid abnormalities, including elevated triglycerides and cholesterol, are common toxicities experienced by patients treated with mTOR inhibitors. These levels should be followed during treatment and, depending on patient cardiac risk factors, lipid-lowering agents may be instituted. Electrolytes should be monitored during treatment with targeted agents because many tyrosine kinase inhibitors have caused profound hypophosphatemia manifested as muscle weakness and fatigue.

SPECIAL CONSIDERATIONS FOR TARGETED THERAPIES

The unique nature of the targeted agents has led to several areas of controversy in the clinical management of patients receiving these drugs. Specifically, the design of clinical trials incorporating such agents is receiving scrutiny. The traditional method of determining the efficacy of a given drug by RECIST is based on the mechanism of action of cytotoxic chemotherapy (Table 18.6)**. These drugs are expected to shrink tumor cells, and thus a "successful" response as defined by RECIST would include a complete response or partial response. Typically, SD would be considered a failure of the agent. However, as noted earlier, targeted agents are generally cytostatic.** Given that these agents may simply inhibit tumor growth, SD may actually indicate an efficacious targeted agent. In fact, some authors have advocated the inclusion of SD into the endpoints of early clinical trials of targeted agents to ensure that potentially beneficial treatments are not eliminated from further study.

For patients with ovarian cancer, response to treatment may be monitored using CA-125 levels. However, it is unclear if this method is reliable for patients being treated with a targeted agent. In the aforementioned study of patients with recurrent ovarian cancer treated with bevacizumab and sorafenib, Azad and colleagues noted that changes in the concentration of CA-125 did not correspond to response based on RECIST measurements in all patients. Of note, three patients with partial response by RECIST had elevations in their CA-125 level that would have required removal from the study if strict CA-125 criteria had been used. Conversely, of eight patients with response by CA-125, only five had responses confirmed by computed tomography results.

It is clear that the expression of the receptors and proteins targeted by these agents varies across each tumor and histology type. The use of a targeted agent in an unselected patient population may lead to lower response rates and lack of further exploration of a potentially useful drug. It is clear that determination of which patients are more likely to benefit from a given targeted therapy is necessary. As molecular testing continues to advance, we anticipate that pretreatment determination of mutation status, gene and protein expression levels, or target function will result in patients being treated with appropriately selected targeted agents. Such predictive biomarkers will be increasingly expected to be included in clinical trials and for drug approvals.

The cytostatic nature of the targeted agents may also limit their effectiveness as a single-agent therapy. As seen in the text, many of these agents may control disease but not eliminate the disease entirely. Thus, the combination of targeted agents with other treatment modalities such as cytotoxic chemotherapy, surgery, and radiation is rational and currently being explored. As the use of targeted agents continues to increase, the considerations noted previously will need to be addressed and consensus achieved to ensure appropriate trial design and patient management.

TABLE 18.6 Response Evaluation Criteria for Solid Tumors (RECIST) Response Definitions

Response	Definition
Complete response (CR)	Disappearance of all target and nontarget lesions
Partial response (PR)	30% decrease in the sum of the diameters of the target lesions; stable nontarget lesions
Stable disease (SD)	Neither sufficient decrease or increase in the sum of the diameters of target lesions to qualify for CR or PD
Progressive disease (PD)	20% increase in sum of the diameters of the target lesions; progressive nontarget lesions; new lesions

CONCLUSIONS

As knowledge regarding tumor biology and pathogenesis continues to expand, the number of targeted agents will no doubt increase exponentially. These agents have the potential to have a profound impact on the treatment of patients with gynecologic malignancies. Future considerations will include determining the appropriate combination of targeted agents with other modalities to optimize survival outcomes and quality of life. Furthermore, directly targeting genes with RNA interference technology and assigning therapies based on the molecular or cellular profile of the tumor hold the promise to personalize the care of each gynecologic cancer patient.

Genes and Cancer: Genetic Counseling and Clinical Management

David G. Mutch, MD, Sheri A. Babb, MS, CGC, Philip J. Di Saia, MD

OUTLINE

Genetic Alterations in Cancer
Mechanisms of Human Gene Mutation
- Single Base Pair Substitutions and Point Mutations
- Larger Deletions
- Insertions
- Duplications
- Inversions
- Translocations

Cancer Epigenetics
Genomic Imprinting and Cancer
Genetic Alterations That Cause Cancer
- Oncogenes
- Tumor Suppressor Genes
- Apoptosis
- Mismatch Repair Defects
- Telomerase

Hereditary Cancer Risk Assessment: Genetic Counseling and Genetic Testing
- Clinically Relevant Hereditary Syndromes
- Hereditary Breast and Ovarian Cancer (*BRCA1* and *BRCA2;* Other DNA Repair Pathway Genes)
- Lynch Syndrome (Hereditary Nonpolyposis Colon Cancer)
- Less Common Inherited Cancer Syndromes Relevant to Gynecologic Oncology

Genetic Counseling and Genetic Testing for Hereditary Cancers
Referral of Gynecologic Cancer Patients for Hereditary Cancer Risk Assessment
- Ovarian Cancer
- Endometrial Cancer
- Referral of the Patient for Genetic Counseling Based on Personal History of Breast Cancer or Family History of Cancer

Genetic Testing
- General Guidelines for Genetic Testing for Hereditary Cancer Risk
- Informed Consent
- Ordering Genetic Testing
- Interpreting the Test Results

Legal Aspects of Genetic Testing
Long-term Contact for Patients and Families With Hereditary Risk for Cancer
DNA Banking
Conclusion

KEY POINTS

1. Cancer is not always inherited, but it is always genetic.
2. The inherited aspect of cancer always needs to be considered and appropriate counseling and testing arranged.
3. Genetic counseling and testing needs to be an integral part of all cancer management.
4. Genetic counselors are necessary for management and treatment of inherited disease.
5. Management is continuously changing, and communication among patients, their families, and the health care team is important.

Cancer is always genetic at the cellular level, but it is not always due to inherited risk. Overall, approximately 5% to 10% of cancers are clearly caused by inherited (germline) mutations. More recent data suggest that 10% to 25% of epithelial ovarian cancers are due to inherited risk. Mutations, if they occur in a gene or genes critical for cell growth, may allow a cell to reproduce in an uncontrolled fashion. This uncontrolled growth of a cell or tissue is known as a cancer. Cancer is seldom the result of a single mutation but is more commonly caused by a multitude of acquired mutations in many different genes, allowing uncontrolled cell division. The concept that cancer is the result solely of genetic or epigenetic changes is relatively new and comes from the past 4 decades of cancer research. Before the 1970s, the cause of cancer was essentially a black box, and its etiology was largely unknown. To some extent, it is still unclear, but we no longer believe that defective immunity, viruses, or metabolic errors directly cause cancer. These factors may contribute to the development of this disease, but the basis of cancer lies in an individual organism's DNA and in that individual organism's ability to express the genetic material in a normal fashion. This is simply related to the DNA sequences that make up that individual's genome that has been inherited and altered

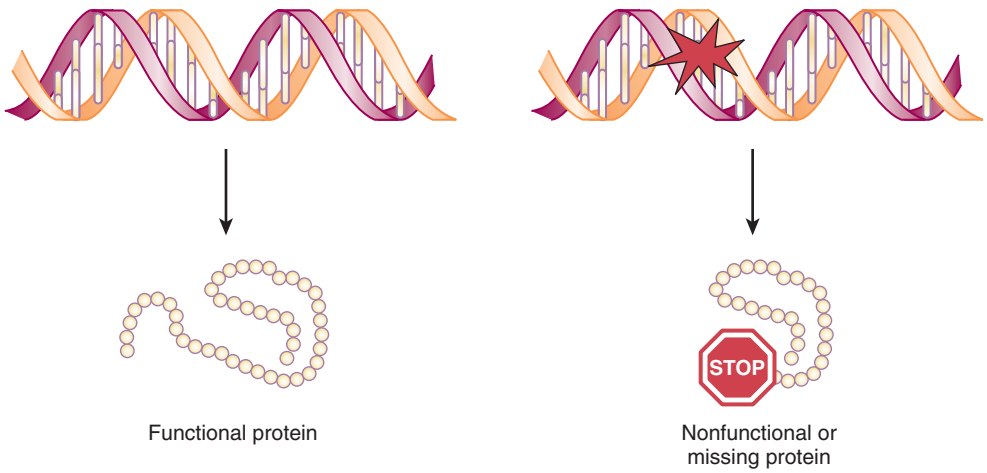

FIGURE 19.1 Disease-associated mutations that alter protein function.

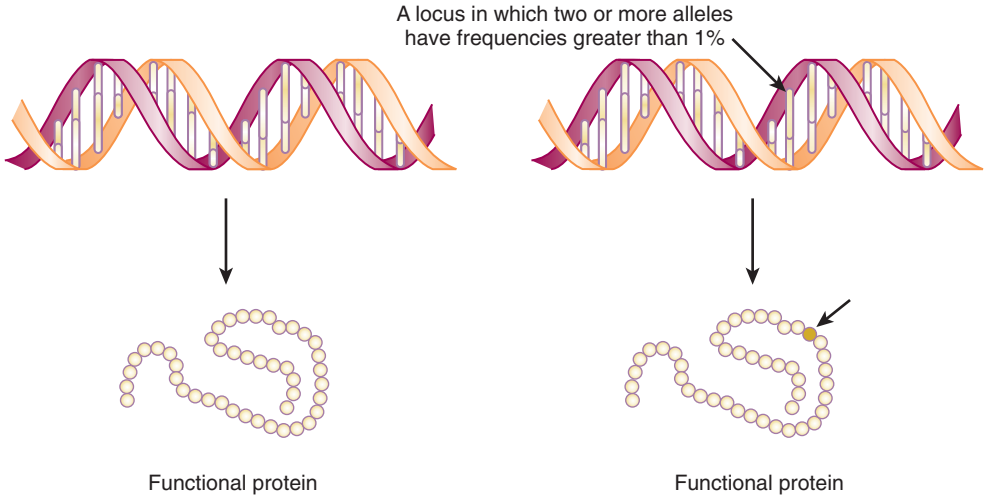

FIGURE 19.2 A depiction of a polymorphism.

through the course of normal living. Thus, cancer is a disease of abnormal DNA expression. Alterations or differences in the DNA sequences are known as mutations (changes in DNA such that a protein alteration occurs) or polymorphisms (changes in DNA that results in a subtle change in gene function and protein structure that do not cause disease). Polymorphisms are one of the factors responsible for normal population differences. There is a fine line between a mutation and polymorphism (Figs. 19.1 and 19.2) (<1% but protein function remains).

An individual may inherit a genetic mutation or may be exposed to an environmental insult that predisposes to the development of a cancer. Such insults can occur from everyday living or as the result of repetitive exposure to an agent that can cause DNA damage such as known carcinogens or other environmental factors that cause DNA damage. In addition, any process that causes cells to divide, such as ovulation, can allow an opportunity for an error in DNA replication to be made. For instance, an individual prone to the development of ovarian cancer can reduce her risk of developing this disease by taking oral contraceptives. This will inhibit ovulation and decrease the damage to the surface of the ovary that could allow a mutation to occur. **Recent hypotheses suggest that ovarian cancer may arise from the epithelium of the tubal epithelium. If this circumstance is true, then the etiology of oral contractive protection is not known.**

Cancers, unlike many other inherited diseases, become apparent after there is an accumulation of several genetic injuries or mutations. In this respect, cancer is different from most inborn errors of metabolism because more than one genetic event is required to allow expression of the disease. One does not inherit cancers as one would inherit cystic fibrosis or sickle cell disease. One may inherit a mutation in a gene that predisposes one to the development of cancer, but most cancers are the result of the accumulation of somatic mutations that result from the process of normal living. Viruses, smoking, eating charcoal-broiled steak, or simply random mistakes made during DNA replication may cause these mutations. After all, a replicating cell must copy 3 billion base pairs—with each division, mistakes will occur.

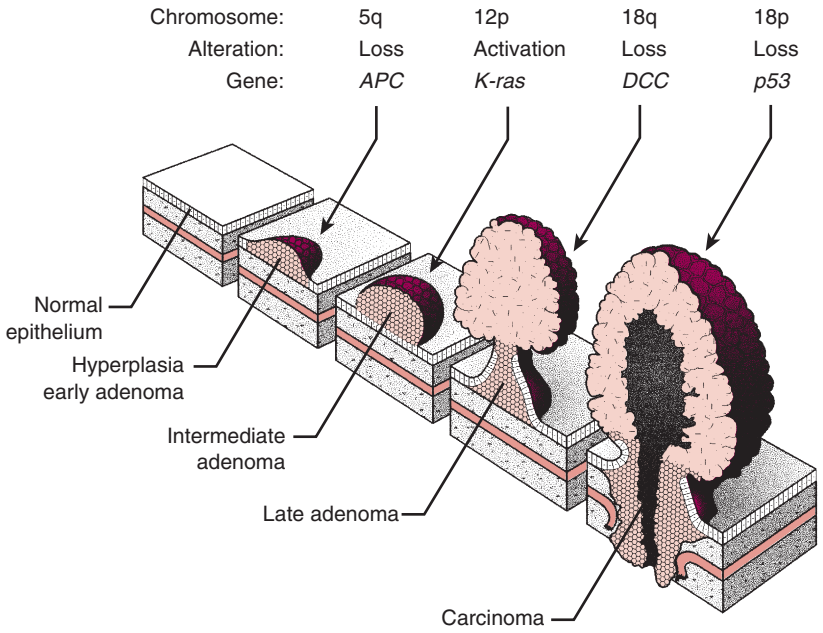

FIGURE 19.3 A model for colorectal tumorigenesis. This shows the molecular progression of normal colon epithelium to frank cancer.

Progression from a normal cell to a malignant cell is the result of the accumulation of a series of mutations. This progression has probably best been demonstrated in colon cancer by Burt Vogelstein and colleagues (Fig. 19.3). In this model, a series of mutations must occur that involve tumor suppressor genes and oncogenes; a benign tumor progresses to a malignant tumor as the necessary mutations occur during a prolonged and somewhat erratic interval.

Three broad classes of genes are involved in the development of cancer. These are tumor suppressor genes, oncogenes, and mismatch repair (MMR) genes. Tumor suppressor genes are responsible for making a product that inhibits cell growth. These types of genes are expressed in a recessive manner, and therefore both alleles need to be defective before the phenotype becomes apparent. Oncogenes are expressed dominantly and are usually responsible for a product that promotes cell growth. Overexpression of an oncogene protein results in uncontrolled cell growth. MMR genes are responsible for repairing DNA damage that results from loss of fidelity in normal DNA replication. If one of these genes does not function properly, errors in DNA can accumulate, and ultimately, some of these errors will occur in genes critical for cell control, resulting in uncontrolled cell growth. The development of cancers is therefore not the result of a single error or insult but rather the accumulation of genetic errors over time.

Mutations are a means of evolution. The paradox of life is that mutations can be responsible for an individual organism's death in the form of cancer or metabolic error, but other mutations can account for the evolution of the species. Therefore, mutations can be good, bad, or even neutral.

GENETIC ALTERATIONS IN CANCER

Genetics is not a new field and has been a study for several centuries from Mendel in 1865 to the present. Johannsen first coined the term *gene* in 1911 as it applied to the unit of a hereditary characteristic. This was further refined to the one gene–one enzyme concept in the 1940s and put forth by Tatum and Beadle. These concepts have been clearly defined in *Drosophila* but apply equally to humans and other organisms; after all, all living things are defined by their DNA. Humans have more DNA than other organisms and are therefore more complex, but the DNA behaves the same way in all organisms.

The one gene–one enzyme concept that developed from the ideas expressed by Tatum and Beadle can be summarized as follows:

1. All biologic processes are under genetic control.
2. These biochemical processes are expressed as a series of stepwise reactions.
3. Each biochemical reaction is ultimately under the control of different single genes.
4. Mutation of a single gene results in an alteration of the cell to carry out a single chemical reaction.

The one gene–one enzyme concept has since been refined and extended to cover proteins that are not enzymes. Now further information suggests that some genes combine with others to form unique proteins, indicating that a few genes may interact to form more than one protein per gene. The human genome is estimated to contain about 3 billion base pairs and was thought to have between 50,000 and 100,000 genes. Now that the human genome has been sequenced, we have discovered that there are only about 30,000 genes. These genes are stored

on linear strands of DNA and interact much more than we previously believed. The genes are not continuous sequences of DNA but consist of coding sequences called exons interrupted by noncoding sequences called introns. Most of the DNA is composed of intronic DNA that is usually not expressed in any form. An approximation of the size of the human genome and its organization can be seen in Fig. 19.4. The functional length of the human chromosome is expressed in centimorgans (cM). A cM is the distance over which there is a 1% chance of crossover during meiosis and is really a measure of "genetic distance." Linkage studies indicate that the human genome is about 3000 cM. The average chromosome contains about 1500 genes in 130 million base pairs. Fig. 19.4 shows the estimated physical and functional size of the genome. Whereas the physical size is estimated in base pairs, the functional size is estimated in centimorgans. Much, if not most, of the human genome is composed of noncoded DNA and is therefore not expressed.

DNA is transcribed into RNA that is translated into protein. Therefore, the sequence of DNA base pairs ultimately determines the sequence of the functional proteins within the cell. All cellular functions are expressed in this manner (Fig. 19.5):

$$\text{DNA} \rightarrow \text{RNA} \rightarrow \text{Protein}$$

Humans and other mammals may be more complex than some other organisms in that pieces of genes may combine with parts of other genes to make a totally new protein. Hence, we

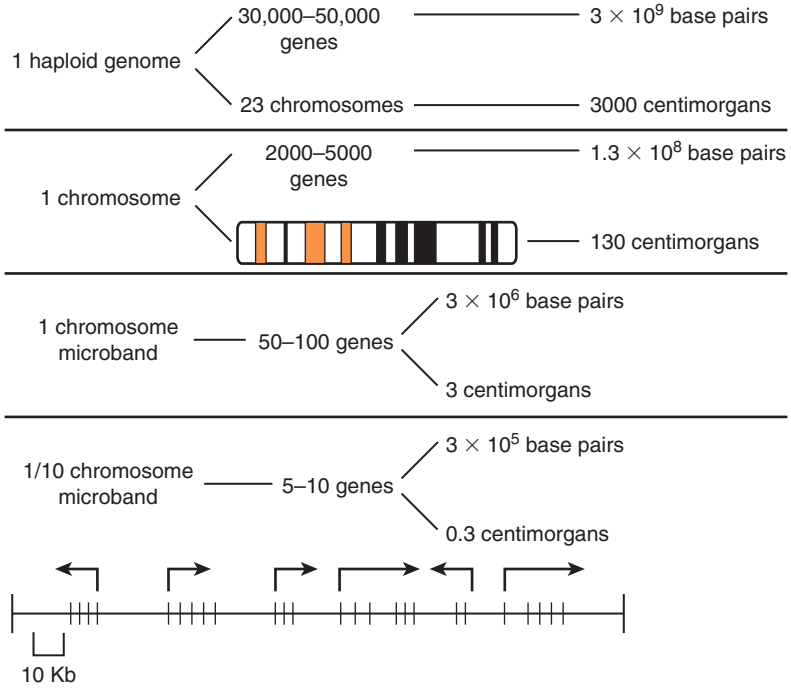

FIGURE 19.4 The structure of the human chromosome demonstrated in terms of functional units (centimorgans) and physical units (base pairs).

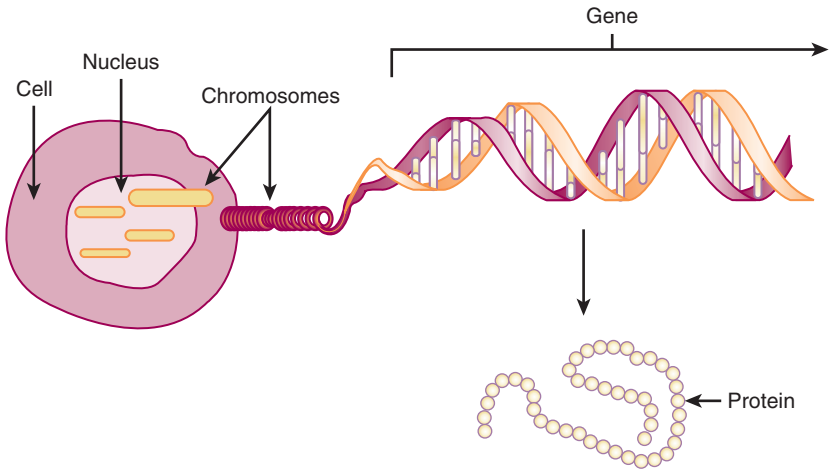

FIGURE 19.5 The progression of protein synthesis from DNA to RNA to protein. (From National Cancer Institute. *Understanding Gene Testing*. Rockville, MD, 1995, National Cancer Institute.)

may essentially increase the number of genes expressed without really increasing the amount of functional DNA or the number of actual genes. Overall, less than 30% of our genetic material is expressed.

MECHANISMS OF HUMAN GENE MUTATION

All cancers result from alterations in DNA structure, leading to changes in the proteins responsible for cellular function. All living organisms use the same 20 amino acids as building blocks for proteins. The translation of a nucleotide sequence from DNA to protein is dependent on a triplet code of nucleotides. Each of these triplet codes is called a *codon.* Some codons have very special functions. The code AUG codes for methionine, and this starts the initiation of synthesis (translation) of every protein. The code UAA is a stop codon and ends translation of a protein (Fig. 19.6). Much of the data available about genetic alterations in cancers come from studies other than of gynecologic malignant neoplasms. These studies often involve hematologic malignant neoplasms such as lymphomas and leukemia because pure subsets of cells are easily obtained. More recently, we have been able to improve our study of solid carcinomas because of our ability to study pure tumor preparations, single out cells, and isolate the DNA with microdissection and laser capture techniques. Using this technique and techniques like it, we can dissect out a single cancer cell, replicate its DNA, and evaluate the mutations that occur in this single cell or group of cells. Fig. 19.7 demonstrates the heterogeneity of cancer and why there is a need for these special techniques. Cancer is the result of clonal expansion, but as the various cells replicate in an uncontrolled manner, they continue to mutate. Initially, cancers usually have a single clonal origin. As the cancer progresses, mutations occur, and therefore some cells may become genetically different from the original cancer. **Hence, the term *mutator phenotype* is often applied to cancers.**

A wide number of and various types of mutations have been described. These mutations are fundamental to the understanding of cancer and of human evolution. Although many types of mutations can occur, some common ones are listed in Table 19.1.

Multiple searchable databases are publicly available that provide a comprehensive listing of gene specific mutations reported in the somatic cancer tissue as well as germline (inherited) mutations. Examples of these databases include The Human Gene Mutation Database (HGMD) (http://www.hgmd.cf.ac.uk/ac/index.php), Clinvar (http://www.ncbi.nlm.nih.gov/clincar), and COSMIC (Catalogue of Somatic Mutations in Cancer; http://www.cancer.sanger.ac.uk/cosmic). These databases are periodically updated as most researchers and commercial laboratories publicly share their data. Illustrations of some common mutations can be seen in Figs. 19.8 to 19.13.

FIGURE 19.8 Example of how a point mutation (a change in a single base pair) can result in changing the meaning of a gene sequence using a common phrase.

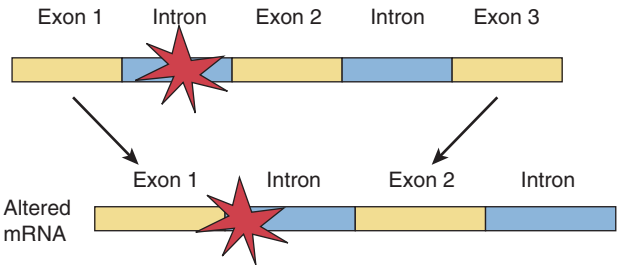

FIGURE 19.9 Cryptic splice site mutations. Splice site mutation, a change that results in altered RNA sequence.

Single Base Pair Substitutions and Point Mutations

DNA replication is the result of an accurate yet accident-prone process. The final accuracy of DNA replication depends on the fidelity of the initial process and the ability of subsequent repair processes to correct any mistakes. Point mutations lead to single changes in the DNA sequence. These single mutations can have very different effects on the reading of a protein, as demonstrated in Figs. 19.10 and 19.11. If this mutation is in a regulatory portion of a gene, loss or alteration of regulation of gene expression can occur. If the mutation is in a coding portion of the gene, an altered protein can be formed. HGMD is one of several catalogs of reported point mutations that can be obtained from the Internet.

One of the most common mutations as the result of substitution occurs in CpG dinucleotides (3′ cytosine-guanine 5′). Data show that these transversions account for about 30% of point mutations. The fidelity of this process is related to the efficiency and accuracy of the DNA polymerase responsible for replication. Other types of these small nucleotide substitutions that can also occur are messenger ribonucleic acid (mRNA) splice junction mutations, translational mutations, and single deletions. Alternatively, mismatches can occur by slipped mispairing, which leads to single base pair mutagenesis and deletion.

Deletion or insertion of a single nucleotide may be secondary to DNA mispairing during replication. This type of mutation often occurs in runs of identical base pairs and is the result of slippage of a single base pair (Fig. 19.14). This mechanism is similar to larger deletions caused by this same mechanism. The significance of this type of mutation to human malignant neoplasia is as yet undefined. As more information becomes available about mismatch repair, we should have a better estimate of the significance of this type of mutation to cancer formation. However, this slippage is common and similar to the errors found in individuals who have an inherited cancer syndrome, hereditary nonpolyposis colon cancer (HNPCC), or Lynch syndrome.

CpG dinucleotides are very susceptible to mutations. Methylation of cytosine results in a high level of mutation because

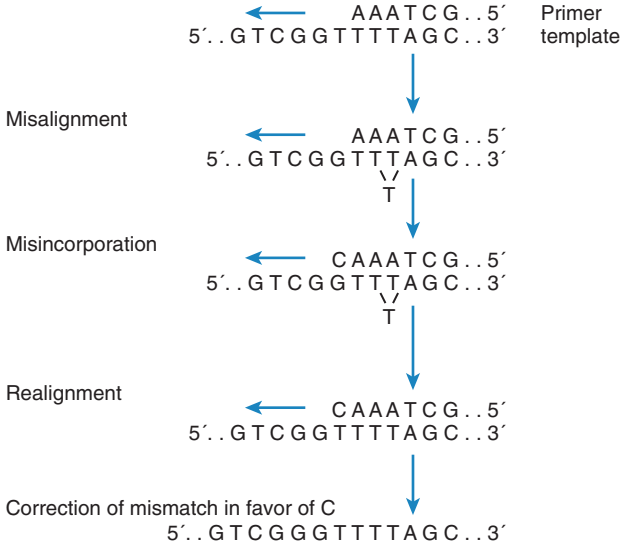

FIGURE 19.14 DNA mispairing that results in a single base deletion of a T. This causes a complete change of sequence. Attempt at correction adds a G or C to the sequence.

of its propensity to undergo deamination. This then forms thymidine and therefore can result in a change of gene expression. The evolution of the human genome seems to indicate a progressive loss of CpG islands because of this transition. The frequency of these islands is about 20% to 30% of the predicted frequency, probably because of the progressive loss of CpG dinucleotides. This excess of transition from cytosine to thymine (C to T) transitions was first reported by Vogel and Rohrborn in a study of the mutations responsible for variants of hemoglobin. Others now also have shown that CpG islands are associated with a high rate of transition, supporting the thought that these mutations play a significant role in human disease (Fig. 19.15).

Larger Deletions

Gene deletions are responsible for more than 150 inherited diseases. Deletions can range from a few base pairs to several

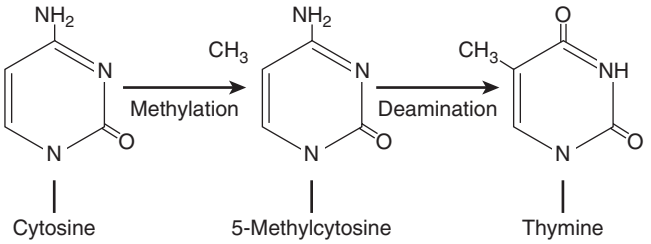

FIGURE 19.15 Cytosine to thymine transition from methylation. (From Korf B, ed. *Human Genetics: A Problem-Based Approach,* 2nd ed. 2000, Blackwell Publishers.)

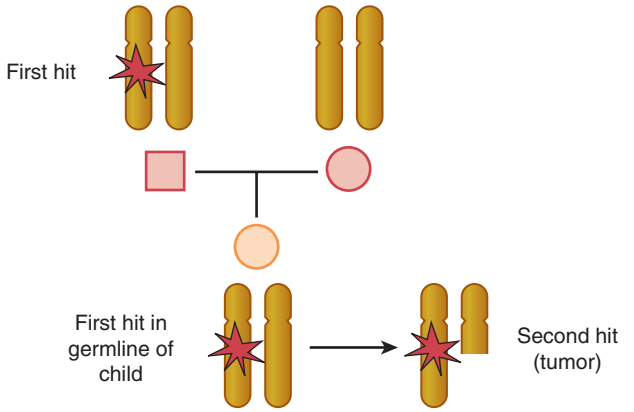

FIGURE 19.16 Knudsen's two-hit theory that is essential to the concept of tumor suppressor genes.

hundred kilobases and are often classified by size. These are also nonrandom in that certain sequences appear to be more prone to deletion than others are. This nonrandomness is apparent when one evaluates genetic disease. Spontaneous deletions often occur in the same sequences of various genes, indicating that some sequences of DNA are more prone to deletion than others.

Deletions occur when there is homologous but unequal recombination between gene sequences. Similar sequences in the human genome can cross over during mitosis or meiosis, resulting in a shortened portion of the gene sequence. Long areas of homology (homology boxes) are thought to be the most likely to have this type of mutation. Repetitive DNA sequences are particularly susceptible to deletions because this can allow slippage. This mechanism is called homolog or unequal recombination between repetitive sequence elements. The most common repetitive sequence is the Alu repeat (up to 106 Alu sequences are in the human genome). Alu repeats are characterized by an average spacing of 4 kilobases and 300–base pair length separated by a short A-rich region. The Alu element is 70% to 90% homologous to the consensus sequence. The 3′ homology (homology boxes) is thought to be the most likely to have this type of mutation. Repetitive DNA sequences are particularly prone to mutation.

There are more than 400 gross gene deletions recorded in the HGMD and 3000 or so smaller gene deletions. Almost 2500 gene deletions of 20 base pairs or fewer have been identified. These can be the result of deletion of repeats or a part of the excision repair process. Deletion is not random; particular sequences are more prone to deletion and often contain regions involving guanine or other repeats. The application of the techniques of molecular biology, such as gene cloning, in situ hybridization, restriction endonuclease mapping of genetic sequences, and polymerase chain reaction analysis of gene transcription, has led to the conclusion that a given chromosome abnormality may be associated with a variety of neoplasms and that a given oncogene may be activated in a variety of human cancers. The most common defects in solid tumors are deletions in specific gene sequences, observed as a loss of part of a banding region or the loss of heterozygosity of a specific genetic allele. Deletion of genetic material in a cancer cell suggests loss of function that regulates cell proliferation and differentiation. Many human solid tumors have been shown to have some type of chromosome deletion. The Tp53 tumor suppressor gene–containing region of chromosome 17p is deleted or mutated in a wide variety of human cancers. The fact that there is such commonality among cancer cell types in the loss of chromosome material suggests that these regions contain genes coding for regulating functions of a wide variety of cell types. Induction of the malignant neoplastic process must involve at least two hits when a tumor suppressor gene is involved. This implies that two mutations or deletions in each of the two alleles are necessary before the effect can be expressed. This is the two-hit theory proposed by Knudson. The possibilities for the two hits necessary to express a recessive gene can be seen in Fig. 19.16. This explained why some people could inherit a predisposition for a malignant disease and also raised the question of whether sporadic cancers could have a genetic basis. In a genetically predisposed cell, the remaining single normal allele may be sufficient to maintain normal growth and regulation; a second deletion or mutation is required to inactivate the remaining normal allele.

Insertions

Most insertions appear to be small, between one and a few base pairs. This phenomenon has been studied extensively, and these insertions often appear to be nonrandom in character. Predisposing factors lead to these insertions. These insertions can be due to slipped mispairings, or they may be mediated by inverted repeat sequences or by symmetric elements. These sorts of DNA sequences are particularly prone to mutation.

Less common are large insertions. The largest insertion known is the 220-kilobase segment inserted into the DMD gene. Alu and LINE (long interspersed nucleotide elements) sequences are especially susceptible to insertion and deletion. Mutations are nonrandom, and some DNA segments are more susceptible to mutation than others are. For example, the myc gene is especially susceptible to insertions; a 50–base pair LINE element has been noted to be inserted in this gene in breast cancer cell lines. The fact that insertional mutations may not be random is underscored by the finding of Fearon and Vogelstein, who reported 10 independent examples of insertions within the

same 170–base pair intronic region of the DCC gene involved in the progression of colorectal cancers.

Duplications

Duplication of small parts of whole exons, or even of whole chromosomes, has played a large part in the development of cancer. This phenomenon also has a large role in the evolution of the human genome. Again, the paradox is that mutations are sometimes good and sometimes bad. Duplication of larger segments of DNA may lead to gene amplification. Gene amplifications can occur in many ways. A gene that is usually present in a single copy in the normal cell may be duplicated or may undergo a small increase in the copy number. Another type of amplification may involve a 10- to 100-fold increase in copies of a genetic locus containing key regulatory genes. A third type of amplification can result in the duplication of whole chromosomes. One can envision how amplification has been important over the course of evolution. We have 23 pairs of chromosomes, and all other organisms have fewer chromosomes. This is due to millions of years of evolution resulting from innumerable insertions and duplications.

Inversions

Inversions are perhaps the least common type of mutation. In this mutation, a long segment of DNA forms a loop and alters its direction; the 3′ end now becomes the 5′ end. These segments can obviously be large or quite small. The most important inversion event in human disease involves the factor VIII gene, causing severe hemophilia A. An MSH2 inversion has been reported in exons 1 to 7 in Lynch syndrome and is one of the few cancer-associated inversions.

Translocations

More than 100 common translocations have been observed in malignant cells. Many of these occur consistently in certain specific cancer types, which argues that these areas are involved in the malignant process of the cell. Some of the translocations may be secondary events in the evolution of more aggressive phenotypic changes. The inherent genetic instability of malignant cells leads to further karyotypic abnormalities as the disease progresses, reflecting additional genetic alterations that increase growth potential. Evidence that malignant transformation does not usually result from a single translocation event comes from the study of patients with ataxia-telangiectasia, who are at high risk for leukemia. These patients have lymphocytes with a characteristic translocation present for many years before a malignant change develops.

A common finding in cancers is some form of genetic instability. This is most clearly manifested in Lynch syndrome (or HNPCC). Lynch syndrome is characterized by genetic instability at microsatellite sequences and has been linked to several MMR genes. Mutation rates in cells that are positive for MMR defects are orders of magnitude higher than MMR intact cells.

Cancers in patients with hereditary cancer syndromes may serve as a model for sporadic disease because mutations that occur in the sporadic tumors are often very similar. The same genes and sequences seem to be targeted. For instance, Krawczak and Cooper demonstrated that the bulk of single base substitutions in the Tp53 gene in sporadic cancers strongly resemble those found in inherited cancers.

CANCER EPIGENETICS

Epigenetics refers to modification of gene expression not specifically related to changes in the DNA sequence of a gene. This is a concept of differential expression of the genotype based on factors outside of the genome. It is interesting that these differences can be inherited and appear to be quite stable. Epigenetic changes can involve chromatin structure; histone modification; changes in transcriptional activity; and, most easily measured in mammals, changes in methylation of CpG loci.

Methylation is the only known covalent modification of DNA in normal mammalian cells. This change occurs at the fifth position of cytosine at 5CG-3′ dinucleotides. About 80% of these types of dinucleotides are methylated and therefore are probably important in cell control and gene expression. Generalized hypomethylation is present in colorectal cancers and endometrial cancers early on in the development of these diseases, but the exact cause and effect of this observation is unclear. Presumably, hypomethylation allows some genes to be overexpressed. Alternatively, some regions on some genes, particularly the promoter region of MMR genes, can cause gene silencing (Fig. 19.17). This allows a tumor suppressor gene to be silenced, thus promoting the development of that cancer. Changes in methylation status are not clonal. Hence, some cancers can have different gene expression in the same cancer because of differential methylation. Changes in methylation

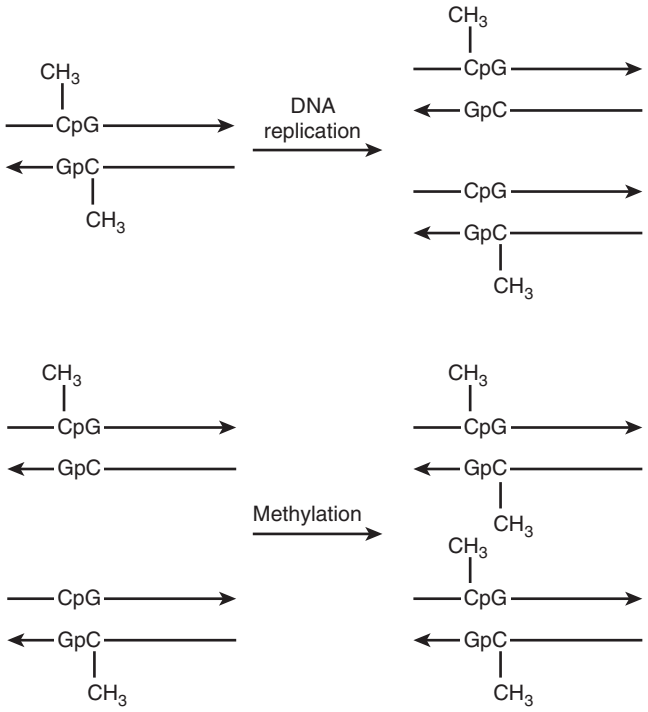

FIGURE 19.17 Methylation can cause gene silencing. (From Korf B, ed. *Human Genetics: A Problem-Based Approach,* 2nd ed. 2000, Blackwell Publishers.)

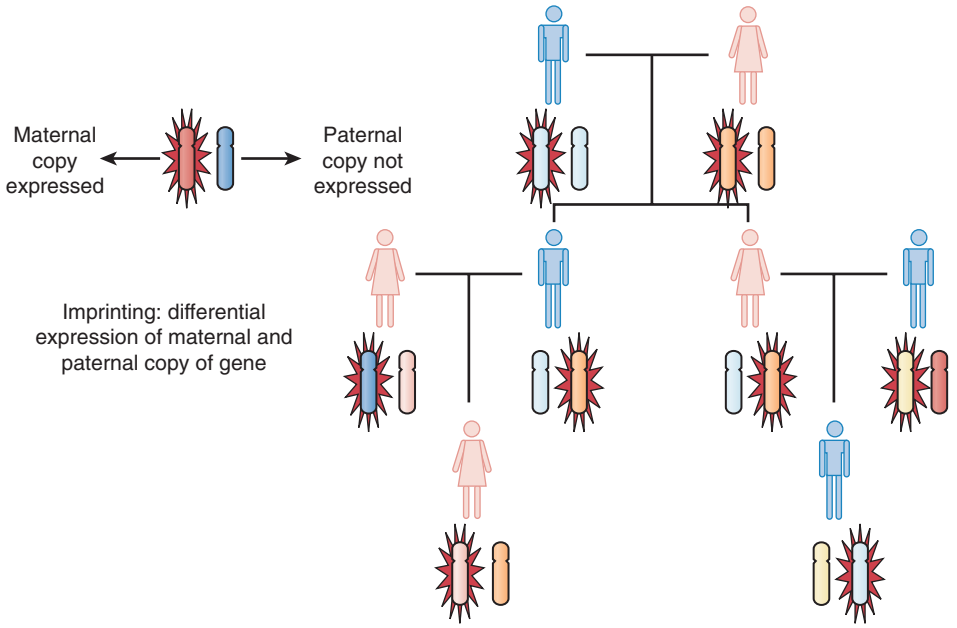

FIGURE 19.18 Significance and mechanism of imprinting. (From Korf B, ed. *Human Genetics: A Problem-Based Approach,* 2nd ed. 2000, Blackwell Publishers.)

status could also cause aberrant chromosome condensation during division and result in abnormal chromosome segregation. Therefore, epigenetics can affect tumor behavior in several ways.

GENOMIC IMPRINTING AND CANCER

Genomic imprinting is a modification of DNA that leads to a different expression of the gene depending on the parent of origin. This may be passed from generation to generation. However, the specific expression of these modifications may increase, decrease, or remain stable from generation to generation (Fig. 19.18). These epigenetic alterations appear to occur commonly in human malignancies and because of their unique properties may lead to novel forms of therapy.

Assumptions are made in Mendelian genetics, which we apply to human disease, that the maternal and paternal alleles are equivalent. We also assume that both copies of the gene are necessary for normal function. This is not true with respect to genomic imprinting. An example of imprinting is the differences noted between the mule and the hinny. The mule is the cross between a maternal horse and a paternal donkey. It is much larger than the hinny, which is a cross between a maternal mule and a paternal horse. Although these two have the same genomic equivalent, they are distinctly different, indicating differential expression of maternal and paternal genes.

Examples of genomic imprinting and cancer are the hydatidiform mole and the teratoma. The hydatidiform mole is composed of paternal chromosomes, and the teratoma is composed of only maternal chromosomes. These examples demonstrate that not only does it take 46 chromosomes to make a human being, but there must also be a balance between maternal and paternal elements.

GENETIC ALTERATIONS THAT CAUSE CANCER

Oncogenes

The past 25 years have contributed significantly to our understanding of the molecular mechanism of cancer and have identified three types of molecular aberrations that can lead to cancer: dominant transforming genes called oncogenes, recessive transforming genes called tumor suppressor genes, and genes responsible for repairing DNA errors (MMR genes). Many oncogenes have been isolated as forms of proto-oncogenes acquired by RNA tumor viruses. We have known for many years that viruses can cause malignant tumors in animals. The link noted in animals spurred a great deal of research aimed at identifying the cancer-causing genes carried by the viruses and finding the human genes that were affected. These investigations surprisingly revealed that the genes implicated in malignant disease were often altered forms of viral genes. These were probably acquired when the virus infected the animal and then moved on to other animals. At other times, the viruses activated host genes that were normally quiescent. The normal versions of these pirated and activated genes, now termed *proto-oncogenes*, carried codes specifying the composition of proteins that encourage and stimulate cell replication. These growth-promoting genes come in various forms. Some specify the amino acid sequences of receptors that are found on the cell surface and bind to molecules known as growth factors. When bound by such factors, the receptor issues an intracellular signal that ultimately causes cells to replicate. Other growth-promoting genes code for proteins that lie inside the cell and govern the propagation of intracellular growth signals. A third group encodes proteins that control cell division and are under nuclear control. These oncogenes can be activated via several mechanisms. The oncogene can be amplified, and many copies of the

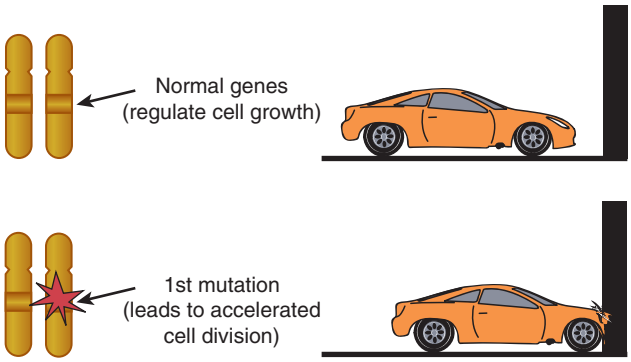

FIGURE 19.19 Schematic of oncogene function.

gene can become activated. Occasionally, the gene may be translocated to another chromosome, where, under the influence of another promoter, it promotes uncontrolled growth.

The three classes of oncogenes are controlled differently. The first comprises a group of peptide growth factors and their receptors. Included in this group are the peptide growth factors and their receptors such as epidermal growth factor receptor (EDGFR) and platelet-derived growth factor (PDGFR). These peptide growth factor receptors likely serve as stimulatory cofactors rather than the actual force that drives the malignant process. Targeted therapy is becoming a reality as our understanding of these cancer-promoting entities increases. Unique molecules are aimed at gene products or proteins activated by these factors. **Another class of oncogenes comes from non–membrane-traversing extranuclear growth factors. These include G-proteins and the ras gene family. Finally, there are oncogenes of the nuclear regulatory variety such as myc.** A schematic of oncogenes representing their function can be seen in Fig. 19.19. A more detailed description of targeted therapy can be found in Chapter 18.

The discovery that viral genes had human counterparts introduced the intriguing possibility that human cancers, including the majority not caused by viruses, might originate from mutations that convert useful proto-oncogenes into harmful genes—that is, oncogenes. Consistent with this notion, studies indicated that alteration of just one copy, or allele, of these proto-oncogenes was enough to transform and render cancerous some types of cells growing in culture. Such dominant mutations cause cells to overproduce a normal protein or make an aberrant form that is overactive. In either case, the result is that stimulatory signals increase within the cell even when no such signals come from the outside.

It is ironic that research on animal RNA tumor viruses (retroviruses) having no ability to cause human cancer provided the first key to uncovering the identity of some oncogenes and the verification that they actually exist. These retroviruses, which infected chickens, rodents, cats, and monkeys, were extremely tumorigenic in that infected animals often showed tumors on initial exposure to the virus. One of these viruses, the Rous sarcoma virus of a chicken, was found to carry a specific gene that it used to transform infected cells to a malignant state. This type of transforming oncogene was termed a *viral oncogene*. A single oncogene carried onto a chicken cell by a Rous sarcoma virus was able to derail and redirect the entire metabolism of the cell, forcing it to grow in a malignant fashion.

In 1976, Varmus and Bishop found that the oncogene in the Rous sarcoma virus was not a viral gene at all; instead, it arose directly from a preexisting cellular gene that had been captured by an ancestor of the Rous sarcoma virus. After it was captured, this gene was used by the Rous sarcoma virus to transform mammalian cells. The early ancestor of the Rous sarcoma virus was capable of replicating in infected cells but was unable to transform them; it instantly gained tumorigenic potency by kidnapping this normal cellular gene, the proto-oncogene. In the end, this work by Varmus and Bishop revealed much more about the cell than it did about the Rous sarcoma virus because it pointed to the existence of a gene residing in a normal mammalian genome that possessed potent transforming ability when appropriately activated, in this case by a retrovirus. Here was clear proof of the presence of at least one gene in the normal cellular DNA that might serve as one of the target genes activated by nonviral carcinogens of the retrovirus; such nonviral agents might also activate this proto-oncogene, converting it to a powerful oncogene. A cell carrying such a mutant gene might, in turn, respond to this damage by launching a program of deregulated growth and thus become a cancer cell.

The information uncovered concerning retroviruses and oncogenes provided little immediate comfort to investigators interested in the origins of human cancer. Retroviruses, similar to Rous sarcoma virus, never infected humans and therefore could not act to mobilize human proto-oncogenes. The possible connection came from a notion that many such proto-oncogenes could be activated through an alternative route. Changes in the DNA sequence created by chemical or physical rearrangement might substitute for the virus. Mutations induced by these chemical or physical conditions in the genomes of target cells in one or another tissue might be as effective as retroviruses in activating latent carcinogenic potential in the proto-oncogenes. By the early 1980s, these suspicions were validated: mutated genes (proto-oncogenes) were found in human tumor genomes. In each case, a change in the sequence of the gene was identified as being responsible for converting a proto-oncogene into an active oncogene. For example, a ras oncogene in one human bladder carcinoma was found to have arisen through a single base change that altered the DNA sequence of a precursor proto-oncogene; myc oncogenes arose through gene amplification in various malignant neoplasms.

Next, researchers tried to ascertain how these genes succeeded in transforming cells. A simple theme emerged that makes it possible to understand and explain the mechanism of action of most, if not all, of the oncogenes. This comes through the understanding of how cells regulate their own growth. The growth and division of a normal cell residing in a particular tissue is controlled largely by its surroundings. A normal cell rarely, if ever, decides its own rate of proliferation; rather, it responds to the signals or messages from surrounding cells. These messages, which may carry growth-stimulatory or growth-inhibitory information, are conveyed by growth factors released by surrounding cells, traverse the intercellular space,

and bind to the cell surfaces. These cells then respond to these growth signals by activating their synthetic machinery, copying their DNA, and dividing. A normal cell will never commit itself to such a growth program without having been simulated by these external signals. Each cell possesses complex machinery that enables it to receive these signals, process them, and launch a growth program. The machinery consists of an array of proteins that function to acquire growth-activating signals and transmit them throughout the cell. These proteins include the following:

1. Cell surface receptors that recognize the presence of growth factors in the extracellular space and transmit signals into the cell's interior
2. Cytoplasmic signal transducers that become activated by these receptors and then pass signals farther into the cell
3. Nuclear transcription factors that are activated by the cytoplasmic signal transducers and in turn respond by activating entire banks of cellular genes

These activated gene banks together orchestrate the cell's growth program; they detail events that, acting in concert, enable the cell to grow and divide. Proto-oncogenes encode many of the proteins in this complex signaling circuitry that enable a normal cell to respond to exogenous growth factors. Oncogenes participate in this signaling circuitry by selecting aberrantly functioning versions of the components of this circuitry. Oncogene proteins succeed in activating these signal circuits even in the absence of stimulation by extracellular growth factors. In doing so, they force a cell to grow even when its surroundings do not contain some of the clues that are normally required to provoke growth.

Other researchers suggest that mutations in at least two proto-oncogenes have to be present and that only certain combinations of mutations lead to malignant change. These findings suggest that individual oncogenes, although powerful controllers of cell metabolism, are not capable of causing malignant neoplasms by themselves. Thus, oncogenes cannot explain most cancers by themselves. This view was strengthened by the discovery of more than a dozen different oncogenes in human tumors (Table 19.2). However, on careful evaluation, only about 20% of tumors turned out to carry expected alterations. None of the tumors had pairs of cooperative alterations sometimes found in cultured cells. It also appeared that the inherited mutations responsible for predisposing people to cancer were not oncogenes. The concept of a recessive-type antioncogene was conceived. This type of gene is called a tumor suppressor gene. This class of gene appears to be equally important in the development of cancer.

TABLE 19.2 Functional Classification of Selected Oncogenes and Associated Human Tumors

Oncogene	Associated Tumors
hst	Gastric cancer

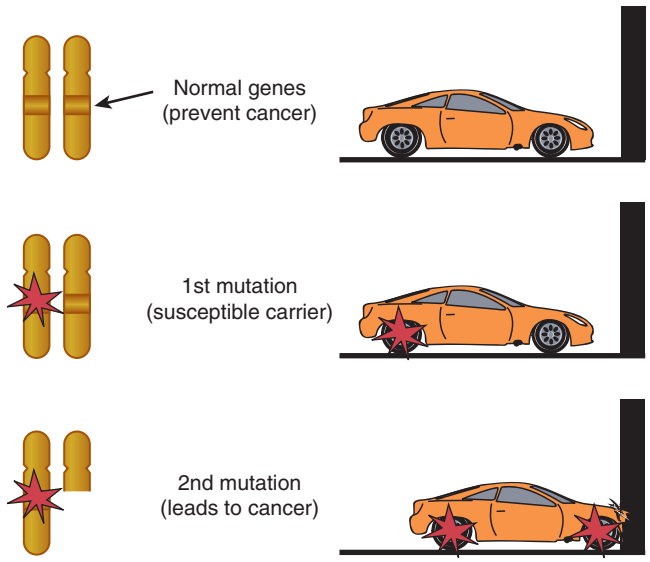

FIGURE 19.20 Schematic of tumor suppressor gene function.

Tumor Suppressor Genes

The direct identification of tumor suppressor genes has been more difficult than the identification of oncogenes. Tumor suppressor genes were first conceived of in a theoretical sense long before any were actually identified. Harris was the first to demonstrate that the malignant characteristics of a cell could be suppressed when malignant cells were fused with nonmalignant cells. Furthermore, loss of portions of chromosomes can be associated with malignant transformation, and transfer of a normal chromosome can reverse these traits into the malignant cells. These data suggested a recessive type of control in normal cells. A schematic of a tumor suppressor gene can be seen in Fig. 19.20.

The first tumor suppressor gene cloned was the *RB* gene; it is the defective gene in retinoblastoma. Knudson extensively studied the epidemiology of retinoblastoma. Most cases of retinoblastoma are sporadic, but some cases appear to be clustered around families. He noted that cases of familial retinoblastoma were more likely to be bilateral or multifocal. On the basis of

these data, he developed the two-hit hypothesis that bears his name (see Fig. 19.16). That is to say that two mutagenic events are required for retinoblastoma to develop. In patients with inherited disease, the first hit was inherited in one allele of the *RB* gene in the germline. Although one abnormality was not enough for development of the disease, there was an increased likelihood that the second allele would be damaged during eye development. The hypothesis of two mutational events developed by Knudson applies specifically to tumor suppressor genes. This is the basis of most inherited gene models.

Tumor suppressor genes have proved difficult to identify, and many techniques have been used to locate such genes within the human genome. Cytogenetic studies provide some clues to the location of tumor suppressor genes. A significant percentage of patients with retinoblastoma or some patients with Wilms tumor have large deletions in 13q14 or 11p13, respectively. These are the regions of the respective tumor suppressor genes responsible for each malignant neoplasm. Significant loss on 5q is associated with adenomatous polyps of the colon. This can be measured on a gel during electrophoresis and is called loss of heterozygosity. Although recurrent loss of a chromosome region associated with a specific malignant neoplasm is highly suggestive that this region is important in the development of the cancer, it is not sufficient to prove that there is a tumor suppressor gene in this region. Fig. 19.16 shows the possible combinations of loss that would lead to the expression of a tumor suppressor gene. Use of genome-wide linkage scans can further localize the presence of such a gene. Much smaller areas of deletion can be detected by molecular techniques such as pulsed-field electrophoresis. Now we can also easily and cheaply sequence long segments of the genome as these technologies improve.

When scientists were first trying to identify the regions of loss, they used DNA probes for specific regions of chromosomes. If allelic loss is noted, this is called loss of heterozygosity; if this loss is disproportionate relative to the general population, this suggests a tumor suppressor gene in the region specific for the probe. An example of loss of heterozygosity can be seen in Fig. 19.16. Here, a region on 10q in endometrial cancers indicates the existence of a possible tumor suppressor gene. By use of various markers, a precise location of the tumor suppressor gene can be identified. A contig of the region must then be built and the region sequenced to look for specific genes. Many regions of loss have been identified by this technique. There are many more candidate regions than actual tumor suppressor genes.

The tumor suppressor gene Tp53 is a gene associated with many cancers that was identified by searching for loss of heterozygosity. Several other tumor suppressor genes have been identified since. This is almost certainly only the tip of the iceberg, and many more tumor suppressor genes are likely to be discovered as investigators learn more about cancer cell genetics and as the potential of the Human Genome Project is realized and new genetic testing technologies continue to bring genetic testing to the forefront of medicine. Several generalizations can be made, and a comparison with the activation of oncogenes is constructive. Mutations in oncogenes are gain of function events and lead to increased cell proliferation and decreased cell differentiation. Oncogene mutations do not appear to be inherited through the germline. In contrast, tumor suppressor gene inactivations are loss of function events, usually requiring a mutational event in one allele followed by a loss or inactivation of the other allele. This loss of gene function leads to loss of cellular control and unchecked growth. Tumor suppressor genes are recessive, and mutations may be inherited as a germline mutation. Somatic mutations may occur in both types of genes and accumulate throughout life. Comparison of oncogenes and tumor suppressor genes is made in Table 19.3. Common tumor suppressor genes are listed in Table 19.4.

TABLE 19.3 Comparison of Oncogenes and Tumor Suppressor Genes

Characteristic	Oncogene	Tumor Suppressor Gene
Number of mutational events in cancer	One	Two
Role of mutation	Gain of function ("dominant")	Loss of function ("recessive")
Germline inheritance	No	Yes
Somatic mutations	Yes	Yes
Genetic alterations	Point mutations, amplifications, gene rearrangements	Point mutations, deletions
Effect on growth control	Activates cell proliferation	Negatively regulates growth-promoting genes
Result of gene transfection	Transforms cells to a partly malignant behavior	Suppresses malignant phenotype

Apoptosis

***Apoptosis* means programmed cell death and refers to the "intentional" induction of cell death. Apoptosis is important in the growth and development of an organism because as an organism matures and differentiates, cells must die to give way to more differentiated and specialized cells.** If a cell does not die and becomes immortal, a tumor or cancer can result. Apoptosis was first described in the 1970s, but only recently have scientists begun to realize the importance of this phenomenon in organism development, differentiation, and cancer formation. Excitement about this process has been driven by the finding that apoptosis is controlled at the molecular level by genes associated with malignant change (ie, oncogenes, proto-oncogenes, and tumor suppressor genes). It is also clear that many of these same controlling elements and pathways are active during development. Many believe that understanding the control of the apoptotic process is essential to understanding the control of the developing organism and control of senescence. Loss of these aspects of cellular control could lead to cancer.

Apoptosis is a distinct mode of cell death that is responsible for the deletion of cells in normal tissues; of note, it also occurs in pathologic conditions. The process of apoptosis is

TABLE 19.4 Tumor Suppressor Genes

Gene	Gene Product	Tumor Associations
RB1 (13q)*	110-kDa nuclear hypophosphorylated protein, negative cell cycle regulator	Retinoblastoma Osteosarcoma Small cell lung cancer Soft tissue sarcoma Breast cancer Bladder cancer
p53 (17p)	53-kDa sequence-specific DNA-binding protein and transcriptional activator	Li-Fraumeni syndrome Most common alteration in human cancer
DCC (18q)	1447–amino acid transmembrane protein with homology to known adhesion molecules; role in terminal cell differentiation	Colorectal cancer
APC (5q21)	2843–amino acid protein that interacts with membrane-associated cadherin-catenin complexes and with microtubules	Familial adenomatous polyposis Gardner syndrome
MTSI (9q21)	148–amino acid protein inhibitor of cyclin-dependent kinase-4	Familial melanoma Bladder cancer
BRCA1 (17q)	1863–amino acid protein with zinc finger–like domains suggesting function as a transcriptional factor	Breast cancer Ovarian cancer
BRCA2 (13q)	Possibly BRUSH I	Familial breast cancer
VHL (3p)	Protein with short homology to a glycan-anchored membrane protein of *Trypanosoma brucei*; no function assigned	Pheochromocytoma Renal cell cancer Pancreatic cancer Hemangioblastomas of CNS and retina
WT1 (11q)	50-kDa gene, related to the early growth response gene; encodes four 46- to 49-kDa proteins, which appear to function as DNA-binding transcriptional repressors	Wilms tumor
NF1 (17q11.2)	Neurofibromin (~2500 amino acids); probably negative regulator for p21 ras	von Recklinghausen neurofibromatosis
NF2 (22q12)	Schwannomin (~600 amino acids), regulator of cellular response to external environment	Neurofibromatosis type 2

characterized histologically by cell contraction, blebbing of the cell membrane, and condensation of the nucleus. Apoptotic bodies are formed that contain intact organelles; surrounding cells eventually phagocytose these. There is no associated inflammatory response. Cell swelling and disintegration of the cell components characterize necrotic cell death, and there is a marked inflammatory response. On a molecular level, apoptotic death causes cellular enzymes to autodigest the genome into little fragments, and this can be identified on polyacrylamide gels by multiple regular fragments seen as a DNA ladder.

Apoptosis is important in the development of the normal organism, and it is important in the development and growth of cancers. It occurs spontaneously in malignant tumors, often markedly retarding their growth, and it is increased in tumors responding to radiation, chemotherapy, heat, and hormone damage. In cancer, apoptosis appears to be a mechanism for deleting cells from the population that have sustained carcinogenic DNA damage; however, when apoptosis of such cells is blocked or inhibited by mutations in genes that help control this process, such as *BCL2* or *Tp53,* these cells are suddenly free to continue replicating and propagating their mutations. This genetic instability may be an early step in the development of cancers. Many of the current cancer treatments, such as radiotherapy and chemotherapy, kill cells by the production of DNA damage. Mutations in BCL2 and Tp53 may then influence the effectiveness of these therapies through their ability to inhibit cell death.

The primary importance of apoptosis related to cancer and cancer treatment lies in its being a regulated phenomenon subject to stimulation and inhibition. Although little is known about how to establish therapeutic agents to affect its initiation, it seems reasonable to suggest that greater understanding of the process of apoptosis might lead to the development of improved treatment possibilities. Inhibitory mechanisms such as *BCL2* proto-oncogene expression may be implicated in the development of resistance to therapeutic agents and may contribute to tumor growth and perhaps to oncogenesis by allowing the inappropriate survival of cells with DNA abnormalities. It is likely that other inhibitory mechanisms will be identified, and a better understanding of the apoptotic process may lead to novel treatment regimens by allowing us to control cell death. Apoptosis is not simply a description of cell death, nor is it a spurious trend in the biology literature. It is a fundamental process and is controlled at the molecular level; as such, it can be understood and manipulated. Fig. 19.21 demonstrates how apoptosis may occur.

Mismatch Repair Defects

A number of mechanisms are involved in the correction of DNA changes that result from exogenous or endogenous mutagenic agents. These mechanisms include base excision repair, nucleotide excision repair, and DNA mismatch repair. The MMR system repairs mistakes that are made in the course of normal cellular division. These mutations often occur in regions of multiple repeats because these regions appear to be particularly prone to DNA slippage. One can intuitively see how this can happen by looking at Fig. 19.22. Six genes must work in concert to repair DNA damage. These genes and an example of how we think they work can be seen in Fig. 19.23.

A paradox of human tumor genesis is that the rates of mutation in normal cells are too low to account for the transformation of benign to malignant. The instability of some colon cancers was the first strong evidence for the so-called mutator phenotype. If a cell cannot repair DNA damage that occurs during the course of normal cell division, mutations can

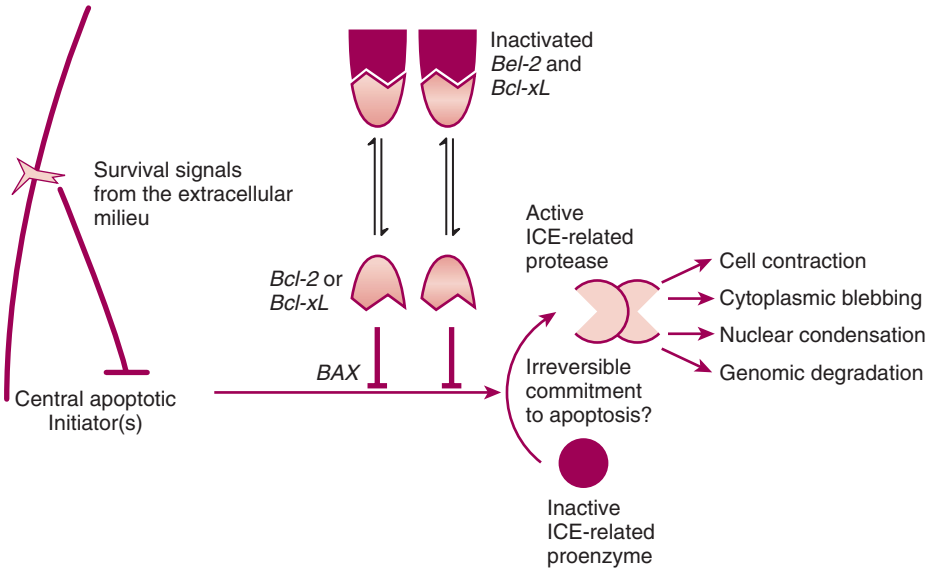

FIGURE 19.21 Possible pathways and possible factors controlling apoptosis. A signal from outside the cell initiates a cascade of events involving *BCL2, BCL-xL,* and *BAX.* This results in the programmed death of the cell. This pathway can be blocked at a number of points, resulting in cell immortality. *ICE,* Interleukin-1βA signal fleukin-1id. (From Rudin CM, Thompson CB. Apoptosis and disease: regulation and clinical relevance of programmed cell death. *Annu Rev Med* 1997;48:267.)

FIGURE 19.22 Mismatch repair occurs by slippage of CA within a CA repeat. This results in the deletion of a CA. This is the exact kind of deletion that the mismatch repair (MMR) system is designed to correct. If the MMR system is not working properly, errors cannot be corrected, and mutations accumulate.

continue to accumulate; eventually, enough mutations occur in genes critical for cell control, and cancer results. Many studies have shown that tumors, which have microsatellite instability (MSI), have defects in mismatch repair. Key metabolic genes usually do not have large areas of microsatellite repeats that are particularly prone to mismatch problems. The mutation rate in nonrepetitive sequences is also elevated 100 to 10,000 times above that in normal cells with normal mismatch repair. Although microsatellite sequences are largely absent from functional genes, mononuclear repeats in some key genes can lead to their inactivation. Examples of such genes include *TGF-BR2H* (A_{10}), *hMSH3* (A_8), *hMSH6/GTBP* (C_8), *IGF2R* (G_8), and *BAX* (G_8). Paradoxically, instability of chromosome numbers is often observed in tumors without MMR defects; tumors with MMR defects often have stability of chromosome number.

Mismatch repair proteins interact to form complexes that recognize mismatched DNA base pairs and abnormal loops of DNA. The repair complexes initiated by MMR genes trigger excision and repair of DNA mutations. This system is critically important in ensuring the fidelity of the replicative process and is highly conserved throughout all living organisms. Areas in the genome that contain simple repetitive DNA base sequences called microsatellites (eg, CACACACA or AAAAAAA) are especially prone to mutation. If the MMR system does not function normally, these errors will go unrecognized and continue to accumulate. Cells in which both copies of one of the MMR genes have been inactivated exhibit the so-called mutator phenotype; this allows cells to accumulate mutations as they divide. These random mutations eventually accumulate in a series of genes that are important in controlling cellular growth; the result is loss of growth control and transformation to cancer.

Cells with a defective MMR system exhibit a phenomenon called MSI. This phenomenon occurs as DNA mismatches cause shortening or lengthening of repetitive DNA sequences and these mismatches go unchecked. This results in generation of alleles in the cancer that contain a greater or lesser number of repeats than are present in normal cells from that individual. Laboratory testing for MSI uses an established consensus panel of five microsatellite markers (D2S123, D5S346, D17S250, Bat 25, and Bat 26). Fig. 19.24 shows an example of MSI detection when mismatch prone regions are compared in blood and tumor.

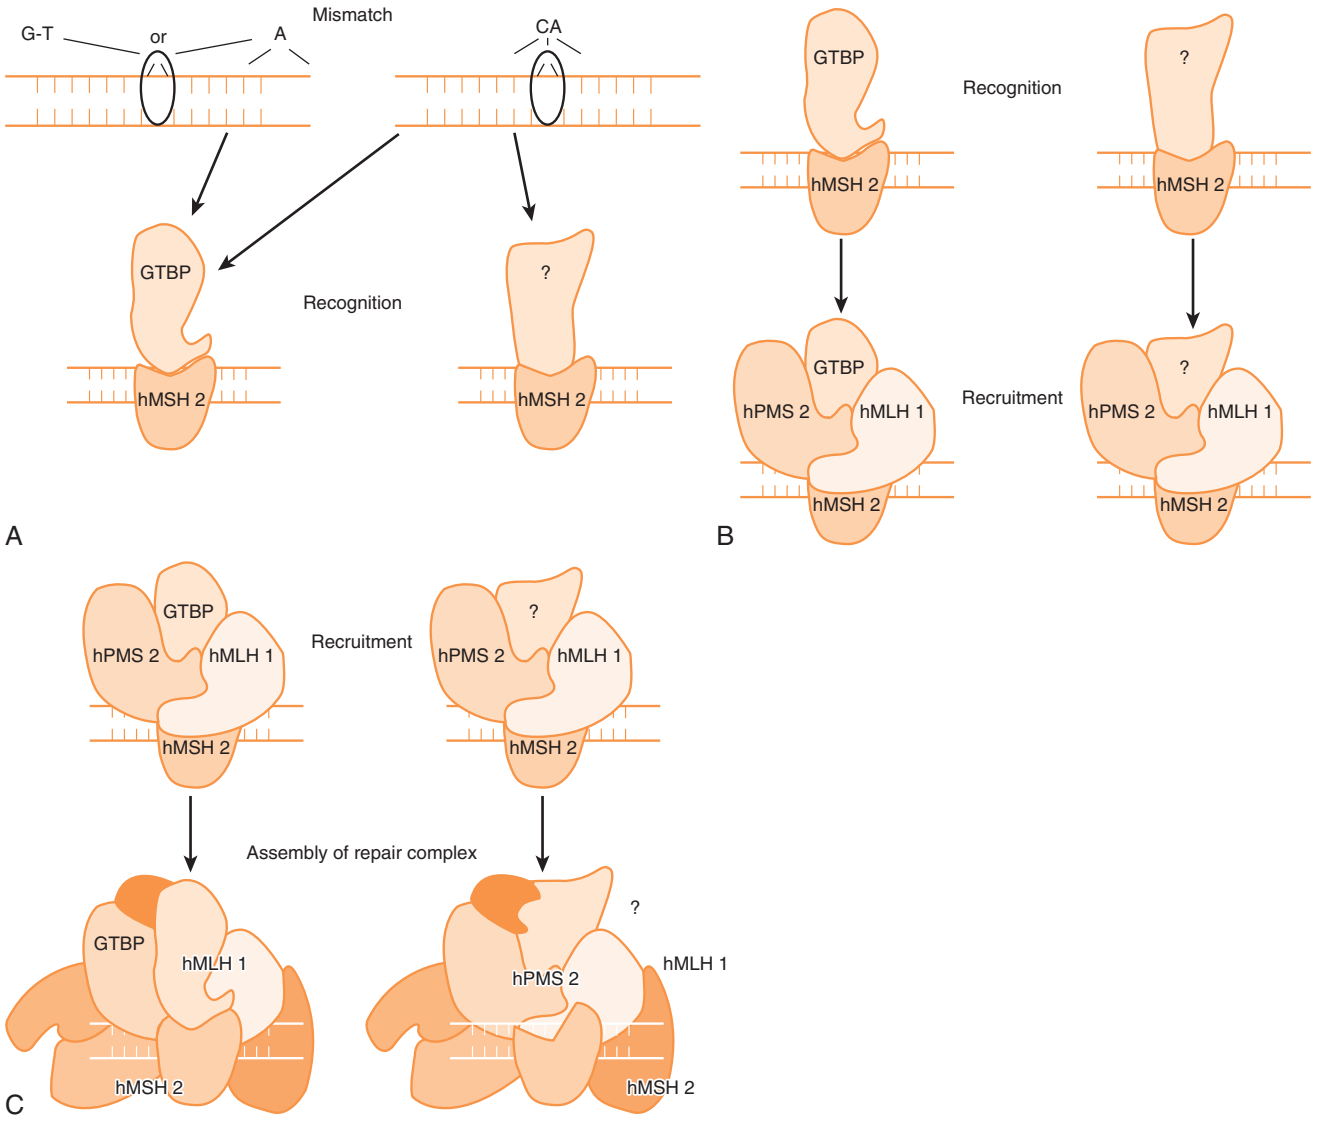

FIGURE 19.23 Demonstration of how mismatch repair is accomplished by the six proteins required for correction. There must be the following: recognition of slippage (A); recruitment of repair complex (B); and, finally, repair (C). (From Karran P. Microsatellite instability and DNA mismatch repair in human cancer. *Semin Cancer Biol* 1996;7:15.)

Germline mutations in MMR genes (MLH1, MSH2, MSH6, PMS2) are present in many families and is known as Lynch syndrome. This syndrome is associated with increased risk for colon cancer, endometrial cancer, ovarian cancer, stomach cancer, small bowel, stomach, renal pelvis, biliary tract, and brain cancer. Mutations in one of the Lynch syndrome genes accounts for about 5% of all colon cancers and approximately 2% of all newly diagnosed endometrial cancers.

The Amsterdam II criteria, used to identify Lynch syndrome based on the pattern of cancer in a family is defined as follows:

1. Three or more relatives with Lynch syndrome–associated cancer; one must be a first-degree relative to the other two.
2. At least two successive generations must be involved.
3. At least one of the cancers must have been diagnosed before the age of 50 years.

Seventy percent of patients with that meet Amsterdam II criteria have a germline mutation segregated around an MMR gene: *hMLH1* (49%), *hMLH2* (45%), and *hPMS2* (6%). Approximately 25% of endometrial cancers have an MMR defect; approximately one-fourth of these are germline mutations, and the rest are largely the result of somatic *MLH1* inactivation resulting from hypermethylation of the promoter region. MMR will be increasingly investigated and more clearly defined during the next decade.

Telomerase

Normal cells divide; this process is repeated many times as an organism grows and matures. Normal cells stop dividing and terminally differentiate, but cancer cells continue to divide. Cells from younger animals divide more times than do cells

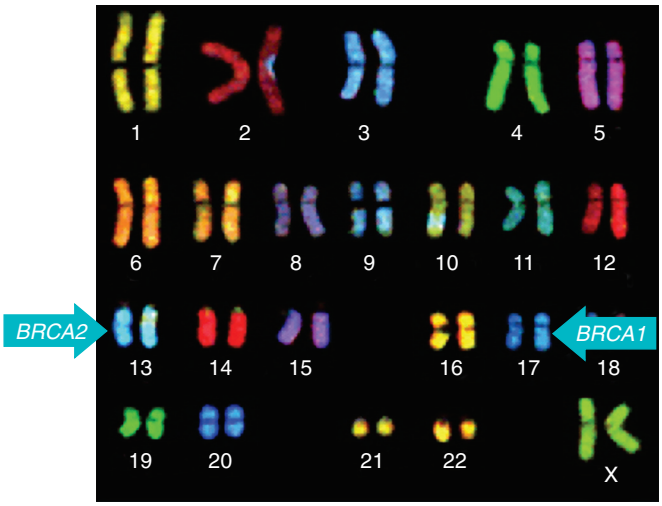

FIGURE 19.24 Karyotype of the human genome showing location of the *BRCA1* and *BRCA2* genes.

from older animals. One difference between normal cells and tumor cells is at the end of their chromosomes. Telomeres, specialized structures at the ends of chromosomes, act as protective caps. In humans, telomeres are made up of 5000 to 15,000 base pairs of TTAGGG repeats. These terminal structures protect the chromosome ends from exonuclease digestion, prevent aberrant chromosome recombination, and form specific complexes that bind proteins.

Normal cells lose about 50 to 100 base pairs from the end of each chromosome every time the cell divides. When a telomere loses a critical number of base pairs, it triggers a signal for the cell to stop dividing and for senescence. Cells have developed several mechanisms to get around this terminal trigger. Some of these are uncommon, such as complex recombination and retrotransport techniques. The most common mechanism is the development of an enzyme complex called telomerase, which adds back telomere sequences lost during replication. Cells that have significant telomerase activity are often immortal cells such as cancer cells and germ cells.

Normal cells lack telomerase activity. Telomerase becomes reactivated in most cancer cells. It is the most prevalent cancer marker known. Therefore, telomerase may be used as a generic cancer marker and as a possible treatment.

HEREDITARY CANCER RISK ASSESSMENT: GENETIC COUNSELING AND GENETIC TESTING

Clinically Relevant Hereditary Syndromes

The advent of linkage analysis and the rapidity of DNA sequencing with other molecular technologies have made it possible to identify many inherited disorders that we could not identify a few short decades ago. Gynecologic malignancies associated with autosomal dominant inherited cancer predisposition that have been identified thus far are as follows:

Disease	Genetic Abnormality
Hereditary breast–ovarian	*BRCA-FA* pathway genes, including *BRCA1, BRCA2, RAD51C, RAD51D, PALB2, BARD1,* and *BRIP1*
Lynch syndrome	*MLH1, MSH2, MSH6, PMS2, EPCAM*
Cowden syndrome	*PTEN*
Li-Fraumeni syndrome	*TP53*
Ovarian cancer: small cell hypercalcemic	*SMARCA4*
PPB	*DICER1*

Ovarian cancer
- Epithelial
  - Hereditary breast and ovarian cancer (HBOC): all epithelial histologies; rarely mucinous; most commonly high-grade serous
  - Lynch syndrome: all epithelial histologies typically endometrioid
- Epithelial: borderline tumors
  - Rarely associated with hereditary cancer syndromes
- Germ cell
  - Not believed to be a part of HBOC
- Sex cord–stomal tumors
  - Granulosa cell tumors
    - Peutz-Jeghers syndrome (PJS)
  - Sex cord tumors with annular tubules
    - PJS
- Sertoli-Leydig and juvenile granulosa cell tumors
  - Pleuropulmonary blastoma (PPB) syndrome

Fallopian tube or primary peritoneal cancer
- HBOC
- Lynch syndrome

Uterine cancer
- Epithelial (majority of uterine cancers)
  - Lynch syndrome (typically endometrioid, less commonly clear cell; rarely uterine papillary serous (UPSC): not typically thought to be associated with HBOC (reports of UPSC associated with HBOC)
  - Mesenchymal (endometrial stromal sarcoma, leiomyosarcoma, other nonspecific sarcomas) (rare)
  - Rarely associated with hereditary cancer syndromes
  - Uterine soft tissue sarcoma
  - Li-Fraumeni syndrome
- Mixed: Malignant mixed Mullerian tumor (MMMT) or carcinosarcoma, adenosarcoma
  - Rarely associated with hereditary cancer syndromes; seen in some cases of Lynch syndrome

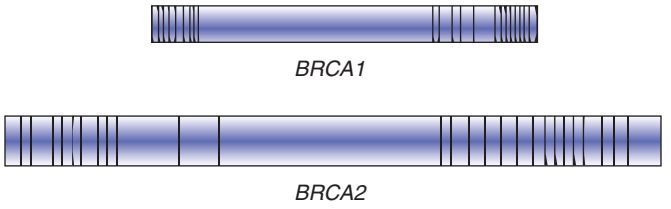
Cervix
- Rarely associated with hereditary cancer syndromes
- Cervix adenoma malignum associated with PJS

Vaginal or vulvar cancer
- No known association with hereditary cancer syndromes

Gestational trophoblastic disease
- No known association with hereditary cancer syndromes

Hereditary cancer syndromes that include increased risk for developing gynecologic cancers.

Commercial clinical genetic testing is available for hereditary cancer risk and has undergone rapid changes in the last several years. Massively parallel sequencing, also called next-generation sequencing (NGS), technology allows for rapid testing of large amounts of DNA sequence. NGS is quicker and less expensive than previous genetic testing tools. It is becoming routine to order a single test that simultaneously evaluates multiple genes thus testing for multiple hereditary cancer syndromes at once. The Supreme Court Decision in June 2013, overturning the ruling on allowing gene patents, particularly *BRCA1* and *BRCA2*, brought an immediate change in the availability of multigene panel testing through multiple different commercial laboratories.



Our understanding of the tumor spectrum associated with the different hereditary cancer predisposition genes, the risks for cancer, and targeted therapy options is growing exponentially. An increasing number of individuals are seeking the advice of physicians and genetic counselors regarding options for genetic testing hereditary risk for cancer. It is important to have an understanding of hereditary cancer syndromes associated with an increased risk for developing gynecologic cancers.

Hereditary Breast and Ovarian Cancer (*BRCA1* and *BRCA2*; Other DNA Repair Pathway Genes)

Hereditary breast and ovarian cancer syndrome is the best known and most well characterized of the hereditary cancer syndromes. *BRCA1* and *BRCA2* and were identified in the early 1990s (1994 for *BRCA1* and 1995 for *BRCA2*). Genetic testing for the predisposition to breast and ovarian cancer by testing for mutations in the *BRCA1* or *BRCA2* genes became clinically available in 1996. The *BRCA1* and *BRCA2* genes are located on chromosomes 17q and 13q, respectively (Figs. 19.25 and 19.26). Both of these genes are quite large, containing at least 20 exons (coding regions) and are of at least 7000 base pairs (see Fig. 19.26). Genetic testing for *BRCA1* and *BRCA2* has changed significantly since 1996; the initial testing in 1996 only included sequencing for *BRCA1* and *BRCA2*. This testing was later updated to include five specific *BRCA1* rearrangements; deletions or duplications not detected through gene sequencing. In 2006, the addition of deletion and duplication (also called large rearrangement testing) for both *BRCA1* and *BRCA2* was automatically run for individuals from high-risk families who met certain family history criteria or as an optional add-on for additional cost. Current testing includes sequencing and deletion and duplication analysis automatically for both genes in every test, regardless of personal or family history. Individuals who had genetic testing for *BRCA1* and *BRCA2* previously may benefit from updated genetic testing, especially if no mutations were identified.

Founder mutations are mutations that are common or even unique to a specific patient population and occur in populations of patients that have been genetically isolated for many generations. The population may have shrunk as a result of a disaster, but the mutation was preserved in a few individuals. When the population reexpands, the frequency of that specific mutation can be quite high within a population (Fig. 19.27). One example of founder mutations occurs in *BRCA1* and *BRCA2*. (Fig. 19.28). Approximately 2% of individuals of Ashkenazi (Eastern European) Jewish ancestry have one of three founder BRCA mutation: 187delAG (*BRCA1*), 5385insC (*BRCA1*), and 6174delT (*BRCA2*). Historically, targeted testing for the specific found mutations was initiated first with reflex testing to full *BRCA1* and *BRCA2* gene testing if none of the three mutations were identified. The adoption of NGS tools for genetic testing is changing this process and the specific testing founder mutation testing is skipped and in favor of proceeding directly to multigene testing. These founder mutations are identified with the NGS technology.

Cancer risks for individuals with *BRCA1* or *BRCA2* mutation are presented as lifetime risk ranges. These are typically

BRCA1
- Tumor suppressor gene on chromosome 17
- Coding region: 5589 nucleotides
- Span 81-kb genomic DNA
- ~1200 different mutations reported

BRCA2
- Tumor suppressor gene on chromosome 13
- Coding region: 10,254 nucleotides
- Span 84-kb genomic DNA
- ~1380 different mutations reported

FIGURE 19.25 Representation of the *BRCA1* and *BRCA2* genes with characteristics of each.

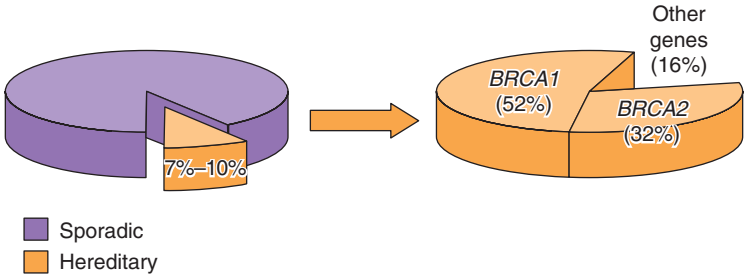


FIGURE 19.26 Hereditary breast and ovarian cancer. Representation of the percent contribution of inherited disease and the percent contribution by each of the known genes predisposing patients to cancer. (Modified from Ford D, Easton DF, Stratton M, et al. Genetic heterogeneity and penetrance analysis of the BRCA1 and BRCA2 genes in breast cancer families. The Breast Cancer Linkage Consortium. *Am J Hum Genet* 1998;62:676.)

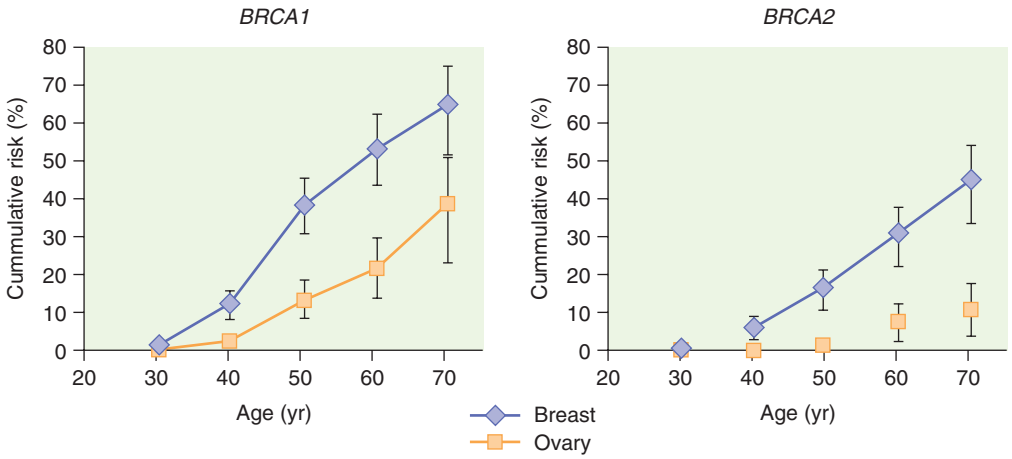

FIGURE 19.27 Cumulative incidence of cancer over time in individuals with *BRCA* mutations. Summary analysis of 22 studies. (Modified from Antoniou A, Pharoah PD, Narod S, et al. Average risks of breast and ovarian cancer associated with BRCA1 or BRCA2 mutations detected in case Series unselected for family history: a combined analysis of 22 studies. *Am J Hum Genet* 2003;72:1117.)

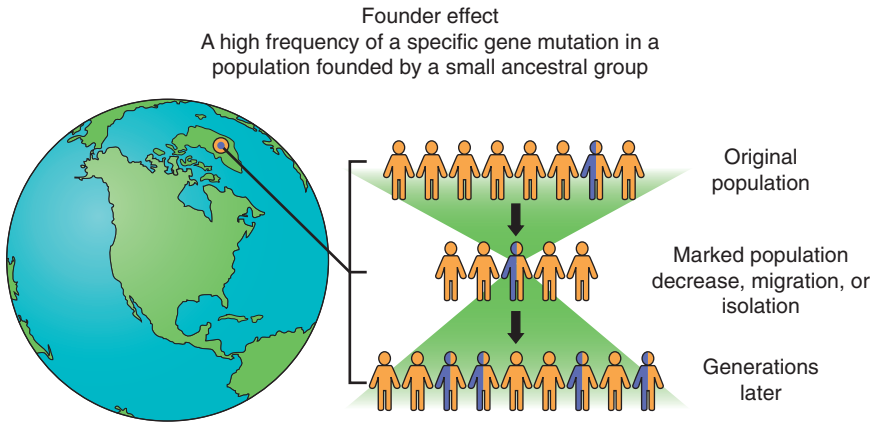

FIGURE 19.28 Representation of founder mutations and how the prevalence can increase in a population over time. *With permission from SGO.*

broad risk ranges because the actual reported risk varies depending on the population studied in any given report. Reports of lifetime risk for ovarian cancer ranges from 8% to 62%. The age of onset for ovarian cancer is not necessarily an indication of hereditary risk. Reported lifetime risk for breast cancer range from 41% to 90%. There is limited data to provide individualized risks or mutation specific risks. Unlike ovarian cancer, early age of onset for breast cancer is a hallmark of hereditary risk, but later ages of onset for breast cancer should not be discounted. This should be considered in the context of the cancer family history when determining concern for inherited risk. Additionally, triple-negative breast cancer seems to have a greater association with *BRCA1* mutations.

Additional genes in the DNA repair BRCA-FA (Fanconi anemia) pathway were reported to confer increased risk for breast and ovarian cancer beginning around 2010. Genes in the DNA repair *BRCA-FA* (Fanconi anemia) pathway include *BRCA1, BRCA2, CHEK2, BRIP1, RAD50, RAD51C, RAD51D, PALB2, BARD1, MRE11,* and *NBN*. Current information suggests a moderately increased risk for cancer for individuals with mutations in these genes as compared with the higher risks reported with mutations in *BRCA1* or *BRCA2*. Some of these genes within the *BRCA-FA* DNA repair pathway may turn out to be associated with a more significant risk for developing cancer than others, and clinical availability of testing this genes will also change over time.

A 2011 study of 360 women with primary ovarian, peritoneal, or fallopian tube carcinoma not selected for age or family history found 24% carried pathogenic mutations in 12 different genes, including *BRCA1, BRCA2 BARD1, BRIP1, CHEK2, MRE11A,MSH6, NBN, PALB2, RAD50, RAD51C,* and *TP53*. The majority were attributed to mutation in *BRCA1* or *BRCA2*. The remaining portion of inherited risk is due to mutations in one of the Lynch syndrome genes or one of the newly identified *BRCA-FA* DNA repair pathway genes. The overall contribution of each gene to the risk of ovarian cancer can be seen in Fig. 19.29. A 2015 study of 1915 women with primary ovarian, peritoneal, or fallopian tube carcinoma not selected for age

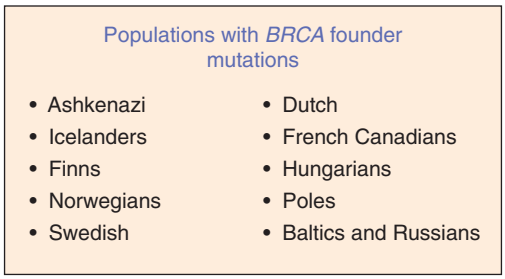

FIGURE 19.29 Populations that have known founder mutations.

or family history found 18% carried a pathogenic germline mutation and suggests that 11 genes comprise the majority of hereditary risk for ovarian cancer: *BRCA1, BRCA2, BRIP1, RAD51C, RAD51D, PALB2, BARD1, MLH1, MSH2, MSH6,* and *PMS2*. Mutations in these genes are rare and in some studies not significantly more frequent in ovarian cancer patients compared with control populations so the data continue to emerge to sort out the significance of these and other *BRCA/FA* pathway genes. National Comprehensive Cancer Network (NCCN) guidelines suggest the following genes to recommend or consider risk-reducing salpingo-oophorectomy (RRSO) if there is a mutation: *BRCA1 or BRCA2* and any of the Lynch syndrome genes, *BRIP1, RAD51C,* and *RAD51D*. Research continues, and data are quickly evolving regarding the frequency of these mutations associated with specific cancer types, the cumulative risk for cancer, and the most appropriate medical management recommendations for cancer detection or prevention for women with hereditary mutations in these genes.

Cumulative risk is the concept of total risk over time. For individuals with a mutation in a gene involved in a DNA repair pathway, mistakes cannot be adequately repaired that occur with normal DNA replication in cellular division as well as with environmental damage. Therefore, there is a greater risk for developing cancer over time compared with an individual at average risk and the development of cancer tends to occur at earlier ages. Cumulative risks of breast and ovarian cancer associated with mutations in *BRCA1* and *BRCA2* are shown in Fig. 19.30.

Pathologic characteristics of tumors have been studied as a method of determining which patients should be referred for hereditary cancer risk assessment. For example, there is a preponderance of triple-negative (ER-/PR-/her2-) breast cancers associated with *BRCA1*. High-grade serous ovarian cancer is most commonly associated with mutations in *BRCA1* or *BRCA2*. However, there are reports of mutations identified in individuals with most of the histologic subtypes. Mucinous ovarian cancers are rarely associated with mutations in *BRCA1* or *BRCA2*. Current recommendations by the Society of Gynecologic Oncologists and NCCN suggest referral of all patients with epithelial ovarian cancer for genetic counseling and genetic testing.

Identification of germline *BRCA* mutations, and possibly the other *BRCA-FA* DNA repair genes, is also becoming more important in treatment decisions. Patients with *BRCA1* or *BRCA2* mutation–associated cancers tend to have longer survival periods compared with patients with no identifiable germline mutations. These cancers have been found to be more susceptible to chemotherapeutic agents that cause DNA damage. The addition of a poly-ADP-ribose polymerase I (PARP) inhibitor exploits the breakdown of this DNA repair pathway, and these tumors may become even more sensitive to the traditional chemotherapeutic agents. PARP inhibitor Olaparib made by Astra Zeneca is now available for clinical use in patients with DNA repair defects.

Management Guidelines for Hereditary Breast and Ovarian Cancer (*BRCA1* and *BRCA2*)

Multiple organizations have published guidelines for genetic risk assessment and management guidelines for individuals with HBOC caused by *BRCA1* and *BRCA2* with small variances among the different groups. These organizations include the US Preventive Services Task Force (USPSTF), NCCN, American Society of Clinical Oncology (ASCO), European Society for Medical Oncology (ESMO), American College of Obstetricians and Gynecologists (ACOG), and Society of Gynecologic Oncologists (SGO). These guidelines are readily available. The NCCN guidelines are reviewed an updated at least annually. The current recommendations (version 1.2016) suggest clinical breast examination every 6 to 12 months and annual breast magnetic resonance imaging (MRI) beginning at age 25 years. Beginning at age 30 to 75 years, annual mammography and annual breast MRI are recommended, often at staggered 6-month intervals. Women with a *BRCA* mutation and a personal history of breast cancer should continue with annual mammography and breast MRI. A discussion of the option of risk-reducing mastectomy is also recommended. Data do not support routine ovarian cancer screening. RRSO is recommended between the ages of 35 and 40 years or when childbearing is complete. The option of delaying RRSO until age 40 to 45 years in women with *BRCA2* mutations may be considered because there appears to be a later average age of onset of approximately 8 to 10 years compared with *BRCA1* mutation carriers. It is important to review a multigeneration family history and take note of the ages of onset of ovarian cancer in the family and adjust this recommendation if there are women with early onset disease. NCCN guidelines also review cancer risks and recommendations for men relative to prostate cancer and mention no specific screening guidelines for pancreatic cancer or melanoma.

Women with *BRCA2* mutations of reproductive age should be made aware of options for prenatal diagnosis and preimplantation genetic diagnosis. Cancer family history should be obtained for their partners and consider genetic testing for *BRCA2*, especially if there is Ashkenazi Jewish ancestry or family history of breast and ovarian cancer. If both parents carry a *BRCA2* mutation, there is risk for a rare autosomal recessive disorder called Fanconi anemia.

As survival improves for patients with ovarian cancer, identification of a mutation can guide cancer screening or prevention recommendations to hopefully keep patients from developing another primary cancer or at least detect the cancer early.

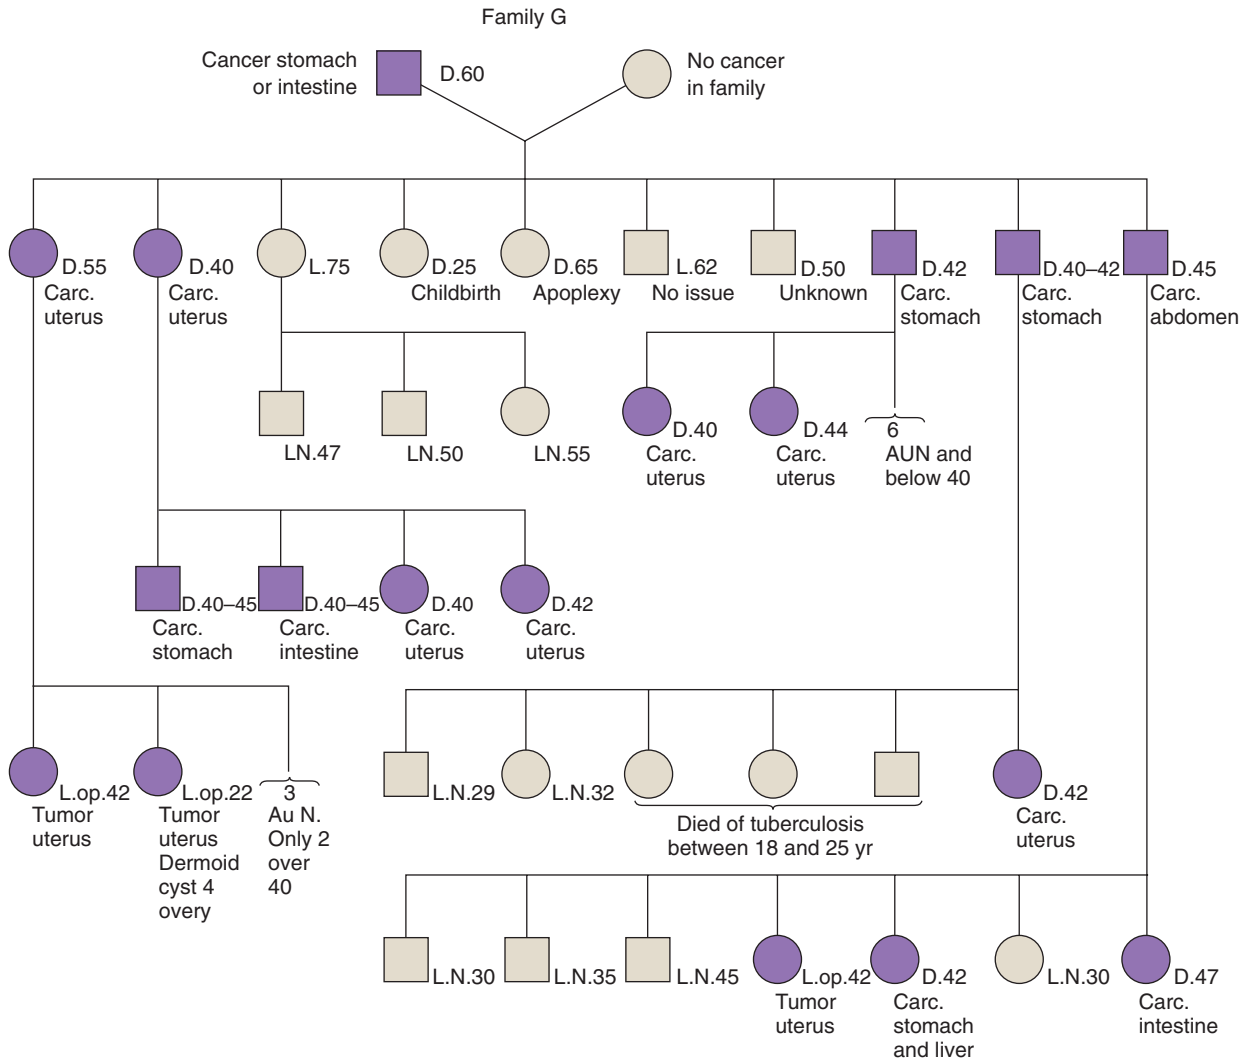

FIGURE 19.30 Pedigree of Warthin's family G. Note the high incidence of stomach cancer. This transitioned to colon cancer through the 1900s.

Lynch Syndrome (Hereditary Nonpolyposis Colon Cancer)

In 1895, a pathologist at the University of Michigan, Aldred Scott Warthin, had a seamstress who had a family with a preponderance of gastric and endometrial cancers. This family became known as family G and is part of the basis for the discovery of Lynch syndrome or HNPCC. Warthin described this family in a report in the *Archives of Internal Medicine* in 1913 (Fig. 19.31). The family pedigree was updated in 1925 but was largely forgotten until Henry Lynch and colleagues discovered two other families with similar pedigrees in Iowa and Nebraska, which they reported in the 1970s. This was proposed as the "cancer family syndrome" (CFS) in 1971, later changed to HNPCC. The current terminology refers to this syndrome as Lynch syndrome, believing that HNPCC fails to adequately acknowledge the importance of extracolonic malignancies such as endometrial, ovarian, upper gastrointestinal (GI) tract, and urinary tract cancers.

Lynch syndrome is inherited in an autosomal dominant pattern and results from a mutation in one of the DNA MMR genes, *MLH1, MSH2, EPCAM, MSH6,* or *PMS2*. These genes code for proteins that proofread DNA and correct mistakes that are made during the normal process of replication. MMR is covered in detail earlier in this chapter.

Mutations in *MSH2* and *MLH1* account for the majority of cases of Lynch syndrome. Mutations in *MSH6, EPCAM,* and *PMS2* account for a smaller percentage. *EPCAM* and *MSH2* are located on 2p21, *MSH6* on chromosome 2p16, *MLH1* on chromosome 3p22, and *PMS2* on chromosome 7p22 (Fig. 19.32). Large germline deletions of the last exon of *EPCAM*, located upstream from *MSH2*, were reported in 2009 in 5 of 27 families suspected of having Lynch syndrome who previously

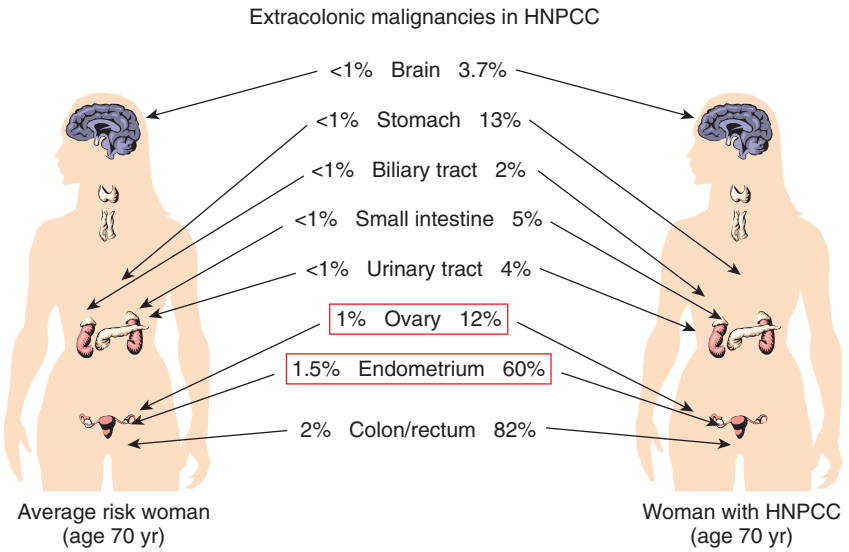

FIGURE 19.31 Various cancers associated with Lynch syndrome and their frequencies.

tested negative for *MLH1* or *MSH2*. Analysis of the 3′ region of *EPCAM* is now standard in genetic testing for Lynch syndrome.

Endometrial cancer is the most common gynecologic cancer in the United States and accounts for 6% of all gynecologic cancers in women. This accounts for around 50,000 cancers per year. Approximately 5% of endometrial cancers are caused by inherited risk, with the majority of this 5% caused by Lynch syndrome. A list of cancer types associated with Lynch syndrome and a comparison of the increased risk with to average risk are depicted in Fig. 19.33 and Table 19.5. The cumulative lifetime risk of endometrial cancer is between 40% and 60%, and the ovarian cancer risk is approximately 12%. The cumulative risk of colon cancer is 40% to 80%. There appears to be lower cumulative risks associated with *MSH6* and *PMS2* perhaps with later ages of onset. Up to 5% of all cases of endometrial cancer and colon cancer are caused by inherited mutations in one of the Lynch syndrome genes. The most common histologic subtype of endometrial cancer associated with Lynch syndrome is endometrioid; uterine papillary serous carcinoma is the least

TABLE 19.5 Risk of Lynch Syndrome

Condition	Risk (%)
Endometrial cancer at any age	1.8
Endometrial cancer diagnosed before 50 years of age	9
Endometrial and colon cancer at any age	18
Endometrial and colon cancer before 50 years of age	43
Endometrial and ovarian cancer	7

TABLE 19.6 Amsterdam Criteria: Three Two One Rule

- Three or more relatives with verified Lynch-associated cancer within the family
  - Colorectal, endometrial, small bowel, ureter, or renal pelvis
  - Any combination of histologies in three different generations
  - One case is a first-degree relative of the other two
- At least two successive generations affected
- One or more cases by 50 years of age
- Exclude familial adenomatous polyposis

TABLE 19.7 Criteria for Referral to a Genetic Counselor for Suspected Lynch Syndrome

- Bethesda guidelines
- Amsterdam Criteria fulfilled
- Persons with two relatives with Lynch syndrome
- Colorectal cancer and first-degree relative with a Lynch cancer before 45 years or a first-degree relative with an adenoma before 40 years of age
- Colorectal cancer or endometrial cancer before 45 years of age
- Right-sided, undifferentiated colon cancer before 45 years of age
- Signet ring colon cancer before 45 years of age
- Adenoma before 40 years of age

TABLE 19.8 Revised Bethesda Guidelines for Testing Colorectal Tumors for Microsatellite Instability

Tumors from individuals should be tested for MSI in the following situations:

1. Colorectal cancer diagnosed in a patient who is younger than 50 years of age
2. Presence of synchronous, metachronous colorectal, or other HNPCC-associated tumors* regardless of age
3. Colorectal cancer with the MSI-H histology diagnosed in a patient who is younger than 60 years of age
4. Colorectal cancer diagnosed in one or more first-degree relatives with an HNPCC-related tumor, with one of the cancers being diagnosed before age 50 years
5. Colorectal cancer diagnosed in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age

*Hereditary nonpolyposis colorectal cancer (HNPCC)–related tumors
MSI, Microsatellite instability.

likely subtype type to be associated with Lynch syndrome. Approximately 2% to 3% of cases of epithelial ovarian cancer are caused by inherited mutations in one of the Lynch syndrome genes. Lynch syndrome associated ovarian cancers tend to be nonserous types.

Family history criteria used to classify a family as having Lynch syndrome are the Amsterdam I and Amsterdam II criteria. Amsterdam I criteria only included colon cancer. Amsterdam II criteria shown in Table 19.6 include other Lynch syndrome–associated cancers. Colon cancers associated with Lynch syndrome have a propensity to occur in the ascending colon, relative to sporadic cases, which are more often distal. Individuals with Lynch syndrome tend to have shorter intervals in formation of adenomatous polyps and transformation to malignancy, as well as earlier ages of diagnosis.

Genetic Testing for Lynch Syndrome

Historically, the recommendation for genetic testing for Lynch syndrome was determined by cancer family history (Table 19.7). In families that fulfill the Amsterdam II criteria, the likelihood that a mutation will be found is quite high; the chance of identifying a mutation in one of the *MMR* genes is between 50% and 92%. The Bethesda criteria were developed to provide guidelines to order MSI for colon tumors (Table 19.8). There are no similar guidelines for endometrial cancer for guidance on when to order tumor genetic screening.

Recent collaborative efforts have focused on the adoption of universal tumor screening (UTS) for all newly diagnosed endometrial and colon cancers to include immunohistochemistry (IHC) and MSI. The Lynch Syndrome Screening Network (http://www.lynchscreening.net) was formed in 2011 to enable ongoing cooperative efforts toward UTS for all patients with newly diagnosed colon and endometrial tumors. Updated information regarding implementation of a universal screening program is available on their website. A 2014 consensus statement from US Multi-Society Task Force recommends that all newly diagnosed colorectal cancers should be tested for MMR deficiency either by IHC testing for *MLH1, MSH2, MSH6,* and *PMS2* and/or MSI testing. Colon tumors that have absent staining of *MLH1* or *MSI-high* should undergo *BRAF* testing of *MLH1* promoter hypermethylation to determine if the abnormal MMR screen is most likely attributable to somatic inactivation of *MLH1*. Similar guidelines have been proposed for all endometrial cancers. However, *BRAF* mutations are not commonly seen in endometrial cancers, so reflex testing should be for *MLH1* promoter hypermethylation if IHC shows absent staining for *MLH1*. Approximately 20T to 25% of all endometrial exhibit MSI as a result of epigenetic inactivation of *MLH1* caused by hypermethylation of the promoter.

NCCN guidelines version 2.2015 for Lynch syndrome provide a detailed grid of tumor testing results and additional

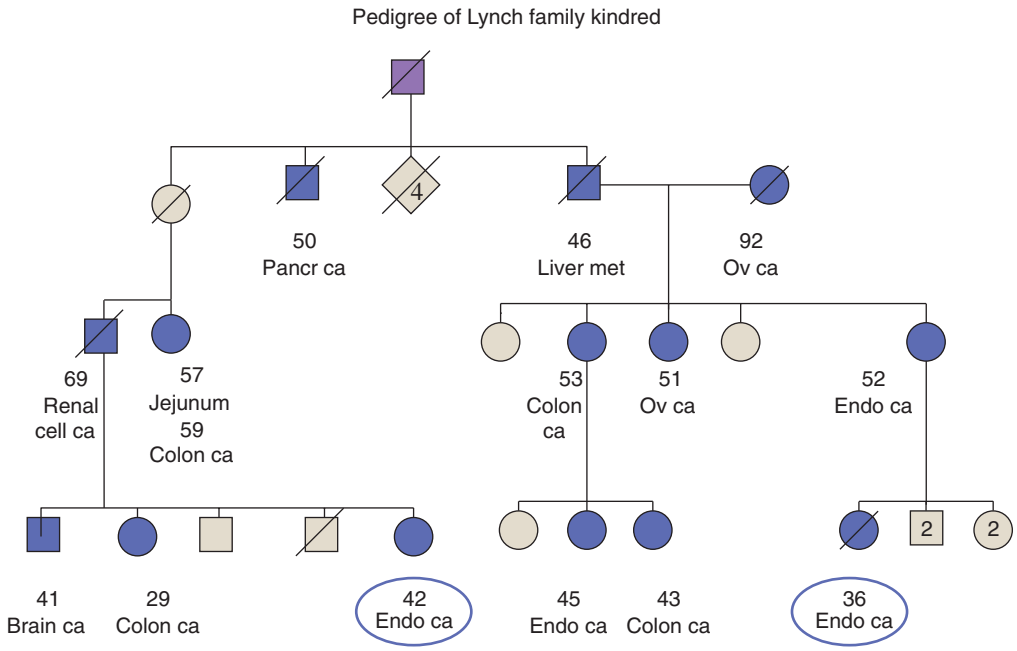

FIGURE 19.34 Typical pedigree of a family with Lynch syndrome.

testing strategies based on those results. A typical screening algorithm is seen in Fig. 19.34.

Data suggest that approximately 2% of all endometrial cancers are caused by Lynch syndrome. As many as 7 of 10 individuals with Lynch syndrome who develop endometrial cancer do not meet any published criteria for Lynch syndrome, and many of these cancers are diagnosed after age 50 years. Multiple studies evaluating the feasibility of implementing an IHC-based screening protocol for lynch syndrome in endometrial cancer show this detects Lynch syndrome that would have been previously missed and increases the referral and uptake for genetic counseling and genetic testing.

If there is no tumor tissue available, then personal and family history of cancer can guide recommendations for genetic testing. Referral of the endometrial cancer patient is discussed below.

With the increased adoption of NGS, genetic testing usually includes multiple genes tested simultaneously. This is true for Lynch syndrome as well. Genetic testing based on cancer family history consistent with Amsterdam II should include all five Lynch syndrome genes. Given the overlap of hereditary cancer syndromes, including colon cancer and other cancer types, testing may include multiple hereditary cancer syndromes, including Lynch syndrome. Genetic testing based on abnormal IHC findings typically involves two or three of the Lynch syndrome genes because of the formation of heterodimers. Reports of IHC showing loss of a single protein yet the germline mutation is in the companion genes.

A typical pedigree of a family meeting the criteria for a Lynch syndrome family can be seen in Fig. 19.35. An example of a pedigree of a family that does not raise suspicion for Lynch syndrome but was identified through abnormal IHC and subsequent genetic testing is shown in Fig. 19.24.

Management Guidelines for Lynch Syndrome (Fig. 19.36)

As noted earlier for HBOC, multiple organizations published guidelines for genetic risk assessment and management guidelines for individuals Lynch with small variances between the different groups. These organizations include the USPSTF, NCCN, ASCO, ESMO, ACOG, and SGO. These guidelines are readily available. The NCCN evaluates current data and updates recommendations at least annually and is freely accessible at NCCN.org. The most recent version for Lynch syndrome, version 2.2015, outlines the following: Colonoscopy initiated between the ages of 20 to 25 years and repeated every 1 to 2 years. For families with a case of colon cancer diagnosed before age 25 years, screening should begin 2 to 5 years younger than the youngest diagnosis. Prophylactic colectomy is not routine but may be recommended for individuals with significant repeat adenomatous polyp formation or for individuals who are unable to undergo regular surveillance. Incidence of and mortality from colorectal cancers in this group have been shown to be reduced by colonoscopy screening (Figs. 19.37 and 19.38). Chemoprevention using aspirin to reduce the risk of colon cancer has been suggested, but data are still forthcoming, and it is not standard of care at this time. There is no clear evidence to support screening for endometrial cancer by annual pelvic examination and pelvic ultrasonography, but annual endometrial sampling is an option. Similarly, screening for ovarian cancer by pelvic ultrasonography and serum CA-125 are options but also lack sensitivity and specificity for the diagnosis of ovarian cancer. Therefore, risk-reducing surgery to include

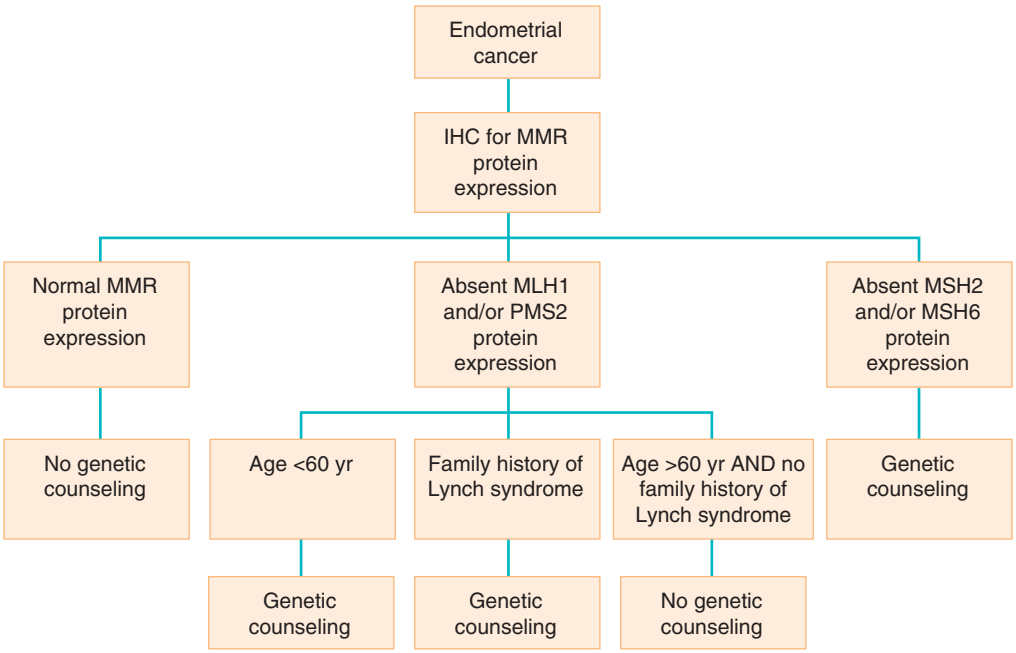

FIGURE 19.35 Screening algorithm used by the Ohio State group. (From Backes, Leon ME, Ivanov I, et al. Prospective evaluation of DNA mismatch repair protein expression in primary endometrial cancer. *Gynecol Oncol* 2009;114:486.)

Surveillance options for carriers of HNPCC-associated mutations

Malignancy	Intervention	Recommendation
Colorectal cancer	Colonoscopy	Begin at age 20–25, repeat every 1–2 years
Endometrial cancer	• Transvaginal ultrasonography • Endometrial aspirate	• Annually, starting at age 25–35 • Consider urine cytology yearly

FIGURE 19.36 Recommended screening in families with Lynch syndrome. (From Cancer Genetics Studies Consortium Task Force Recommendations. Modified from Burke W, Petersen G, Lynch P, et al., Recommendations for follow-up care of individuals with an inherited predisposition to cancer. I. Hereditary nonpolyposis colon cancer. Cancer Genetics Studies Consortium. *JAMA* 1997;277:915.)

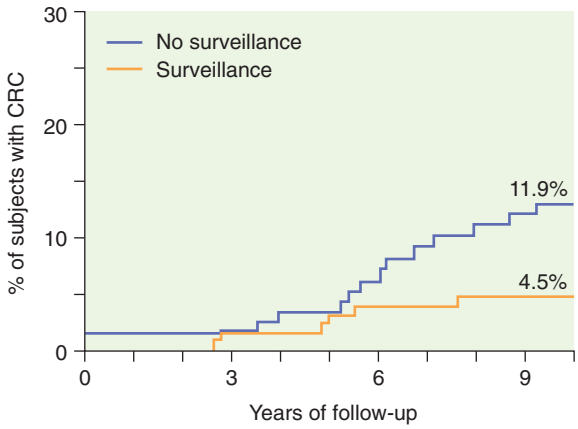

FIGURE 19.37 Effect of recommended colon screening on incidence of colon cancer in families with Lynch syndrome. Regular recommended screening decreases the incidence. (Modified from Järvinen HJ, Mecklin JP, Sistonen P. Screening reduces colorectal cancer rate in families with hereditary nonpolyposis colorectal cancer. *Gastroenterology* 1995;108:1405.)

hysterectomy and bilateral salpingo-oophorectomy is an option that should be considered for women who are age 40 years or after childbearing is completed. Research continues to evolve in developing better screening tools and chemoprevention options for ovarian cancer and endometrial cancer. If the patient is being explored for another reason, consideration should be given to counseling regarding possible risks and benefits of a total hysterectomy with bilateral salpingo-oophorectomy. Data are also limited, suggesting efficacy regarding screening and prevention for the other Lynch syndrome–associated cancers such as gastric, small bowel, pancreatic, kidney, and brain tumors. Breast cancer is not typically considered a Lynch syndrome–associated cancer, but there are reports of increased risks in some Lynch syndrome families. There are not enough data to suggest increased breast cancer screening in individuals with Lynch syndrome at this time.

Guidelines for management of individuals with inherited cancer risk are updated regularly and across multiple professional organizations and should be consulted when counseling high-risk individuals regarding cancer screening and prevention. In our era of medical specialties, it is reasonable to arrange for referral to high-risk specialists for each cancer type for an initial consult to discuss the risks, benefits, and limitations of screening and prevention for the various cancer types. The pattern of cancer types and ages of diagnosis of cancer in the family may impact the medical management recommendations.

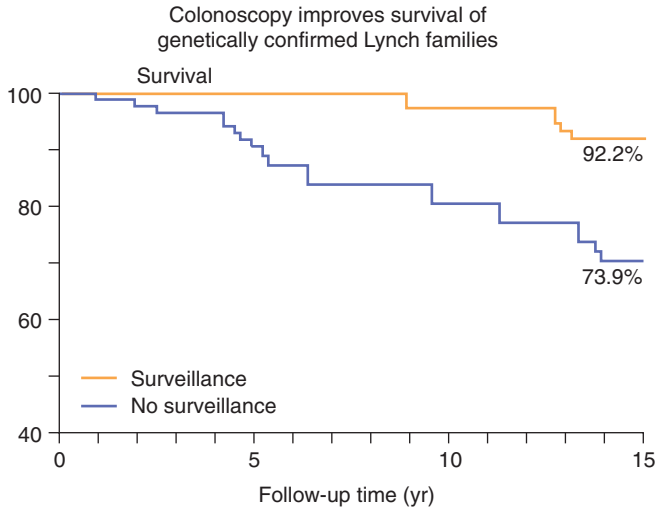

FIGURE 19.38 Effect of colon screening on mortality caused by colon cancer in families with Lynch syndrome. Regular recommended screening decreases mortality from Lynch syndrome. (From Järvinen HJ, Aarnio M, Mustonen H, et al. Controlled 15-year trial on screening for colorectal cancer in families with hereditary nonpolyposis colorectal cancer. *Gastroenterology* 2000;118:829.)

Less Common Inherited Cancer Syndromes Relevant to Gynecologic Oncology

Other less common hereditary cancer syndromes that include gynecologic malignancies as part of the tumor spectrum include PJS, Cowden syndrome, and Li-Fraumeni syndrome. Two additional genes recently described and available clinically that are associated with hereditary cancer risk and gynecologic cancer are *DICER1* (PPB) and *SMARCA4*.

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome is characterized by hamartomatous polyps of the GI tract, particularly the small intestine. Intussusception and bleeding are the usual symptoms. PJS is also characterized by flat pigmented lesions that look like dark bluish freckles visible on the mucosal surfaces such as the mouth and lips, buccal mucosa, soles of the feet, palms of the hands, and perianal area. These hyperpigmented lesions occur in about 95% of cases and are seen on very characteristic surfaces; the most easily seen are those on the lips and buccal mucosa. The pigmented lesions tend to present within the first 2 years of life. After puberty, the external lesions can fade, often making the diagnosis difficult later in life. However, the buccal lesions tend to persist, so this is always an important area to examine.

The clinical diagnosis of PJS occurs in an individual has two or more of the following: (1) two or more PJS type hamartomatous polyps of the small intestine; (2) mucocutaneous hyperpigmentation of the mouth, lips, nose, eyes, genitalia, or fingers; or (3) family history of PJS. PJS is named after Dr. Johannes Laurentius Augustinus Peutz, who first described the syndrome in 1921, and Dr. Harold Joseph Jeghers, who subsequently described this syndrome in 1949.

The PJS susceptibility gene, *STK11*, was identified in 1998. *STK11* maps to chromosome 19p13. *STK11*, a tumor suppressor gene, is a serine/threonine kinase that regulates energy metabolism and cell polarity. A mutation in *STK11* is identified in 80% to 94% of individuals who meet clinical criteria for PJS.

The cancer types associated with PJS include breast, colon, stomach, small intestine, pancreas, gynecologic, testicle, and lung. The cumulative risk for colon cancer is approximately 40% and for breast cancer is 45% to 50%. Pancreatic cancer risk is estimated to be 11% to 36%, and screening is recommended to be initiated between ages 30 and 35 years.

The gynecologic cancers associated with PJS include specific types of ovarian and cervical cancer. A very unusual ovarian stoma tumor known as sex cord–stromal tumors with annular tubules have the distinction of almost always being associated with PJS and are fortunately usually benign and are usually found incidentally. Other ovarian tumors that are associated with PJS are tumors of low malignant potential, granulosa cell tumors, Sertoli-Leydig cell tumors, and mucinous tumors. The overall risk for ovarian cancer in individuals with PJS is approximately 18% to 21%. Another gynecologic tumor associated with PJS is a rare cervical cancer known as adenoma malignum. This tumor appears to be histologically benign but can behave quite aggressively. Therefore, patients with PJS should have annual cervical examinations with this in mind, and any abnormality should be evaluated aggressively.

Patients with PJS have a significantly elevated risk of developing a malignancy. One meta-analysis suggested that the risk could be as high as 93%. However, most studies put the risk at 50% or below.

Management guidelines for Peutz-Jeghers syndrome. Surveillance for cancers associated with PJS is outlined in current NCCN guidelines and the practice guideline published in 2015 by the American College of Gastroenterology. Increased breast cancer screening to include annual mammography and breast MRI and clinical breast examination every 6 months is recommended beginning at approximately age 25 years. There are insufficient data to recommend risk-reducing mastectomy or risk-reducing oophorectomy for women with *STK11* mutations. Annual testicular examination should begin around age 10 years. No specific recommendations have been made for screening for lung cancer beyond education regarding symptoms and smoking cessation. Screening of the small intestine should begin by age 8 to 10 years and screening of the colon at 2- to 3-year intervals. Upper endoscopy should be considered starting in the late teens and continued every year or two to screen for stomach cancer. Annual pelvic examination and Pap smears should be initiated at age 18 to 20 years with consideration of annual transvaginal ultrasonography. Magnetic resonance cholangiopancreatography or endoscopic ultrasonography beginning at age 30 to 35 years can be considered. The greatest morbidity from the GI tract occurs in the 20s from large GI hamartomas; endoscopic resection of these may be helpful early in life. Finally, genetic counseling is critically important to help the patient and family assess risks of this disease, make future reproductive choices, and undergo testing.

Cowden Syndrome

Cowden syndrome was first described in the family of Rachel Cowden in 1963. This is a multiple hamartoma syndrome and is characterized by individuals with multiple hamartomas and a predisposition to a variety of cancers. The criteria for genetic testing for Cowden can be seen in Table 19.9 and can be found on the NCCN's website for Cowden syndrome. Patients who meet the criteria for Cowden syndrome should be offered counseling and, if indicated, subsequent genetic testing. Management guidelines for Cowden syndrome include initiating clinical breast examination at age 25 years and mammography and breast MRI at age 30 years consideration of annual endometrial biopsy and prophylactic hysterectomy at completion of childbearing. Men and women should initiate thyroid examination at age 18 years, colonoscopy at age 35 years, and renal ultrasonography at age 40 years as well as dermatologic examination. These recommendations are regularly reevaluated and updated, and one must check current sources before making recommendations.

TABLE 19.9 Criteria for Genetic Testing for Cowden Syndrome

Testing criteria	Known PTEN mutation in the family
	Individual meeting clinical criteria for Cowden syndrome
	Individual with personal history of adult Lhermitte-Duclos disease *or* ASD and microcephaly *or* trichilemmomas (two or more biopsy proven)
	Individuals meeting two or more major criteria below (one must be macrocephaly)
	Individuals meeting three major criteria without macrocephaly
	Individuals meeting one major criteria and three or more minor criteria
	Individuals meeting four or more minor criteria
Major criteria	Breast cancer
	Follicular thyroid cancer
	Macrocephaly
	Endometrial cancer
	Macular pigmentation of the glans penis
	Multiple GI hamartomas or ganglioneuromas
	Specific mucocutaneous lesions: biopsy-proven trichilemmoma, multiple palmoplantar keratoses, multifocal oral mucosal papillomatosis, multiple cutaneous facial papules
Minor criteria	Thyroid lesions (adenomas or goiter)
	Intellectual disability (IQ ≤75) or ASD
	Colon cancer or papillary thyroid cancer or follicular variant of papillary thyroid cancer or renal cell carcinoma
	GI hamartomas or testicular lipomatosis or lipoma
	Vascular anomalies such as multiple intracranial developmental venous anomalies
Diagnosis in an individual	Any single pathognomonic criterion but mucocutaneous lesions if meeting specific criteria one major and at least three criteria or at least four minor criteria alone
Diagnosis in a family in which one individual has characteristics diagnostic for Cowden syndrome	Individuals must have at least one of the following:
	Pathognomonic criteria
	Any one major criteria with or without minor criteria
Two minor criteria or history of Bannayan-Riley-Ruvalcaba syndrome	

ASD, Autism spectrum disorder; *GI,* gastrointestinal.

Li-Fraumeni Syndrome

Li-Fraumeni syndrome was first described in 1969. This was noted as a familial clustering of soft tissue sarcomas and a clustering of diverse neoplasms, including early-onset breast cancer. In 1988, Li-Fraumeni published the follow-up of 24 families. This established what is now known as the classic criteria for diagnosing this syndrome (Table 19.10). Approximately 70% of individuals who meet the classic criteria are found to have a *TP53* mutation. Approximately 20% of individuals who meet other criteria for Li-Fraumeni syndrome called the Chompret criteria are found to have a mutation in *TP53*. Any woman with personal history of early-onset breast cancer and no *BRCA* mutation should be considered for *TP53* testing. In 1990, deleterious germline mutations were discovered in the tumor suppressor gene *p53*, establishing a molecular diagnosis for Li-Fraumeni syndrome.

Gynecologic cancers are not a one of the major cancers associated with Li-Fraumeni syndrome, although the overall cumulative risk for cancer with Li-Fraumeni syndrome is

TABLE 19.10 Diagnostic Criteria for Li-Fraumeni Syndrome

Classic Criteria (Must Meet All Conditions)

Proband of younger than 45 years of age with a sarcoma
Plus
First-degree relative younger than 45 years of age with any cancer
Plus
Additional first- or second-degree relative in the same lineage with any cancer or sarcoma

Chompret Criteria

Proband with a tumor belonging to the LFS tumor spectrum (eg, soft tissue sarcoma, osteosarcoma, brain tumor, premenopausal breast cancer, adrenocortical carcinoma, leukemia, lung bronchoalveolar cancer) before age 46 years *and* at least one first- or second-degree relative with a LFS tumor (except breast cancer if the proband has breast cancer) before age 56 years or with multiple tumors *or*

Proband with multiple tumors (except multiple breast tumors), two of which belong to the LFS tumor spectrum and the first of which occurred before age 46 years *or*

Proband with adrenocortical carcinoma or choroid plexus tumor, regardless of family history

LFS, Li-Fraumeni syndrome.

approximately 90%, and this includes multiple cancer types as well as gynecologic cancers. The screening recommendations have typically focused on early and more frequent breast cancer screening, consideration of risk-reducing mastectomy, colonoscopy beginning at age 25 years and repeating every 2 to 5 years, annual dermatologic examination, an awareness by pediatrician of the risk for childhood cancers, and avoidance of therapeutic radiation therapy whenever possible given the hypersensitivity to radiation-induced DNA damage. Recent publications include consideration of annual whole-body MRI. There are no specific screening or prevention recommendations for gynecologic malignancies at this time given the lower incidence of these cancer compared with the other cancer types in individuals with this syndrome.

GENETIC COUNSELING AND GENETIC TESTING FOR HEREDITARY CANCERS

The National Society of Genetic Counselors redefined genetic counseling in 2006 as the process of helping people understand and adapt to the medical, psychological, and familial implications of genetic contributions to disease. This process integrates interpretation of family and medical histories to assess the chance of disease occurrence or recurrence; education about inheritance, testing, management, prevention, resources, and research; and counseling to promote informed choices and adaptation to the risk or condition. A searchable directory of board-certified genetic counselors has been developed to assist physicians, patients, and other genetic counselors in locating genetic counseling services. Genetic counselors can be searched by state, city, counselor's name, work setting, and type of specialist such as inherited cancer risk assessment. This directory can be found on the National Society of Genetic Counselors' website (http://www.NSGC.org).

The ASCO published an expert statement on the collection and use of a cancer family history for oncology providers in 2014. ASCO recommends minimum cancer family history intake by physicians should include documentation of family history of cancer in first-degree relatives (parents, children, and siblings) and second-degree relatives (grandparents, aunts, uncles, nieces, nephews, half siblings). This should include the primary cancer, age of diagnosis for each cancer, and notation of maternal or paternal lineage. Additionally, patients should be asked if anyone in the family had genetic testing for hereditary cancer risk and obtain a copy of these results. Ethnicity should be noted, particularly Ashkenazi Jewish ancestry. This level of detail may be necessary to determine the appropriateness for referral for hereditary cancer risk assessment.

Formal hereditary cancer risk assessment should include review of at least a three-generation pedigree, including first-, second-, and third-degree (cousins) relatives from both maternal and paternal families. Occasionally, expansion of the pedigree beyond these relatives may reveal important information that will guide recommendations for genetic testing and medical management. The choice of genetic tests since the adoption of multigene panels that cover multiple hereditary cancer syndromes relies less on family history than prior methods of gene-specific testing or syndrome-specific testing. The cancer family history is still of great importance when interpreting results and providing follow-up recommendations based on the pattern of cancer and ages of diagnosis in the family.

Information to document for each family member, if available, to document a detailed cancer family history includes the following:

- Current age or age at death
- History of benign tumors and specific diagnosis
- History of colon polyps, including the total number and types of polyps
- Cancer history; verify by obtaining pathology report or other medical records if possible; age of diagnosis; primary cancer site and treatment; prior genetic testing (if so, obtain a copy of the result)
- Reproductive history, including menarche, age first birth, menopause, and hormone use
- History of cancer prevention surgeries or cancer screening history
- Environmental exposures such as smoking

This level of detail may not be available for all relatives. It is not unusual for the cancer family history to be different from that initially reported to the physician after the patient initiates this conversation with family members. Limitations of obtaining cancer family history, as outlined in the ASCO expert opinion piece, include limited patient knowledge of family history, small families, or families with limited communication. Families with few at-risk women may also mask the presence of hereditary risk for breast and ovarian cancer. It is also important to inquire about updated cancer family history information at follow-up visits and to encourage the patient to call when the cancer family history information changes. Updated cancer family history information may change the risk assessment and recommendations.

Verification of the reported cancer diagnoses in a family is important because the risk assessment and subsequent recommendations are based on this verbal family history. Gynecologic cancers are notoriously misreported within a cancer family history. Data show that the accuracy of verbal family history deceases with increasing degrees of relatedness. It is also important to obtain medical records to confirm any cancer diagnosis in the patient presenting for genetic counseling for accurate tumor type and histology information. Verification of the total number and types of colon polyps is also important because many patients may not have accurate recall of this history for themselves and are unlikely to know this information about family members. The pathology report is the most reliable source for verification of both the age of diagnosis and histology and should be obtained whenever possible. The pathology report provides minimal personal information, so family members may be more willing to share these reports if they are reluctant to share their medical information with family members. It is still appropriate to proceed with hereditary cancer risk assessment and genetic testing if the family history cannot be verified. Patients need to understand that the both the risk assessment and recommendations are based on the

family history as presented, and accurate information provides the best base for these recommendations.

Patients should be encouraged to gather the medical family history even if they decline referral for genetic counseling. This is a gift of information to the next generation because the family history may significantly impact future medical recommendations for that family, and as the older generations passes, this information may not be easy to accumulate.

A formal genetic counseling assessment should include discussion of the psychosocial issues some experience living with a personal history of cancer or cancer family history. The patient may experience recall of emotions and memories of family members diagnosed with cancer in the process of gathering and reviewing the cancer family history and should have an opportunity to address these emotions. This is especially true for a genetic counseling client who was young when his or her family member was diagnosed or died or if the individual was a primary caregiver for the relative with cancer. The genetic counseling appointment should also include discussion of the potential emotional impact of undergoing genetic testing and learning that one is at significant increased risk for cancer. Survivor guilt is also a common response for individuals who undergo testing and learn they did not inherit the familial mutation previously identified in other family members. Referral for psychological support for any patient undergoing hereditary cancer risk assessment is appropriate. Finally, the genetic counselor can be available to schedule annual follow-up visits to review and update family history and review updated genetic testing options or updates to the recommendations for follow-up based on family history or genetic testing results.

REFERRAL OF GYNECOLOGIC CANCER PATIENTS FOR HEREDITARY CANCER RISK ASSESSMENT

Ovarian Cancer

Although the hallmark for hereditary cancer is early age of onset, this is not necessarily the case for ovarian cancer. All patients with epithelial ovarian cancer, fallopian tube cancer, and primary peritoneal cancer should be offered genetic counseling and genetic testing for hereditary cancer risk regardless of their age of onset or cancer family history. Current data suggests that 10% to 20% of all epithelial ovarian cancers are associated with a mutation in a hereditary cancer predisposition gene. This is sufficient to recommend genetic testing regardless of family history of cancer. Current SGO guidelines note that nearly one third of women with hereditary ovarian cancer have no close relatives with cancer, and 35% of women with hereditary ovarian cancer are diagnosed after age 60 years.

It is appropriate to refer an unaffected woman for hereditary cancer risk assessment who has a close relative, especially a mother or sister, with ovarian cancer. Ideally, the relative with ovarian cancer should initiate genetic testing. If the relative with ovarian cancer is either unwilling to proceed with genetic testing or is deceased and never had genetic testing, it is appropriate to refer the unaffected woman for genetic counseling for hereditary cancer risk assessment and consideration of genetic testing.

Timing of Referral for Patients With Ovarian Cancer

We support providing referral information very near the time of diagnosis for all ovarian cancer patients for several reasons beyond the high mortality rate for ovarian cancer:

1. Patients with ovarian cancer often express concern regarding risk for their daughters and granddaughters very early in their ovarian cancer journey, so they are already thinking about it.
2. Providing referral near the time of diagnosis gives the patient a choice. Patients who are not ready to proceed will tell their physicians. The option can be revisited after treatment is complete if the patient has not revisited during her treatment process.
3. Many patients with ovarian cancer are proceeding with counseling and testing at some point during the initial treatment phase, especially in the past few years with greater public awareness of cancer genetics. This is also a great time because many patients with ovarian cancer have family members with them during the treatment phase.
4. The daughters and sisters of patients with ovarian cancer are often offered genetic testing by their gynecologists at the first visit they mention their mother or sister has ovarian cancer. Ideally, the patient with ovarian cancer should initiate testing first.
5. Hereditary ovarian cancer also includes risks for cancers that are not gender specific, so it is equally important for the male relatives to undergo testing.
6. Identification of a mutation in one of the hereditary genes may impact reproductive decisions for at-risk relatives still of childbearing age.
7. We can offer DNA banking for patients who decline testing upfront.

Borderline ovarian tumors and nonepithelial ovarian tumors are not commonly associated with hereditary cancer syndromes.

Endometrial Cancer

Approximately 3% of all endometrial cancers are caused by inherited risk related to Lynch syndrome. Referral of patients with endometrial cancer for hereditary cancer risk assessment is based on the cancer family history or personal history of endometrial cancer and the results of tumor genetic screening studies that may be performed as part of the pathologic diagnosis of the cancer after surgery. A 2015 joint practice guideline from the American College of Medical Genetics and Genomics and the National Society of Genetic Counselors suggests referral of the endometrial cancer patient for genetic counseling that meets the following:

1. Diagnosis of endometrial cancer before 50 years of age
2. Endometrial cancer at any age if there is a first-degree relatives with colon or endometrial cancer at any age
3. Synchronous or metachronous colorectal or endometrial cancer
4. Endometrial cancer showing MMR deficiency on tumor screening

5. Endometrial cancer and two additional cases of any of the Lynch syndrome–associated cancers in the same person or close relatives
6. Epithelial endometrial cancer and two additional Cowden syndrome criteria in the same person

A significant cancer family history warrants referral for hereditary cancer risk assessment even in patients with endometrial cancer with normal tumor screening results. It is always possible that the tumor screening results represent a false-negative result or the individual developed endometrial cancer by chance but still has a hereditary risk for cancer in the family.

Referral of the Patient for Genetic Counseling Based on Personal History of Breast Cancer or Family History of Cancer

Other criteria for referral for hereditary cancer risk assessment for HBOC as outlined by the NCCN guidelines include:

- Women with a personal history of breast cancer and ovarian cancer at any age
- Women with a personal history of ovarian cancer and a close relative with breast cancer at younger than 50 years of age or ovarian cancer at any age

Given the stringency of these criteria, many inherited cancers may be missed. Other features that may be useful in deciding whether a patient should be referred to a genetic counselor for counseling and possible testing are outlined in Table 19.11.

TABLE 19.11 Testing Criteria for Breast Ovarian Cancer Syndrome*

Individual from a family with a known deleterious *BRCA1* or *BRCA2* gene mutation
Personal history of breast cancer plus one or more of the following:
Diagnosed before or at 45 years of age
Diagnosed before or at 50 years of age with
An additional breast cancer primary
At least one close blood relative with breast cancer at any age
At least one close relative with pancreatic cancer
At least one close relative with prostate cancer
An unknown or limited family history
Diagnosed at of age 60 with
Triple-negative breast cancer
Diagnosed at any age with
At least one close blood relative with breast cancer before 50 years of age
At least two close blood relatives with breast cancer at any age
At least one close blood relative with ovarian cancer
At least one close blood relative with pancreatic cancer
At least two close blood relatives with prostate cancer
A close male blood relative with ovarian cancer
An individual of ethnicity associated with a higher mutation frequency
Personal history of ovarian cancer
Personal history of male breast cancer
Personal history of prostate cancer at any age with a close relative with breast, ovarian, or pancreatic cancer at any age
Personal history of pancreatic cancer and Ashkenazi Jewish ancestry
Family history meeting any of the above criteria
See NCCN guidelines for the most up-to-date and detailed description for counseling and testing.

*For more detailed information, see the National Comprehensive Cancer Network (NCCN) guidelines.

GENETIC TESTING

General Guidelines for Genetic Testing for Hereditary Cancer Risk

Genetic testing should always be initiated in an affected relative, if possible, to determine if there is an identifiable mutation in one of the hereditary cancer genes. If the relative with cancer does not have a mutation, it may be appropriate to test another affected relative in the event there is a mutation in the family and the first person tested is a phenocopy and developed cancer by chance. If no mutation is identified in the affected relative, it is not appropriate to pursue genetic testing in the unaffected relative. The cancer family history should be used to guide recommendations for increased cancer screening and prevention because genetic testing is not informative. If an affected relative is found to have a mutation, targeted mutation-specific testing can be offered to unaffected relatives. It is important to always obtain both maternal and paternal cancer family history for any patient undergoing genetic testing to determine if there may be additional cancer risk from the other side of the family. It is important to confirm the parental origin of a mutation and not just assume the mutation explains the family history. It is possible that more than one mutation may be traveling in a family. Without confirmation of the lineage or presence of the mutation in other affected relatives, a multigene test may still be appropriate.

Criteria for referral for hereditary cancer risk assessment and genetic testing continue to evolve. Referral to a genetic counselor for risk counseling and possible testing should not be limited to those with high-risk criteria. Some features may not be apparent at first glance in the patient's history. Inaccurate histories are common; furthermore, as families become smaller, the accuracy of family history in predicting inherited disease becomes less. Referral to a counselor can occur at any time, but immediately after or during treatment seems like the most practical and common.

Informed Consent

Informed consent is a necessary component of genetic testing. The rapid adoption of multigene panels and the impact on the informed consent process was recently addressed by ASCO. Informed consent should include the following:

- Psychosocial assessment and support
- Purpose of the test and who to test
- Discussion of options of gene specific testing versus multigene testing
- Possible test results
- The implication of those results with particular attention to the implications of a mutation in a less well-characterized gene or in a gene association with a hereditary syndrome not suggested by the personal or family history of cancer
- Likelihood of finding a mutation

- Technical aspects and accuracy of the test including possibility that test will not be informative, paying particular attention to the current high rate of variants of uncertain significance
- Fees involved in testing and counseling
- Information regarding concerns for genetic discrimination and medical privacy and confidentiality
- Psychosocial aspects, including anticipated reaction to results, timing and readiness for testing, family issues, and preparing for results
- Utilization of test results, including options and limitations of medical surveillance and strategies for prevention
- Options and limitations of medical screening and prevention without genetic testing as well as how genetic testing can impact recommendations
- Importance of sharing genetic test results with at-risk relatives: risks for children, siblings, or other biologic relatives who may inherit an identified mutation
- Laboratory policy on storage of DNA sample and possible use for future research
- Potential reproductive implications to family of mutation in a gene linked to a recessive disorder (ie, ATM, Fanconi anemia, constitutional MMR syndrome)
- Option of DNA banking to allow for genetic testing in the future for the patient's family

Most health insurance plans provide coverage for the majority of the cost of genetic testing, and many have published criteria for coverage that are easily accessible on the Internet.

Ordering Genetic Testing

Genetic testing is usually performed on a blood sample with DNA extraction from the lymphocytes. Some laboratories offer the option of buccal swabs or buccal spit kits as an alternative to a blood draw. Before 2013, *BRCA1* and *BRCA2* were only available through a single laboratory. This changed after the Supreme Court ruling overturning gene patents. Multigene testing, including *BRCA1* and *BRCA2*, is available through a multitude of laboratories. The cost of genetic testing for the multigene panels varies significantly among laboratories. Most medical insurance plans cover the cost of genetic testing for hereditary cancer risk if the patient or family is suggestive of hereditary cancer risk. Many of the commercial laboratories have financial assistance programs, and some offer a set out-of-pocket cost for those without insurance coverage. ASCO's 2015 Policy Statement Update for Genetic and Genomic Testing for Cancer Susceptibility notes a commitment to ensure access to high-quality cancer genetic services and supports continued expansion of third-party reimbursement. There seems to be a push to reduce the cost and increase accessibility to genetic testing for hereditary cancer risk. The costs and options for multigene testing are changing rapidly, and it is best to obtain up-to-date information directly from the laboratory of choice. A listing of laboratories providing genetic testing for hereditary cancer risk can be found on GeneTests (http://www.genetests.org). GeneTests, funded by the National Institutes of Health, provides an updated listing of laboratories offering clinical and research genetic testing and information on genetic testing and its use in diagnosis, management, and genetic counseling.

Interpreting the Test Results

Regardless of the number of genes included on a multigene panel, each gene has four possible results.

1. **Positive:** Deleterious mutation identified. This is a true positive, meaning the mutation is known to be significantly alter the function of the gene and is associated with increased risks of developing cancer.
2. **Negative for mutation-specific testing in the context of a known mutation identified in a family member:** This is a true negative and typically indicates that this individual is at general population risk to develop cancer. However, it is still important to assess the detailed cancer family history for both the maternal and paternal families. One cannot always assume parental origin based on the reported cancer family history because there are cases of more than one hereditary mutation in a given family.
3. **Negative:** No mutation identified in an individual for whom no mutation has been identified in other family members. This is not a true negative. In this case, the negative genetic testing result does not necessarily rule out hereditary risk. Testing another relative in the family diagnosed with cancer may be recommended. Recommendations for cancer screening and prevention should be based on personal medical history and cancer family history, not negative genetic testing results. Possible explanations for a negative result include:
   a. There could be a hereditary mutation in one of the genes listed earlier that is not detectable by the current technology.
   b. There could be a hereditary mutation in a gene not tested.
   c. There could be a hereditary mutation in the family that she did not inherit and developed cancer for other reasons.
   d. There may not be inherited cancer risk in the family.
4. **Variant of uncertain significance (VUS):** This is an inconclusive result. This means an alteration in the gene has been identified, but it is unknown whether the alteration will affect gene function. The rate of VUS findings varies from 10% to 41% in the multigene panels depending on the number of genes tested and the number of newly characterized genes and differs among laboratories. No recommendations for cancer screening or prevention should be made based on a VUS. Testing unaffected relatives for the VUS is not appropriate because medical recommendations cannot be made based on the presence or absence of a VUS. Appropriate medical management should be based on family history and personal medical history. The laboratory that identified the VUS may offer family research testing to the parents or other close relatives who have had cancer because these data can be helpful in attempting to establish the clinical significance of a variant.

An algorithm for the various possible test results can be seen in Figs. 19.39 and 19.40.

LEGAL ASPECTS OF GENETIC TESTING

Concern over the legal consequences of genetic evaluation remains a barrier for patients and health care providers when considering genetic testing for hereditary risk. There is fear over

genetic discrimination in health insurance, life insurance, and disability insurance procurement and even discrimination with regard to employment. Both state and federal legislation has been passed preventing discrimination on the basis of genetic information. Current efforts for health care reform focus on reducing "preexisting" conditions being used by insurance companies to determine coverage and rates for health care insurance. There is also some increased protection to individuals under the Health Insurance Portability and Accountability Act (HIPAA). This law offers protection of those who are members of group insurance plans, including the federal group plans Medicare and Medicaid.

The Genetic Information Nondiscrimination Act (GINA) of 2008 offers expanded protection of individuals and groups. GINA expands on the protection offered by HIPAA to further limit the ability of insurance carriers to raise rates or deny coverage to individuals and groups. Again, the actual impact of these laws need to be tested in court, and it is therefore difficult to predict exactly what effect these laws will ultimately have on genetic discrimination. Several important points should be considered here: (1) the actual incidence of genetic discrimination is exceedingly small, with few cases nationwide that address this issue; (2) genetic testing is becoming routine in many areas of medicine, and most insurance companies have guidelines for coverage for genetic testing; and (3) national sympathy clearly sides with those with the possibility of genetic disease. Nonetheless, part of counseling should include the possibility of discrimination with information gained from the test.

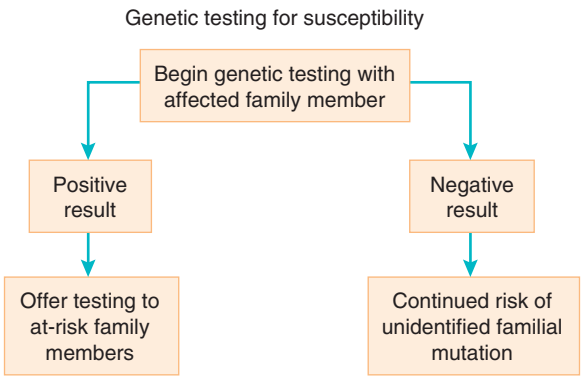

FIGURE 19.39 Algorithm for testing and management of an affected individual.

It is the duty and obligation of the physician to inform the patient of the risks of a positive genetic test result. However, there is also a duty of the physician to inform other family members who are at risk for the disease. Case law at this time generally falls on the side of favoring the individual's right to privacy over the physician's obligation to inform other family members. However, there is a case litigated in 1996, *Safer v Estate of Pack,* in which an individual with familial adenomatous polyposis died from colon cancer. He requested that his family not be informed. His daughter developed colon cancer at the age of 36 years and sued her father's physician's estate, claiming that he had an obligation to warn those at risk and that he had failed to fulfill these obligations. The case was dismissed, but this was later reversed by the New Jersey Court of Appeals, which ruled that a physician's obligation may extend beyond that of the immediate family and that the physician had an obligation to tell the patient that he had an obligation toward the health of his children.

Genetic tests are unique compared with many other medical tests in that they affect not only the individual but may also affect immediate and extended family. We can encourage our patients to share this information with their family members by providing them with tools and written communication to assist them in sharing this information. The best recommendation is to have family members schedule genetic counseling appointments to review the information and discuss options for genetic testing and cancer screening and prevention based on family history and genetic testing results.

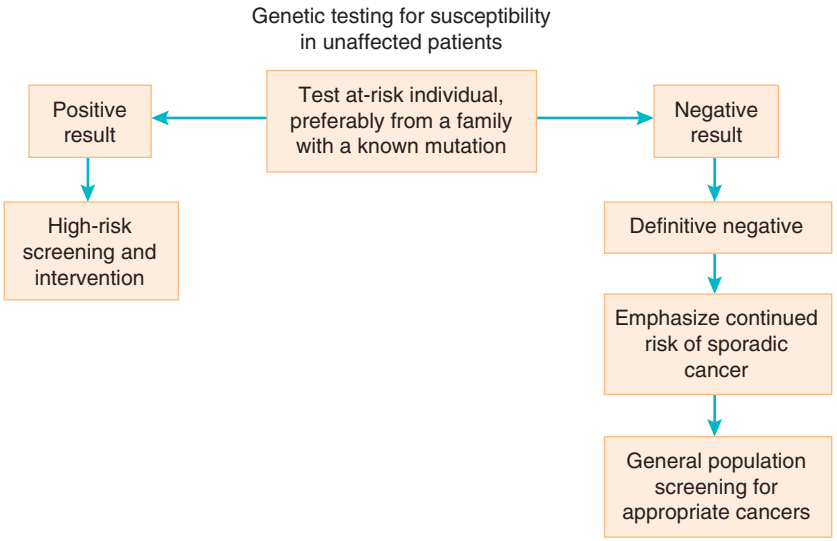

FIGURE 19.40 Algorithm for testing and management in individuals who are not affected but have a family history.

Finally, there is a duty by physicians to meet the standard of care. This is defined as what is reasonable or what a reasonable physician should do for his or her patient. Genetic testing and counseling are quite new, so clear standards have not been established. However, it is clear that it is important to take a family history and inform patients of diseases for which they may be at risk and offer testing for these diseases when available. Although there are no universally established standards, most specialties, such as the ASCO and the American Medical Association, have their own guidelines. This information provides a reasonable template for clinicians to follow.

LONG-TERM CONTACT FOR PATIENTS AND FAMILIES WITH HEREDITARY RISK FOR CANCER

Health care providers caring for families with hereditary risk for cancer should encourage patients to maintain annual contact with their high-risk specialists and genetic counselor to discuss updates to cancer family history and any updates to the cancer screening and prevention recommendations. Additionally, the popular media continues to provide more coverage regarding celebrities with hereditary risk and new scientific discoveries. Patients should be encouraged to schedule follow-up appointment to review new information in context with their personal history. Patients should also be provided resources for support both through mental health providers as well as local and national support groups for the specific hereditary cancer syndromes or cancer types. Different patients have different needs, and providing them with a variety of resources allows them to find information that fulfills individual needs.

Significant technologic advances are bringing about rapid changes in the availability of genetic testing as well as in follow-up recommendations. Changes in family history may significantly impact the risk assessment and subsequent recommendations. Additionally, the future generations need to be made aware of the cancer family history and known mutation in the family (if identified) and encouraged to seek genetic counseling for hereditary cancer risk to understand the risks and options for genetic testing.

A number of Internet support organizations are available for specific hereditary cancer syndromes and specific hereditary cancer types. Examples include FORCE: Facing Our Risk of Cancer Empowered (http://www.facingourrisk.org). FORCE is a nonprofit organization with an advisory board of cancer genetic specialists that provides updated information and support for individuals concerned with HBOC. Be Bright Pink (https://www.brightpink.org) focuses on prevention and early detection of breast and ovarian cancer in young women. Two examples of organizations that focus on the different syndromes associated with hereditary risk for colon cancer include Hereditary Colon Cancer Takes Guts (http://www.hcctakesguts.org) and Colon Cancer Alliance for Research & Education for Lynch Syndrome (CCARE Lynch Syndrome; http://www.fightlynch.org).

Other valuable websites include national cancer organization such as the National Cancer Institute (http://www.cancer.gov) and American Cancer Society (http://www.cancer.org).

Because this information is changing rapidly, detailed chart documentation, scans of tables, charts, and articles discussed can become a part of a patient's medical record for reference to compare current recommendations or scientific information with what was discussed with a patient in past appointments.

DNA BANKING

DNA banking is an option for all cancer patients even if a mutation is identified. Advances in technology and genetic testing and research will likely bring about significant changes in genetic testing and in our understanding of the roles of genes. DNA banking is also an important option for terminally ill cancer patients, when the patient or family does not have the time for traditional genetic risk assessment or are simply overwhelmed by planning for the end of life and cannot process additional medical information. There is no guarantee a family will use the stored DNA, and costs for future genetic testing are uncertain. However, DNA storage is reasonable cost ranging from less than $100 to more than $300 with storage times from 5 years to 25 years or more. This allows for the option for genetic testing in the future for the family.

CONCLUSION

The field of hereditary cancer risk assessment and management of these high-risk families continues to evolve. Our understanding of the spectrum of cancer and risk of cancer is changing as new technologies are used for broader genetic testing and the criteria for who to test change. Referral to health care professionals with expertise in cancer genetics and management of high-risk patients is essential.

Focused cancer family history should be part of the initial evaluation of all patients. Maternal and paternal pedigrees should be constructed to include at least three generations (the patient, her parents, and her grandparents) if hereditary risk is suspected. Information regarding the family member's age at diagnosis and additional details such as bilaterality of breast cancer are very helpful. Updates of the family history should be asked about at annual examinations because additions and new diagnoses may alter the initial recommendation regarding genetic testing.

Guidelines for offering genetic testing continue to evolve. All patients with epithelial ovarian cancer should be offered genetic testing. Other indicators of a possible hereditary cancer syndrome include early age at diagnosis, multiple primary cancers (eg, breast and ovarian cancer, colon and endometrial cancer, or bilateral breast cancer), cancer in two or more close relatives on the same side of the family, or rare cancers such as male breast cancer or ureteral cancer. If after review of the patients' pedigree a hereditary cancer syndrome is suspected, the patient should be referred for genetic counseling and possibly testing. The counselor may expand on the pedigree and request documents to verify cancer diagnoses. These documents include pathology reports, operative reports, and death certificates.

The ASCO and NCCN offer guidelines for cancer predisposition testing that are followed by most cancer geneticists.

Genetic testing is recommended when the individual has a personal history or family history suggestive of a cancer susceptibility syndrome, when the test can be adequately interpreted, and when the test result will influence medical management.

It is critically important that counseling be done both before and after testing. Appropriate counseling will provide the following:

1. Informed consent
2. Psychological assessment and support
3. Purpose of the test and who should be tested
4. General information about the genes and the mutations to be tested for
5. Possible test results and implications of these results
6. Accuracy of the tests and the likelihood of finding a mutation
7. Cost of testing
8. Possible consequences of testing (ie, genetic discrimination)
9. Importance of sharing results with family members
10. Banking DNA for future testing
11. Options for treatment if testing is declined
12. Management strategies if the test result is positive. These include surveillance, prevention, and prophylaxis

GLOSSARY

Allele Alternative forms of the same gene. Because of the paired nature of chromosomes, every gene exists in two copies. Each is an allele.

Antioncogene See tumor suppressor gene.

***c-erb-b2* proto-oncogene** Also referred to as HER-2 or neu, this gene encodes a protein that is structurally similar to the receptor for epidermal growth factor. When it is amplified, the gene is of prognostic significance in breast and ovarian neoplasms.

Capping The addition of 7-methylguanosine residues to the 5′ end of most eukaryotic mRNA.

Chromosome One mechanism for activating oncogenes.

Chromosome translocation Exchange of genes or a portion of genes between different chromosomes.

Cloning An in vivo method to produce unlimited quantities of specific DNA fragments from as little as a single DNA molecule. Also, the process by which a DNA molecule is joined to another DNA molecule that can replicate autonomously in a specially designed host, usually a bacterium or yeast.

Codon A group of three nucleotides forming a base-coding message in the gene sequence. In ras genes, for example, the 12th, 13th, or 61st codon is often mutated, leading to oncogene activation.

Complementary DNA (cDNA) DNA synthesized from mRNA template such that the DNA sequence is complementary to the mRNA.

Contig The sequence of DNA created by use of Yeast artificial chromosomes (YACs), Bacterial artificial chromosomes (BACs), and cosmids to fill an unknown region of DNA suspected of having a candidate gene.

Cosmid Used for large-scale analysis of the human genome when large DNA fragments of known sequence are needed (40 kb).

Cytoplasmic signal transduction molecules Proteins within the cytoplasm of cells responsible for transmitting signals from one event to the next event.

DNA probe A short segment of DNA in which the base sequence is specifically complementary to a particular gene segment. The probe is used, for example, on the Southern blot assay to determine whether a certain gene is present in a tumor sample undergoing DNA analysis.

Exons The coding portion of genes.

Gel electrophoresis A molecular biology laboratory technique in which DNA, RNA, or proteins are separated according to molecular weight, charge, and spatial characteristics in an electric field applied to a gel. For example, because DNA is negatively charged, it migrates toward the positively charged electrode.

Gene amplification The presence of multiple copies of a gene within a cell that is normally present in only two copies per somatic cell. An increased number of copies of an individual gene, usually a proto-oncogene, per cell.

Gene deletion The deletion of part or all of a gene through removal of DNA sequences by any of several mechanisms.

Gene expression The active transcription of a gene into an RNA molecule followed by translation of the protein product.

Gene rearrangement The process by which part or all of a gene is moved from its normal location in the genome to another site within the genome.

Genomic imprinting An epigenetic modification of a parental allele of a gene that leads to differential expression of that allele.

Growth factor Protein that acts on cells to promote cell growth.

Growth factor receptors Proteins that interact with growth factors and transmit the growth signal to the cell.

HER-2 See *c-erb-b2* proto-oncogene.

Heteronuclear RNA A form of RNA, a pre-mRNA, that exists before splicing and consists of both introns and exons.

Heterozygosity Two different forms of the same gene in a cell. An oncogene is generally heterozygous. For example, one allele may be mutated while the other copy remains normal. In addition, different forms of a gene may be normal variants. Variations in the exact base sequence within DNA are common in the genome among humans. These are called polymorphisms and are often responsible for the heterozygous state.

Informative A term used to describe the situation in which two homologous chromosomes from an individual can be distinguished from one another at a given locus; *heterozygous* is an alternative term.

Insertion The addition of a DNA sequence into the genome.

Introns Portions of genomic DNA that are interspersed between exons and are transcribed along with the exons into heteronuclear RNA.

Locus A general term to describe a defined chromosome region.

Loss of heterozygosity Losses of specific regions of DNA from one copy of a given chromosome that can be distinguished from the region retained on the other chromosome.

Messenger RNA (mRNA) The mature form of processed RNA used as a template for directing translation of proteins.

Myc proto-oncogenes The proto-oncogene family that includes *c-myc, N-myc, L-myc,* and *R-myc*. They encode nuclear-associated DNA-binding proteins that affect DNA replication and transcription.

Neu See *c-erb-b2* proto-oncogene.

Nonsense mutation A nucleotide substitution that results in a truncated protein product by generating a stop codon specifying premature cessation of translation within an open reading frame.

Nuclear transcription factors Proteins involved in regulating the expression of genes by controlling transcription. Some factors enhance and others repress gene expression, and others do both, depending on the intracellular environment.

Oncogenes Genes that regulate cell growth in a positive fashion (ie, promote cell growth). Oncogenes include transforming genes of viruses and normal cellular genes (proto-oncogenes) that are activated by mutations to promote cell growth.

Open reading frame A sequence of DNA representing at least some of the coding portion of a gene that is transcribed and subsequently translated into a protein because it does not contain any internal translation termination codons.

Palindrome (inverted repeats) Sequences that look the same if read forward or backward. This allows the sequence to fold back on itself, and it is particularly susceptible to mutation.

Point mutation The replacement of one nucleotide in the DNA sequence of the wild type with another nucleotide.

Polymorphism Variation in the exact base sequence of DNA that makes up the genome. These occurrences are normal and common in humans. Polymorphisms are used in the study of molecular genetics because they are inherited. Ones found near or within disease genes can be used to study linkage in genetics.

Primers Short DNA pieces that are complementary to portions of specific DNA sequences.

Promoter The DNA sequence of a gene to which RNA polymerase binds and initiates transcription.

Proto-oncogenes Any of a number of genes that encode various proteins involved in normal cell growth and proliferation, including growth factors, growth factor receptors, regulators of DNA synthesis, and phosphorylating modifiers of protein function. These are cellular genes that are the normal counterparts of transforming viral oncogenes.

***ras* gene** A family of genes that encode similar cell membrane-bound proteins involved in signal transduction. Three types, *K-ras, N-ras,* and *H-ras*, are the widely studied ras genes in human tumors. Their proto-oncogene becomes activated by point mutations, most often in specific codons, of the gene sequence.

RB The first tumor suppressor gene to be discovered. It is a 4.7-kilobase gene, located on chromosome 13q14, and encodes a 110,000-dalton nuclear phosphoprotein that suppresses the cell cycle. Absence of *RB* is the cause of retinoblastoma, and research is revealing that it is involved in the pathogenesis of many other neoplasms.

Reverse transcriptase An enzyme discovered in retroviruses that has the unique ability to transcribe DNA from an RNA template. This is the reverse of the normal physiologic process.

***Tp53* gene** A tumor suppressor gene that encodes a nuclear phosphoprotein that arrests cells from entering the S-phase of the cell cycle. Located on chromosome 17(p13), *Tp53* is postulated to contribute to diverse tumorigenesis.

Transcription The process of converting the DNA code into a complementary mRNA segment.

Translation The process by which specific amino acids are incorporated into a protein as dictated by the sequence of the mRNA template.

Translocation Nonhomologous recombination.

Tumor suppressor gene A gene that suppresses cellular growth and proliferation. Therefore, when its protein products are absent, it contributes to tumor development or progression. Also known as antioncogenes, these normal cellular genes encode proteins that are thought to normally regulate growth in a negative fashion.

Uninformative The term used to describe the situation when the two homologous chromosomes from an individual cannot be distinguished from one another at a given locus; *homozygous* is an alternative term.

Vector A DNA vehicle that can be propagated in living cells (eg, bacteria and yeast) into which foreign DNA can be inserted and propagated with the vector DNA. Examples of vectors include bacterial plasmids; cosmids; bacteriophages; and, most recently, yeast artificial chromosomes.

Wild type The term used to describe the normal gene or gene product. In contrast, a gene that has had its DNA sequence altered is referred to as a mutant gene, and its resultant product is a mutant protein. A gene that encodes a proto-oncogene, for example, is a wild-type gene because it is unaltered.

Palliative Care and Quality of Life

Dana M. Chase, MD, Siu-Fun Wong, PharmD, FASHP, FCSHP, Lari B. Wenzel, PhD, Bradley J. Monk, MD

OUTLINE

Evolution of Palliative Care
Quality of Life in Gynecologic Cancers
- Quality of Life in Ovarian Cancer
- Quality of Life in Cervical Cancer
- Quality of Life in Endometrial Cancer

Management of Common Physical Symptoms
- Fatigue
- Pain
- Nausea and Vomiting
- Diarrhea and Constipation
- Cachexia and Malnutrition

Psychosocial and Spiritual Needs of Patients and Families
- Strategies for Breaking Bad News and Preserving Hope

Management of Psychosocial and Spiritual Distress
Quality of Life Issues in Advanced and Recurrent Ovarian Cancer
- Pleural Effusions
- Small Bowel Obstruction
- Ascites
- Role of Palliative Surgical Procedures

Quality of Life Issues in Advanced and Recurrent Uterine and Cervical Cancer
- Ureteral Obstruction
- Fistula
- Sexual Dysfunction
- Anxiety and Depression

End-of-Life Decision Making
- Patient Benefit
- Patient Self-determination
- Legal Developments That Have a Bearing on End-of-Life Decision Making
- Surrogate Decision Making
- Futility
- Hospice

KEY POINTS

1. Palliative care is interdisciplinary care that seeks to prevent, relieve, or reduce the symptoms of a disease without affecting a cure.
2. Certain treatments may not result in improved survival but may result in decreased symptoms. Clinical trials have therefore begun measuring quality of life (QoL).
3. Other QoL measures include survivorship. That is the process of helping the patient have the highest QoL after treatment.
4. Often pain associated with cancer is undertreated. Other symptoms, especially psychological ones, are often ignored or not recognized.
5. A multidisciplinary team is required to recognize and care for this aspect of cancer care and includes social workers, pastoral care, nutritionists, oncologists, pain specialists, psychologists, physical therapists, and caseworkers.
6. Palliative care is an important emerging field in cancer care.

EVOLUTION OF PALLIATIVE CARE

Once viewed as limited and focused care during the final days of life, the scope of palliative medical care and quality of life (QoL) research has evolved since the 1990s. **Although several definitions of palliative care exist, it is broadly defined as interdisciplinary care that seeks to prevent, relieve, or reduce the symptoms of a disease or disorder without affecting a cure.** "Palliative care" and the related term "palliative medicine" are being used with increasing frequency in the United States and have become the labels of choice throughout the world to describe programs based on the hospice philosophy. When approaching death, including care at the end of life, the Institute of Medicine (IOM) recommends: "Palliative care should become, if not a medical specialty, at least a defined area of expertise, education and research."

Palliative care overlaps with "terminal care," "death and dying," "hospice," "end-of-life care," "comfort care," and "supportive care." The term "supportive care," which is often used by oncologists, is particularly ill defined and sometimes refers to comfort care or palliative support of critically ill patients, particularly those suffering from the adverse effects of cancer treatment. All of these terms have a number of meanings and are often unfamiliar to clinicians. They outline the relationships of health care professionals with patients and family members during the terminal stages of life and the treatment of advanced malignancies (Table 20.1)

TABLE 20.1 Issues in Palliative and End-of-Life Care

Emphasis on the trajectory
Symptom control and psychological support
Comprehensive assessment
Cancer pain management
Communicating effectively

Withdrawing and withholding therapy
Advanced care planning
Cancer doctors and burnout

TABLE 20.2 Improving End-of-Life Care: Recommendations of the Institute of Medicine

1. Reliable and skilful supportive care
2. Effective use of knowledge to prevent and relieve pain and other symptoms
3. Policymakers, consumers, health practitioners, and organizations:
   - Measure quality of life (QoL) and other outcomes.
   - Develop tools for improving QoL and hold health care organizations accountable.
   - Revise payment mechanisms to encourage good end-of-life care.
   - Reform laws and regulations that impede effective use of opioids.
4. Change medical education to ensure relevant attitudes, knowledge, and skills.
5. Recognition of palliative care as a defined area of expertise, education, and research
6. Research establishment to strengthen knowledge base.
7. Promote public education.

Barriers to Optimal End-of-Life Care Identified by the American Society of Clinical Oncology

1. Inappropriate attitudes of health care professionals and patients (eg, reluctance to discuss death and dying)
2. Ineffective communication about the prognosis
3. Unrealistic expectations and treatment options
4. Failure of physicians to recognize and emphasize the importance of symptom management and psychosocial support
5. Social attitudes (eg, fear of opioid addiction)
6. Economic barriers, including lack of universal access to care and underfunding of end-of-life care
7. Fear of the attending physician losing control of the patient's care; hospice teams to work more closely with attending physicians
8. Lack of systematic education for physicians about clinical and psychosocial aspects of care

Modified from the Institute of Medicine's Report and ASCO Task Force.

QoL is a concern in all areas of medicine and of primary importance in the palliative care setting. Within the clinical setting, assessment of a patient's QoL begins with an understanding of a patient's knowledge about his or her condition and potential management strategies, his or her values, and his or her personal cost–benefit calculations. **Certain therapies have no chance of improving survival endpoints but may have an acceptable therapeutic index based on a reasonable balance between the toxicity of the intervention and the resolution of symptoms secondary to the condition being treated. With this concept in mind, investigators and clinicians have begun to collectively measure QoL in clinical trials and community-based practices in an attempt to define alterations in QoL and to prospectively ascertain interventions that might improve "survivorship."** It is no longer appropriate to simply survive one's illness; rather, one must avoid the "killing cure," allowing patients to enjoy life and function productively while interacting with their environment during multimodality cancer treatment.

The gynecologic oncologist is in a unique position to function collectively as a primary care provider, surgeon, radiation oncologist, and chemotherapist, allowing comprehensive transfer of treatment with an emphasis on the patient's QoL. Reports from the Institute of Medicine's Committee on Care at the End of Life and the American Society of Clinical Oncology (ASCO) Task Force on Cancer Care at the End of Life, both published in 1998, clearly acknowledge the physician's responsibility in caring for patients throughout the continuum of their illness (Table 20.2). The ASCO document asserts: "In addition to appropriate anti-cancer treatment, comprehensive care includes symptom control and psychosocial support during all phases of life."

In addition, in 2015, the Society of Gynecologic Oncology has published recommendations regarding improving the quality and cost of gynecologic oncology practice. These recommendations include prompt referral to palliative care services for advanced and recurrent gynecologic cancer patients. In addition, the recommendations discourage the use of unnecessary chemotherapy and surgery close to the end of life in these patients because research has shown an alarmingly high percentage of patients receiving these procedures within the last 6 months of life. Furthermore, multiple studies have indicated that trainees are not adequately prepared in the realm of palliative care support for gynecologic cancer patients.

Gynecologic oncologists are not only faced with the challenge of providing end-of-life care, but they must also explore ways to integrate palliative care throughout the continuum of illness. Indeed, recent literature suggests that gynecologic oncologists recognize the growing importance of their role as the patient's disease progresses. It is in this role, when the challenges of effective, compassionate care and communication are heightened, that an understanding of the principles and the clinical practice of palliative medicine are critical. A review of the recommendations for and barriers to effective palliative and end-of-life care as outlined by the Institute of Medicine and ASCO is listed in Table 20.2.

Palliative care is differentiated from other medical specialties by its fundamental philosophy of care delivery; care is collaboratively provided by an interdisciplinary team prompted by issues and concerns of the patient and family. "Family" as defined by the patient and staff may include friends as well as relatives.

Palliative care is, by definition, care delivered through the coordinated efforts of the team that is collectively confident and skilled when assessing and addressing the physical, psychosocial, and spiritual needs of the patient and family. It differs from more traditional "multidisciplinary" care that is directed by a physician, which allows team members to simply focus on their own areas of expertise. In contrast, the palliative care "intradisciplinary" team recognizes that all information about the patient and family is relevant. Thus, the home health aide or the pharmacist may have a point of view that would be helpful for the care plan. **Common members of these multidisciplinary teams include medical social workers, pastoral care, nutritionists, radiation oncologist, medical oncologist, pain specialists, psychologists, physical therapists, and caseworkers.** Early in the treatment of a gynecologic cancer, side effects of therapy should be anticipated and treated prophylactically. Later, some symptoms may be dealt with without the extensive evaluation associated with the assessment of tumor response or disease status. However, the development of symptoms often indicates disease progression, and appropriate laboratory or radiographic studies may lead to an alteration of treatment. As the cancer progresses, making cytotoxic therapy less likely to be effective, the workup of new symptoms must be tailored to the individual patient based on the prognosis as well as on the desires expressed by the patient and family. In end-of-life care, there is no room for long-term evaluation or a "wait and see" attitude. In fact, within even just 1 day of referral to palliative care services, symptom burden improves for patients. **Data have indicated that the triad of younger age (<50 years), a history of pain, and depression or anxiety can perhaps capture patients that will have higher symptom burden and should perhaps be either watched carefully for palliative care needs or referred early to palliative care services.** Furthermore, QoL improves, depression decreases, and the use of chemotherapy close to death is reduced when patients are introduced at least once to palliative care services during their treatment experience. As a result, control of annoying symptoms may be pursued more aggressively, and management may resemble that given in an intensive care situation but without an extensive diagnostic evaluation. Control of symptoms is not an end in itself, but it should be sought to allow the patient time to optimize QoL and to support the patient in reaching peace with self and closure with important people in the patient's life.

QUALITY OF LIFE IN GYNECOLOGIC CANCERS

QoL varies depending on the gynecologic cancer disease site, stage, and treatment. In ovarian cancer, for example, the majority of patients present in their 60s with advanced metastatic disease. These patients experience a decline of QoL before diagnosis. However, many respond well to treatment, which creates symptomatic improvement, easing the disease burden and therefore improving QoL. Unfortunately, most patients with advanced ovarian cancer have recurrences, and despite poor outcomes, patients are often treated with multiple rounds of chemotherapy. In contrast, patients with cervical cancer overall present at a younger age with minimal symptoms in the earlier stages of disease. However, whether it is fertility-terminating surgery or chemotherapy and radiation, the therapy can be life-altering or toxic. Despite its initial expectation of lower toxicity index, the use of targeted therapy has not yet demonstrated a significant alleviation of the adverse drug event burden as originally intended. These side effects suffered, however, may be acceptable in the event of likely cure. However, in the advanced cases, when these women have recurrences, their already low QoL, combined with new symptoms related to recurrence, makes further treatment difficult in the setting of often ineffective therapy. Furthermore, patients with cervical cancer are often of lower socioeconomic status and present with unique social and emotional challenges, especially in the setting of cancer diagnosis, treatment, and follow-up care. Patients with endometrial cancer are perhaps the most favorable in terms of QoL in that they frequently present in early stage and are often treated with surgery alone. However, their medical comorbidities, including obesity and diabetes, are challenging to address in survivorship.

Quality of Life in Ovarian Cancer

Because the majority of patients with ovarian cancer present in advanced stages, most women enter treatment with some QoL dysfunction likely related to symptom severity at presentation. The study of QoL in ovarian cancer therefore must take into consideration this baseline level of dysfunction and monitor the effect of surgery or chemotherapy. Because the prognosis is generally poor for those with advanced ovarian cancer, the goal of therapy is perhaps to extend life without greatly compromising the patient's QoL. In clinical trials, great attention is now paid to measuring QoL throughout the study of cancer therapeutics. QoL has also been monitored posttherapy to document the needs and deficiencies of these women. In the measurement of QoL, a standardized and validated measure, the Functional Assessment of Cancer Therapy-Ovarian (FACT-O), is frequently used in clinical trials. The FACT-O is a combination of the FACT-G (General) plus additional questions related specifically to ovarian cancer (Tables 20.3 and 20.4). The FACT-G is composed of four subscales: the physical, social/family, emotional, and functional well-being. Patients can answer on a scale of 0 to 4, with 0 being not at all and 4 being very much. In the physical well-being subscale, the patient is asked to elaborate on pain, nausea, and lack of energy and how these physical symptoms affect their life and how bothered by these symptoms the patient is. The social/family well-being subscale addresses the amount of emotional support the patient has from her friends, family, and partner. The emotional well-being subscale targets the patient's feelings and emotions regarding her illness and how anxious she is about dying from this disease. Finally, the functional well-being subscale concerns the patient's ability to function in society, such as her ability to work, sleep, and enjoy life. This subscale looks at the patient's ability to accept illness and move on to live a "normal" life again. In the final section of the FACT-O, there is an additional concerns scale that targets specific symptoms, life-altering changes, and chemotherapy in ovarian cancer. In 2011, Donovan et al. performed a comprehensive review of the QoL literature related to ovarian

TABLE 20.3 TABLE 1 The FACT-G Versus the EORTC QLQ-CS

FACT-G	QLQ-C30
Physical Well-Being	1. Short of breath
1. Lack of energy	2. Pain
2. Nausea	3. Need to rest
3. Trouble meeting the needs of family	4. Trouble sleeping
4. Pain	5. Felt weak
5. Side effects of treatment	6. Lacked appetite
6. Ill feeling	7. Felt nauseated
7. Forced to spend time in bed	8. Vomited
	9. Constipation
Social/Family Well-Being	10. Diarrhea
1. Close to friends	11. Fatigue
2. Emotional support from family	12. Staying in bed or chair
3. Support from friends	13. Strenuous activity
4. Family acceptance of illness	14. Long walk
5. Satisfaction with family communication about illness	15. Short walk
	16. Help with daily functions
6. Feeling close to partner	17. Limited in work or daily activities
7. Satisfaction with sex life	18. Limited in leisure activities
Emotional Well-Being	19. Difficulty concentrating
1. Sadness	20. Feeling tense
2. Satisfaction with coping with illness	21. Worry
3. Losing hope in the fight against illness	22. Irritable
4. Feeling nervous	23. Depressed
5. Worry about dying	24. Difficulty with memory
6. Worry that condition will get worse	25. Physical condition affecting family life
Functional Well-Being	26. Physical condition affecting social life
1. Ability to work	27. Physical condition affecting financial status
2. Work is fulfilling	
3. Enjoying life	
4. Accepting illness	
5. Sleeping well	
6. Enjoying the things I usually do for fun	
7. Content with quality of life

cancer between the years 2000 and 2011. They sought to find the most important symptoms that should be recorded to measure QoL in ovarian cancer trials. **The panel of experts identified the following "core" ovarian cancer symptoms: abdominal pain, bloating, cramping, fear of recurrence or disease progression, indigestion, sexual dysfunction, vomiting, weight gain, and weight loss.** In addition, ovarian cancer–specific symptoms were suggested to be of value in the design of future QoL endpoints: abdominal pain, bloating, cramping, fear of recurrence, indigestion, sexual dysfunction, vomiting, weight gain, and weight loss.

Several prospective randomized trials in the United States have used the FACT-O measure to assess QoL. The Gynecologic Oncology Group (GOG) has used the FACT-O in prospective phase III randomized trials to monitor QoL during various experimental treatment protocols (Table 20.5). The first ovarian cancer GOG trial using the FACT-O was published by Wenzel et al. in 2005. They published the QoL results for a randomized trial of interval secondary cytoreduction in advanced ovarian cancer patients. In this trial (GOG protocol 152), 424 patients were enrolled, and 380 (90%) of these women completed the initial and midtreatment questionnaires. Roughly 80% of the patients continued to complete the measures at the second though fourth assessment points. In this study, a better QoL as measured by the FACT-O was associated with improved overall survival (OS). Although the FACT-O results did not differ between the groups receiving this surgical intervention or not, this trial did emphasize that improvements in QoL existed for women in both arms at 6 and 12 months after therapy.

Notably, an effective treatment regimen demonstrated for women with stage III ovarian cancer that has been optimally surgically debulked is a combination of intraperitoneal (IP) and intravenous (IV) chemotherapy. GOG 172, a phase III trial comparing IP cisplatin and paclitaxel plus IV paclitaxel with IV cisplatin and IV paclitaxel, demonstrated that the IP/IV regimen was associated with the longest median survival time (65.6 months for IP/IV vs. 49.7 months for IV) that has yet been reported in women with optimally debulked stage III ovarian

TABLE 20.5 Prospective Gynecologic Oncology Group (GOG) Trials Including Quality of Life Measurements

Cancer Site	GOG Protocol Number	Study Title
Ovarian	GOG 152 (2005)	A randomized trial of interval secondary cytoreduction in advanced ovarian carcinoma
	GOG 172 (2007)	A randomized trial intravenous paclitaxel and cisplatin versus intravenous paclitaxel, intraperitoneal cisplatin and intraperitoneal paclitaxel in patients with optimal stage III epithelial ovarian carcinoma or primary peritoneal carcinoma
	GOG 218 (2013)	A randomized trial of intravenous carboplatin and paclitaxel with or without bevacizumab
Cervical	GOG 169 (2006)	A randomized trial of cisplatin versus cisplatin plus paclitaxel in advanced cervical cancer
	GOG 179 (2005)	A randomized trial of cisplatin with or without topotecan in advanced carcinoma of the cervix
	GOG 204	A randomized trial of paclitaxel plus cisplatin versus vinorelbine plus cisplatin versus gemcitabine plus cisplatin versus topotecan plus cisplatin in stage IVB, recurrent, or persistent carcinoma of the cervix
	GOG 240	A randomized trial of chemotherapy with or without bevacizumab for advanced or recurrent cervical cancer
Endometrial	GOG 122 (2007)	A randomized trial of whole abdominal irradiation and combination chemotherapy in advanced endometrial carcinoma
	LAP-2	A randomized clinical trial of laparoscopy (scope) versus open laparotomy (open) for the surgical resection and staging of uterine cancer

LAP, long-acting release.

cancer. This statistically significant and clinically meaningful difference between IP and IV chemotherapy prompted a National Cancer Institute (NCI) Clinical Announcement (2006) alerting the public and health professionals to the superiority of IP chemotherapy in the optimal disease setting. However, the superior survival outcomes, demonstrated with the IP regimen in GOG 172, was associated with considerable toxicity, and patients randomized to IP therapy reported significantly worse QoL before cycle 4 (P <0.0001) and at 3 to 6 weeks after treatment (P = 0.0035). However, there were no significant overall QoL differences between regimens 1 year posttreatment. Despite the reported benefits of IP therapy for progression-free survival (PFS) and OS, this study demonstrated physical and functional well-being deficits both during and after therapy in the IP arm. Neurotoxicity and abdominal discomfort were also more prevalent in the IP arm. Although the QoL scores improved over time, specifically at 12 months from initial treatment, this manuscript perhaps prompted physicians to reconsider this treatment modality secondary to toxicity concerns. In addition, IP is a more difficult treatment for the treatment team to administer as well as potentially more toxic. However, ultimately, the QoL differences between regimens were not significant long term. In 2015, Wright et al. looked at the use and effectiveness of IP chemotherapy in 823 women at six different institutions. These authors demonstrate a relatively poor acceptance of IP chemotherapy (<50%) despite published survival advantages. They cite certain factors as potential barriers to IP/IV chemotherapy usage including toxicities, patients' preferences, the inconvenience of administration, potentially higher rates of extraabdominal cancer recurrences, and beliefs that other chemotherapy regimens may be comparable with fewer toxicities. This study did demonstrate improved survival advantages, but IP chemotherapy usage is associated with younger age and fewer medical comorbidities, thus perhaps explaining the less than 50% adoption of this route of treatment.

In 2009, von Gruenigan et al. combined the results from the above described trials and reported the specific line items in the FACT-O that were reported between cycles. For example, the authors report significant differences in concerns such as pain, nausea, feeling ill, and side effects of treatment. Because significant functional well-being deficits were also reported, they suggest interventions aimed at specific side effects as a means to improve patients' functional status. Social well-being went relatively unharmed except for satisfaction with one's sex life. Emotional deficits were also noted across all items except for acceptance of illness. This study demonstrated that when broken down into individual line items, perhaps interventions can be designed to target improvement in these various areas. In 2013, Monk et al. reported on the QoL outcomes of a randomized trial incorporating bevacizumab into the carboplatin and paclitaxel IV chemotherapy. This study included a maintenance of bevacizumab versus placebo for a total of 22 cycles (treatment given every 3 weeks). During the initial chemotherapy phase of six cycles of carboplatin and paclitaxel, the patients on bevacizumab experienced significantly lower QoL scores (worse QoL) than those on chemotherapy alone. It was curious that bevacizumab compromised QoL during the chemotherapy phase only of treatment. Most striking, though, is perhaps the idea that extending PFS did not translate into enhanced QoL according to the authors. However, although QoL was not improved, the authors use the QoL data to conclude that this new regimen is an acceptable alternative to standard care.

Several European studies have also evaluated QoL in prospective trials. Although these studies use different QoL tools, it is important to comment on some of these studies in which QoL data in the United States are lacking. First, in 2010, Vergote et al. published the results of a randomized trial of neoadjuvant chemotherapy followed by interval surgical cytoreduction versus primary surgical debulking followed by chemotherapy. The QoL results were then published in 2013. Per the authors, QoL was assessed by the European Organization for Research and Treatment of Cancer (EORTC) Quality of Life Questionnaire Module-C30 (QLQ-C30) core questionnaire version 3, which consists of a global health status and QoL scale,

multi-item functional scales and symptom scales, and a scale regarding financial difficulties. The trial results demonstrated similar OS outcomes between the two groups. The authors chose to limit inclusion to the QoL analysis to institutions with at least 50% compliance and more than at least 35% during the follow-up period. There were no statistically significant differences between the two groups, although those with the primary debulking group at baseline had more pain but less dyspnea.

In addition, the AURELIA trial studies the use of physician's choice chemotherapy with or without bevacizumab in platinum-resistant recurrent ovarian cancer. Using the EORTC Quality of Life Questionnaire–Ovarian Cancer Module 28 (EORTC QLQ-OV28) and Functional Assessment of Cancer Therapy–Ovarian Cancer symptom index (FOSI), the investigators demonstrated that with the use of bevacizumab, there was greater than 15% improvement in QoL and abdominal or gastrointestinal (GI) symptoms specifically. The CALYPSO trial was another European trial that randomized patients with platinum-sensitive ovarian cancer to carboplatin and pegylated liposomal doxorubicin versus carboplatin and paclitaxel. The QoL results, published in 2012, were generated by the EORTC QoL-QC30 questionnaire and OV28 ovarian cancer module. In this trial, patients treated with carboplatin and pegylated liposomal doxorubicin had improved QoL scores and fewer cancer- and chemotherapy-related symptoms. This study, although designed as a noninferiority trial, did suggest that improved outcomes with the experimental arm were not at the expense of decreased QoL

Quality of Life in Cervical Cancer

Although patients with cervical cancer may present with pelvic pain or bleeding (or both) in more advanced stages, cervical cancer may also be detected based on screening tests alone. The usual treatment involves surgery for early stage followed by possible radiation, chemotherapy, or both for high-risk cases versus chemotherapy and radiation alone for more advanced stages. **Patients with cervical cancer present with a unique set of symptoms, side effects from treatment, and socioeconomic issues not seen in patients with ovarian cancer. For example, these women have a lower median age at presentation; this group also has a larger percentage of Latina or nonwhite patients and a larger percentage of lower income patients. Furthermore, the chemotherapy and specifically the radiation received by these women produce such symptoms as sexual dysfunction and urinary and bowel dysfunction that perhaps affect women in unique ways.**

In the measurement of QoL for cervical cancer, there are, similar to ovarian cancer, two tools that are most widely used, the FACT-Cx and the QLQ-CX24. The FACT-Cx is composed of the same physical, social, functional, and emotional well-being subscales as the FACT-G but in addition it has a seven-item scale for concerns related specifically to cervical cancer. These concerns involve vaginal discharge, bleeding, odor, narrowing or shortening, constipation, and dysuria. The GOG has published studies in advanced cervical cancer that have used the FACT-Cx. These patients have a poor median survival time, typically less than 6 months, and therefore it is still of debate whether or not treatment is futile in this setting. This is especially of concern in such advanced cancer when symptomatology can be debilitating and further aggressive treatment perhaps does more harm than good. This is an ideal patient population to study QoL because if QoL decreases with treatment, then one might argue against treatment in a disease in which OS is so poor.

In 2006, GOG protocol 169 was published by McQuellon et al. and reported QoL endpoints in a randomized trial that compared cisplatin versus cisplatin plus paclitaxel in advanced cervical cancer (see Table 20.5). Despite the impressive deficits in QoL compared with the general population, these two treatment regimens did not differ with regards to QoL. The cisplatin and paclitaxel arms did demonstrate improvements in response rate and PFS; therefore, the QoL data help to promote this regimen. In 2005, the QoL data from GOG 179 were published by Monk et al. This randomized trial studied cisplatin as compared with cisplatin and topotecan in advanced or recurrent cervical cancer cases. The FACT-Cx was used to document QoL between these two regimens in addition to exploring its relation to prognosis. There were statistical differences in QoL between the two regimens, but of interest was the relationship of the FACT-Cx to OS. As the FACT-Cx score increased, so did OS, and this was statistically significant. Finally, in GOG protocol 204, which studied multiple platinum-doublets in this population, it demonstrated again no difference in QoL scores between these regimens. The QoL data were published in 2010, and there were no reported differences among the four regimens. In 2015, Penson et al. reported the QoL results of GOG protocol 240, which introduced bevacizumab into the standard chemotherapy treatment of advanced or recurrent cervical cancer. Using the Functional Assessment of Cancer Therapy—Cervix Trial Outcome Index (FACT-Cx TOI), there were no significant differences in QoL. Thus, despite improved PFS and OS, this did not necessarily translate into improved QoL. The FACT-Cx TOI in this analysis was associated with survival in that for every increment of 10 on the QoL score, hazard of progression or death was also incrementally affected. This same concept of QoL scores at baseline predicting outcomes in QoL analyses has been demonstrated in multiple investigations. In fact, Chase et al. did demonstrate that on several GOG cervical cancer trials, QoL measurement alone at baseline could predict the development of toxicity, including leukopenia, anemia, and GI toxicity. This association remained significant despite controlling for important patient characteristics such as performance status, age, and treatment type. Finally, in a randomized Japanese GOG study of carboplatin and paclitaxel versus cisplatin and paclitaxel in advanced or recurrent cervical cancer, the investigators used hospitalizations as an objective measurement of QoL. The carboplatin arm demonstrated less hospitalization time, which the authors suggest might equal improved QoL of that regimen.

Several other areas within the trajectory of cervical cancer have been explored in relation to QoL. These include preinvasive disease, surgery, radiation therapy, and survivorship. In 2013, a multicenter observational and cross-sectional study of 842 women in the United Kingdom was published. This study

included women without dysplasia and genital warts as well as a spectrum of preinvasive cervical and vulvar disease. QoL assessment indicated a significant negative impact of these diseases on psychosocial well-being, including sexual functioning. Of note, anxiety and depression as well as pain were particularly noteworthy in women with genital warts. These effects on QoL not only persist throughout treatment but are also demonstrated in survivorship. For example, several studies have indicated that long-term effects can include worsening lymphedema and bowel, genitourinary, and sexual function after completion of multimodality treatment including chemotherapy or radiation. In addition, psychosocial functioning is affected in the long term. This prompted researchers to evaluate a program of telephone counseling for cervical cancer survivors. A total of 204 patients were randomized to telephone counseling versus usual care. This study not only demonstrated improvements in depression, gynecologic, and cancer-specific concerns in the intervention group but also demonstrated positive effects on biomarkers for psychosocial stress, with decreased levels of cytokines such as various interleukins. The hope is that research will continue to demonstrate improvements in patient-reported outcomes that can be objectively measured by biomarkers of stress and that ultimately this can link to clinical outcomes.

Quality of Life in Endometrial Cancer

Endometrial cancer usually presents with vaginal bleeding and at an early stage. Treatment is surgical and occasionally involves postoperative chemotherapy, radiation, or both. **Likely because of the less invasive or aggressive treatment, with the majority of patients presenting at an early stage, there are not as many studies that focused exclusively on QoL in patients with endometrial cancer. A Cochrane review published in 2012 but edited in 2015 included trials in advanced or recurrent endometrial cancer. Of the 14 randomized trials reported, no QoL results were identified and thus analyzed.** In fact, in the GOG, there are only two published reports of QoL in patients with endometrial cancer, and there has yet to be an endometrial cancer–specific subscale incorporated into this research. In 2007, Bruner et al. published the results of the QoL components of GOG protocol 122, which compared whole-abdominal irradiation (WAI) and combination chemotherapy in advanced patients with endometrial cancer (see Table 20.5). In this study using the FACT-G in addition to the Fatigue Scale (FS), Assessment of Peripheral Neuropathy (APN), and Functional Alterations due to Changes in Elimination (FACE), QoL was measured before and after therapy. The WAI arm suffered greater deficits in the FS and FACE scores, but these scores somewhat improved over the varying time points. Conversely, the neuropathy scores were worse in the chemotherapy arm. Interestingly, the FACT-G scores did not differ between the two arms at any time point. The data generated in this study provide patients with the risks and benefits of each therapy and can perhaps shed light on whether QoL concerns in patients can overshadow the potential survival benefits of one modality.

In 2009, the QoL data were published from Europe's Post Operative Radiation Therapy in Endometrial Cancer (PORTEC-2) trial, in which patients received external-beam versus vaginal brachytherapy. This study used the QLQ-C30 measure in addition to subscales from the prostate cancer and ovarian cancer module, which included both bowel and bladder symptoms and sexual functioning symptoms from those scales. Despite the lack of significant differences between groups, there was a low level of sexual functioning in the two groups. The vaginal brachytherapy group overall reported better social functioning, fewer bowel symptoms, and less limitation in activity because of these side effects compared with external-beam radiation therapy. These results suggest the use of a treatment modality potentially as effective with less impact on QoL. In another GOG trial, Kornblith et al. published the results of the QoL component of the LAP-2 protocol, which compared patients undergoing laparoscopic staging versus laparotomy. The measures used included the FACT-G as well as a six-item scale consisting of items related to surgical side effects. In addition, they used the Physical Functioning Subscale of the Medical Outcome Study-Short Form (MOS-SF36. PF), which was developed to assess activities of daily living. The differences in QoL between these two groups favored the laparoscopy group, but this difference was modest. The authors very eloquently describe that to spare one patient the short-term QoL decline with laparotomy, 10 patients would have to be offered laparoscopy. In fact, only better body image persisted in the laparoscopy group at 6 months; all other measurements became comparable by that time point. QoL data can be complex in analysis and interpretation but can shed light on misconceptions regarding the benefits of one therapy or intervention over another.

More recently, several endometrial trials have focused on diet and exercise interventions focused on the prevalence of obesity in these patients. A systematic review and meta-analysis of body mass index and QoL in endometrial cancer included four studies with a total of 1362 patients. Indeed, obese endometrial cancer survivors demonstrate poorer physical, social, and role functioning compared with nonobese patients. One hundred patients with posttherapy endometrial cancer stage I to IIIA participated in a 6-month study of a home-based exercise intervention. In this study, the nonobese women demonstrated higher baseline QoL. Although the obese women had fewer improvements in QoL, both the obese and nonobese groups demonstrated some improvements in QoL with this exercise intervention over the period of 6 months.

The SUCCEED trial looked at an intervention of self-efficacy, weight loss, and QoL in obese endometrial cancer survivors. This study included 75 women randomized to usual care versus an intervention. The intervention group demonstrated significant improvements in the Weight Efficacy Life-style questionnaire. Essentially, this questionnaire measures a patient's ability to resist weight gain and maintain healthy lifestyle behaviors. However, the FACT-G differences (QoL measurement tool) between the groups were reported as minimal except perhaps in the fatigue domain. Future trials such as the feMMe or the REWARD trial will look at the incorporation of the intrauterine device, weight loss interventions, and/or metformin in low-risk endometrial cancer patients.

MANAGEMENT OF COMMON PHYSICAL SYMPTOMS

Even when cancer can be treated effectively and a cure or life prolongation achieved, there are always physical, psychosocial, or spiritual concerns that must be addressed to maintain function and to optimize the QoL. Symptoms are a reminder to the patient and caregivers of the cancer and the potentially devastating effects of treatment. **Symptoms related to cancer and its treatment have not attracted much notice in the past when patients and physicians alike felt that pursuing them might detract from the "real" goal of controlling the tumor.** Consequently, symptoms have been taken for granted by the medical profession. Successful and appropriate management of physical symptoms can allow the care team to focus on the psychosocial closure of life and provide the patient an opportunity to participate more fully in the decisions of care and to rebuild or establish stronger relationships with family, friends, and coworkers.

Many physicians and nurses find symptom management in patients with advanced disease to be a frustrating experience because the symptoms may persist or progress. **Although the symptoms are not always completely controlled, acknowledgment of the problem and working toward its relief offer invaluable support to the patient.** Reliance on medical and drug therapies has been the traditional method to control symptoms. There is increasing recognition that nonpharmacologic approaches have significant benefits for individual patients. **Nontraditional approaches such as acupuncture, biofeedback, aromatherapy, massage, and herbal medicine may have a role in the management of symptoms. Each of the following four physical symptoms is addressed in detail: fatigue, pain, nausea and vomiting, and diarrhea and constipation.**

Fatigue

Fatigue is perhaps the most common symptom experienced by patients with gynecologic cancers. Fatigue is the most prevalent (60%–96%) and one of the least understood symptoms that affect cancer patients. Several factors are implicated in the causes of fatigue, for example, anemia, pain, nutrition, insomnia, cognitive dysfunction, and psychological distress. Fatigue has been reported by gynecologic patients as severe, distressing, and uncontrollable. Unfortunately, cancer-related fatigue is not relieved by rest and might not improve posttherapy. **Patients have identified fatigue with cancer as the major obstacle to normal functioning and good QoL.** Although almost a universal symptom of patients undergoing primary antineoplastic therapy or treatment with biologic response modifiers, it is also extremely common in populations with persistent or advanced cancer. Perhaps this is the result of inadequate attention on the part of health care professionals coupled with patients' reluctance to discuss their fatigue.

Given the prevalence and impact of cancer-related fatigue, there have been remarkably few studies of the phenomenon. Its epidemiology has been poorly defined, and the variety of clinical presentations remains anecdotal. Perhaps this is secondary to the inability of fatigue to be measured in any way other than subjectively. The existence of discrete fatigue syndromes linked with predisposing factors or potential etiologies has not been confirmed, and clinical trials to evaluate putative therapies for specific types of cancer-related fatigue are almost entirely lacking.

Patients and practitioners can generally differentiate the "normal" fatigue experienced by the general population from the clinical fatigue associated with cancer or its treatment. The term "asthenia" has been used to describe fatigue in oncology patients but has no specific meaning apart from the more common term. This condition is inherently subjective and multidimensional. Typically, it develops over time and is characterized by diminishing energy, mental capacity, and the psychological condition of cancer patients (Table 20.6). It is also linked with lethargy and malaise in the revised National Cancer Institute Common Toxicity Criteria. These classifications may enhance awareness of fatigue and improve reporting of the condition.

When fatigue is primarily related to a treatment, there is generally a clear temporal relationship between the condition and the intervention. In patients receiving cytotoxic chemotherapy, for example, it often peaks within a few days and declines into the next treatment cycle. **During the course of fractionated radiotherapy, it is often cumulative and may peak over a period of weeks.** Occasionally, it persists for a prolonged period beyond the end of chemotherapy or radiation treatment. The relationship between fatigue and demographic characteristics, physiologic factors, and psychosocial factors is

TABLE 20.6 Proposed Criteria for Cancer-Related Fatigue

The following symptoms commonly present almost daily during the same 2-week period in the past month:

- Significant fatigue, diminished energy, or increased need to rest disproportionate to any recent change in activity level

Plus five (or more) of the following:

- Complaints of generalized weakness or limb heaviness
- Diminished concentration of attention
- Decreased motivation or interest in engaging in usual activities
- Insomnia or hypersomnia
- Experience of sleep as unrefreshing or nonrestorative
- Perceived need to struggle to overcome inactivity
- Marked emotional reactivity (eg, sadness, frustration, or irritability) when feeling fatigued
- Difficulty completing daily tasks attributed to feeling fatigued
- Perceived problems with short-term memory
- Postexertional malaise lasting several hours
- The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning
- There is evidence from the history, physical examination, or laboratory findings that the symptoms are a consequence of cancer or cancer-related therapy
- The symptoms are not primarily a consequence of a comorbid psychiatric disorders, such as major depression, somatization disorder, or delirium

not well defined. The specific mechanisms that precipitate or sustain the syndrome are unknown. **Fatigue may present a final common pathway to which many predisposing or etiologic factors contribute** (Table 20.7). The pathophysiology in any individual may be multifactorial. Proposed mechanisms include abnormalities in energy metabolism related to increased nutritional requirements (eg, caused by tumor growth, infection, fever, or surgery), decreased availability of metabolic substrate (eg, caused by anemia, hypoxemia, or poor nutrition), or the abnormal production of substances that impair metabolism or normal function of muscles (eg, cytokines or antibodies). Other proposed mechanisms link fatigue to the pathophysiology of sleep disorders and major depression. Further research is necessary to determine mediating mechanisms and optimal interventions.

A detailed characterization of fatigue combined with an understanding of the most likely etiologic factors is necessary to develop a therapeutic strategy (Fig. 20.1). The initial approach to fatigue should involve a screening tool. The recommended screen for cancer-related fatigue begins with a simple question: How would you rate your fatigue on a scale of 0 to 10 over the past 7 days? The score generated from this scale can drive the approach to treatment. A score of 0 to 3 is considered mild, 4 to 6 moderate, and greater than 6 severe. Those in the moderate to severe range should be evaluated immediately, but mild fatigue may be reevaluated. Evaluation of fatigue can then be approached differently depending on the patient's being in active treatment, remission, or the end of life. Patients screening positive for moderate to severe fatigue should undergo a comprehensive assessment includes the description of fatigue-related phenomena, a physical examination, and a review of laboratory and imaging studies that may allow a possible hypothesis concerning pathogenesis, which, in turn, may suggest appropriate treatment strategies. Patients may describe fatigue in terms of decreased vitality or lack of energy, muscular weakness, dysphoric mood, insomnia, impaired cognitive functioning, or some combination of these disturbances. Although this variability suggests the existence of fatigue subtypes, this has not yet been confirmed. Regardless, the patient's history should clarify the spectrum of complaints and attempt to characterize features associated with each component. This information may suggest specific causes (eg, depression) and influence the choice of therapy. Neurologic and psychological evaluation may also help further clarify potential causes of fatigue in some patients. Other characteristics are similarly important. Onset and duration, for example, distinguish acute and chronic fatigue. Acute fatigue of recent onset is anticipated to end in the near future. Chronic fatigue is persistent for a prolonged period (weeks to months or longer), and it is not expected to remit in a short time. Patients perceived to have chronic fatigue typically require more intensive evaluation as well as a management approach focused on both short- and long-term goals. Other important descriptors of fatigue include the severity, daily pattern, course over time, exacerbating and palliative factors, and associated distress. An assessment of cancer-related fatigue should also include consideration of broader concerns, including global QoL, other symptoms, and disease status. Fatigue may be only one of numerous factors that influence QoL. Among these factors are progressive physical decline, psychological disorders, social isolation, financial concerns, and spiritual distress. Optimal care of the cancer patient includes a broader assessment of these factors and should be directed toward maintaining or enhancing QoL. Successful strategies should ameliorate fatigue within a broader approach of patient care. Evaluation of the patient regarding the nature of fatigue, options for therapy, and anticipated outcomes is an essential aspect of the therapy. **Unfortunately, results of a patient survey indicate that patients and their oncologists seldom discuss fatigue.**

An initial approach to cancer-related fatigue includes efforts to correct potential etiologies, if possible and appropriate. This may include elimination of nonessential centrally acting drugs, treatment of a sleep disorder, reversal of anemia or metabolic abnormalities, or management of major depression. Referring to the National Comprehensive Cancer Network (NCCN) guidelines for the approach to pain, emotional distress, anemia, and nutrition may prove helpful. Perhaps sleep disturbances, interventions aimed at increasing activity levels, and the management of comorbidities may be more straightforward. Many of these initial interventions are relatively simple and pose minimal burdens to the patient, health care provider, and caregiver.

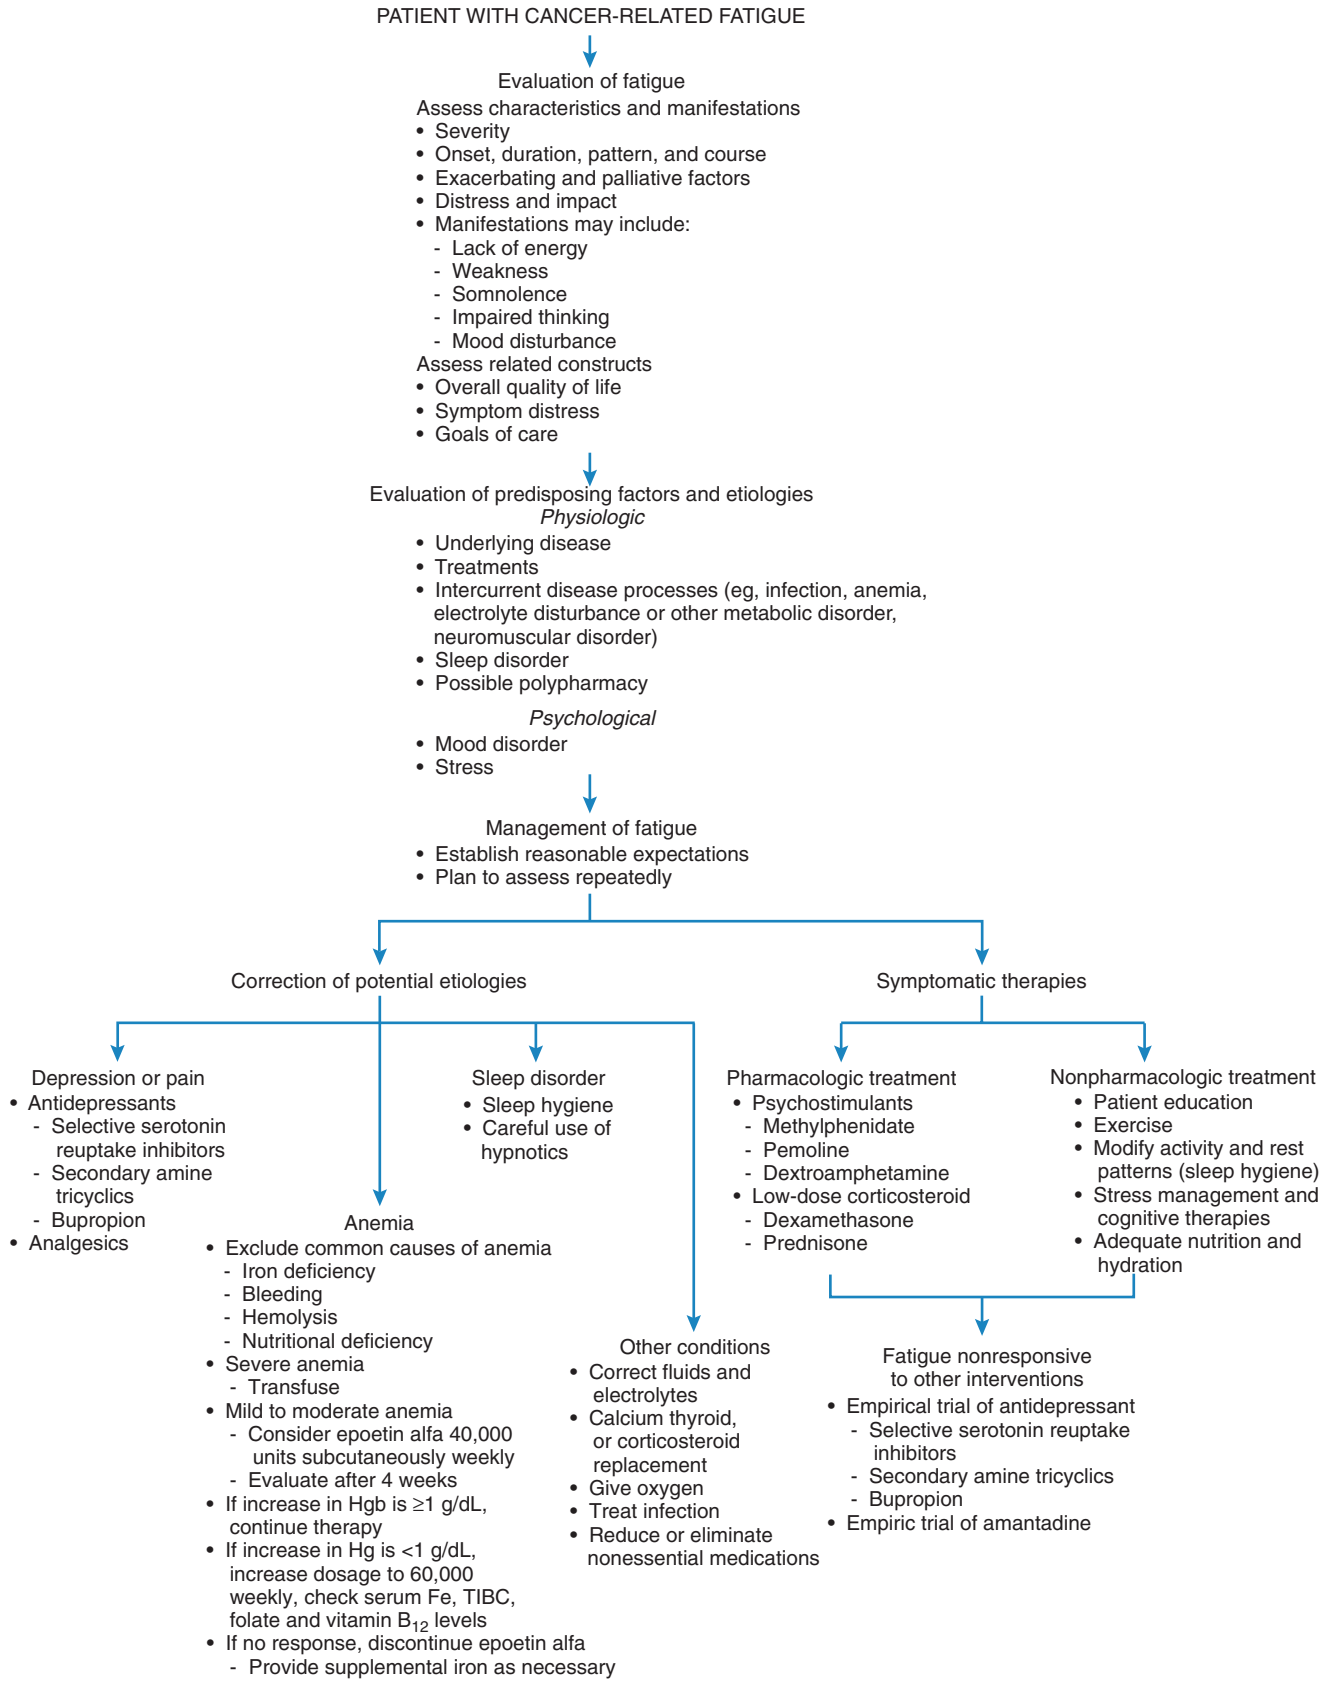

FIGURE 20.1 Evaluation and approach to management of a patient with cancer-related fatigue. *Hgb,* Hemoglobin; *TIBC,* Total iron-binding capacity. (Adapted from Portenoy RK, Itri LM: Cancer-related fatigue: guidelines for evaluation and management. *Oncologist* 1999;4(1):1-10. Copyright 1999 AlphaMed Press. All rights reserved.)

In general, education and counselling are advised in the initial treatment of cancer-related fatigue. Patients and family may be requested to document fatigue levels in a diary or on a scale and to describe associations or exacerbations and timing of the symptom. Similar to the approach to urinary incontinence, patients may be counseled toward behavior modifications or adjustments to help avoid this symptom such as eliminating nonessential potentially "tiring" behaviors that may call for unnecessary expenditure of energy. Conversely, increasing physical activity has been proposed as a treatment for cancer-related fatigue. A Cochrane analysis demonstrated improvements in fatigue with an exercise intervention. Adherence to the US Surgeon General's recommendations for 30 minutes of exercise on most days of the week may thus be advisable for cancer patients in recovery. Physical therapy referrals should be made in certain patients, and caution with activity should be obvious in certain patients such as those with bone metastasis, neutropenia, anemia, thrombocytopenia, or active infection. Therapies such as massage, acupuncture, or psychosocial interventions are also described in the NCCN guidelines.

In patients with fatigue-associated major depression, treatment with an antidepressant is strongly indicated. As many as 25% of cancer patients develop major depression at some point during their illnesses. Patients at greatest risk are those with advanced disease, uncontrolled physical symptoms (eg, pain), or a previous history of a psychiatric disorder. Although the relationship between depression and fatigue is not well understood, they often occur together and both adversely affect QoL. **Despite the high prevalence in the cancer population, depression is often underdiagnosed and consequently undertreated.** A trial with an antidepressant is usually warranted in a patient with fatigue associated with any significant degree of depressed mood and similarly can be therapeutic when concurrent anxiety or pain exists. In addition, brief, focused psychological counseling can be helpful for several reasons when a mood disorder (eg, depression or anxiety) and a physical symptom (eg, pain or fatigue) co-occur. First, counseling offers the patient an opportunity to identify and express her fears, which are often driving the depressed or anxious mood. Second, the depressed or anxious mood can exacerbate existing physical symptoms such as pain. Therefore, provision of counseling has the dual benefit of reducing the mood disorder, which by extension reduces fatigue and pain. Third, brief, focused counseling can offer the patient important behavioral modifications such as time and energy management strategies that permit and teach the patient to conserve energy physically and emotionally for the priorities in their life. This is useful to address the practical challenges associated with fatigue and pain management.

Anemia may be a major factor in the development of cancer-related fatigue. Anecdotally, transfusion therapy for severe anemia has often been associated with substantial improvement in fatigue. Compared to other cancers, gynecologic cancers are especially known for being associated with severe anemia, with hemoglobin levels less than 9.9 g/dL in many cases. Not only does anemia have a significant correlation with poor performance status, but it may also be implicated in tumor sensitivity to radiation and chemotherapy. It has been suggested that an optimal oxygen level for tumors to respond to therapy is reflected by a hemoglobin level between 12 and 14 g/dL. However, recent data of increased risk of thrombotic event associated with hemoglobin level higher than 12 g/dL should be taken into consideration.

New data demonstrate the association between chemotherapy-induced mild to moderate anemia and both fatigue and QoL impairment. For example, combined data from 413 patients and three randomized placebo controlled trials of epoetin alfa, the recombinant form of human erythropoietin (EPO), reveal that treated patients experienced a significant increase in hematocrit, a reduced need for transfusion, and a significant improvement in overall QoL. Patients with an increase in hematocrit of greater than 6% also demonstrated significant improvement in energy level and daily activities. Additional studies in patients treated with chemotherapy and radiation therapy for various gynecologic tumors confirm that epoetin alfa has positive effects on hemoglobin levels. Two large, prospective, randomized, multicenter community trials have demonstrated that patients experience significant improvement in energy levels, activity level, functional status, and overall QoL when epoetin alfa is administered as an adjunct to cytotoxic chemotherapy.

Blood transfusion is an option for the treatment of cancer-related anemia; however, transfusions are associated with poor outcomes and QoL caused by infections, allergies, or dependence on medical centers. For those reasons, many practitioners rely on growth factors, including epoetin alfa (rHuEPO—Epogen or Procrit) or darbepoetin alfa (Aranesp), to treat anemia. Kurz et al. concluded that rHuEPO increases hemoglobin levels and decreases transfusions in patients with gynecologic malignancies undergoing polychemotherapy without compromising QoL. It has even been suggested that rHuEPO may be given prophylactically in older patients (>65 years) and those with baseline hemoglobin levels of less than 10.5 g/dL who are going to be given chemotherapy consisting of carboplatin and paclitaxel. Although Aranesp has a longer half-life and therefore may be given less frequently, there are few clear advantages compared with Procrit. Unfortunately, this therapy is not without risks, and there are concerns that the risk of venous thromboembolism (VTE) is increased for these patients. Results from meta-analyses from 2008 to 2013 indicated an association between increased risk of thrombotic events and erythropoiesis-stimulating agents (ESA) usage with statistically significant risk and odds ratios ranging from 1.48 to 1.69. The increased risk for thromboembolism in patients with cancer became a black box warning in the updated Food and Drug Administration (FDA) labels and subsequently as part of the Risk Evaluation and Mitigation Strategy (REMS). The increase FDA restrictions stemmed from eight randomized studies showing a decrease in OS or decreased locoregional disease control with EPO usage, including a cervical cancer study. More recently, research has shown that survival may be decreased in women receiving rHuEPO for correction of anemia for hemoglobin levels over 12 g/dL. Therefore, currently, patients with

cancer may be counseled about the risks and benefits of the use of growth factors for the correction of anemia.

The NCCN and ASCO guidelines recommends that EPO should not be recommended to patients who are receiving myelosuppressive chemotherapy with curative intent. Patients who are undergoing palliative treatment may receive EPO under REMS guidelines and with the informed consent of the patient. Many of the pharmacologic therapies for fatigue associated with medical illness have not been rigorously evaluated in controlled trials. Nonetheless, there is evidence to support the use of several drug classes. Psychostimulants, such as methylphenidate and dextroamphetamine, have been well studied for the treatment of opioid-related somnolence and cognitive impairment and depression in elderly and medically ill patients. There are no controlled studies of these drugs for cancer-related fatigue, but empiric administration may yield favorable results in some patients. The national guidelines, however, are cautious in their suggestion of these interventions.

A clinical response to one drug does not necessarily predict a response to the others, and sequential trials may be needed to identify the most beneficial therapy. Methylphenidate has been more extensively evaluated in the cancer population than other stimulant drugs and is often the first drug to be administered. It is available in a chewable formulation that can be absorbed through the buccal mucosa for patients who are unable to swallow or take oral medications.

Adverse effects associated with the psychostimulants include anorexia, insomnia, tremulousness, anxiety, delirium, and tachycardia. To ensure safety, slow and careful dose escalation should be undertaken to minimize potential adverse effects. A regimen of methylphenidate, for example, usually begins with a dose of 5 to 10 mg once or twice daily (morning and, if needed, midday). If the drug is tolerated, the dose is increased. Most patients appear to require less than 60 mg/day, but some require much higher doses.

Extensive anecdotal observations and very limited data from controlled trials support the use of low-dose corticosteroid therapy in fatigued patients with advanced disease and multiple symptoms. Dexamethasone and prednisone are most commonly used. There have been no comparative trials.

The selective serotonin reuptake inhibitors, secondary amine tricyclics (eg, nortriptyline and desipramine), and bupropion are sometimes associated with the experience of increased energy that appears disproportionate to any change in mood. For this reason, these agents have also been tried empirically in nondepressed patients with fatigue. Given the limited experience in the use of these drugs for this indication, an empirical trial should be considered only in severe and refractory cases.

Amantadine has been used to treat fatigue in patients with multiple sclerosis, but it has not been studied in other patient populations. This drug is usually well tolerated, and an empirical trial may be warranted in selected patients with severe refractory cancer-related fatigue.

Nonpharmacologic approaches for the management of cancer-related fatigue are supported mainly by favorable anecdotal experience (Table 20.8). Patient preferences should be considered in the selection of one or more of these approaches. In particular, sleep hygiene principles should be tailored to the individual patients and might include the establishment of a specific bedtime, awake time, and routine procedures before sleep. Patients should also be instructed to avoid stimulants and central nervous system (CNS) depressants before going to sleep. Whereas regular exercise performed at least 6 hours before bedtime may improve sleep, napping in the late afternoon or evening may worsen it.

Cancer and its treatment can also interfere with dietary intake. With aggressive approaches to management, the patient's weight, hydration status, and electrolyte balance should be monitored and maintained to every extent possible. Regular exercise may improve appetite and increase nutritional appetite. Referral to a dietitian for nutritional guidance and suggestions for nutritional supplements may be useful.

The NCCN cancer-related fatigue guidelines were recently updated. This update includes further emphasizing the incorporation of fatigue as a cancer patient's "vital sign." Specific attention should now be paid toward improving sleep hygiene and enhancing the education of family members on cancer-related fatigue. In summary, the strategy aimed at combating fatigue should include physical activity, psychosocial interventions (ie, mindfulness-based therapy), nutrition counselling, and sleep interventions. Pharmacologic interventions such as psychostimulants can be used, but particular attention toward medications to address comorbidities, sleep, pain, anemia and mood is considered important.

TABLE 20.8 Nonpharmacologic Interventions for the Management of Cancer-Related Fatigue

Patient Education
Consider the patient's preferences, education level, and readiness to learn
Use of a patient's diary

Exercise
Individualize exercise program
Use of rhythmic and repetitive types of exercise
Initiate gradually

Modification of Activity and Rest Patterns
Assess sleep hygiene
Establish routine sleep patterns
Avoid use of stimulants before sleep
Regular exercise

Stress Management and Cognitive Therapies
Use of stress reduction techniques or cognitive therapies
Use of relaxation therapy, hypnosis, or distraction
Adequate nutrition and hydration
Proper diet
Monitor weight and hydration status regularly
Referral to a dietitian

Pain

Cancer pain can be managed effectively through relatively simple means in up to 90% of the 8 million Americans who have cancer or a history of cancer. Unfortunately, pain associated with cancer is often undertreated. Although cancer pain or associated symptoms cannot always be eliminated, proper use of available therapies can effectively relieve pain for most patients. Management of pain extends beyond pain relief and encompasses the patient's QoL and the ability to work productively, to enjoy recreation, and to function normally in the family and society.

State and local laws often restrict the medical use of opioids to relieve cancer pain, and third-party payers may not reimburse for noninvasive pain control treatments. Thus, clinicians should work with regulators, state cancer pain initiatives, and other groups to eliminate these health care system barriers to effective pain management (Table 20.9).

Flexibility is the key to management of cancer pain. Thorough discussions with the patient and their families encouraging them to be active in pain management are critical (Table 20.10). Patients often need reassurance to report pain because effective treatment strategies exist. Failure to assess pain is a critical factor leading to undertreatment. Thus, a simple screening tool should be used to inquire about the patient's pain level. This is described as "universal screening" by the NCCN. The goal of the initial assessment of pain is to characterize the pain by location, intensity, and etiology. This can be accomplished through a detailed history, physical examination, social assessment, and diagnostic evaluation. The mainstay of pain assessment is patient self-reporting. To enhance pain management across all settings, clinicians should teach patients to use pain assessment tools in their homes. Clinicians should listen to the patient's descriptive words about the quality of the pain, inquiring about its location, severity, and aggravating or relieving factors and the patient's cognitive response to the discomfort. Finally, goals for pain control should be clear with active engagement of the patient in the decision process. Continued assessment of cancer pain is crucial. **Changes in pain patterns and the development of new pain should trigger diagnostic evaluation and modification of the treatment plan.** Persistent pain indicates the need to consider other etiologies (eg, related to disease progression or treatment, and alternative—perhaps more invasive—treatment; Fig. 20.2). Pain related to an oncologic emergency should be addressed immediately. This includes pain resulting from a bone fracture or impending fracture, brain or epidural metastases, infection, or obstructed or perforated viscous.

Drug therapy is the cornerstone of cancer pain management. It is effective, relatively low risk, and inexpensive and usually works quickly. Even within the same family of analgesic drugs, individual variations in tolerability and side effects are well recognized. Recommendations for pharmacologic therapy begin with the World Health Organization (WHO) ladder (Fig. 20.3), a three-step hierarchy for analgesic pain management. Substitution of drugs within a category should be tried before switching therapy. The simplest dosage and schedule as well as the least invasive pain management modality should be attempted first. For mild to moderate pain, nonsteroidal antiinflammatory drugs (NSAIDs) (WHO ladder step 1) are often effective (see Table 20.10). When pain persists or increases (Table 20.11), opioids can be added (WHO ladder step 2). Moderate to severe pain requires opioids of higher potency and dose (WHO ladder step 3) (Table 20.12). **Dosing should be on a regular schedule (ie, "by the clock") to maintain a level of drugs that would help prevent the recurrence of pain.** Ask for patient and family cooperation in establishing the effective level when administering medications to prevent long-term cancer pain on an around-the-clock basis with additional doses ("as needed" and usually required).

TABLE 20.9 Barriers to Cancer Pain Management

Problems related to health care professionals
Inadequate knowledge of pain management
Poor assessment of pain
Concern about regulation of controlled substances
Fear of patient addiction
Concern about side effects of analgesics
Concern about patients becoming tolerant to analgesics
Problems related to patients
Lack of cultural competency and communication
Reluctance to report pain
- Concern about distracting physicians from treatment of underlying disease
- Fear that pain means disease is worse
- Concern about not being a "good" patient

Reluctance to take pain medications
- Fear of addiction or of being thought of as an addict
- Worries about unmanageable side effects
- Concern about becoming tolerant to pain medications

Problems related to the health care system
Low priority given to cancer pain treatment
Inadequate reimbursement
- The most appropriate treatment may not be reimbursed or may be too costly for patients and families.

Restrictive regulation of controlled substances
- Problems of availability of treatment or access to it

Adapted from U.S. Department of Health and Human Services. *Management of Cancer Pain: Adults.* Washington, DC, 1994, Author.

TABLE 20.10 Recommended Clinical Approach

A Ask about pain regularly.
Assess pain systematically.
B Believe the patient and family in their reports of pain and what relieves it.
C Choose pain control options appropriate for the patient, family, and setting.
D Deliver interventions in a timely, logical, coordinated fashion.
E Empower patients and their families.
Enable patients to control their course to the greatest extent possible.

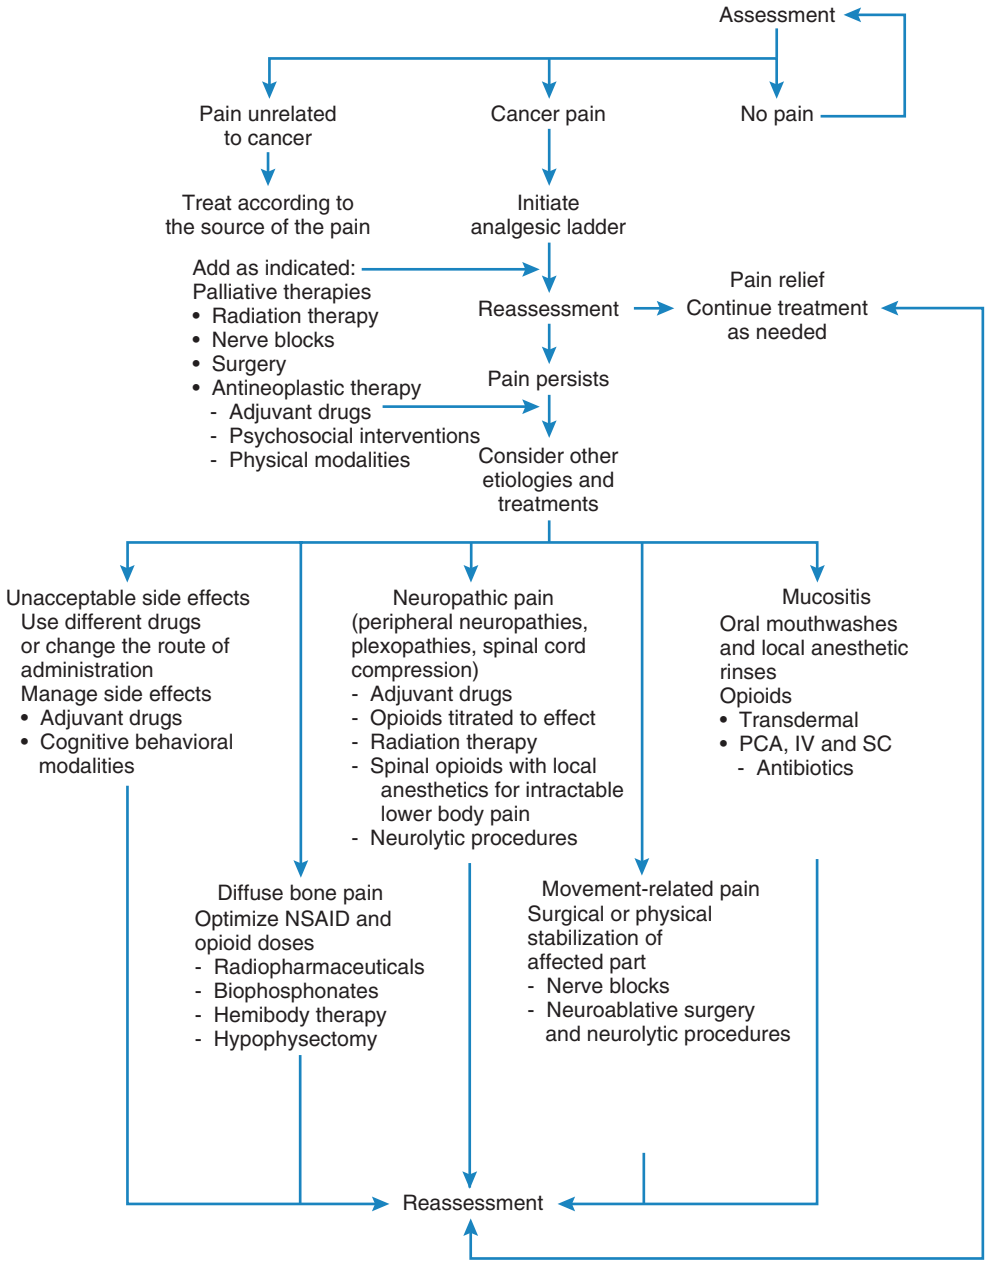

FIGURE 20.2 Continuing pain management. *IV,* Intravenous; *NSAID,* nonsteroidal antiinflammatory drug; *PCA,* patient-controlled analgesia; *SC,* subcutaneous. (Adapted from U.S. Department of Health and Human Services. *Management of Cancer Pain: Adults.* Washington, DC, 1994, Author.)

Oral administration is preferred because it is convenient and usually cost effective. When patients cannot take oral medications, other less invasive (eg, rectal or transdermal) routes should be offered. Parenteral methods should be used only when simpler, less demanding, less costly methods are inappropriate or ineffective. An assessment of the patient's response to several different oral opioids is usually advisable before abandoning the oral route in favor of parenteral, neurosurgical, or other invasive approaches. Rectal administration is a safe, inexpensive, and effective route for the delivery of opioids as well as nonopioids when patients have nausea or vomiting. Rectal administration is inappropriate for patients who have diarrhea, anal or rectal involvement, or mucositis; are neutropenic or thrombocytopenic; are physically unable to place the suppository in the rectum; or who prefer other routes. Transdermal administration is also feasible but does not allow rapid dose titration. Patient-controlled analgesia (PCA) devices can be used both on an inpatient or outpatient basis. The opioid may be administered orally or via a dedicated portable pump to deliver the drug intravenously, subcutaneously, or epidurally (intraspinally). Intraspinal administration should be considered for patients who develop intractable pain or intolerable side effects from other routes of administration. Use of this route requires skill and expertise that may not be available in certain

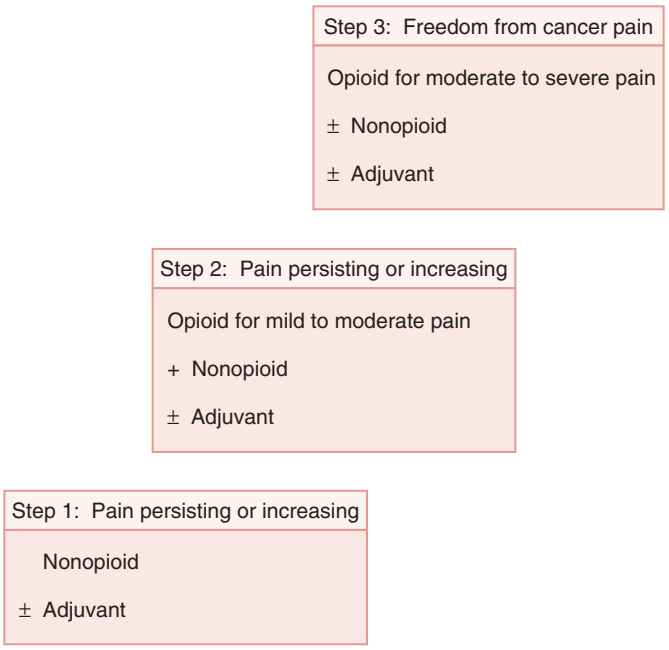

FIGURE 20.3 World Health Organization three-step analgesic ladder. (Adapted from World Health Organization. *Cancer Pain Relief and Palliative Care*. Geneva, Switzerland, 1990, Author.)

settings. Table 20.13 presents the advantages and disadvantages of regional administration. This route is often efficacious because gynecologic tumors often affect the pelvis, making profound analgesia frequently possible without motor or sympathetic blockade. Drugs and routes of administration that are not recommended for the management of cancer pain are summarized in Table 20.14.

The general principles to pain management are described by the NCCN and were updated in 2015. This includes a dose of medication that sustains pain relief for the full time period before the next dose. The dose should be calculated based on the patient's requirements for the previous 24 hours. A sustained dose with an around-the-clock medication should be started in addition to an as needed medication. The around the clock and as needed doses are increased based on the severity of the uncontrolled pain. Of note, noncombination opioid preparations are preferred to eliminate the risk of overdosing acetaminophen or ibuprofen. The "as needed" medication should be about 10% to 20% of the sustained total 24-hour dose. Before converting to a transdermal approach, the pain should be relatively well-controlled by an around-the-clock opioid pain regimen. The maximum fentanyl transdermal dose is 100 mcg/h, but if a patient requires a higher dose, multiple patches may be used. An IV dose of 0.67 mg/day of IV morphine or 2 mg/day of oral morphine is equivalent to 1 mcg/h of transdermal fentanyl. Although the patch lasts typically for 72 hours, cachectic patients, fever, or heat from external sources such as electric blankets may increase the absorption of the transdermal fentanyl and thus may be contraindications to patch use. Some patients may require a new patch every 48 hours. The idea of opioid rotating to decrease cost, intolerance, or a change in the patient's condition is suggested.

Clinicians who follow patients during long-term opioid treatment should watch for potential side effects and administer agents to manage them, and, in some cases, prophylactically. Constipation, as well as nausea and vomiting, both common side effects to opioid analgesics, are discussed later. Drug-induced sedation is common and can be treated by a reduction in opioid dose or use of low-dose CNS stimulants such as caffeine, methylphenidate, dextroamphetamine, or modafinil in the morning or early afternoon may be considered. Patients should also be assured that tolerance may develop over time, especially after an opioid dose escalation. Patients receiving long-term opioid therapy generally develop tolerance to the respiratory depressant effects of these agents. When indicated for reversal of opioid-induced respiratory depression, administration of naloxone is recommended with titration in small increments to improve respiratory function without reversing analgesia. Careful monitoring is mandatory until the episode of respiratory depression resolves. For more subacute respiratory depression, simply withholding one or two doses until the symptoms resolve followed by restarting at 25% of the total dose is often effective. A combination of opioids and NSAIDs is frequently used to optimize cancer pain management, especially in patients with bone and lymphatic involvements. Dry mouth, urinary retention, pruritus, myoclonus, altered cognitive function, dysphoria, euphoria, sleep disturbances, sexual dysfunction, physiologic dependence, tolerance, and inappropriate secretion of antidiuretic hormone are also reported side effects of opioid agents.

Adjuvant drugs are valuable during all phases of pain management to enhance the analgesic efficacy, treat concurrent symptoms, and provide independent analgesia for specific types of pain. These adjuvants include corticosteroids, anticonvulsants, antidepressants, neuroleptics, local analgesics, hydroxyzine, and psychostimulants. Corticosteroids provide a range of effects, including mood elevation, antiinflammatory activity, antiemetic activity, and appetite stimulation, and may be beneficial in the management of cachexia and anorexia. They also reduce cerebral and spinal cord edema and are essential in the emergency management of elevated intracranial pressure and epidural spinal cord compression. Anticonvulsant agents are used to manage neuropathic pain, especially lancinating or burning pain. They should be used with caution when administered to patients undergoing marrow suppressant therapy such as chemotherapy and radiation. Tricyclic antidepressants (TCAs) are useful in the pharmacologic management of neuropathic pain. These drugs have innate analgesic properties and may potentiate the analgesic effects of opioids. Perhaps the most widely reported experience has been with amitriptyline, a tertiary amine, which may be more efficacious but secondary amines (ie, nortriptyline, imipramine) are usually better tolerated. The use of serotonin–norepinephrine reuptake inhibitors such as duloxetine and venlafaxine have increased because of better tolerance. More frequently, anticonvulsants have become more popular, especially with the availability of pregabalin, which has a more desirable side effect profile than the antidepressants and less dizziness than its parent drug, gabapentin.

TABLE 20.11 Dosing Regimens for Acetaminophen and Nonsteroidal Antiinflammatory Drugs*

Medications	Common Proprietary (Trade) Name	Usual Daily Dose (Adults)		Usual Daily Dose or Maximum Dose (Adults)
		Dosage and Route	Frequency	
Acetaminophen	Tylenol, others	325–650 mg PO	q4h	Immediate release: 3250 mg
		650–1000 mg PO	qid	ER: 3900 mg
		650 mg PR	q4h	
SALICYLATES				
Aspirin (acetylsalicylic acid)	Others	600–1000 mg PO	qid	4000 mg
Same for buffered and enteric-coated oral formulations		300–600 mg PR	q4h	
Magnesium salicylates	Doan's, others	650 mg PO	qid	4000 mg
Choline magnesium trisalicylate	Trilisate	500–1000 mg PO	tid	4000 mg
		750–1500 mg	bid	
Diflunisal	Others	500–750 mg PO	bid	1500 mg
Salsalate	Disalcid	750–1500 mg PO	bid	3000 mg
PROPIONIC ACID DERIVATIVES				
Fenoprofen	Nalfon, others	200–600 mg PO	qid	3200 mg
Flurbiprofen	others	50–75 mg PO	qid	300 mg
Ibuprofen (OTC and Rx)	Motrin, Advil, Midol, others	200–800 mg PO	qid	3200 mg
Ketoprofen	Others	25–75 mg PO	tid–qid	300 mg
		200 mg ER PO	daily	200 mg XR
Naproxen	Aleve, Anaprox Naprosyn, EC-Naprosyn, Midol, Pamprin, others	220–500 mg PO	bid–tid	1500 mg
		750–1000 mg ER PO	daily	1000 mg ER
Oxaprozin	Daypro, others	600–1200 mg PO	Daily	1800 mg
ACETIC ACID DERIVATIVES				
Diclofenac	Voltaren, Voltaren-XR, Cataflam, Flector (transdermal), others	50–75 mg PO	bid-tid	200 mg (PO)
		100 mg–XR	Daily–bid	32 g/day total to affected area(s)
		1%–3% patch, Gel, cream, solution (TDS)	bid	
Indomethacin	Indocin, Indomethacin ER	25–50 mg PO	tid–qid	200 mg (both PO and PR)
		75 mg ER PO	bid	150 mg ER
		50 mg PR	bid–tid	
Sulindac	Others	150–200 mg PO	bid	400 mg
Tolmetin	Others	400–600 mg PO	tid	1800 mg
PYRANOCARBOXYLIC ACID				
Etodolac	Others	200–400 mg PO	tid–qid	1000 mg
		400–600 mg ER PO	Daily–bid	1200 mg ER
PYRROLIZINE CARBOXYLIC ACID				
Ketorolac	Sprix (intranasal), Others	10 mg PO	qid	40 mg
		15.75 mg/nostril	tid–qid	126 mg (intranasal)
		15–30 mg IM/IV	qid	120 mg–IM/IV
FENAMATES (ANTHRANILIC ACIDS)				
Meclofenamate	Others	50–100 mg PO	tid–qid	400 mg
Mefenamic acid	Ponstel, others	250 mg PO	qid	not established
ENOLIC ACID DERIVATIVES				
Meloxicam	Mobic, others	7.5–15 mg PO	daily	15 mg
Piroxicam	Feldene, others	10-20 mg PO	daily	20 mg
NAPHTHALAKANONE				
Nabumetone	Others	1000–2000 mg PO	daily	2000 mg
COX-2 SELECTIVE AGENT				
Celecoxib	Celebrex, others	50–200 mg	daily-bid	Not established

*Most nonsteroidal antiinflammatory drugs have negligible hepatic metabolism, except for etodolac, ketorolac, nabumetone, oxaprozin, and meloxicam. Celecoxib and mefenamic acid undergo metabolism via cytochrome P450 2C9 isoenzymes. Excretion is via the kidney, primarily as metabolites. Sulindac and nabumetone are inactive prodrugs converted by the liver to active metabolites

bid, Twice a day; *ER,* extended release; *IM,* intramuscular; *IV,* intravenous; *OTC,* over the counter; *PO,* oral; *PR,* rectal; *q,* every; *qid;* four times a day; *Rx,* prescription; *SR,* sustained release; *TDS,* transdermal; *tid,* three times a day; *XR,* extended release.

*Caution: Recommended doses do not apply to patients with renal or hepatic insufficiency or other conditions affecting drug metabolism and kinetics.
[†]Fentanyl TDS: Doses above 25 μ/h should not be used in opioid-naïve patients.
[‡]Recommended doses do not apply to patients with renal or hepatic insufficiency or other conditions affecting drug metabolism and kinetics. Starting doses should be lower for elderly patients.
[§]Published tables vary in the suggested doses that are equianalgesic to morphine. Clinical response is the criterion that must be applied for each patient; titration to clinical responses is necessary. Because there is not complete cross-tolerance among these drugs, it is usually necessary to use a lower than equianalgesic dose when changing drugs and to retitrate to response.
APAP, acetaminophen; *bid,* twice a day; *CR,* controlled-release; *ER,* extended release; *IM,* intramuscular; *MRX1,* may repeat one time as needed; *NA,* not available; *q,* every; *SC,* subcutaneous; *SL,* sublingual; *TDS,* transdermal; *XR,* extended release.

TABLE 20.13 Advantages and Disadvantages of Intraspinal Drug Administration

System	Advantages	Disadvantages
Percutaneous temporary catheter	Used extensively both intraoperatively and postoperatively Useful when the prognosis is limited (<1 mo)	Mechanical problems include dislodgment, kinking, and catheter migration
Permanent silicone-rubber epidural	Catheter implantation is a minor procedure Dislodgment and infection are less common than with temporary catheters Bolus injections, continuous infusions, or PCA (with or without continuous delivery) can be given	
Subcutaneous implanted injection	Increased stability; less risk of dislodgment Can deliver bolus injections or continuous infusions (with or without PCA) Useful when the prognosis is limited (<1 mo)	Implantation more invasive than external port Approved only for epidural catheter in the United States Potential for infection increases with frequent injections Need for more extensive procedure
Subcutaneous reservoir	Potentially reduced infection in comparison with external system	Difficult to access, and fibrosis may occur after repeated injection
Implanted pumps (continuous and programmable)		Potentially decreased risk of infection Need for more extensive operative procedure; need for equipment with programmable systems

PCA, Patient-controlled analgesia.
Adapted from U.S. Department of Health and Human Services. *Management of Cancer Pain: Adults.* Washington, DC, 1994, Author.

TABLE 20.14 Drugs and Routes of Administration Not Recommended for Treatment of Cancer Pain

Class	Drug	Rationale for Not Recommending
Opioids	Meperidine	Short (2- to 3-h) duration; repeated administration may lead to CNS toxicity (tremor, confusion, or seizures) because of cumulation of neurotoxic active metabolite, normeperidine; high oral doses required to relieve severe pain (especially >800 mg/day and in the presence of renal dysfunction); may further increase the risk of CNS toxicity
Miscellaneous	Cannabinoids	Side effects of dysphoria, drowsiness, hypotension, and bradycardia preclude its routine use as an analgesic
	Cocaine	Has demonstrated no efficacy as an analgesic or co-analgesic in combination with opioids
Opioid agonist–antagonists	Pentazocine Butorphanol Nalbuphine	Risk of precipitating withdrawal in opioid-dependent patients; analgesic ceiling; possible production of unpleasant psychomimetic effects (eg, hallucinations)
Partial agonist	Buprenorphine	Analgesic ceiling; can precipitate withdrawal
Antagonist	Naloxone Naltrexone	May precipitate withdrawal; limit use to treatment of life-threatening respiratory depression
Combination preparations	Brompton's cocktail	No evidence of analgesic benefit to using Brompton's cocktail over single opioid analgesics Painful; absorption unreliable; should not be used for short (2- to 3-h) duration;
	DPT (meperidine, promethazine and chlorpromazine)	Efficacy poor compared with that of other analgesics; high incidence of adverse effects
Anxiolytics	Benzodiazepine (eg, alprazolam)	Analgesic properties not demonstrated except for some cases of neuropathic pain; added sedation from anxiolytics may limit opioid dosing
Sedative–hypnotic drugs	Barbiturates Benzodiazepine	Analgesic properties not demonstrated; added sedation sedative–hypnotic drugs limit opioid dosing
Route of Administration	**Rationale for Not Recommending**	
Intramuscular	Painful; absorption unreliable; should not be used for children or patients likely to develop dependent edema or in patients with thrombocytopenia	

CNS, Central nervous system.
Adapted from U.S. Department of Health and Human Services. *Management of Cancer Pain: Adults.* Washington, DC, 1994, Author.

Local analgesics have been used to treat neuropathic pain but are limited in their effectiveness without concurrent use of an opioid, antidepressant, and/or anticonvulsant. Psychostimulants, as discussed earlier, may be useful in reducing opioid-induced sedation when opioid dose adjustment (eg, reduced dose and lengthening dosing intervals) is not effective.

Patients should be encouraged to remain active and participate in self-care when possible. Noninvasive physical and psychosocial modalities can be used concurrently with drugs and other interventions to manage pain during all phases of treatment. The effectiveness of these modalities depends on the patient's participation and communication concerning which methods best alleviate pain. **Generalized weakness, deconditioning, and aches and pains associated with cancer diagnosis and therapy may be treated by cutaneous stimulation such as heat or cold, massage, pressure, and vibration.** Unfortunately, these modalities sometimes increase pain before relief occurs. Massage should not be substituted for exercise in ambulatory patients. Exercise is useful for treating subacute and chronic pain because it strengthens weak muscles, mobilizes stiff joints, and helps to restore coordination and balance, thus enhancing patient comfort and providing cardiovascular conditioning. Physical therapists may be consulted to increase weightbearing exercise. Repositioning is also effective to maintain correct body alignment and prevent or alleviate pain and possibly prevent ulcers. Immobilization is only effective to stabilize fractures or otherwise compromised limbs or joints. Finally, acupuncture, which involves inserting small solid needles into the skin, may be an effective alternative to more standard therapies.

Cognitive behavioral interventions are an important part of a multimodal approach to pain management. They help to give the patient a sense of control and to develop appropriate skills to deal with pain. These skills include relaxation and imagery, cognitive distraction and reframing, patient education, psychotherapy, biofeedback, structured support, and support groups and pastoral counseling.

With rare exceptions, a less invasive analgesic approach should precede invasive palliative approaches. However, for a few patients in whom behavioral, physical, and drug therapy do not alleviate pain, invasive therapies are useful. These include radiation therapy to destructive bone metastasis, palliative surgical approaches, and nerve blocks.

Because vulvar cancers and occasionally ovarian or endometrial cancers occur in elderly patients, they especially require comprehensive assessment and aggressive management when cancer pain occurs. **Older patients are at risk for undertreatment of pain because of underestimation of their sensitivity to pain, the expectation that they tolerate pain well, underreporting because of declined cognitive functions, and the misconceptions about their ability to benefit from the use of opioids. Careful consideration should be given to elderly patients who are in pain and who have multiple chronic diseases that increase their risk for drug–drug and drug–disease interactions.** In addition, visual, hearing, motor, and cognitive impairments may require simpler pain assessment scales and more frequent pain assessments. NSAIDs are more likely to cause gastric and renal toxicity and other drug reactions such as cognitive impairment, constipation, and headaches in older patients. Alternative NSAIDs (eg, choline magnesium trisalicylate) or co-administration of misoprostol should be considered to reduce gastric toxicity. Older persons tend to be more sensitive to the analgesic effects of opioids. In addition, the peak opioid effect is higher, and the duration of pain relief is longer. Drug clearance may also be slower, thus making cautious initial dosing and subsequent titration and monitoring necessary. Elderly patients may not be able to physically place rectal suppositories or activate PCA devices. Because of the addictive property of opioid analgesics, the NCCN and the FDA have incorporated a detailed algorithm, the REMS, for monitoring patients for both safety and abuse. Transdermal, transmucosal, and long-acting opioids are included in this list of highly monitored medications, and health care providers are encouraged to identify patients at risk for abuse or misuse.

Nausea and Vomiting

Nausea and vomiting also have a high prevalence in patients with advanced cancer. **The cause may be divided into physiologic, treatment-related, metabolic, and psychological causes.** As is the case in many symptoms of advanced cancer, the causes of nausea are often multifactorial. **More than 50% of patients receiving opioids experience nausea in the first 10 to 14 days of therapy until they develop tolerance to this side effect.** Many palliative specialists may prescribe antiemetics for the first weeks of opioid therapy. The most successful therapy is given orally and prophylactically. Nausea and vomiting tend to be the most feared symptom related to cancer treatment. Chemotherapy-induced nausea and vomiting (CINV) may occur in 70% to 80% of patients receiving chemotherapy. CINV can be divided into four subcategories. The NCCN defines *acute CINV* as occurring shortly after chemotherapy administration but resolving within the first 24 hours. *Delayed CINV* occurs after 24 hours, peaks 48 to 72 hours, and resolves by 6 to 7 days. *Anticipatory CINV* is described as a learned or conditioned response before chemotherapy, and finally, *breakthrough CINV* can occur when a patient experiences symptoms despite appropriate therapy.

An evaluation and approach to the management of patients with chemotherapy-induced emesis appears in Fig. 20.4. Agents used to control nausea and vomiting have different mechanisms of action and may be used in combination for better control (Table 20.15). There are basically three main classes of drugs for CINV: 5-HT serotonin receptor antagonists, corticosteroids, and the neurokinin-1 (NK_1) antagonists. The ASCO recently updated its guidelines for the use of antiemetics in oncology; these recommendations, with some additions, are detailed in Fig. 20.5. All have a high therapeutic index for CINV and should be considered first-line therapy. **The 5-HT3 antagonist blocks serotonin receptors of the peripheral GI tract and the chemoreceptor trigger zone (CTZ) to prevent vomiting. Corticosteroids are often used to enhance the effect of other agents, yet they have an unclear antiemetic action. It has been postulated that corticosteroids overcome the adrenal insufficiency that causes nausea and vomiting in patients with advanced**

cancer. Dexamethasone (20 mg IV) is most effective when administered with a 5-HT3 antagonist. There are several 5-HT serotonin receptor antagonists that all have similar therapeutic and side effect profiles. Several large, multicenter, double-blind, randomized phase III trials have shown that palonosetron performs superior to other agents in this class in preventing emesis associated with both moderate and high emetic risk chemotherapy regimens, particularly for delayed emesis. The three-drug combination of 5-HT receptor antagonists in addition to dexamethasone and receptor antagonists are indicated for the control of CINV in high-dose chemotherapy regimens. NK_1 receptor antagonist plays a significant role as an adjunct for acute CINV control and single agent for delayed CINV control. For breakthrough CINV, the following agents may be

considered as a replacement or adjunct agent when first-line therapeutics fail: metoclopramide, phenothiazines, butyrophenones, and cannabinoids. Metoclopramide has its effect locally in the gut and is excellent to control vomiting because of gastric stasis. In chemotherapy prophylaxis, it can be combined safely with steroids or benzodiazepines. Phenothiazines partially inhibit the CTZ and are the drugs of choice for mild CINV. Ondansetron is the drug of choice for radiation-induced nausea and vomiting. Benzodiazepines are indicated for anticipatory vomiting and can be used in patient with nausea caused by high anxiety. The amnesic effects of benzodiazepines are helpful to many patients. Olanzapine, an atypical antipsychotic, has been found to be effective for CINV, especially for patients with high rates of nausea. However, olanzapine should be used with caution in elderly patients because of its boxed warning and precautions. Patients who describe around-the-clock nausea, not just intermittent with meals, may have a CNS lesion or a proximal small bowel obstruction that must be evaluated. Cannabinoids are best used in younger patients and have equivalent or superior activity compared with the phenothiazine agents. Specifically, the cannabinoids dronabinol and nabilone, both approved by the FDA, are indicated for refractory CINV and despite dysphoric side effects hindering their prescription, patients have been shown to prefer the use of these agents for subsequent chemotherapy cycles. In anticipatory CINV, the most important concept is the prevention of acute and delayed emesis with the above drugs. However, ultimately when one is faced with controlling anticipatory CINV, benzodiazepines and behavioral therapy are suggested. Finally, when CINV proves to be refractory, one must consider other causes of nausea and vomiting. With the change of legislature, the use of medical marijuana may be sought by patients. Although the route of administration (inhalation, nasal, and edible) may all be effective. Physicians must become familiar with state and federal requirements before prescribing to assure patient safety and to honor professional oath.

Last, an important concept in CINV is the selection of therapy based on the risk assessment of the chemotherapeutic agents used, a concept highlighted in the recent ASCO guidelines. The emetogenicity of these antineoplastic drugs is separated into four categories: high, moderate, low, and minimal risk. For example, a high-risk drug such as cisplatin requires combination treatment with 5-HT receptor blockers, NK_1 receptor antagonist, and corticosteroids followed by corticosteroid and NK_1 receptor antagonist for delayed CINV. Low emetogenic drugs (eg, paclitaxel) may only require dexamethasone without additional agents for acute CINV.

Diarrhea and Constipation

Diarrhea is a common complication of pelvic radiation and systemic chemotherapy. It can generally be managed with intestinal opioid receptor agonist such as loperamide. Rarely, tinctures of opium or octreotide are required for refractory or secretory diarrhea (Table 20.16). **Patients who have been previously treated with antibacterial therapy or are immunocompromised should be tested for *Clostridium difficile*** (eg, enzyme-linked immunosorbent assay [ELISA] for enterotoxin) before antidiarrheal therapy. When detected, metronidazole or vancomycin therapy is usually effective. Rarely, cholestyramine is needed to control the symptoms of *C. difficile* infectious diarrhea. A search for more unusual infectious etiologies such as salmonella, shigella, *Escherichia coli,* and parasites has not been cost effective among gynecologic oncology patients in the absence of foreign travel or other data, which might suggest these etiologic agents.

Constipation is highly prevalent in patients with advanced cancer. Close to 90% of patients receiving opioids have difficulty passing stool or pass stool infrequently. **One cardinal rule of palliative care is "the hand that writes the opioids writes the laxative at the same time."** Other causes of constipation are advanced disease, other medications such as anticholinergic agents, inability to eat a high-fiber diet, insufficient fluid intake, and lack of activity.

A specific discussion regarding opioid-induced constipation is warranted here. Of note, a tolerance to the opioid used with regards to constipation does not occur. In general, a mild stimulant laxative and a stool softener should be used prophylactically, for example, senna with docusate. Adequate fluid intake and physical activity should be encouraged. Such agents as Metamucil that increase fiber content in the stool are not recommended. If constipation persists, secondary etiologies, such as bowel obstruction, should be considered. Impaction should be ruled out, and then secondary anticonstipation agents should be considered. These agents include magnesium hydroxide or citrate, bisacodyl, lactulose, sorbitol, polyethylene glycol, naloxegol, and methylnaltrexone. Various enemas or agents such as metoclopramide may also be added. A general approach should be to begin patient on a stool softener and stimulant; if in 48 hours no bowel movement results, then additional agents should be started such as Milk of Magnesia or lactulose. If no bowel movement in 72 hours, then fecal impaction should be assessed and treated. If no impaction is present, then such interventions as an enema, mineral oil, or magnesium citrate should be tried. If impacted, a glycerine suppository or oil retention enema should be used.

Metabolic causes of constipation include hypercalcemia and hypokalemia. **Evaluation of complaints of constipation should include consideration of bowel obstruction and spinal cord compression.** A manual rectal examination is critical when evaluating this complaint.

Several treatment options are now available for nonsurgical candidates with bowel obstructions secondary to advanced cancer. A discussion of these treatments follows.

Cachexia and Malnutrition

Cachexia is defined by Femia and Goyette as loss of over 5% of body weight over 2 to 6 months. Clearly, cachexia is related to nutritional status because the cancer itself causes metabolic alterations such as increased muscle protein breakdown and glucose metabolism, and the treatment of cancer affects appetite and food intake. The literature supports the fact that the patient's body habitus, and therefore QoL, is altered by these changes. Furthermore, it is evident that malnutrition contributes to poor outcome in gynecologic oncology patients. Clearly,

TABLE 20.16 Antidiarrheal Agents (Adult Dosages)

Medications	Common Proprietary (Trade) Name	Dosing Regimen	Comments
		ANTISECRETORY	
Bismuth subsalicylate	Kaopectate, Pepto-Bismol, Kao-Tin, Maalox Total Stomach Relief Liquid	2 tablets or 30 mL q1h up to 8 doses per day (regular strength) or four doses/day (maximum strength)	Contains aspirin. Watch for maximum daily dose of aspirin; may cause Reye syndrome. Interferes with radiologic examinations of GI tract (bismuth is radiopaque); stool may appear gray-black in color.
Octreotide	Sandostatin, others	0.1–0.5 mg SC 2–3 times per day (maximum, 2.4 mg/day) LAR: 10–40 mg IM per month	50% dose reduction in patients requiring dialysis or with liver cirrhosis
		ANTIPERISTALTIC	
Loperamide	Imodium A-D, others	4 mg; then 2 mg after each stool (maximum, 8 mg/day OTC; 16 mg/day Rx) Maintenance: 2–4 mg q6h	
Diphenoxylate 2.5 mg/ atropine 0.025 mg	Lomotil, Lonox, others	2 tablet or 10 mL (5 mg diphenoxylate) qid (maximum, 20 mg/day)	Use with extreme caution in patients with hepatorenal disease or abnormal liver function; may cause hepatic coma.
Difenoxin 1 mg/atropine 0.025 mg	Motofen	2 tablets; then 1 tablet after each loose stool Maintenance: 1 tablet q3–4h (maximum, 8 tabs per day)	Use with extreme caution in patients with hepatorenal disease or abnormal liver function; may cause hepatic coma.
Opium	Opium Tincture (C-II), Paregoric (C-III)	Opium tincture: 0.6 mL qid Paregoric: 5–10 mL qid	
Codeine	Codeine sulfate	15–60 mg q4h	

GI, gastrointestinal;

oncologists need to be aware of the implications of malnutrition in patients receiving therapy because poor nutritional status may negatively affect a patient's response to therapy as well as her QoL during therapy.

Nutritional support using dietary supplements and shakes (e.g., Ensure) along with the oncologist's attention to this issue may improve the response to treatment for some patients. Nutritional counseling, oral nutritional supplementation, and home parenteral nutrition (TPN) have also been linked to improved QoL. Finally, although appetite stimulants such as megestrol acetate (Megace) are thought to improve cancer-related anorexia and cachexia, they have not been shown to affect survival or global QoL. However, of note, Megace is thought to be more effective than either eicosapentaenoic acid (α-3-omega fatty acid) or marijuana derivatives, and only corticosteroids may perform as effective as Megace. Unfortunately, Megace carries the risk of VTE perhaps as high as a sixfold increase, and this might limit its use in the gynecologic oncology patient population.

On the contrary, oncologists and patients may differ when it comes to nutrition and hydration in the supportive or palliative care setting. Brown et al found that the majority (63%) of patients would like nutrition and hydration to be continued even though the use of respiratory supports, such as oxygen or ventilators, might be limited. The authors state that patients may not consider nutritional support "heroic." Even though patients might not agree with discontinuation of nutritional support, the management of malnutrition in the palliative setting remains controversial. For example, although TPN or home parenteral nutrition is considered by many to be unnecessary in terminally ill patients, there is some evidence that it has a positive impact in certain patient populations, including patients with a life expectancy of longer than 3 months. TPN carries its own risks and discomfort, so strong QoL studies need to address this issue.

PSYCHOSOCIAL AND SPIRITUAL NEEDS OF PATIENTS AND FAMILIES

Management of only the physical symptoms of cancer is now considered to be an inadequate approach to oncologic care. It is well recognized that physical and psychological symptoms are intertwined and can benefit from a multidisciplinary approach to care. **A growing body of literature suggests that tailored psychosocial interventions can enhance not only QoL for cancer survivors but may have the additional benefit of improving neuroendocrine and immune functioning, which could positively affect disease states. If proven effective, this complementary and cost-efficient approach could significantly improve patient care, QoL, and aspects of survival.** The effect of cancer on the family and patient is profound and touches every area of their lives. Effective care of the patient requires that these needs be addressed. A team of professionals is needed to foster effective communication in the patient–physician relationship, to assess the effect of disease and its

treatment on the patient's psychosocial and spiritual well-being, and to achieve optimal care for the patient and family.

Strategies for Breaking Bad News and Preserving Hope

Perhaps the most important tool in caring for patients and their families is effective communication. Transferring information about the diagnosis, prognosis, risks, and benefits of treatment and progression of disease is a difficult and unavoidable responsibility. **Sharing bad news and responding to the questions presented by the patient and family require compassion, empathy, and skill.** Unfortunately, development of these skills has not historically been emphasized in medical training even though powerful medical institutions and societies (eg, ASCO, IOM, American Cancer Society, NCI) demand excellence and vigilance when caring for people with progressing cancer. The absence of an integrated formal palliative care curriculum throughout medical training continues to promote a skill set gap.

Identification of cancer progression, or progressive cancer-related symptoms, is often the catalyst for planning alterations in care and readdressing issues about the patient's and family's goals and objectives. Breaking bad news is a difficult and emotionally laden task for the physician. Thoughtful planning and delivery of such information, however, can shape the patient's subjective experience of the physician and perception of his or her degree of support and caring. The individual's response to news is often determined by the adequacy of information given and whether the person delivering the information showed and responded to the patient's concerns.

Although wishes vary from one individual to another, most patients (80%) want to know their diagnosis, their chance of cure, and the adverse effects of any treatments. Significantly, patients do vary in the degree of information that they are able to assimilate at one time. Traditionally, men with advanced disease, older patients, and individuals from lower socioeconomic backgrounds are likely to want to hear fewer details and may comfortably defer to the physician or family with regard to decision making. In most cases, patients want to hear the diagnosis from the physician who will be responsible for their care.

When breaking bad news, it is critical to project reasonable hope and confidence. Despite the most sensitive and effective communication style, patients are left with major concerns about their situation as it relates to their physical, social, psychological, and spiritual well-being. **Open communication should be maintained, and these concerns should be explored throughout the continuum of care using expertise and support from other team members. Excessive concern about the need to preserve hope can lead to false optimism or less than full disclosure over time. This approach leads to poor coping skills and failed expectations. Lending strength does not require that the physician be less than honest but that the truth be disclosed over a period of time in a setting where the patient has the support required and with repetition so that information can be assimilated and understood in small amounts.** Patients should be encouraged and nurtured to develop their own coping strategies and defense mechanisms in dealing with their illness. This strategy brings hope against all odds. For example, if asked, "Doctor, I know I am dying, but can there still be a miracle?" The answer is, "Yes, there can be." This suggests that the medical information is clearly understood but demonstrates confidence to overcome suffering and despair. However, it is unusual for patients to so clearly articulate their inevitable demise; more likely, they would ask, "Is there still hope?" **The physician's capacity to appropriately convey hope through articulation of a comprehensive care plan will help the patient to recognize that quality time is a reasonable expectation.** Forcing a patient to adopt the physician's view of the odds (chance of a cure) does not take into consideration what can generally harm the personal framework that patients must deal with. It also corrodes the patient–physician relationship that must endure through the palliative therapy or future care. **Thus, maintaining hope is best achieved through honesty, cautious optimism, compassion, and acceptance of the vulnerability experienced by all cancer patients.**

Timing is critical to breaking bad news. Judging what portion of the information should be disclosed is an art. Conveying a balance of honesty and maintaining hope can sometimes seem impossible, often because physicians tend to project their own concerns onto patients and assume that they will give up hope. In reality, hope is an innate characteristic that is rarely abandoned by open and compassionate discussion of the prognosis and treatment options. When there are no remaining viable cytotoxic treatment options, there are still many palliative options that can achieve meaningful therapeutic ends, thus preserving hope and avoiding a sense of helplessness. It is useful for patients to hear such optimism in the face of a generally poor prognosis. As the patient's illness advances, feelings of helplessness because of a loss of control and fear of dying may resurface. At this point, the physician can openly recognize the patient's fear and grief and externally acknowledge his or her own attitudes toward death. Unfortunately, doctors and other staff tend to spend less time with patients as the disease progresses and patients deteriorate into a terminal condition. This is presumably because the health care professionals feel helpless (and perhaps even threatened) when confronted with the imminence of death. Many health care professionals fail to realize the importance of compassion and active palliative care. Actively participating in symptom management and compassionate listening helps to ease the patient's mind, thus allowing the patient to ask questions that help plan realistically for the future and maintain a sense of control. Although most patients know when they are dying and can verbalize this realization, they also retain hope. The physician is uniquely poised to encourage and reinforce the patient's hope without giving false or insincere reassurance. One study that focused on end-of-life preferences of gynecologic cancer patients reported that only 5% of 108 patients would stop fighting after receiving a poor prognosis with no medically recommended treatment options left. Most (70%) of these patients expressed their resolve to continue fighting against their disease, even under the poorest prognostic circumstances. Proper management involves directing resources to assist with this fight and fostering this hope

TABLE 20.17 Psychosocial Challenges Experienced by Cancer Patients

Threat of or Actual:

- Loss of ability to engage in employment because of side effects or symptoms
- Loss of ability to participate in all social activities previously enjoyed because of symptoms of side effects or infection concerns
- Guilt feeling about the impact of the diagnosis on people about whom the patient cares
- Diminished sense of self-esteem and self-worth
- Changes in body image
- Discrimination or stigmatization by others
- Role conflicts (eg, meeting the demands of multiple responsibilities, including those of being a patient)
- Loss of comfort with sexual intimacy with a significant other
- Fear of the dying process and concerns about symptoms that conjure up images of physical suffering (eg, pain, cachexia, and shortness of breath)

Adapted from Portenoy RK. *Principles and Practice of Supportive Oncology*. Philadelphia, 1998, Lippincott-Raven, pp 109-118.

among dying patients. The involvement of other professionals familiar with care for the dying can relieve the physician of being the sole provider of hope with sensitive attention to incurable problems.

MANAGEMENT OF PSYCHOSOCIAL AND SPIRITUAL DISTRESS

Approaching "the person, not the disease" is a prerequisite to understanding the patient's experience and providing appropriate physical, psychosocial, and spiritual care. A cancer diagnosis creates a profound sense of loss of control and fear for many individuals. Changes in physical function and the effect on psychosocial issues may further compound this sense. Stressors commonly experienced by patients undergoing cancer treatment may be as problematic for the patient as the physical decline. Table 20.17 highlights the complex challenges faced by patients.

Patients are often reluctant to disclose struggles, including feelings of depression and anxiety, if they do not perceive this disclosure to be relevant to their physical care. Recent research has shown that many individuals are fearful of burdening their family members emotionally, physically, and financially during their final days. A recent prospective study examining the prevalence of depressed mood and request for euthanasia among terminally ill cancer patients noted that of 138 patients, 32 patients (22%) had depressed mood and made an explicit request for euthanasia. The risk to request euthanasia for patients with depressed mood was 4.1 times higher than that of patients without depressed mood at inclusion (95% confidence interval, 2.0–8.5). This information heightens our awareness to formally evaluate depression in terminally ill cancer patients and provide timely intervention as indicated.

Discussions about resources available to assist patients and families, including the role and function of community agencies, support groups, and hospice programs, are critical. There

TABLE 20.18 Tasks of Dying Patients

Practical

- Complete a family trust.
- Put affairs in order.
- Complete advanced directives.
- Communicate wishes regarding funeral and burial arrangements.
- Plan for the future of surviving family members.

Psychosocial

- Grieve the loss of dreams for the future.
- Accept the reality of the prognosis and impending death.
- Use medical intervention and own internal resources to cope with physical deterioration.
- Express thanks and love to family and friends.
- Find closure around interpersonal conflicts ("I forgive you; please forgive me").
- Say goodbye to family and friends.

Spiritual

- Engage in life review; reflect on the past and present.
- Make meaning of one's life.
- Resolve existential or spiritual conflict.

Adapted from Loscalzo M, Zabora J. Care of the cancer patient: responses of family and staff. In Bruera E, Portenoy R, eds. *Topics in Palliative Care,* vol 2. New York, 1998, Oxford University Press. © Oxford University Press. Reproduced by permission of Oxford University Press, Inc., www.oup.com.

are many tasks that a patient should have the opportunity to accomplish in the time before death. These tasks are summarized in Table 20.18.

Identification and treatment of psychosocial problems, including depression and anxiety, should involve interventions and expertise that will offer optimal care to the patient and family. As noted earlier, pharmacologic interventions are often necessary but should be considered in combination with psychological counseling, supportive interventions, and education for the patient and family. Determination of the appropriate referral depends in large part on the type and magnitude of the psychosocial or psychological disruption, as well as the extent to which this diagnosis interfaces with physical symptomatology such as pain or fatigue. Optimal programs include a team consisting of psychiatry, psychology, social work, and chaplain services. In addition, **novel programs are acknowledging, if not incorporating, aspects of complementary and alternative medicine (CAM) based on recognition that a substantial proportion of cancer patients seek out various CAM methodologies.**

Psychosocial care must continue to address the needs of the family as death imminently approaches and after death occurs. The health care team has an opportunity through the period of anticipatory grieving to assess and monitor the family and to identify risk factors indicating the need for more intensive intervention. **An understanding of the spectrum of grief and the nature of "normal" grief is essential for providers to effectively support grieving families, identify abnormal reactions, and intervene.** Table 20.19 illustrates the range of bereavement services that may be available for family members.

TABLE 20.19 Interventions for Bereaved Individuals*

Provision of information or education: offers education to surviving family members about grief response, explaining death to children, practical information to facilitate problem solving and arranging for disposition of the body (eg, funeral and burial arrangements), and future memorial activities
Bereavement follow-up: offers formalized contracts by the staff or volunteers at identified intervals to provide support, monitor for difficulties, and arrange for intervention as needed
Individual or family grief counseling: offers counseling for bereaved individuals experiencing grief; some individuals may require long-term psychotherapy or psychiatric care if bereavement-related depression or risk of suicide exists
Bereavement support groups: offers a forum for the mutual support among bereaved individuals; may have a special purpose (eg, for parents who have lost a child) or have a particular religious affiliation
Memorial or remembrance services: offered by the hospital or hospice to acknowledge the grief process

*Families of patients who die in hospitals would not necessarily have knowledge of or access to any follow-up if a bereavement program is not in place at the institution. Bereavement follow-up is typically a part of hospice services, and institutions may successfully partner with local hospices to make this service accessible for these families. Adapted from Portenoy RK. *Principles and Practice of Supportive Oncology*. Philadelphia, 1998, Lippincott-Raven, pp 109-118.

QUALITY OF LIFE ISSUES IN ADVANCED AND RECURRENT OVARIAN CANCER

Pleural Effusions

Dyspnea is the subjective feeling of respiratory distress and thus is often an interplay between anxiety and hypoxia from tumor burden. Some have suggested that supportive care of this symptom should include the provider's ability to address the patient's subjective breathlessness. Because dyspnea may indicate a poorer prognosis and shorter interval to death, addressing this symptom is paramount to enhancing QoL in the time period near death.

Dyspnea may result from a combination of three different complications: (1) obstructive pathology such as pleural effusions, (2) cancer cachexia or malnutrition and weakness, and (3) an increase in ventilator requirements such as metabolic acidosis or anemia. Perhaps gynecologic oncologists most frequently encounter this tumor effect in the ovarian cancer patients because the dyspnea may be secondary to pleural effusions. It is suggested that thoracocentesis and chemical pleurodesis be reserved for palliative situations in which chemotherapy or other treatments are not likely to reverse the effusions. For symptomatic control or when mechanical control of the pleural effusion is not an option, most advocate opioids, oxygen therapy, or both. Benzodiazepines as well as oxygen therapy may also have a role in control of dyspnea, although evidence is lacking. Finally, some have advocated activity modifications to prevent the onset of dyspnea, which may involve caregiver instruction to tailor activities of daily living.

Small Bowel Obstruction

Although epithelial ovarian cancer is a surface-spreading disease that rarely invades vital organs, partial or complete bowel obstruction is often seen at the time of initial diagnosis or, more frequently, in association with recurrent disease. **Obstruction may be secondary to extrinsic compression of the small bowel or hypoperistalsis caused by mesenteric and bowel surface implants.** The symptoms, which are almost always present, are intestinal colic, continuous abdominal pain, nausea, and vomiting. In most cases, nausea and vomiting can be relieved by conservative measures, and intestinal symptoms usually resolve after primary cytoreductive surgery and multiagent cisplatin-based cytotoxic chemotherapy. Despite the high objective response rate of primary epithelial ovarian cancer to several platinum-based combination chemotherapeutic regimens, most patients with advanced disease often develop IP recurrences and require a salvage regimen for palliation of symptoms. Several therapeutic strategies have been used in these patients, such as including retreatment with cisplatin or carboplatin or the use of paclitaxel, hexamethylmelamine, oral etoposide, tamoxifen, gemcitabine, liposomal doxorubicin, vinorelbine, or topotecan. Multiple clinical factors must be considered when selecting the most appropriate salvage therapy. Unfortunately, in patients previously treated with cisplatin, other therapeutic agents are not likely to be effective in relieving symptoms of bowel obstruction or ascites.

For most patients who present with bowel obstruction secondary to recurrent IP cancer, initial management should include proper radiographic documentation of the obstruction, hydration, correction of any electrolyte abnormalities, parenteral alimentation, and intestinal intubation and decompression. There is a fair representation of various treatment options in the literature. A recent retrospective study found that surgery carries a higher morbidity, although chemotherapy and surgery had similar outcomes in terms of reobstruction. Of note, conservative management alone has much earlier reobstruction rates. In some patients, the obstruction may be relieved with this conservative approach. **However, palliative surgery is usually considered in almost every patient at some time before disease progression and death. When surgery is indicated, the type of surgery depends on the extent of the disease as well as on the number and location of obstructions.** If the obstruction is mainly contained in one area, this area can be either resected (if secondary cytoreduction is indicated) or bypassed. Because the success of secondary cytoreduction depends on the chemosensitivity of the residual disease present after debulking surgery, **intestinal bypass is generally preferable rather than resection** because most patients present after multiple failed attempts at cytotoxic therapy resulting in chemotherapy-resistant cancer. In addition, intestinal bypass surgeries such as enterocolostomy are usually associated with reduced morbidity compared with a radical resection. At the time of operation, the balloon at the end of a long intestinal tube can often be palpated and used to identify the small bowel proximal to the obstruction. This small bowel can then be anastomosed in a side-to-side fashion to the most appropriate area of colon, thus bypassing the site of obstruction. Obviously, it is critical to obtain a preoperative

Gastrografin enema to ensure that there is no obstruction of the lower colon beyond the bypass site. In rare cases, the colon may be encased in tumor, necessitating a colostomy with or without bypass surgery. Sadly, multiple sites of obstruction are common in patients with recurrent epithelial ovarian cancer. **When multiple sites of obstruction are present, resection of several segments of intestine is usually not indicated.** In inoperable cases or situations when the patient or oncologist decides to proceed with medical or conservative management, several options exist. A percutaneous endoscopic gastrostomy allows patients to hydrate themselves by mouth. By decreasing intestinal secretions, octreotide has improved QoL and lessens hospitalization. Moretti et al. used temporary nasogastric drainage with the simultaneous use of octreotide and antiemetic and analgesics in a terminal patient. Critical in their algorithm is fluid management because they stress keeping daily water intake to between 0.5 and 1.5 L. In the last month of life, this combined medical and conservative approach decreased pain, nausea, dry mouth, thirst, dyspnea, feelings of abdominal distention, and drowsiness in the palliative setting. **In such cases, an ileostomy or even a proximal jejunostomy may be necessary to provide adequate intestinal diversion. On the contrary, if the extent of disease is so great that the morbidity of intestinal surgery seems excessive, stomach decompression with a gastrostomy may be effective in palliating symptoms** of obstruction and ascites such as pressure, nausea, vomiting, and pain. When the stomach and anterior abdominal wall are not involved with tumor, drainage tubes can often be placed percutaneously, thus avoiding the morbidity of a laparotomy.

With careful attention to nutrition, chemosensitivity or resistance of disease, and the sites of intestinal obstruction, some degree of palliation can generally be obtained with surgery, chemotherapy, or gastric decompression. Careful attention to each of these factors is necessary to avoid unnecessary morbidity and unindicated surgery in these debilitated terminal patients with recurrent or refractory ovarian cancer.

Many have attempted to define the prognostic factors which predict benefit after surgery and some of the key factors include age older than 65 years, nutritional status, tumor burden, rapidly reaccumulating ascites, poor nutritional status, carcinomatosis, previous chemotherapy for recurrence, and radiation therapy to the whole intestine. Krebs and Gopelrud used a predictive index by scoring patients with a value of 0, 1, or 2 in six of these categories and found that patients who scored higher than six had worse outcomes with surgery. However, if surgery is chosen, the patient must understand the possibility of living with an ileostomy in roughly 50% of cases with potential complications of fistula(s) for the balance of the patient's life. In a study by Mangili et al., only surgical treatment was a prognostic factor for improved survival; however, it is likely that patients who were offered surgery had other qualities that predisposed them to improved survival.

Ascites

Because malignant ascites is almost always the result of IP cancer, treatment of these effusions generally involves therapy directed against the associated malignant neoplasm. However, treatments are occasionally directed specifically toward the palliation of symptoms related to malignant ascites, particularly when the IP cancer is refractory to all known treatments. **The traditional treatment with diuretics and salt and fluid restriction is rarely effective. Therefore, patients usually undergo therapeutic paracentesis, resulting in an imbalance of protein and electrolytes.** For this reason, novel therapies such as IP immunotherapy and drainage using a Denver peritoneal venous shunt have been proposed to palliate symptoms associated with malignant ascites. One series involved 42 patients who were treated over a 5-year period with a peritoneal venous shunt, which diverted peritoneal fluid into the vascular space. This treatment relieved symptoms with neither hematogenous metastasis nor evidence of disseminated intravascular coagulation. Interestingly, the median survival time of patients with breast and gynecologic cancer after surgery was significantly longer than that of patients with primarily gastric and intestinal neoplasms, resulting in an improvement in QoL.

Management approaches with diuretics with or without serial paracentesis versus permanent indwelling catheters are case dependent. A recent phase I/II trial using monoclonal antibodies against ascites-specific malignant cells, specifically epithelial cell adhesion molecule (EpCAM) on the surface of ascitic tumor cells, in the control of ascites, but randomized controlled studies are still lacking. Other approaches suggested include the use of vascular endothelial growth factor (VEGF) antagonists to reduce ascites because VEGF may be implicated in the formation of ascites by increasing vascular permeability. A hope for cure is no longer possible when a woman develops recurrent disease associated with symptomatic bowel obstruction and ascites. However, a sense of optimism and hope are still common, not for a cure but toward a goal of symptom relief and palliation with chemotherapy, surgery, tube drainage, or supportive care. Only through careful patient selection and insight into the toxicity associated with these therapies can hope for acceptable QoL be realized. A Cochrane review published in 2010 failed to support or refute the use of drains for ascites because it did not find any eligible trials to review.

Role of Palliative Surgical Procedures

The role of surgery to palliate bowel obstruction was discussed earlier. Surgery can be useful in the palliation of pain or fistula during the terminal phase of ovarian cancer progression. The advantages and disadvantages of these procedures must be continually weighed. Cytoreductive surgery for debulking as a means to palliate pain is indicated when effective chemotherapy exists to treat unresected residua.

QUALITY OF LIFE ISSUES IN ADVANCED AND RECURRENT UTERINE AND CERVICAL CANCER

Ureteral Obstruction

A patient with bilateral ureteral obstruction and uremia secondary to the extension of cervical or uterine cancer presents a serious dilemma for the clinician. **Management should be divided into two subsets of patients: (1) those who have not**

received prior radiation therapy and (2) those who have recurrent disease after pelvic radiation.

Ureteral obstruction resulting from endometrial cancer differs from obstruction secondary to cervical cancer in that it is more frequently associated with disease outside of the pelvis and because it is more difficult to cure. In addition, adequate doses of radiation are more difficult to deliver to the corpus than to the cervix using standard brachytherapy techniques, thus contributing to the lower rate of pelvic control among patients with endometrial cancer after radiation therapy.

Patients with bilateral ureteral obstruction from untreated cancer or from recurrent pelvic disease after surgical therapy should be seriously considered for urinary diversion followed by appropriate radiation therapy. However, because the salvage rate in this clinical situation is low, **supportive care alone allowing progressive uremia and demise must be considered as an alternative to more aggressive therapy.** Placement of retrograde ureteral stands using cystoscopy should be attempted first if supportive care alone is declined. When this is not possible, a percutaneous nephrostomy should be placed followed by an attempt at antegrade stent placement. A third option is surgical urinary diversion such as a urinary conduit and anastomosing both ureters into an isolated loop of ileum (Bricker procedure) or creating a continent pouch from a segment of bowel. When necessary, urinary diversion is usually performed before the radiation has begun, thus allowing for surgical assessment of the extent of the disease. If extrapelvic disease is discovered at laparotomy, therapy is altered because the chance of a cure is greatly diminished.

The patient with a bilateral ureteral obstruction after a full dose of pelvic radiation therapy presents a more complicated problem. Fewer than 5% of these patients will have obstruction caused by radiation fibrosis, and often this group is difficult to identify. To identify patients whose obstruction is a result of recurrent disease, an examination under anesthesia, cystoscopy, and proctoscopy with multiple biopsies is recommended. **When recurrent cancer is absent, simple diversion of the urinary stream can be lifesaving;** therefore, all patients must be considered to belong to this category until the recurrent malignancy is found.

When the presence of recurrent disease is established as the cause of bilateral ureteral obstruction, the decision process becomes difficult and somewhat philosophical. Numerous studies suggest that "useful life" is not achieved by urinary diversion in this subset of patients. Brin and colleagues reported on 47 patients (five with cervical cancer) with ureteral obstruction secondary to advanced pelvic malignancy undergoing diversion. The results of this report are discouraging. The average survival time was 5.3 months; only 50% of the patients were alive at 3 months, and only 20% were alive at 6 months. After the diversion, 63.8% of the survival time was spent in the hospital. Delgado also reported on a group of patients with recurrent pelvic cancer and renal failure who were treated with urinary conduit diversion. Delgado's results show an insignificant increase in survival time, and he suggests that these patients should never undergo urinary diversion because a more preferable method of expiration (uremia) is then eliminated from the patient's future. Obviously, this decision should be made in consultation with the family and even with the patient, if possible. When urinary diversion is performed, accentuation of the other clinical manifestations of recurrent pelvic cancer (ie, severe pelvic pain, repetitive infections, and hemorrhage) is generally observed, leading to increased suffering. Pain control and progressive cachexia burden the physician and the patient. Episodes of massive pelvic hemorrhage are associated with difficult decisions concerning transfusion. An extension of the inpatient hospital stay is inevitable, and the financial impact of the patient on her family is often considerable.

Fistula

Urinary or colon fistulas are common sequelae of progressive cervical cancer and uterine corpus cancer. **Because both urinary and intestinal fistulas have a great impact on QoL, consideration should always be given to diversion of either the urinary or fecal stream to reduce symptomatology.** Bladder drainage can often sufficiently reduce the incontinence associated with a urinary fistula without the need for surgical urinary diversion. Ureteral ligation with percutaneous nephrostomy drainage is another option. However, urinary conduit or other surgical procedures are often necessary to adequately divert the urinary stream. Surgical repair of a urinary fistula secondary to recurrent cancer or radiation is rarely successful with existing surgical techniques.

Colovaginal fistulas can generally be palliated with a colostomy. Although controversial, a loop colostomy often provides adequate fecal stream interruption to prevent further fistula drainage. However, some surgeons argue that an end colostomy with a Hartmann pouch is necessary to completely interrupt the fecal stream. In either situation, a mini-laparotomy is generally all that is required to adequately accomplish the palliative goal.

Sexual Dysfunction

The treatment of women with gynecologic malignancies may result in vaginal abnormalities that interfere with sexual function. **Disturbances in sexuality are more common after the treatment of vulvar, vaginal, and cervical carcinoma compared with corpus and ovarian cancer.** This is a result of the frequent use of radical surgery and radiotherapy to treat the three former malignancies. The reported frequency of sexual dysfunction after surgery, radiotherapy, or both varies considerably. **A total of 4% to 100% of women report a shortened vagina after a radical hysterectomy, and 17% to 58% have reduced lubrication.** However, until recently, there were no reliable data on reductions in vaginal elasticity or genital swelling during sexual stimulation after radical hysterectomy. A report from Sweden published in the *New England Journal of Medicine* in 1999 demonstrated a statistically significant decrease in vaginal elasticity (23%) among women treated for early cervical cancer compared with a control group (4%). In addition, this study of 256 patients with cervical cancer, who were retrospectively surveyed and compared with 350 control participants, also showed a decrease in lubrication during arousal and a reduction in perceived vaginal length after treatment. Furthermore, a large number of women indicated that

these changes and their effects on sexual intercourse distressed them. Interestingly, the frequency of orgasms and orgasmic pleasure were similar in the two groups, although dyspareunia was more common in the women who had cervical cancer. Finally, **this study did not show any significant difference among those women treated with radical surgery versus radiotherapy,** although other retrospective comparisons have documented a significant increase in sexual dysfunction among those patients treated with radiation versus surgery. A direct comparison between radiation and surgery in the treatment of cervical cancer emphasizing not only outcome but also QoL and sexual function is needed. **Regular vaginal dilatation is widely recommended to those women treated with radiation as a way to maintain vaginal length and elasticity.** Again, this intervention has never been tested in a prospective fashion. **The appropriate use of hormone replacement therapy and lubricants may also improve coital function.**

Dyspareunia resulting from gynecologic cancer therapy should be evaluated and treated, because dyspareunia can lead to loss of desire and can cause women to become sexually avoidant. This often leads to difficult interpersonal relationships between the woman and her partner. Loss of sexual desire in the postcancer population is common and represents a challenging problem. Long after ordinary physical health has been regained, women may describe feeling little or no sexual desire. Counseling and support groups may be helpful in overcoming this frustration.

Anxiety and Depression

The prevalence of depressive and anxiety disorders among women with gynecologic cancers approaches 50%. In a study by Fowler et al., depressive and anxiety symptoms were high in women who had sought consult by a gynecologic oncologist, 42% and 30%, respectively. The severity and prevalence of these psychological symptoms correlated highly with the number of gynecologic symptoms. Of note, older women and those women without a partner were more likely to suffer from depression and anxiety.

The prevalence and severity of symptoms may fluctuate during the patient's treatment course. Chan and Woodruff tracked the psychosocial state in patients with gynecologic cancer to identify risk factors for maladjustment during treatment. Although most patients adjusted well in their sample of 74 women, those with lower socioeconomic status and those without family support or religious belief suffered greater from adjustment disorders. Furthermore, pain, health-related QoL, and poor performance status have been shown to affect these psychological disorders.

There is limited evidence reporting the optimal pharmacologic and psychosocial interventions in depressive disorders among cancer patients. Four classes of drugs have been used: TCAs, serotonin reuptake inhibitors (SSRIs), neuroleptics, and benzodiazepines. It has been suggested that TCAs may be particularly helpful in patients with insomnia and cachexia and that SSRIs may be indicated for patients with low energy, although the evidence regarding dosages and drug choice are heterogeneous. The neuroleptics, such as haloperidol, and the benzodiazepines are not only indicated in patients with anxiety but can ameliorate nausea and vomiting simultaneously. Apart from medical therapy, it has been shown that actively seeking support for psychological concerns enhances QoL and mood. It is not surprising that treatment of depressive and anxiety disorders in these patients might require medical therapy combined with such psychosocial therapy as can be found in cancer support groups.

END-OF-LIFE DECISION MAKING

As summarized in the American College of Obstetrics and Gynecology Committee Opinion published in May 1995, **the moral character of medicine is based on three values central to the human relationship:**

1. **Patient benefit;**
2. **Patient self-determination; and**
3. **The ethical integrity of the health care professional.**

Patient Benefit

The obligation to promote the good of the patient is a basic presumption of medical care and the defining feature of a physician's ethical responsibility. To promote the patient's good is to provide care in which benefits outweigh burdens or harms. Benefits, in turn, are understood only relative to the goals that the patient and physician hope to achieve through medical care.

Patient Self-determination

The inherent value of individual autonomy or self-determination is one of the fundamental bases of democracy in the United States and provides certain protection during end-of-life decision making. In health care, the value of individual autonomy is as firm in the ethical and legal doctrines as in informed consent. Under this doctrine, the patient has a right to control what happens to her body. This means that:

1. **no treatment may be given to the patient without her consent (or if she lacks decision-making capacity, the consent of her surrogate)**
2. **the patient (or her surrogate) has the right to refuse unwanted medical treatment. This right is not contingent on the presence or absence of a terminal illness, on the agreement of family members, or on the approval of physicians or hospital administrators.**

In the medical context, physician respect for patient self-determination consists of an active inclusion of the patient in decisions regarding her own care. This involves frank discussion of the diagnosis and prognosis; the relative risks and benefits of alternative treatments; and, based on these discussions, the identification or the operative goals of care.

Legal Developments That Have a Bearing on End-of-Life Decision Making

In the 1990s, several developments in the law influenced end-of-life decision making. First, in June 1990, in a decision on the *Cruzan* case, **the United States Supreme Court affirmed**

that patients have a constitutionally protected right to refuse unwanted medical treatments. The ruling reaffirms states' authority to adopt procedural requirements for the withdrawal and withholding of life-prolonging medical interventions. A second legal development was the passage of the federal Patient Self-Determination Act (PSDA), which took effect on December 1, 1991. The PSDA requires Medicaid- and Medicare-participating health care institutions to **inform all adult patients of their rights "to make decisions concerning medical care, including the right to accept or refuse medical or surgical treatment and the right to formulate an advance directive."** Under the PSDA, institutions are legally required to provide this information to patients upon admission for care or upon enrollment in health maintenance organizations (HMOs). The institution must note in the chart the existence of an advance directive and must respect such a directive to the fullest extent under state law.

An advance directive is the formal mechanism by which a patient may express her values regarding her future health status. It may take the form of a proxy directive, an instructional directive, or both. Proxy directives, such as the durable power of attorney for health care, designate a surrogate to make medical decisions on behalf of the patient who is no longer competent to express her choices. Instructional directives, such as "living wills," focus on the types of life-sustaining treatments that a person would or would not choose in various clinical circumstances.

A patient's goals of care are very likely to change with time in different clinical circumstances. As a static expression of the patient's wishes, an instructional directive may thus be a limited tool that could conceivably undermine a patient's most current desires. With this in mind, the patient's appointment of a proxy who knows her interest and accepts the role of surrogate decision maker may be the best way of ensuring that her wishes will be carried out (proxy directive).

Surrogate Decision Making

If the patient who lacks decision-making capacity has not designated a health care proxy, state law may dictate the order in which relatives should be asked to serve as surrogates. **The person selected should be one who knows the patient's values and wishes and will respect them in his or her role as a surrogate decision maker.** If there is conflict regarding the decision of a surrogate, it may be appropriate to seek the advice of an ethics committee or consultant or, possibly, the courts.

In proxy decision making for a dying patient, surrogates and health care providers should be aware that there is documentation and gender disparity in clinical medicine and research in court decisions surrounding the right to refuse life-sustaining treatment. In review of "right to die" cases, it was found that courts honored the previously stated treatment decisions of men in 75% of cases, but they respected the prior choices of female patients in only 14% of cases. Given the persistence and pervasiveness of social attitudes to take women's moral choices less seriously than those of men, gynecologists and patient surrogates must prevent these vices from undermining their advocacy for female patients. Likewise, this evidence should further motivate women to make a treatment decision as explicit as possible.

Futility

Treatments that offer no benefit to patients are clearly not obligatory. However, there is no single point at which all patients will conclude that they have completed a certain number of therapeutic interventions, thus making further control of their disease impossible. Although the cancer is increasingly less likely to respond to second-, third-, or fourth-line agents, this is not necessarily an indication of their potential efficacy in the individual patient. Ovarian cancer, in particular, is a disease entity that requires treatment individualized to the needs and presentations of each patient in ways that other disease practices do not.

The American Medical Association (AMA) Council On Ethical and Judicial Affairs to date has not defined an approach to determine what treatment is and is not medically futile, although the council has discussed related issues concerning end-of-life care in many reports. For example, it has affirmed the ethical standing of withdrawing and withholding unwanted interventions, noted the constructive role that advanced care planning can play in preempting difficult and conflicting situations, and advised the use of a range of orders not to intervene. The council has also opposed physician-assisted suicide out of concern that recent calls from citizens and professionals for physician-assisted suicides are a response to experiences of excessive and futile interventions at the end of life. Because definitions of futile care are value laden, universal consensus on futile care is unlikely to be achieved. Rather, a process-based approach has been proposed that includes four distinguishable steps aimed at deliberation and resolution, two steps aimed at securing alternatives in case of irresolvable differences, and a final step aimed at closure when all alternatives have been exhausted (see Fig. 21.5). This has been outlined by the report of the Council on Ethical and Judicial Affairs of the AMA published in its journal in March 1999.

First, earnest attempts should be made to deliberate over and negotiate a prior understanding among the patient, proxy, and physician about what constitutes futile care for the patient and what falls within acceptable limits for the physicians, family, and possibly also the institution. This prior understanding is best achieved before critical illness occurs. If serious disagreement is irresolvable, provisions can be made for a sensitive and orderly transfer of care at such a time that it can preempt later conflicts.

Second, joint decision making should also be made at the bedside between the patient or proxy and physician. This joint decision making should:

- make use of outcome data whenever possible
- incorporate the physician's and patient's or proxy's intent or goals for treatment
- abide by established standards of deliberation and informed consent

Third, the assistance of an individual consultant or a patient representative is a further step and is often helpful to reach

a resolution within all parties' acceptable limits. The role of this individual consultant is not to singlehandedly resolve the conflict but rather to facilitate discussions that help to reach that end.

Fourth, an institutional committee, such as an ethics committee, may be involved if disagreements are irresolvable. A final step may occur if the outcome of the institutional process coincides with the patient's desire but the physician remains unpersuaded. In such a case, arrangements may be needed for transfer to another physician within the institution.

Alternatively, arrangements for transfers to another institution may be sought if the physician's position does not agree with that of the patient. Finally, if transfer is not possible because no physician and no institution can be found to follow the patient's or the proxy's wishes, it may be because the request is considered offensive to medical ethics and professional standards in the eyes of a majority of the health care profession. In such cases, by ethics standards, the intervention in question need not be provided, although the legal ramifications of this course of action are uncertain.

Because of the complicated nature of these proceedings, the AMA Council recommends that all health care institutions, whether large or small, adopt the policy of medical futility and those policies on medical futility follow their process approach presented earlier.

Hospice

Palliative care programs often foster identification with hospice, and some have integrated hospice home care or inpatient programs. **In the United States, hospice has come to mean primarily a government-regulated organization or program for dying persons and their families that typically focuses on home care and is limited to the following patients and situations:**

1. Life expectancy of 6 months or less
2. A focus on comfort measures. This is sometimes (but not always) defined by hospice programs as a desire to forgo various "aggressive" and often expensive management approaches. These approaches may usually include cardiopulmonary resuscitation; blood product replacement; and some forms of radiotherapy, surgery, chemotherapy, and acute care hospitalization, at least insofar as these treatment modalities are used to try to cure or prolong life rather than to palliate symptoms
3. A general preference for care at home (except where inpatient hospice is available and specifically sought)
4. A willingness to sign a form acknowledging the desire to enter a hospice program and to focus on comfort care
5. Health insurance that covers hospice

Many hospice programs also require a primary caregiver to be either in the home or regularly available. Another requirement reported by patients or family members is that they had to agree to forgo cardiopulmonary resuscitation, calls for emergency services, and future hospitalization. This requirement is not embodied in federal hospice regulations or the PSDA.

Although hospice staff may be perceived as more knowledgeable and empathic than conventional home care workers, hospice may actually provide much fewer hours of formal care, particularly home health aide time. This finding was recently documented for home care patients with amyotrophic lateral sclerosis. Thus, patients and families are often forced to choose between hospice care with insufficient home health aide support and a conventional home care approach that includes significantly more hours of home health aide time. Hospice programs in the United States are increasingly constricted by the eligibility requirements created by Medicare and other insurers and by the limits of reimbursement, thus making it difficult to cover expensive treatments or provide as much home health aide time as conventional programs. Many programs have become extremely cautious about admission or recertification in the face of the threat posed by an unsympathetic and perhaps ill-conceived government audit that scrutinizes long-stay patients and those with diagnoses other than cancer. At the same time, HMOs and insurers have attempted to "unbundle" hospice services, providing and paying for only part of the hospice package (eg, home nurses without social service, chaplains, volunteers, or bereavement care).

Throughout the world, palliative care is developing as an area of special clinical expertise. It is a recognized specialty in Great Britain and Australia and has been the subject of national attention in the Canadian undergraduate medical curriculum. Although a fledging field, it can boast of multiple clinical centers and training programs; various fine textbooks, journals, and educational conferences; and a small body of research expertise. **The challenge that palliative care faces today is to avoid orthodoxy while moving toward greater unanimity about the nature of the field, with improved standards for palliative care professionals and programs.**

Port-site Recurrences
Conclusions

KEY POINTS

1. Minimally invasive surgery (MIS) is practiced by more than 90% of gynecologic oncologists.
2. Knowledge of anatomy, the disease process, and surgical technique is key during these complicated surgical procedures.
3. Several studies have shown that 10 to 20 cases are needed to gain proficiency with a certain procedure.
4. MIS reduces blood loss, transfusions, length of hospital stay, and wound complications without compromising adequacy of the procedure or staging even in (extremely) morbidly obese patients.
5. Survival outcomes for endometrial and cervical cancer are similar after MIS and laparotomy.
6. Several safe methods exist to extract an enlarged uterus after MIS. Morcellation is not recommended when there is suspicion or proven preinvasive or invasive disease.
7. Laparoscopy can be used in ovarian cancer to assess the extent of disease and chance of complete debulking surgery. MIS in advanced or recurrent ovarian cancer is still under investigation, and prospective trials are ongoing.

LAPAROSCOPIC SURGERY IN GYNECOLOGIC ONCOLOGY

Recent advances in the techniques of minimally invasive surgery (MIS) have greatly expanded its role in the management of gynecologic malignancies. Before the 1990s, MIS was mostly limited to laparoscopy for diagnosis of pelvic disease and for tubal sterilization procedures. The great majority of gynecologic oncology procedures for definitive surgical management were performed via large midline abdominal incisions to accomplish appropriate extirpation of the malignancy and surgical staging. Laparotomy causes significant trauma to the patient with many potential associated morbidities, which are increased in incidence and severity in patients with comorbid conditions. The potential applications for MIS in patients diagnosed with gynecologic malignancies have gradually expanded over the past 20 years with improvements in video-laparoscopic instrumentation and surgical training. Since 2005, advances in robotic surgery have led to the increased use of MIS for comprehensive surgical management of patients with gynecologic cancers. Most gynecologic oncologists now offer MIS as an option for surgical management of patients diagnosed with cervical, endometrial, and ovarian neoplasia.

Advanced laparoscopic procedures have been an option for a subpopulation of gynecologic oncology patients in the 1990s. The goal of MIS is to decrease patient discomfort, hospital stay, and short- and long-term morbidity while at the same time providing an overall improvement in quality of life (QoL) and allowing for earlier implementation of other adjuvant therapies if necessary. Incorporating laparoscopic procedures into the comprehensive management of gynecologic oncology patients has been only moderately successful secondary to limitations of the available technology; a difficult and long learning curve; variability in surgeon training and experience; longer operative

times; and patient factors limiting the use of MIS such as prior surgeries, extent of disease, and obesity. Technologic limitations to rapid implementation of complicated laparoscopic surgery in gynecologic oncology include a limited two-dimensional field of vision, counterintuitive motions often required for the surgeon and assistant, limited degrees of freedom of the instruments, and ergonomic disadvantages for the surgeon. Advanced robotic technologies have improved most of these limitations, allowing for expansion of the role of MIS in patients with gynecologic cancer.

As illustrated in other chapters in this textbook, there is a long history in the evolution of surgery in patients with gynecologic cancers. These include incorporation of modifications to radical surgical procedures that reduce the toxicities of treatment with the goal of obtaining the optimal oncologic outcome while improving overall patient QoL. It is important that the goals of cancer control and patient safety are not compromised by a given surgical approach. In other words, MIS serves as another tool to achieve these goals rather than a separate end itself. The historical advantages of laparotomy compared to laparoscopy include maximal surgical exposure, three-dimensional (3D) vision, direct tissue palpation and manipulation, and ease of suturing and other instrument use. Improvements in MIS technology, such as the robotic platform and 3D laparoscopy, have allowed MIS to get a step closer to the surgical experience with laparotomy. The previously mentioned disadvantages of MIS are balanced by potential patient outcome–related improvements. Regardless of surgical approach, it is still imperative that the surgeon adheres to the primary surgical principles of optimal exposure, meticulous tissue dissection, expert knowledge of anatomy, and an understanding of the natural history of the diseases being treated to overcome any potential compromise.

LAPAROSCOPIC SURGICAL STAGING OF GYNECOLOGIC MALIGNANCIES

The cornerstone of appropriate surgical staging is an accurate pelvic and paraaortic lymph node dissection. Incorporation of MIS into the surgical management of patients with gynecologic cancer was not feasible until a technique for adequate laparoscopic lymph node dissection was made possible. Pioneering descriptions of laparoscopic procedures for pelvic lymph node (PLN) dissection came from Europe in the late 1980s by Dargent and Querleu and coworkers. Although exciting in terms of the prospects of MIS, there were concerns regarding the adequacy of lymph node dissection, operative risks, and ability to access the paraaortic nodes. Since that time, laparoscopic skills evolved, and this approach has been demonstrated to be feasible with many descriptions of the surgical technique and outcomes of the laparoscopic pelvic and paraaortic lymph node dissections now reported. Data concerning the laparoscopic approach in the surgical treatment of gynecologic oncology patients are primarily nonrandomized and retrospective, aiming to establish the feasibility of MIS lymphadenectomy in highly selected patients. Only a few multicenter prospective randomized clinical trials have been completed regarding the feasibility of comprehensive laparoscopic management in patients with gynecologic cancer. These trials have demonstrated that laparoscopy does not have inferior outcomes compared with laparotomy in terms of surgical procedures, adequacy of staging, complications, and survival.

ROBOTIC SURGERY IN GYNECOLOGIC MALIGNANCIES

Robotic surgery overcomes many of the technologic limitations of laparoscopy. The robotic platform provides the surgeon with superior high-definition 3D vision, magnification, wristed instruments, and motion scaling. The surgeon has much more ability to directly control the operative field compared with traditional laparoscopy, thus eliminating many important disadvantages of laparoscopy. The operator of the robotic platform not only has improved vision but also controls the direction and distance of the camera from the operative field without relying on the assistant. In addition, the surgeon has three other port sites to use for a dissector, cutting instrument, and another retracting instrument. Loss of haptic feedback is a potential disadvantage; however, the experienced surgeon is able to overcome loss of this sense with heightened visual feedback and meticulous surgical technique. In addition, there are no significant ergonomic disadvantages and a reduced risk of injury to the surgeon and much less risk of fatigue has been demonstrated in some studies. These significant technological improvements have allowed the gynecologic surgeon to perform much more complicated surgeries via MIS on a heterogeneous group of patients. Ten years after Food and Drug Administration approval of robotic surgery for gynecologic surgery (2005), many publications have confirmed the safety and feasibility of robotic surgery compared with traditional laparoscopy and laparotomy. Initial series focused mostly on staging procedures for endometrial cancer; however, the experience has evolved to more advanced procedures such as radical hysterectomy, radical trachelectomy, and even ovarian cancer debulking surgery and pelvic exenteration. It is now the dominant MIS surgical approach in gynecologic oncology

MINIMALLY INVASIVE SURGERY LEARNING CURVE

Recent advances in the techniques of MIS have greatly expanded its role in the management of gynecologic malignancies. Several recent studies have shown an increasing use of laparoscopy as a treatment modality in gynecologic malignancies. Although advanced laparoscopic technology has been available for more than 2 decades, the incorporation of MIS into surgical management of the gynecologic oncology patient has been relatively slow. Whether this relative lack of mainstream adaptation of LS into the practice is a result of technology or training limitations is unclear, although strong biases support both potential causes. Although difficult to quantify, there is a long and difficult learning curve related to laparoscopy and advanced pelvic operations. The availability of the robotic surgery platform is rapidly expanding the role and adaptation of MIS in the surgical

management of women with gynecologic cancer. Nevertheless, these procedures remain major surgeries performed through small incisions and therefore offer unique challenges to the surgeon. Appropriate patient selection, along with a comprehensive understanding of surgical techniques and contraindications, allows for optimal utilization of MIS in the gynecologic oncology patient population.

Little information exists to define the learning curve for laparoscopy and gynecologic oncology surgical procedures. Eltabbakh reported on 75 consecutive patients for laparoscopic management of women with endometrial cancer undergoing laparoscopic-assisted vaginal hysterectomy (LAVH), bilateral salpingo-oophorectomy (BSO), and PLN sampling. There was both a significant decrease in operating time and a significant increase in the number of PLNs harvested with increasing surgeon experience. The experience of the operative assistant has also been shown to be important in major laparoscopic procedures for gynecologic malignancies. Scribner and associates reported a significant difference in successful completion of laparoscopic lymphadenectomies when the first assistant was a skilled attending surgeon compared with a resident or fellow in training. The primary surgeon's experience is the most important factor in improving outcomes in gynecologic oncology laparoscopic surgery. Melendez and colleagues noted improvements in operating room time and a decrease in complications over time in patients with endometrial cancer; however, it required 12 years to gain this experience in 124 patients with endometrial cancer, which reflects a highly selected population of patients. Based on this report and others, it likely requires roughly 20 to 25 laparoscopic endometrial cancer cases to gain proficiency in this procedure, but individual surgeon experience and outcomes are quite heterogeneous. In the largest single-institution report on transperitoneal laparoscopic pelvic and paraaortic lymph node dissection, Schneider and colleagues estimated 20 operations were required to gain the needed experience for laparoscopic pelvic lymphadenectomy and up to 100 for paraaortic lymphadenectomy.

The robotic platform is being more rapidly adapted by gynecologic oncologists to perform extrafascial and radical hysterectomies with pelvic and paraaortic lymph node dissections and is similarly associated with a learning curve. Seamon and colleagues determined that proficiency for hysterectomy with pelvic and paraaortic lymph node dissection in women with endometrial cancer is achieved at 20 cases, and further efficiency continues to improve over time. Holloway and colleagues demonstrated improved operating room times and ability to perform aortic node dissections in a similar group of patients with improvement in patient safety over time. The learning curve for the robotic radical hysterectomy has not been defined but likely is longer than the extrafascial hysterectomy because this is a more complicated surgical procedure. Patient selection based on previous surgical history and, most important, level of obesity significantly influence the learning curve (in addition to surgeon experience in both laparoscopic and robotic MIS.)

The laparoscopic surgical technique is principally different from open laparotomy in the loss of 3D vision, counterintuitive movements, subtle tactile sensation, limitations of instrumentation, and a heavy reliance on skilled surgical assistance. The surgeon needs to compensate for these losses with a thorough understanding of abdominal and pelvic anatomy when operating laparoscopically. In a prospective, randomized trial, Coleman and Muller reported significant improvement in laparoscopic proficiency in residents exposed to a laboratory-based skills curriculum. Training specifically geared toward laparoscopic surgery using models, cadavers, and animal laboratories is important in gaining proficiency in advanced laparoscopic surgery. The learning curve for robotics does appear to be distinctly different from that for laparoscopy as investigators have demonstrated that surgical drills and suturing are performed with enhanced precision and dexterity when comparing robotic technologies with laparoscopy in a training laboratory. In a 2002 survey of laparoscopy training among Society of Gynecologic Oncology (SGO) members, 85% reported receiving no or limited laparoscopic training during their fellowship. A follow-up survey in 2009 among members of the SGO demonstrated that 91% performed laparoscopic surgery in their practices even though 76% reported that they had limited or no exposure to laparoscopic training during fellowship. Ninety-seven percent of gynecologic oncologists now perform robotic surgery. The introduction of simulators, formal resident and fellow training, and the dual-console da Vinci system (Intuitive Surgical) in 2009 allow for a safe training environment and similar patient outcomes compared with traditional laparoscopic surgery. A recent survey of gynecologic oncology fellows showed that most fellows considered even advanced pelvic procedures such as radical hysterectomy and trachelectomy appropriate for MIS. Sixty percent of fellows performed at least 11 procedures per month, an increase compared with 2007. The transition from laparoscopy to robotic surgery for the MIS management of gynecologic cancers will likely further diminish experience in laparoscopic surgery in this population. There may be an advantage to the robotic platform for novice minimally invasive surgeons given the ability for higher magnification and 3D vision. However, any novel technology does not obviate the need for sound surgical principles and technique, knowledge of anatomy, and understanding of the natural history of the diseases being treated.

MINIMALLY INVASIVE SURGICAL TECHNIQUE

Positioning of the Patient

Positioning of the patient is critical in advanced MIS. For most gynecologic procedures, the appropriate position is in a dorsal lithotomy position with adjustable Allen stirrups to allow for manipulation of the uterus and LAVH as indicated. In patients who do not have a uterus or in whom the uterus is not anticipated to be removed, placement in a supine position may be appropriate. The patient's arms should be tucked by her side to allow mobility and ergonomic comfort for the operating surgeon and assistant. Care should be used in protecting both the upper and lower extremities with appropriate padding to prevent pressure points and nerve injuries. For laparoscopic surgery, video monitors should be placed on each side of the

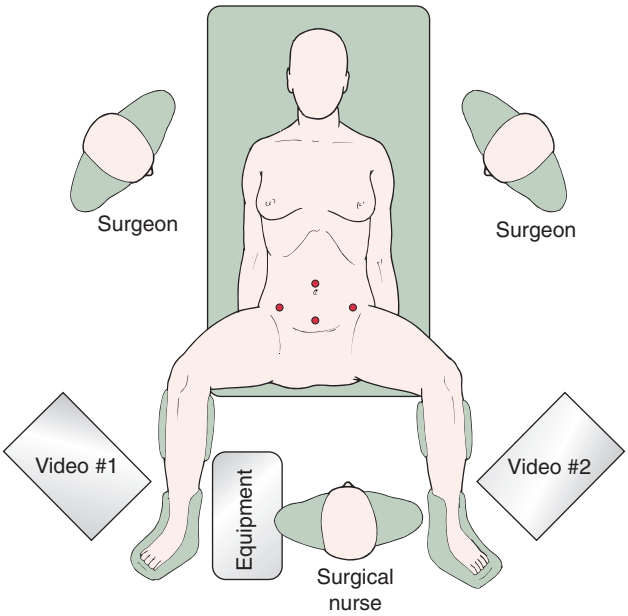

FIGURE 21.1 Operating room setup for laparoscopic surgery. Positioning of patient for laparoscopic gynecologic surgery. Note: Arms tucked (*1*), two video monitors toward foot of table (*2*), and modified dorsal lithotomy position with adjustable stirrups (*3*).

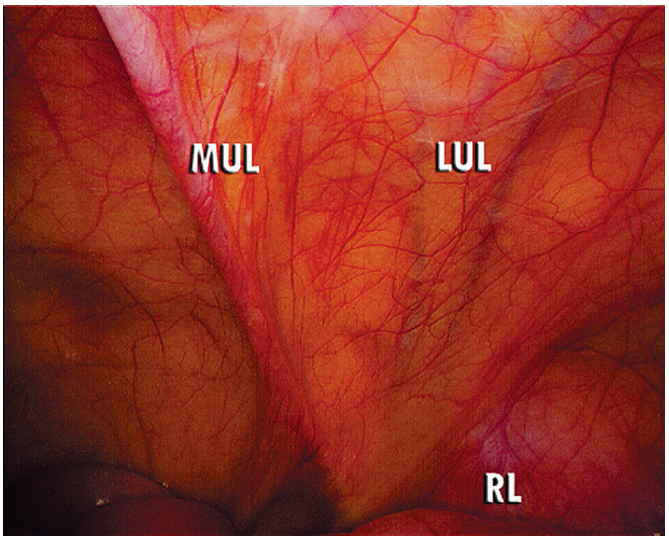

FIGURE 21.2 Anterior abdominal wall. *LUL,* Lateral umbilical ligament; *MUL,* medial umbilical ligament; *RL,* round ligament.

table across from the operating surgeon and the assistant and located toward the foot of the table. This allows for comfortable positioning of the surgeon in a natural angle of viewing the video monitor and minimizing of counterintuitive surgical movement. Placement of the monitors toward the patient's head can be considered when extensive upper abdominal surgery will be undertaken (Fig. 21.1).

Port Sites and Setup

The number, position, and size of trocars for laparoscopic surgery depend on the surgery anticipated. In cases that require removal of an adnexal mass or lymph nodes, a 10- to 12-mm accessory port will be needed for extraction of the specimen. Most laparoscopy (LS) can be accomplished successfully with the placement of a 5- or 10-mm port at the level of the umbilicus for camera placement, a 10- to 12-mm port suprapubically, and a 5-mm port in each of the lateral lower quadrants. Gynecologic oncologists usually use a total of four to six ports to obtain adequate exposure and accomplish advanced pelvic procedures. Safe placement of the primary port, or camera port, is the most critical part of the procedure in terms of minimizing major surgical complications. A number of surgical approaches have been described and accepted for placement of the primary port. An oropharyngeal tube should be used to achieve gastric decompression before placement of the Veress needle or primary trochar. Lateral ports can safely be placed in a line one-third of the distance from the anterior superior iliac spine to the umbilicus. Care should be taken when placing the lateral port and to do so under direct visualization with inspection of the deep inferior epigastric vessels lying along the lateral boundary of the rectus abdominis muscles. These can be directly identified lateral to the obliterated umbilical ligaments (Fig. 21.2). Transillumination will not reliably reveal the location of these vessels.

The port-site setup for robotic surgery is different from that for laparoscopic procedures because ports are generally placed above the umbilicus (Fig. 21.3). Various port setups have been described for robotic gynecologic oncology surgery. Most gynecologic oncologists use one or two laparoscopic port and two additional laparoscopy ports to be controlled by the bedside assistant. In addition, the robot must be "docked" or attached to the ports, which is accomplished between the legs or from the side of the patient. When the surgical procedure commences, the experienced robotic surgeon can efficiently alternate (swap) control of the various robotic ports through a unique clutching system using both hand and foot controls, can operate all instruments in real time, and has direct control of both monopolar and bipolar electrosurgical energy sources. Although there is less reliance on the bedside assistant, that person is still instrumental in facilitating the case through robotic instrument changes, manipulation of vaginal instruments, suction irrigation, and use of an additional grasping instrument for retraction.

In addition to multiport surgery the options have expanded to single-port surgery or laparoendoscopic single-site surgery (LESS) and robotic single-site surgery. Single-port surgery uses a GelPort or Single Incision Laparoscopic Surgery (SILS) port in a 2- to 3-cm (umbilical) incision. Through this port, the camera port and usually two or three additional trocars are placed. Possible advantages include better cosmesis and decreased postoperative pain. Disadvantages such as port crowding, crossing of instruments, and need for advanced laparoscopic skills have limited the uptake for advanced and complicated pelvic surgeries. Robotic single site surgery allowed for computerized optical reversal of crossing instruments and hands with improved ergonomics and 3D visualization. Recently, an articulated needle driver has been added to the

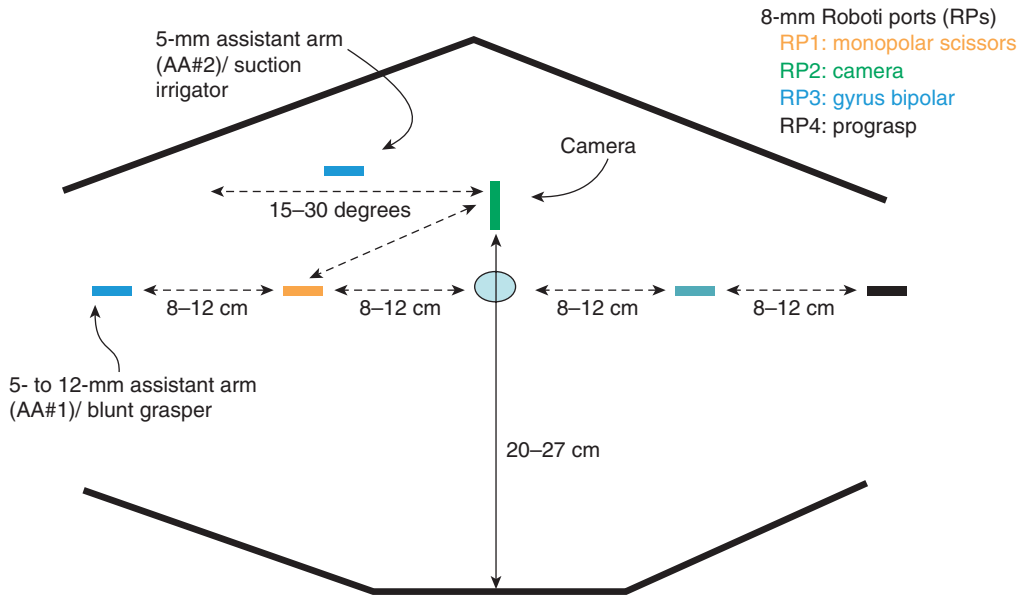

FIGURE 21.3 An example of a robotic port set up for endometrial cancer staging (many variations exist depending on surgeon preference and experience). Trocar placement for hysterectomy, pelvic and aortic lymphadenectomy. Note the robotic ports (RP) are 8 mm, assistant arm (AA) #1 is 5 to 12 mm, and AA#2 is a 5-mm port. Although the placement of RP#1 and 3 corresponds to approximately the midclavicular line, AA#1 and RP#4 are at the midaxillary line. (From Seamon LG, Cohn DE, Valmadre S,, et al. Robotic hysterectomy and lymphadenectomy for endometrial cancer: technical aspects and details of success: the Ohio State University method. *J Robotic Surg* 2008;2:71.)

single-port platform, further improving surgeon comfort and easier applicability or single-site surgery. Cases have to be carefully selected because single ports will not allow for use in very obese patients with thick subcutaneous tissues, and the use of adequate uterine manipulators is imperative without the availability of ports to provide retraction and manipulation.

Surgical Procedure and Technique

After the ports are placed, actual surgical technique varies little except for the surgical steps required to complete various aspects of the procedure. After successful insufflation and placement of the trocars are accomplished, visual inspection of the abdominal cavity is undertaken, and the patient is placed in a steep Trendelenburg position. **As in any surgical procedure, excellent exposure should be accomplished initially and maintained throughout the case.** Use of steep Trendelenburg position is necessary, in lieu of packing the bowel, to achieve adequate visualization of the pelvis and lower abdominal region. Lysis of any adhesions holding the small bowel or omentum into the pelvis or lower abdomen should occur before beginning the pelvic and upper abdominal dissection. The small bowel is carefully placed in the upper abdomen by flipping the bowel from a caudad to a cranial position, exposing the mesentery of the small bowel and the aortic bifurcation (Fig. 21.4). Care should be taken with this maneuver by using blunt instruments and gentle technique. In obese patients, body habitus may not allow a steep Trendelenburg position because of unacceptably high peak inspiratory pressure. Surgery may be able to be completed by decreasing the amount of Trendelenburg positioning

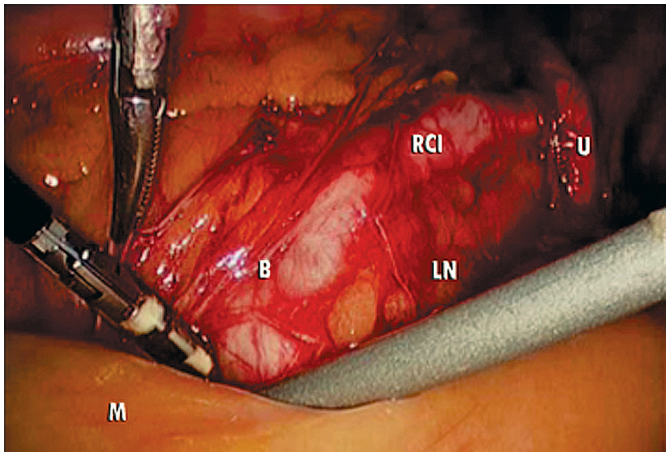

FIGURE 21.4 Paraaortic area. *B,* Aortic bifurcation; *LN,* right paraaortic lymph nodes; *M,* bowel mesentery; *RCI,* right common iliac artery; *U,* ureter.

(while the robot is undocked) or by decreasing the insufflation pressure slightly. Adjusting the respiratory frequency and tidal volume may further improve ventilation. In addition, obesity may prevent adequate mobilization of the small bowel out of the pelvis and upper abdomen to allow for retroperitoneal dissection. Some authors have advocated the use of additional port sites to help circumvent this problem; laparoscopic paddle or fan retractors may also improve exposure.

The key to successful advanced MIS is the same as that for open laparotomy: access to the retroperitoneum. In the pelvis,

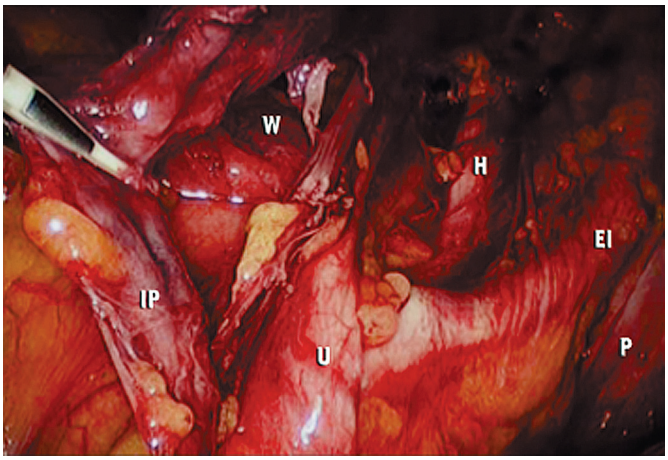

FIGURE 21.5 Pelvic sidewall. *EI,* External iliac artery; *H,* hypogastric artery; *IP,* infundibulopelvic ligament; *P,* psoas muscle; *U,* ureter; *W,* peritoneal window.

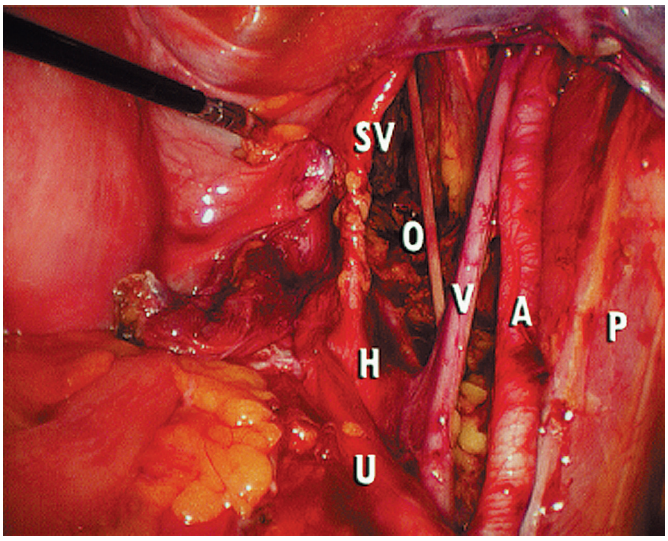

FIGURE 21.6 Pelvic sidewall retroperitoneal anatomy. *A,* External iliac artery; *H,* hypogastric artery; *O,* obturator nerve; *P,* psoas muscle; *SV,* superior vesicle artery; *U,* ureter; *V,* external iliac vein.

this is accomplished by dividing the round ligament laterally or opening the pelvic peritoneum lateral and parallel to the infundibulopelvic ligament. Some surgeons prefer to keep the round ligament intact so they can retract against it to keep the paravesical space open while dissecting tissue. Dissection is then carried down to the level of the external iliac artery, which is then followed in a cephalad and medial direction to the common iliac artery. At this point, the ureter can be found crossing the pelvic brim, and a window can be created between the ovarian vessels and the ureter (Fig. 21.5). Development of the pararectal space is under direct visualization after identification of the bifurcation of the common iliac vessel and the ureter. The surgeon places traction on the ureter, medially developing the pararectal space between the hypogastric artery laterally and the ureter and rectum medially. Care must be taken during this dissection to avoid disrupting the cardinal web deep in the retroperitoneum. Because of the positive pressure environment of MIS resulting from the pneumoperitoneum, the boundaries of the paravesical space can be identified visually during laparoscopic surgery. The superior vesicle artery and umbilical artery are clearly visible as the medial umbilical ligament (see Fig. 21.2). Dissection is carried along the external iliac artery to the level of the superior vesicle artery. At this point, the superior vesicle artery is retracted in a medial direction, and the paravesical space is easily developed with the bladder and superior vesicle artery medially and external artery and obturator node bundle laterally. After this is accomplished, the uterine artery can be clearly identified at the origin of the superior vesicle artery from the hypogastric artery. This retroperitoneal pelvic dissection is the cornerstone of any laparoscopic surgery performed in the pelvis, including removal of an adnexal mass, LAVH, laparoscopic radical hysterectomy (LRH), and PLN dissection (Fig. 21.6). Dissection can be facilitated with a variety of energy sources and clip appliers, each with its own advocates.

Extension of the incision along the peritoneum overlying the right common iliac artery and then along the aorta to the level of the duodenum allows for exposure of the paraaortic

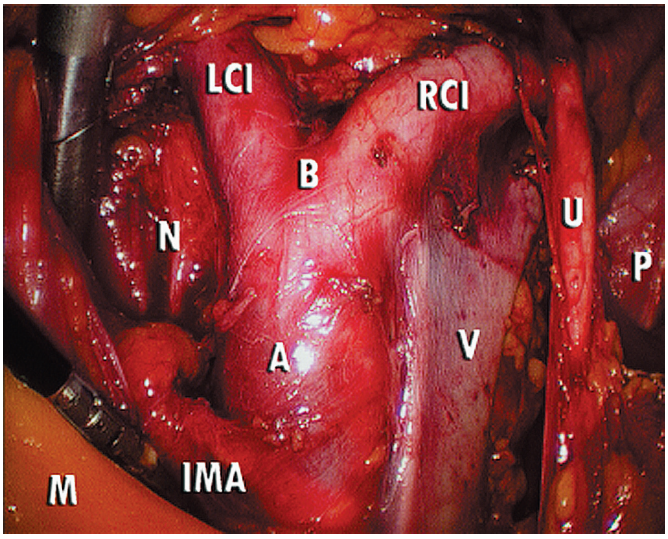

FIGURE 21.7 Paraaortic retroperitoneal anatomy. *A,* Aorta; *B,* aortic bifurcation; *IMA,* inferior mesenteric artery; *LCI,* left common iliac artery; *M,* bowel mesentery; *N,* sympathetic nerve; *P,* psoas muscle; *RCI,* right common iliac artery; *U,* right ureter; *V,* inferior vena cava.

retroperitoneum (Fig. 21.7). During this dissection, the peritoneum attached to the base of the cecum can be elevated in an anterior-cephalad direction, providing excellent exposure to the right paraaortic lymph node region. Margins of resection are identical to an open approach and can be extended to the level of the renal vessels. The left-sided paraaortic lymph node dissection requires dissection underneath the inferior mesenteric artery, mobilizing the descending colon and rectosigmoid off the left common iliac artery and retracting the inferior

mesenteric artery and ureter laterally and cephalad. This gives excellent exposure to the left paraaortic lymph nodes inferior to the inferior mesenteric artery. Dissection can be continued above the inferior mesenteric artery in a similar manner. Some authors have advocated sacrificing the inferior mesenteric artery to get enhanced exposure to the upper left paraaortic nodes.

Unfortunately, the potential limitations previously described for MIS compared with laparotomy lead to the potential for inherent compromises in surgical technique. Therefore, the surgeon needs to obtain experience over time to optimize patient outcomes and emphasize excellent surgical technique. Knowledge of anatomy, the disease process, and surgical technique is key during these complicated surgical procedures. To minimize complications that are possible with any major surgical procedure, vigilance and meticulous surgical technique are required.

APPLICATIONS OF MINIMALLY INVASIVE SURGERY IN GYNECOLOGIC ONCOLOGY

Cervical Cancer

The pioneering reports describing the use of advanced laparoscopic techniques in gynecologic oncology were initially described in patients with cervical cancer in which laparoscopy was used for PLN dissection in patients with early-stage disease to assess the feasibility for abdominal radical hysterectomy. One of the initial concerns about MIS in cervical cancer was that the laparoscopic approach would not be as thorough as laparotomy in assessing metastatic cancer and performing a comprehensive lymphadenectomy. Early studies in patients undergoing initial laparoscopic lymphadenectomy before laparotomy confirmed that a thorough pelvic and paraaortic lymphadenectomy is possible via LS, with no positive nodes discovered at laparotomy performed after laparoscopic lymphadenectomy. Nevertheless, the completeness of laparoscopic dissection was dependent on the experience of the surgeon, and the most common area for missed lymph nodes was lateral to the common iliac bifurcation. After the feasibility of laparoscopic lymphadenectomy was established, the use of MIS for radical surgery in patients with early-stage cervical cancer and for preradiation surgical assessment in patients with advanced disease was made possible.

Early-stage Cervical Cancer: Radical Hysterectomy

The establishment of the feasibility of laparoscopic lymphadenectomy led to the renewed interest in radical vaginal hysterectomy with laparoscopic lymphadenectomy and the development of novel minimally invasive radical hysterectomy techniques. Several groups worldwide have demonstrated the feasibility of the Schauta radical vaginal hysterectomy, laparoscopic-assisted radical vaginal hysterectomy (LAVRH), and total LRH with the goals of maintaining a high level of cancer control with improved patient outcomes in women with early-stage cervical cancer. The Schauta radical vaginal hysterectomy, described more than 100 years ago, and its subsequent modifications are performed completely vaginally; however, the surgeon does not have the opportunity to perform a retroperitoneal lymph node dissection. The LAVRH has many descriptions but usually involves a laparoscopic phase that includes the lymphadenectomy followed by developing the pararectal and paravesical spaces, dividing the parametria and paravaginal pedicles, and completing the remainder of the procedure vaginally. For the LRH, the entire radical pelvic operation is completed with MIS techniques. One advantage of the LAVRH over the LRH is the ability to precisely define the vaginal incision. Additionally, the performance of LAVRH allows for the development of the MIS skills required to perform a fertility-sparing radical vaginal trachelectomy. Currently, the favored laparoscopic approach is the LRH or robotic-assisted radical hysterectomy (RARH) because there is no need for a perineal phase for the performance of a vaginal incision, exposure is improved, visualization of critical anatomy and surgical planes is better, and anatomic limitations are fewer as a result of a narrow pelvis or lack of uterine descensus. Most important, however, is the fact that LRH mimics the well-established steps of an abdominal radical hysterectomy, thereby making LHR easier to adopt. Certainly, LRH is a technically challenging procedure. Most surgeons who use robotic techniques feel that the superior vision and wristed instruments provide optimal MIS capacity to perform the meticulous dissection required for the radical hysterectomy. Thus, the availability of the robotic platform allows for a significant shortening of the learning curve for MIS radical pelvic procedures and increased uptake of radical hysterectomy via the minimally invasive approach.

There is no doubt that the LARVH, LRH, and RARH are feasible for patients with early-stage cervical cancer. It has been demonstrated that these techniques can accomplish the oncologic goals of the surgery, allowing for the identification of critical anatomy, performance of a thorough lymph node dissection, and completion of the radical resection of the primary tumor with adequate margins. Most reports on LARVH and LRH demonstrate rates of complications comparable to those seen with the traditional open approach. A number of single-institution series reveal that the operative time is longer for LRH and RARH but associated with a decreased length of hospital stay (Tables 21.1 and 21.2). More recent series are larger and also report recurrence and survival data, which compare favorably with matched historical patients undergoing a traditional radical hysterectomy for cervical cancer. A recent meta-analysis comparing abdominal radical hysterectomy with laparoscopic or robotic radical hysterectomy demonstrated less estimated blood loss, shorter length of stay (LOS), fewer wound-related complications, and febrile morbidity in patients undergoing minimally invasive radical hysterectomy. A large multi-institutional retrospective comparison reported similar findings with increased operating time for robotic radical hysterectomy compared with open radical hysterectomy but with lower blood loss and transfusion rates. Overall complication types were similar but occurred less frequently in the robotic radical hysterectomy group; intraoperative complications occurred in 4% versus 11%, and postoperative complications were seen in 30% versus 27% of patients undergoing robotic and open radical hysterectomy, respectively. Of note, recurrence and survival rates were similar. The traditional abdominal radical hysterectomy and the LRH/LARVH procedures are now being

compared in a prospective randomized study, and recruitment is ongoing.

Most authors stress that there is a lengthy learning curve for LRH and that complications decrease and overall operative efficiency improves as the surgeon gains experience. Therefore, these procedures should be performed by highly skilled and experienced surgeons in selected patients to obtain optimal outcomes. Of note, improvements in subspecialty training, collective and individual experience in performing the traditional abdominal radical hysterectomy, better perioperative care, and a general trend toward decreased hospital stay have demonstrated an overall improvement in the outcomes of patients

undergoing the open abdominal approach. In fact, the shortest average length of hospital stay reported in many of the LRH series is similar to that reported in contemporaneous series of open radical hysterectomy. There is a lack of prospective data to compare cost and morbidity between the two approaches, and retrospective data do not definitively establish a significant advantage or disadvantage for the laparoscopic approach. **Currently, it appears that with appropriate training and experience, minimally invasive radical hysterectomy is at least comparable to the open technique with regard to cost, morbidity, other perioperative outcomes, and survival.**

Early-Stage Cervical Cancer: Fertility-Sparing Surgery

The ability to perform an adequate laparoscopic lymphadenectomy combined with the revival of the radical vaginal hysterectomy have led to the development of novel techniques for fertility preservation in young patients with early-stage cervical cancer. The laparoscopic vaginal radical trachelectomy (LVRT) is one of the most exciting applications of MIS in gynecologic oncology. In an effort to define the potential number of patients in whom this procedure would be considered, Sonoda and coworkers reported on 435 patients undergoing radical hysterectomy. Eighty-nine of these patients were younger than 40 years of age and had tumors that met the criteria for fertility-sparing radical trachelectomy (which represented 20% of their early-stage population) (Table 21.3). This study clearly shows that there is a substantial population of patients who may benefit from this approach.

The LVRT technique combines laparoscopic pelvic and common iliac lymph node dissection with a radical vaginal trachelectomy (with preservation of the uterine fundus and creation of a neocervix). This procedure was initially described by Dargent in 1987; since then, several centers have reported preliminary results on fertility-sparing radical trachelectomy with laparoscopic lymphadenectomy. Survival and fertility follow-up reports have been encouraging. To date, more than 300 cases have been reported with a recurrence rate of 4.1% and a death rate of 2.5%, which falls well within the range of survival seen with traditional radical hysterectomy in similar populations. Randomized prospective comparisons are not available, but case-control studies in matched patients reveal equivalent oncologic outcomes when comparing radical hysterectomy with radical trachelectomy. Plante et al. reported on the obstetric outcomes of 72 patients undergoing the surgery over a 12-year time span. A total of 50 pregnancies occurred in 31 women. Infertility rates and first and second trimester pregnancy loss did not appear to be increased. Of the patients reaching the third trimester, 22% had preterm delivery (although only 8% were delivered before 32 weeks). **There appear to be enough data now published to consider fertility-sparing radical trachelectomy a viable option for select and motivated patients. Chuang and colleagues first reported robotic fertility-sparing radical trachelectomy in which the entire procedure is performed minimally invasively without a perineal or vaginal phase. Subsequent reports, limited by a small number of patients enrolled, have demonstrated the feasibility of robotic radical trachelectomy with decreased blood loss and LOS compared with open radical trachelectomy and without compromise of histopathologic or cancer outcomes. Approximately half of the patients who attempted pregnancy were able to conceive, and pregnancy rates were higher in the open surgery group. Whether this is due to shorter follow-up times in the MIS group or a true difference will have to be determined in future studies.**

TABLE 21.3 Suggested Clinical Eligibility Criteria for Laparoscopic Radical Vaginal Trachelectomy or Robotic Radical Trachelectomy

1. Confirmed invasive cervical cancer: squamous, adenocarcinoma, or adenosquamous
2. FIGO stage Ia1 with lymphovascular space involvement, FIGO Ia2 to Ib1
3. Desire to preserve fertility
4. No clinical evidence of impaired fertility
5. Lesion size <2 cm
6. Patient is a candidate for a vaginal hysterectomy
7. Estimated cervical length ≥2 cm clinically
8. Adequate resolution of acute inflammation postcone
9. No evidence of extracervical or metastatic disease

FIGO, Federation of International Gynecologists and Obstetricians.

Advanced-Stage Cervical Cancer: Surgical Staging

Patients with advanced-stage disease or bulky early-stage cervical cancers are generally treated with definitive radiotherapy and concurrent chemotherapy. For this group of patients, laparoscopy has been used for surgical staging and to assist radiation oncologists in the safe placement of interstitial brachytherapy implants. Even positron emission tomography or computed tomography scans will not identify all patients with extrapelvic disease. Although controversial, surgical staging has been advocated to accurately define the extent of disease and guide the subsequent radiation fields. In patients with gross evidence of lymph node metastasis, their removal has been demonstrated in retrospective studies to improve survival compared with radiation of these nodes without debulking.

Before advanced MIS techniques, retroperitoneal lymphadenectomy for surgical staging of cervical cancer was performed at the time of extraperitoneal laparotomy. This approach afforded the surgeon excellent exposure to both the pelvic and paraaortic nodes with the ability to debulk grossly positive nodes. A transperitoneal laparotomy approach is not recommended because it is associated with a significant increase in the rate of severe postirradiation enteric morbidity compared with extraperitoneal laparotomy, presumably secondary to adhesion formation. Both transperitoneal and extraperitoneal laparoscopic approaches have been described for surgical staging of cervical cancer. Initially, there was concern that transperitoneal laparoscopic lymph node dissection would be associated with increased adhesion formation as experienced with transperitoneal laparotomy for lymphadenectomy. The extraperitoneal laparoscopic approach avoids this risk, but the surgeon only has access to the common iliac and paraaortic

lymph nodes and is unable to perform a PLN dissection. However, transperitoneal laparoscopy, in general, is associated with fewer intraperitoneal adhesions compared with laparotomy. Blinded studies in animal models reveal a similar rate and severity of adhesions between transperitoneal laparoscopic lymph node dissection and extraperitoneal laparotomy; however, transperitoneal laparoscopic lymphadenectomy is associated with significantly fewer adhesions compared with transperitoneal laparotomy.

Multiple single-institutional series exist describing laparoscopy for pretreatment lymphadenectomy for advanced cervical cancer. The procedure is feasible with acceptable morbidity compared with laparotomy. A significant advantage for the laparoscopic approach is avoiding potential complications of a large abdominal incision and quicker postoperative recovery, allowing the patient to proceed to definitive radiation therapy more quickly. Although laparoscopic resection of nodes grossly involved with metastatic disease is technically feasible, it is definitely more difficult compared with laparotomy, especially when the nodes are fixed to vessels. Therefore, some surgeons prefer extraperitoneal laparotomy in case they encounter nodes that require debulking. The robotic platform obviates many of the inherent disadvantages of laparoscopy. As in laparoscopy, the robotic approach can be used for pelvic and paraaortic lymph node dissection. In addition, advantages of robotic surgery enable the surgeon to perform the more complicated debulking surgeries if necessary.

Endometrial Cancer

Laparoscopy

In the population of patients diagnosed with a gynecologic malignancy, MIS is most often applied for those diagnosed with endometrial cancer. Before the availability of advanced laparoscopic procedures, vaginal hysterectomy was a less invasive option for definitive surgical therapy, especially in patients with severe comorbidities and an increased risk of complications secondary to laparotomy. In fact, assuming the disease is confined to the uterus, the curative potential of the hysterectomy should be equivalent regardless of the surgical approach. The disadvantages of the vaginal hysterectomy in endometrial cancer include the inability to fully inspect the peritoneal cavity and retroperitoneum (lymph nodes) for metastatic disease and potential inability to complete BSO. The addition of laparoscopy to the vaginal hysterectomy essentially eliminates these disadvantages. Most patients with endometrial cancer present with apparent early-stage disease. Approximately 15% to 25% will be upstaged as a result of surgical staging. The majority of patients with extrauterine disease have occult (without gross evidence) spread. Current disease assessment modalities such as preoperative imaging, intraoperative palpation, gross inspection, and frozen section of the uterus all are inaccurate compared with comprehensive surgical staging that includes bilateral pelvic and paraaortic lymph node dissection. Comprehensive surgical staging with lymphadenectomy provides the best definition of the biologic nature of the disease and allows the oncologist to make informed postoperative treatment decisions.

Laparoscopic-assisted vaginal hysterectomy bilateral salpingo-oophorectomy (LAVH-BSO) or total laparoscopic hysterectomy (TLH) can be substituted for total abdominal hysterectomy bilateral salpingo-oophorectomy (TAH-BSO) in the algorithm presented earlier in this book for the management of endometrial cancer.

The overall management of patients with apparent early-stage endometrial cancer continues to evolve. Endometrial cancer remains the least uniformly managed gynecologic malignancy, even among gynecologic oncologists. It remains controversial whether all patients should have surgical lymph node assessment and, in those undergoing lymphadenectomy, the extent to which lymph node dissection should be performed. Nevertheless, until laparoscopic lymph node dissection was described, comprehensive surgical staging of endometrial cancer by MIS was not feasible. The earliest series published on MIS management of endometrial cancer primarily described pelvic lymphadenectomy with a minimum of patients undergoing a paraaortic lymph node dissection. The ability to perform laparoscopic lymphadenectomy evolved from pelvic nodes to right-sided paraaortic nodes to a bilateral paraaortic lymph node dissection to the level of the inferior mesenteric artery. Although controversial, recent reports on surgical staging of endometrial cancer recommend that selected patients at high risk for extrauterine disease have a bilateral paraaortic dissection to the level of the renal vessels. This technique has been described laparoscopically but is technically difficult and likely currently applied to a small minority of patients undergoing MIS management of endometrial cancer.

Until recently, most data describing the experience of laparoscopy in management of endometrial cancer came from single institutions and are primarily retrospective studies. It is clear that advances in MIS technology, training, and experience allow the surgeon the opportunity to ensure removal of the uterus and adnexae, inspect the peritoneal cavity, define the retroperitoneal anatomy, and perform a thorough pelvic and paraaortic lymph node dissection. The reported benefits of a laparoscopic approach in endometrial cancer are lower blood loss and transfusion rates, shorter hospital stay, faster postoperative recovery, and superior short-term QoL, albeit at the expense of longer operative times. However, these studies are biased by the fact that they represent only selected patients (eg, those with low body mass indexes [BMIs]) compared with an institution's entire population of patients with endometrial cancer. Additionally, these series vary as to whether comprehensive surgical staging was performed and, if so, as to the extent of lymph node dissection (Table 21.4). Surgeon experience and patient factors such as obesity or previous abdominal surgery contribute to the many disadvantages of the laparoscopic approach in endometrial cancer, especially if the goal is comprehensive surgical staging. In a study of two California databases from 1997 to 2001, only 7.7% of patients diagnosed with endometrial cancer underwent surgery via a laparoscopic approach. A recent survey of members of the Society of Gynecologic Oncologists (29% responding) revealed that use of MIS as a surgical treatment option for endometrial cancer has continued to increase, with almost 70% of gynecologic oncologists

stating that this is the procedure they perform most via the MIS approach.

Several prospective randomized trials comparing laparoscopic and open surgery for endometrial cancer staging have been conducted. In 2009, the Gynecologic Oncology Group (GOG) reported the results of the LAP-2 (Laparoscopy compared with laparotomy for comprehensive surgical staging of uterine cancer: Gynecologic Oncology Group Study) trial, which enrolled 2531 patients with apparent early-stage endometrial cancer. All patients in this study were to undergo complete surgical staging and were randomly assigned in a 2:1 ratio of laparoscopy to laparotomy. Of the 1678 patients on the laparoscopy arm, 25.8% required conversion to laparotomy (of note, conversion to laparotomy was mandatory if lymph node dissection could not be completed laparoscopically). More than half of these conversions were a result of poor visualization (exposure), 16% were from metastasis, and 11% were from bleeding. Fig. 21.8 graphs the likelihood of converting from laparoscopy to laparotomy as a function of BMI, age, and evidence of metastatic disease. In this landmark study, there was no significant difference in rate of node positivity between the two groups; however, significantly fewer patients in the laparoscopy arm (78.5%) compared with the laparotomy arm (86.4%) had lymph nodes histologically identified from all four primary nodal regions (which include the right and left periaortic and bilateral PLNs). The incidence of intraoperative complications, reoperations, and readmissions was similar, but significantly fewer Common Toxicity Criteria grade II or greater postoperative complications (P <0.0001) occurred on the laparoscopy arm (14.3%) compared with the laparotomy arm (21.1%). Similar transfusion rates were seen between the groups (7% to 9%). Consistent with other studies in the literature, operative time was significantly longer for the laparoscopic arm (203 minutes) versus the laparotomy arm (136 minutes). For patients successfully completing laparoscopic surgery, the average length of hospital stay was 2 days versus 4 days for laparotomy (P <0.0001). During the perioperative period, the LAP-2 study revealed significantly better overall QoL, pain scores, resumption of normal activities, and time until return to work in the laparoscopy arm. By 6 months after surgery, no significant QoL differences were found except in that of body image. Previously reported but small single-institution studies reveal no differences in survival between laparoscopy and laparotomy for the surgical management of endometrial cancer. **LAP-2 also examined this most important survival endpoint. The estimated 3-year overall survival rates from this study are 89.8% for laparoscopy and 89.9% for laparotomy, with similar rates of recurrence and death from disease. Other international studies such as the Dutch study by Mourits et al. in which patients were randomized to TLH versus abdominal hysterectomy (without lymph node staging) and the Australian study (Laparoscopic Approach to Cancer of the Endometrium [LACE] trial) by Janda and**

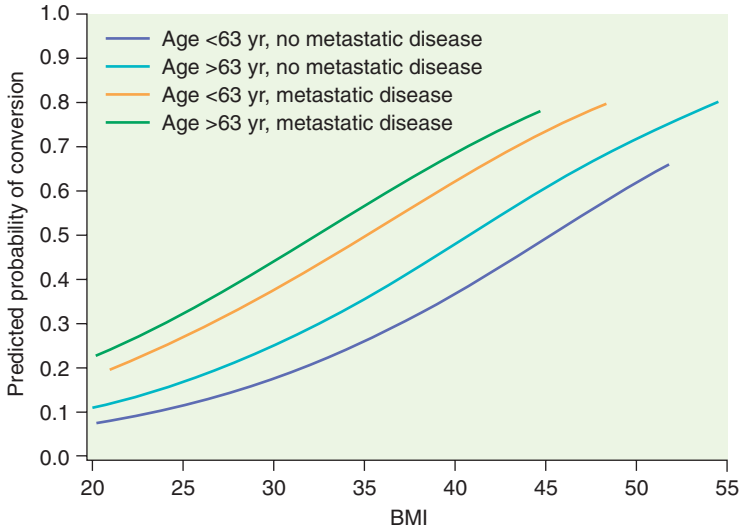

FIGURE 21.8 Predicted probability curve for risk of conversion by body mass index (BMI), age, and metastatic disease. (From Walker JL, Piedmonte MR, Spirtos NM, et al. Laparoscopy compared with laparotomy for comprehensive surgical staging of uterine cancer: gynecologic Oncology Group Study LAP2. *J Clin Oncol* 2009;27:5331.)

coworkers, which also included pelvic lymphadenectomy reported similar findings. The latter also found better QoL up to 6 months after TLH and with fewer complications.

Laparoscopy offers selected patients with endometrial cancer the potential benefits of shorter hospital stay, less need for blood transfusion, and decreased postoperative complications with a similar risk of intraoperative complications. Nevertheless, laparoscopic hysterectomy with pelvic and paraaortic lymph node dissection remains difficult to learn and is least likely to be offered or successful in patients with obesity, the group of patients most likely to benefit from MIS. Although morbid obesity is the most common risk factor for developing endometrial cancer, it is also the major limitation to successful laparoscopic surgical management. Most studies reporting the use of MIS for the treatment of endometrial cancer describe a population of patients with a mean BMI lower than that typically seen in the overall population of patients with endometrial cancer. Even the LAP-2 study represents a selected group of patients because the median BMI was 28 kg/m^2 in both arms. The rate of conversion from laparoscopy to laparotomy ranges quite widely between single-institution reports. Variables such as intent to perform comprehensive staging, adhesions, intraoperative complications, discovery of metastatic disease, and surgeon experience have all been reported as important factors. In the LAP-2 study, the overall conversion rate was 25.8% and strongly influenced by BMI (with a rate of 17.5% in patients with a BMI of 25 kg/m^2 and a rate of 57% in patients with a BMI greater than 40 kg/m^2).

Robotics

As previously mentioned, recent developments in robotic technology have allowed the surgeon to gain advantages compared with laparoscopy, and this technology has rapidly been adopted by gynecologic oncologists independent of their prior laparoscopic experience. Relatively large single-institution and pooled reports reveal that the robotic surgical staging of patients with endometrial cancer is feasible and that the patient experiences the typical benefits of MIS compared with laparotomy. Furthermore, these reports have shown that robotic surgery is likely applicable to a larger portion of patients diagnosed with endometrial cancer compared with laparoscopy, including patients who are morbidly obese (see Table 21.4). Seamon and colleagues demonstrated that comprehensive surgical staging is feasible in a relatively heavy group of patients (mean BMI, 34 kg/m^2), as robotic pelvic and paraaortic dissection was performed in 85% of the patients overall and in 67% of the patients with BMI more than 45 kg/m^2. Gehrig and coworkers compared their robotic and laparoscopic experience in obese patients (BMI >30 kg/m^2) with endometrial cancer and demonstrated a significant difference in hospital stay, blood loss, and operating room time in favor of the robotic group. Seamon and colleagues compared 105 patients with endometrial cancer undergoing robotic surgery with 76 patients managed laparoscopically and revealed a similar ability to complete surgical staging. However, comprehensive surgical staging was able to be performed in heavier patients compared with laparoscopy (BMI, 34 kg/m^2 vs. 29 kg/m^2), and with significantly shorter LOS, lower conversion to laparotomy, and shorter operating room time in favor of the robotic group. Compared with laparotomy, the advantages of the robotic approach are more dramatic in obese patients with endometrial cancer. In a matched cohort study in patients with a median BMI of 40 kg/m^2 and multiple comorbidities, patients managed robotically experienced a decreased LOS (1 vs. 3 days) and significantly lower rates of overall complications (odds ratio [OR], 0.29), blood transfusion (OR, 0.22), and wound complications (OR, 0.10) compared with laparoscopy (Fig. 21.9). Even in extreme morbid obese patients (mean BMIs, 48, 51, and 54 for laparoscopic, robotic, and open hysterectomy, respectively), MIS (laparoscopic and robotic) was associated

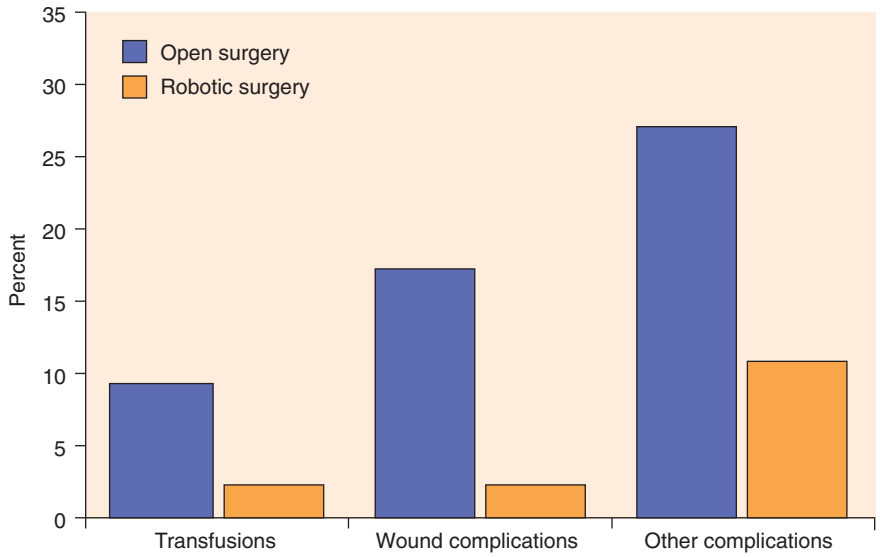

FIGURE 21.9 Transfusion rates, postoperative complications, and wound complications for laparotomy compared with robotic hysterectomy lymphadenectomy for endometrial cancer. The blood transfusion rate (9% compared with 2%; odds ratio [OR], 0.22; 95% confidence interval [CI] 0.05–0.97; $P = 0.046$), wound problems (17% compared with 2%; OR, 0.10; 95% CI 0.02–0.43; $P = 0.002$), and complications (27% compared with 11%; OR, 0.29; 95% CI 0.13–0.65; $P = 0.003$) were reduced for robotic surgery. (From Seamon LG, Fowler JM, Richardson DL, et al. A detailed analysis of the learning curve: robotic hysterectomy and pelvic-aortic lymphadenectomy for endometrial cancer. *Obstet Gynecol* 2009;114:16.)

with lower rates of blood loss and shorter hospital stays despite longer operative times. Similarly, comorbidities, not weight and BMI, were predictive of an increased risk of perioperative complications.

In addition, recurrence rates and survival appear similar to open surgery in retrospective reviews. Although it is most critical that the surgeon have expertise in the management of patients with endometrial cancer, it appears that the learning curve for comprehensive robotic staging of endometrial cancer is not as difficult as laparoscopy. Experiences from several institutions have shown that 10 to 20 cases are needed to gain proficiency with the procedure. Operative times improve as the surgeon and the surgical team become more familiar with the setup and techniques. The robotic platform is now the dominant surgical approach in the management of women with apparent early-stage uterine cancer.

Single-Site Surgery

In 2009, Fader and Escobar reported their initial experience with LESS for gynecologic cancer surgery. Larger series have since been published and have demonstrated safety and feasibility of the single-site approach for endometrial cancer. Although single-site surgery has been reported in moderately obese patients (median BMI, 32–33), abdominal wall thickness remains a limiting factor for the single port in extreme morbidly obese patients.

Minimally Invasive Sentinel Lymph Node Assessment

In an attempt to reduce the risk of side effects and complications (bleeding, lymphocele, lymphedema, longer operating time) seen with comprehensive lymph node dissection, sentinel lymph node (SLN) assessment has been developed and has been part of standard of care in breast cancer, melanoma and vulvar cancer for several years. SLN assessment is now also an acceptable part of standard of care in women with endometrial cancer and cervical cancer and has been incorporated in the National Comprehensive Cancer Network's guidelines (version 2.2015). SLN assessment can be performed using open and minimally invasive techniques, and equipment is available for laparotomy, laparoscopic, and robotic approaches. Blue dye (isosulfan blue, patent blue, methylene blue) has been studied most extensively. Other available methods include radiolabeled technetium-99 with lymphoscintigraphy, indocyanine green dye (ICG) with immunofluorescence detection, and a combination of the various methods. Some studies advocate for using ICG only given the high detection rates and ease of administration as well as a low risk of allergic reaction (1:40,000). For cervical cancer, peritumoral injection is intuitive and relatively easy. In contrast, the best location of injection is not as clear for endometrial cancer. Investigators have studied hysteroscopic tumor injection, fundal or subserosal injection, cervical injection, or a combination of multiple injection sites. Although combined location injection methods have improved SLN detection rates, the overall accuracy of intracervical injection alone is high. Certainly, some surgeons have expressed concern about missing aortic SLNs, but staging studies have demonstrated that the risk of isolated positive aortic lymph nodes in the setting of negative PLNs is rare (1%–2%). However, it is important to keep in mind that in high-risk patients (high-grade histology or deep myometrial invasion), the risk of paraaortic lymph

node involvement increases to 4%, and as such, the safety of intracervical injection for SLN assessment in high-risk patients has not yet been confirmed. Most surgeons prefer to perform cervical injections only, and injection protocols vary. In general, 1 mL of dye is injected at the 3 and 9 o'clock position. Some believe dye should be injected superficially (submucosal) and deep (intrastromal), but others inject superficially only. Next, ports are placed, and the retroperitoneal spaces are developed. Care should be taken to maintain excellent hemostasis because blood can obscure visualization of the various types of dye. SLNs are dissected, labeled for location, and sent separately. Detection rates (any detection) vary from 80% to 95% in endometrial cancer and 84% to 99% in cervical cancer depending on the study and methods used, and best detection in cervical cancer is seen in tumors smaller than 2 cm. Bilateral detection varies between 60% and 85% for cervical cancer and 52% and 79% in endometrial cancer. Adherence to an SLN algorithm is critical for successful application of SLN assessment; all suspicious or enlarged lymph nodes should be removed, and a site-specific complete lymphadenectomy is performed when SLNs are not identified. When adhering to these principles, the negative predictive value is high (95%–100%), and false-negative rates are low. Most institutions use ultrastaging (serial sectioning of the SLNs with immunohistochemistry in addition to standard hematoxylin and eosin stain) to assess for metastatic disease; however, the clinical significance of micrometastases detected with ultrastaging has not been defined at this time.

Removal of a Large Uterus

If the uterus is too large or the vaginal opening is too small to remove the uterus through the vagina, the surgeon can place the uterus in a laparoscopic bag (through the vagina or a port site). Sometimes this allows for removal of the uterus through the vagina, providing a smoother outer surface and more equal distribution of pulling forces. If still unsuccessful, the midline camera port can be slightly extended to allow for uterine removal in the laparoscopic bag (mini-laparotomy). Some surgeons bivalve or morcellate the uterus in the bag; however, removing the uterus intact for complete pathologic assessment is preferred. Certainly, power morcellation is not recommended when operating on patients with invasive or preinvasive disease.

Uterine Manipulation for Minimally Invasive Surgery

Adequate uterine and vaginal manipulation is a requirement for successful completion of MIS to identify the correct planes of dissection and to avoid additional ports to retract and move the uterus. Early studies reported increased incidence of positive peritoneal cytology after laparoscopic hysterectomy (10%) compared with open hysterectomy (2.8%). However, more recently, two prospective studies comparing pelvic washings before and after insertion of the uterine manipulator found no significant increase (0%–4%) in positive cytology after insertion of the manipulator. Tubal contamination was reported to be higher after robotic compared with laparoscopic hysterectomy, and avoiding manipulation of the tubes but rather retracting using the round ligaments may be considered. There has been no evidence that true lymphovascular invasion is more common with the use of uterine manipulators in endometrial or cervical cancer. Most important, there is no evidence that the use of a uterine manipulator leads to increased risk of recurrence or worse prognosis, although randomized studies have not been performed.

Adnexal Mass

One of the most common clinical scenarios presented to gynecologic surgeons is that of the suspicious adnexal mass. Because most masses are asymptomatic, the major reason for surgical removal is to determine if a malignancy is present. The finding of a persistent ovarian mass represents a major reason for surgery in gynecology. Killackey and Neuwirth reported that 17% of laparotomies in gynecology are performed primarily for this indication. It has been reported that 5% of persistent premenopausal ovarian masses and 20% to 50% of those in postmenopausal women are malignant. This risk of malignancy (and potential need for surgical staging or cytoreduction) has led to the recommendation that suspicious ovarian masses be removed through a vertical midline incision. This recommendation, however, is made with the assumption that a gynecologic oncologist or other trained surgeon will be available to provide surgical support if required. This surgery may include radical pelvic or upper abdominal dissection, retroperitoneal lymphadenectomy or lymph node debulking, or bowel resection. Most gynecologists do not have such assistance on standby for every surgery performed for a pelvic mass. Potential advantages of minimally invasive approaches to the pelvic masses are cost savings and decreased morbidity in those women without cancer and early diagnosis and referral for appropriate surgical management in those who are found to have malignancies.

Postmenopausal women undergoing laparotomy for ovarian masses have a much greater likelihood of malignancy than premenopausal women. Postmenopausal patients with ovarian masses differ from premenopausal patients with respect to the predictive value of CA-125. An elevated CA-125 level has a positive predictive value for malignancy of 80% to 98% in this population. Postmenopausal patients with an adnexal mass and an elevated CA-125 level are presumed to have a malignancy and should have surgery by an ovarian cancer specialist regardless of the ultrasound findings. The ability to identify patients preoperatively at highest risk for cancer (with the appropriate selection of surgical approach and consultation or referral for surgical management of this potential cancer) is often challenging. Although pelvic ultrasonography, tumor markers, and clinical presentation all contribute to risk stratification for ovarian cancer, the definitive evaluation of a mass is determined during surgery. However, multiple scoring systems have been devised to provide the surgeon with a preoperative probability of a mass being malignant. The SGO and the American College of Obstetrics and Gynecology jointly published referral guidelines and management recommendations for patients who present with a pelvic mass. Chapter 10 includes a comprehensive discussion of risk assessment of an adnexal mass in both premenopausal and postmenopausal women. In general, if a surgeon stratifies the risk of an adnexal mass into low-, medium-, and high-risk categories for malignancy, then the risk of finding an

"unexpected" ovarian cancer at the time of surgery should be extremely low.

Minimally Invasive Surgery Management

Several authors have reported on the LS management of suspected benign ovarian masses. In 1992, Nezhat et al. reported 1209 adnexal masses managed laparoscopically. The majority of patients had endometriosis or functional cysts. However, 64 patients had benign ovarian tumors, and four were malignant. There were no reported major complications in removing masses up to 25 cm in diameter, clearly demonstrating the technical feasibility of managing ovarian masses laparoscopically. Since then, multiple authors have reported on the use of laparoscopic oophorectomy in both premenopausal and postmenopausal women. The complication rates in these nonrandomized reviews of laparoscopic surgery vary from 0% to 18% and include bowel injury, ureteral injury, wound infection, hematoma, and hemorrhage. **A consensus of these retrospective reviews and small randomized trials is that laparoscopic management of adnexal masses is associated with decreased or similar operating time and decreased perioperative morbidity, including pain, infection, and blood loss compared with laparotomy.** These studies also show a decreased LOS and potential cost savings; however, major complications are still possible.

More recently, authors have reported on using laparoscopy in the initial management of ovarian masses suspicious for malignancy. Dottino and coworkers reported on 160 patients with suspicious adnexal masses who had no evidence of gross metastases or extension above the umbilicus. No distinction was made based on other risk factors for malignancy; however, all of these patients were referred for gynecologic oncology consultation. A total of 141 patients were successfully managed laparoscopically. Invasive ovarian cancer was discovered in nine patients, borderline ovarian tumors in eight, and nongynecologic cancer in four. Dottino and associates reported a 3% incidence of intraoperative complications requiring conversion to laparotomy and only one incidence of intraoperative spillage of tumor. This was a sex cord–stromal tumor, which did recur locally. Canis et al. reported on 230 adnexal masses suspicious or solid at ultrasound examination evaluated initially by laparoscopy. Twenty percent of the invasive cancers and 50% of the borderline tumors had cyst puncture or rupture at the time of diagnosis. One case of tumor dissemination occurred with morcellation of an immature teratoma. **These studies highlight the need to prevent tumor spill and morcellation for all suspicious masses.** There is concern that the positive-pressure carbon dioxide environment established during pneumoperitoneum may predispose patients to intraperitoneal seeding. Animal studies have shown an increased seeding rate in the pneumoperitoneum group compared with control participants. This may be explained by peritoneal damage and exposure of the underlying basal lamina, which could facilitate implantation. No clear conclusions can be drawn regarding the risk to humans, but **these studies suggest cyst rupture or spillage should be avoided in all ovarian masses that could possibly be malignant.**

The algorithm presented in Fig. 21.10 is based on a strategy of maximal use of MIS combined with minimal risk of unexpected finding of ovarian cancer or intraabdominal tumor spill. The presence of a unilocular cystic mass in premenopausal women is rarely malignant regardless of size. This fact is important because most of these patients are candidates for ovarian conservation with cystectomy. The same criteria for conservative management can be used with MIS as is already being done with laparotomy. Cystectomy has been described using a variety of techniques using MIS. Equipment such as needle aspirators and intraabdominal bagging devices can allow for cyst decompression without spillage. Techniques have been described for either transabdominal or transvaginal cyst aspiration and removal. Large cysts can be aspirated transvaginally and removed via a posterior colpotomy with no intraabdominal spillage. Size limits for removal of unilocular cysts seem to be related to safety of trocar insertion, surgical exposure, and experience of the surgeon. If oophorectomy is to be performed, the aspiration of the unilocular cyst will allow most of these to be removed through the anterior abdominal wall trocar site. More complex cysts that are believed to be benign can be removed in a bag through a colpotomy or by extending the midline port-site incision at the end of the case. Some multilocular ovarian neoplasms larger than 8 cm in size that are thought to be benign based on ultrasonography have a large dominant cyst. These can be managed through a posterior colpotomy

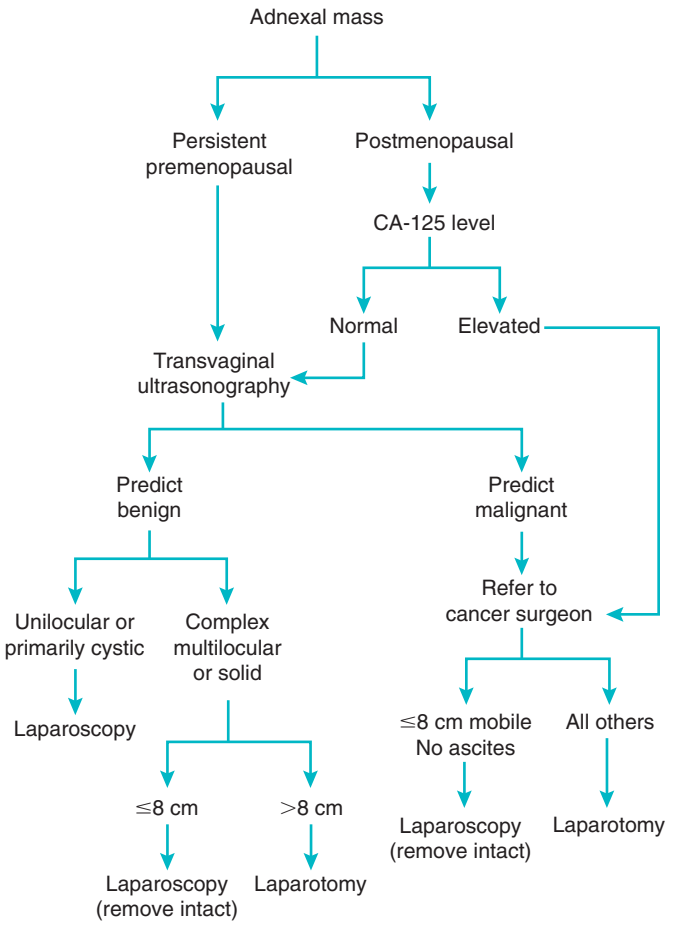

FIGURE 21.10 Suggested management of an adnexal mass.

with transvaginal drainage of the dominant cyst and subsequent removal of the ovary through the colpotomy. Suspicious masses should not be intentionally aspirated or morcellated outside of a controlled situation that prevents tumor spill and intraperitoneal dissemination.

If known ultrasound criteria are used, the negative predictive value for ovarian malignancy in premenopausal women should be greater than 95%. If the schema is adhered to, the few women with malignancies should have their tumors removed with no intraabdominal spillage (see Fig. 21.10). The rare finding of malignancy will still allow for appropriate timely referral, surgical staging, and treatment. Because the majority of premenopausal women have masses with benign characteristics, this approach could substantially reduce the number of laparotomies performed for ovarian masses.

When the transvaginal ultrasound examination is consistent with probable malignancy, a different approach is recommended (see Fig. 21.10). The positive predictive value of ultrasonogarphy alone ranges from 30% to 80%. Patients should have primary therapy by a physician trained to deal with ovarian cancer surgery and staging. These tumors can be managed with MIS if they are 8 cm or smaller and can be removed intact (and in a bag) through a colpotomy or mini-laparotomy. If malignancy is documented, these patients should have further surgery by appropriately trained physicians as soon as possible. Patients with ovarian masses larger than 8 cm that are suspicious for malignancy or those that cannot be removed without controlled rupture by laparoscopy should undergo laparotomy by ovarian cancer specialists. Patients who are found to have disease spread beyond the ovary at time of MIS should have a confirmatory biopsy of the extraovarian disease (higher yield than biopsy of a cyst) and referral for definitive therapy and staging as soon as possible.

Ovarian Cancer

Diagnosis of Ovarian Cancer

As a result of the relatively poor ability to predict malignancy with existing preoperative technology, a number of studies have looked at using laparoscopy to assess the presence or absence of ovarian cancer. Aspiration cytology of ovarian cyst fluid has a poor negative predictive value in the range of 58% to 80%. Case reports have raised the possibility that aspiration or biopsy of malignant ovarian cysts may lead to peritoneal tumor implantation, limiting its application for diagnostic purposes. Also, use of therapeutic aspiration is ineffective for resolution of an ovarian cyst, with a recurrence rate as high as 67%. Therefore, routine or intentional cyst aspiration is not recommended, especially in the presence of a suspicious mass. Reports of success are likely to include functional cysts because aspiration does nothing to interrupt the pathologic process of an ovarian neoplasm or endometrioma. When laparoscopic biopsy is highly suspicious for malignancy, definitive surgery should be performed if a trained ovarian cancer surgeon is available; otherwise, the surgery should be aborted, and the patient should be referred immediately to such a specialist.

Ovarian Cyst Rupture

The main concern about managing a suspicious adnexal mass with MIS, especially when a cancer is apparently confined to the ovary, is that rupture may cause dissemination of malignant cells into the peritoneal cavity and adversely affect surgical stage and thus survival. MIS is more likely than laparotomy to result in capsular rupture because it potentially includes more tumor manipulation, and masses often must be drained before removal from the peritoneal cavity. In an assessment of outcomes in the laparoscopic management for adnexal masses, both benign and malignant, mass rupture occurred in 25% of the cases. Therefore, use of laparoscopy has been discouraged because of the potential for rupture of a malignant ovarian cyst. However, the prognostic impact of cyst rupture in an encapsulated stage I ovarian cancer remains controversial. Any spillage should be managed with copious irrigation, as is the case with open surgery.

Another concern regarding MIS for ovarian cancer has been the possible effects of a delay in referral for subsequent definitive surgery and staging after an initial diagnosis of cancer. In an early report by Maiman et al. of 42 patients referred for malignant ovarian neoplasms excised laparoscopically, the mean interval to laparotomy was 5 weeks, and more than 10% of these patients did not undergo subsequent exploratory surgery. The impact of this delay on survival is not known. In a review of 48 cases of surgical staging after laparoscopic removal of malignant ovarian masses, Lehner and associates reported that a delay of more than 17 days was associated with an increased risk of advanced-stage disease for malignant and low-malignant-potential tumors on univariate analysis. These concerns are heightened by Kindermann et al.'s retrospective survey of 192 cases of ovarian malignancy initially diagnosed laparoscopically. Patients with a delay of more than 8 days between laparoscopic biopsy and definitive surgery had an increased risk of port-site metastasis and progression to stage III disease. In this report, only 7% of the apparent stage I tumors were removed intact as a result of biopsy, capsule rupture, and morcellation, making interpretation of these data difficult. These findings suggest that all efforts should be made to avoid intraoperative spillage from the ovary and to limit delay until definitive surgery. If patients are managed according to Fig. 21.10, the unexpected finding of ovarian malignancy should be less than 5%. The few malignant masses that are managed with MIS should be removed without intraabdominal rupture, and survival is unlikely to be negatively affected. Managing patients according to this schema allows for appropriate and timely referral of patients with ovarian malignancy to physicians appropriately trained to manage these patients.

Early-stage Ovarian Cancer

The location and frequency of subclinical metastasis in patients with presumed early-stage ovarian cancer have encouraged investigation of the use of laparoscopic surgery for this patient population. Many areas traditionally evaluated during open laparotomy can be adequately assessed via MIS, including

peritoneal cytology, the diaphragm, the omentum, the pelvic and paraaortic lymph nodes, and the pelvic peritoneum. Areas that are less likely to be fully visualized laparoscopically include the abdominal peritoneum and the bowel mesentery and serosa secondary to less ability to "run the bowel" and the inability to palpate. Review of the literature indicates that the most common sites of subclinical metastasis in ovarian cancer include peritoneal cytology, the pelvic and paraaortic lymph nodes, the diaphragm, and the pelvic peritoneum, all of which can be adequately evaluated laparoscopically or robotically (see Table 11.16). **The inability to thoroughly evaluate the abdominal peritoneum and bowel mesentery could potentially lead to a 3% to 5% risk of understaging.** Laparoscopic staging may be particularly helpful in patients who have undergone a recent exploratory laparotomy for removal of an adnexal mass found to be malignant who did not have appropriate staging. In 1995, Childers et al. reported on the technical feasibility of laparoscopic staging of presumed stage I ovarian cancer. They found metastatic disease in eight of 14 patients, including three with positive paraaortic nodes, three with pelvic disease, and two with positive cytology. Following this report, several small series of laparoscopic staging in this patient population have been published. In a case-controlled series, Chi and coworkers demonstrated equivalent node counts and omental size removed in patients undergoing laparoscopic versus open procedures. There was no significant difference in the rate of metastatic disease between the groups, although the numbers are too small to provide adequate power.

To date, there are no randomized trials looking at surgical staging or survival outcomes in early-stage ovarian cancer managed laparoscopically. An attempted Cochrane meta-analysis in 2009 was unsuccessful because of the low number of studies in the literature. In 2013, Park and associates conducted a meta-analysis of laparoscopic staging in early ovarian cancer and were able to include 11 observational studies. Operative outcomes were similar to those of laparotomy. The overall rates of upstaging and conversion to laparotomy were 22.6% and 3%, respectively, and the tumor rupture was reported at 25.4%. One port-site metastasis was found. A large multi-institutional retrospective review included 300 patients with apparent early-stage ovarian cancer. It compared 150 patients who underwent laparoscopic staging at initial diagnosis with 150 patients who had delayed staging after incidental diagnosis. Patients in the delayed staging group were younger and more likely to be premenopausal with a possible desire for fertility-sparing surgery. Conversion to laparotomy and tumor spillage was higher in the group with immediate staging (16% and 12% vs. 2% and 2%) and upstaging was three times more common (24.9% vs. 7.4%) in the immediate staging group, which also included more poorly differentiated tumors. There were no differences in complication rates, disease-free survival, or recurrence, although the follow-up time was short. No port-site recurrences were identified. These studies and other small studies demonstrate that laparoscopic staging is feasible and safe for apparent early-stage ovarian cancer. Peritoneal surface metastases are the most challenging to identify with limited ability to manipulate tissues during laparoscopic surgery.

Advanced Ovarian Cancer

Minimally invasive surgery has had a limited role in the management of advanced ovarian cancer. However, more recently, there has been a renewed interest in incorporating MIS as part of the initial evaluation of patients with suspected advanced ovarian cancer. Since the early 1980s, authors have reported its role in second-look laparotomy. Initial studies from the early 1980s using laparoscopy followed by immediate laparotomy indicated a false-negative predictive value of 29% to 55% for laparoscopic surgery. With advances in video equipment and surgical technology, there was a brief resurgence of use of laparoscopic surgery in the second look setting. Even using more modern minimally invasive technology, the negative predictive value was 86%, indicating continued deficiencies in the technique. In addition, complete intraperitoneal investigation was only successful in 41% of patients because of adhesions from prior surgery. This information, in combination with the fact that second-look surgery has been determined to be of no therapeutic value, caused laparoscopy for second look to fall out of favor.

Several studies have emphasized the importance of a complete cytoreduction to no gross residual disease for optimal cancer outcomes and survival. However, if optimal or complete cytoreduction is not feasible because of disease distribution or patient factors, neoadjuvant chemotherapy can be considered. To determine the extent of disease in and the feasibility of primary cytoreductive surgery, laparoscopy can be useful. Several algorithms have been developed, some including just findings at laparoscopy and some using radiologic and serologic markers. Using laparoscopy, exact tumor location, extent of tumor spread, and invasion in surrounding structures are assessed, and each parameter receives a score. Findings at laparoscopy have been demonstrated to correlate well with findings at laparotomy, and the total score provides the surgeon with an estimated chance of successful primary debulking surgery to no gross residual disease. Prospective trials are currently ongoing to evaluate the safety, feasibility, and predictive values of laparoscopy to determine resectability at the time of ovarian cancer diagnosis, as well as surgical and survival outcomes (SCORPION [Surgical Complications Related to Primary or Interval debulking in Ovarian Neoplasm] trial NCT01461850, MD Anderson Moon Shot trial, LapOvCa-trial NTR2644).

Laparoscopy has also been used for interval debulking surgery after neoadjuvant therapy. A recent small study comparing 10 patients who underwent laparoscopy and 11 who underwent laparotomy found that laparoscopic interval cytoreduction was feasible with similar recurrence rates. However, the authors recommended that endoscopic surgery for advanced ovarian cancer should be used cautiously because the disease-related mortality rate was higher, and disease-free intervals were shorter in those undergoing endoscopic surgery. Larger prospective trials are needed to determine the safety of endoscopic surgery for advanced ovarian cancer and are currently ongoing (Minimally Invasive Interval Debulking Surgery in Ovarian Neoplasm: a Feasibility Study [MISSION] Trial NCT02324595; Feasibility of Interval Debulking Surgery by Laparoscopy for Peritoneal Carcinosis in Chemosensitive Patients [CILOVE] trial NCT01905163).

In addition, ports for intraperitoneal chemotherapy can be placed with laparoscopic guidance in patients without such

access before initiating primary chemotherapy. Last, some investigators have reported on the use of (hand-assisted) laparoscopy as well as robotic surgery for radical intraperitoneal tumor debulking at the time of primary or secondary cytoreductive surgery. These studies lack conclusive data for adequacy of surgery or prospective (randomized) comparison with open technique for morbidity and survival. MIS debulking may be most appropriate for patients requiring a limited number of advanced procedures.

COMPLICATIONS OF LAPAROSCOPIC SURGERY

An evaluation of MIS indicates that adverse events can be categorized into two broad groups—complications that are part of laparoscopic abdominal surgery in general and those that are related to a specific surgical procedure or disease process. Advantages to a MIS technique include smaller incisions, less tissue manipulation and damage, and decreased adhesion formation. Many postoperative complications associated with laparotomy also are decreased. Nevertheless, these are still major surgical procedures performed via minimized access, and therefore major surgical complications are possible, some unique to MIS. Many complications related to the specific surgical procedures will occur at least at a minimum rate and can vary with complexity of the procedure and surgeon experience. General complications such as trocar insertion, injuries to bowel or vessels, CO_2 pneumoperitoneum extravasation, and port-site herniations are unique to MIS. Major intraoperative complications during MIS are fortunately uncommon. Approximately 50% of serious intraoperative complications in laparoscopy occur with trochar insertion. In general, gynecology major vascular injuries are almost exclusively related to trochar insertion; however, in gynecologic oncology, such injuries may also occur during retroperitoneal dissection. Gastrointestinal (GI) and urologic injuries are more common than major vascular injuries. Most GI injuries will be related to placement of ports, mobilization of the bowel to gain exposure, adhesiolysis, thermal damage, port-site hernias, and occasionally secondary directly to the surgical dissection. Prevention of GI injuries is most important because these types of complications often go unrecognized and may be more difficult to identify during an MIS case. Vigilance is required in addressing serious and subtle signs or symptoms that may indicate an occult GI injury resulting from MIS. There should be a high index of suspicion and the expectation should be continuous improvement in the patient's status postoperatively. In gynecologic MIS, most urologic complications result from adnexectomy or hysterectomy. A marked increase in major genitourinary complications was noted after the advent of advanced gynecology MIS procedures. Genitourinary complications are prevented by meticulous dissection, wide mobilization of the bladder off the lower uterine segment and cervix, and skeletonization of the uterine vessels.

As noted previously in this chapter, a number of studies have reported on complications associated with laparoscopic pelvic and paraaortic lymphadenectomy and radical pelvic dissection. Most series of MIS in gynecologic oncology report a decrease in perioperative and postoperative complications compared with laparotomy. In early series, there appeared to be an increased number of ureteral, bladder, and vascular injuries compared with open techniques. Prevention of complications begins long before the actual operative procedure with appropriate treatment selection and preoperative counseling. Selection of a surgical route is often based on a surgeon's formal training and experience. It is recommended that surgeons develop a careful accumulated experience of increasingly complex MIS procedures. Further analysis almost uniformly indicates that there is a learning curve associated with advanced MIS, and larger, more mature series have intraoperative complication rates comparable to an open approach.

The overall incidence of MIS complications is difficult to quantitatively define because it is primarily based on retrospective reports and very likely to be underreported. The data on MIS complications are mostly anecdotal, based on single institutional experience and even less commonly based on meta-analysis and rarely prospective or randomized studies. This is not unique to MIS because most data on surgical complications are retrospective and therefore biased and imprecise. Various series on MIS in gynecology and gynecologic oncology report the incidence to be less than 1% to greater than 10%. The actual rate of surgical complications that occur in MIS depends on institutional and surgeon experience, types and mix of surgical procedures, and associated patient comorbidities. Chi and associates reported on the risk factors for complications and conversion to laparotomy in 1451 patients undergoing a wide variety of laparoscopic procedures by a gynecologic oncology division over a 10-year time frame. Significant complications occurred in 2.5% of the patients and were associated with increased age, previous radiation, and malignancy. The complication rates reported in this series fall within the accepted range using an open technique. Likewise, the need to convert to laparotomy has been associated with prior abdominal surgeries, obesity, bleeding, and adhesive disease. Conversion rates decrease with increased surgeon experience and should not be considered a complication but rather sound intraoperative judgment. Similar conclusions can be drawn from the experience with LAVH compared with abdominal or vaginal hysterectomy.

In general, MIS offers many potential advantages and disadvantages to the surgeon (and therefore the patient) but introduces additional layers of technological, human, and procedural complexity for any given surgical procedure traditionally performed via laparotomy. There is no substitution for knowledge of anatomy, the steps in the surgical procedure itself, and the natural history of the patient's disease or condition. Counterintuitive movement, depth perception, and blind aspects to the surgical field are all unique potential compromises to MIS, especially laparoscopy. Major complications in MIS can often be attributed to misperception rather than a pure technical error. These are all obviated, especially earlier in the surgeon's experience, by deliberate camera work and meticulous dissection, which eventually become more instinctual and automatic as the surgeon gains experience. There is no substitute for continued practice and accumulated experience, which allows for development of innate skills in avoiding potential problems. Knowledge of energy sources used is critical in preventing MIS

surgical complications. Meticulous skeletonization of pedicles and mobilization of adjacent structures away from the field of dissection reduce the chance of unintended thermal damage. Laparoscopy gives partial loss of haptic feedback and loss of 3D vision, but the current robotic technology gives no haptic or touch feedback but allows for high-definition 3D vision. Both limitations in sensory feedback can be overcome with practice and experience while maintaining rigorous surgical discipline.

Port-site Recurrences

Since 1978, port-site recurrences have been reported in multiple carcinomas, including gynecologic malignancies. Concern has been expressed that incisional seeding may be increased in laparoscopic surgery, potentially leading to a reduction in overall survival. A review of the literature by Ramirez et al. in 2003 found 31 articles describing port-site metastases in 58 patients with gynecologic cancer. These included 33 invasive ovarian cancers, seven low-malignant-potential tumors of the ovary, 12 cervical cancers, four endometrial cancers, and one each of fallopian tube and vaginal cancer. In the ovarian cancer patients, 83% had advanced-stage disease with most reporting carcinomatosis and ascites. The median time to diagnosis was 17 days, and it is unclear how this affected survival. Reports of abdominal wall metastasis after paracentesis in a similar population are common. It appears that proper preoperative assessment may have spared many of these patients a laparoscopic procedure. The 12 patients with cervical cancer reported with port-site metastasis are cause for concern given that there are only a few isolated reports of metastases to an abdominal scar. Of these 12 patients, 75% had laparoscopic lymphadenectomy, and the majority had positive nodes. Half of the patients had recurrence in the port used for placement of the laparoscope. The median time to port-site recurrence was 5 months, and of the 11 patients for whom data were given, only 27% were without evidence of disease with a median 12-month follow-up. Of the four patients reported to have port-site recurrences in endometrial cancer, only one had disease limited to the uterus. The small number of port-site recurrences makes it difficult to document any benefit to clipping the fallopian tubes or minimizing uterine manipulation as a way to prevent these complications. Analysis of a large prospective database identified 1694 patients who underwent laparoscopy for a malignant intraabdominal condition. Twenty (1.2%) of patients were diagnosed with a port-site metastasis at a median time from laparoscopy of 7 months (range, 0.1–26.2 months). Fifteen patients had ovarian cancer, two cervical cancer, and one uterine cancer, and 95% had synchronous metastases at the time of port-site metastasis.

A number of factors have been proposed to explain the etiology of port-site metastasis. Studies have suggested that the risk may be increased with the use of carbon dioxide compared with other insufflating agents. The positive pressure associated with a pneumoperitoneum has been associated with increased tumor growth and a high incidence of port-site metastasis when compared with gasless laparoscopy. Some investigations have shown the potential aerosolization of viable tumor cells and efflux with gas through the trocar sites. Also theorized is a diminution of inflammatory response using minimally invasive versus open laparotomy incisions. Childers et al. reported port-site metastasis to be 0.3% per trocar site, which is comparable with the 0.1% risk of abdominal wall seeding with percutaneous biopsy of abdominal malignancies. As a result of the advanced stage of most of the reported cases, it is not clear whether port-site metastases occur because of the aggressive nature of the disease or because of risk factors uniquely associated with laparoscopic surgery. To date, use of laparoscopy has not been associated with a decrease in survival rates for patients with cancer.

CONCLUSIONS

Laparotomy causes significant trauma to the patient with many potential associated morbidities, which are increased in incidence and severity in patients with comorbid conditions. In an attempt to reduce surgical morbidity, minimally invasive procedures have been developed and have been shown to be feasible and safe alternatives to open surgery with shorter LOS, decreased blood loss, and similar or decreased postoperative complications. Uptake of traditional laparoscopy was slow and only moderately successful secondary to a difficult and long learning curve, variability in surgical experience, longer operative times, and patient factors such as surgical history and obesity. However, now almost 10 years after the introduction of the robotic platform in gynecologic surgery, the majority of procedures for endometrial and cervical cancer in the United States are performed using a minimally invasive approach.

The technological improvements offered by robotic surgery have allowed gynecologic surgeons to perform much more complicated surgeries via MIS on a heterogeneous group of patients. Surgeons at the beginning of their learning curve will need to build their case complexity appropriately and consider operating room duration along with other potential surgical risks. Previous laparoscopic experience is very helpful, at least in the initial phase of adapting to robotics; however, the robotic platform translates quite nicely from laparotomy because surgeons are able to mimic the procedure robotically from their laparotomy experience. As technology continues to improve and surgeons gain more experience, a higher proportion of patients diagnosed with a gynecologic malignancy is eligible for MIS, and benefits are especially also seen in extremely morbidly obese patients. Technology advances do not substitute for subspecialty training, surgical experience and judgment, and knowledge of disease and anatomy. It is also a certainty that the technology will continue to change and improve and hopefully will become less expensive.

Epidemiology of Commonly Used Statistical Terms and Analysis of Clinical Studies

Wendy R. Brewster, MD, PhD

OUTLINE

Epidemiology
Evidence-Based Medicine
Measures in Epidemiology
Analysis of Clinical Trials
Types of Clinical Trials
Evaluation of Clinical Trials
Placebo Treatment Groups
Controls Used in Clinical Trials
Studies of Therapy
Blinding
When to Stop a Clinical Trial

KEY POINTS

1. Epidemiology is the study of distribution of disease and factors the determine disease occurrence in populations.
2. As much as possible, medical decisions should be based on quality evidence. The best evidence is a properly designed randomized controlled trial. Evidence from nonrandomized but well-designed control trials is of lesser quality. Next in reliability is well-designed cohort or case-control studies, which have been repeated by several investigators. Opinions of respected authorities and extensive clinical experience are least reliable.

EPIDEMIOLOGY

Epidemiology is the study of distribution of disease and the factors that determine disease occurrence in populations. The focus is on groups rather than the individual. Persons within a population do not have equal risk for disease occurrence, and the risk of a disease is a function of personal characteristics and environmental exposures. Patterns of disease occurrence within specific populations can be evaluated to determine why certain groups develop illness when others do not. The impact of epidemiology on gynecologic oncology is evidenced by the significance of studies such as the association with infection of oncogenic human papillomavirus and cervical cancer, obesity and the risk of endometrial cancer, and the risk factors for gestational trophoblastic neoplasia. Epidemiologic studies are unique in their focus on human populations and their reliance on nonexperimental observations. Epidemiologic methods are used in searching for causes of disease, disease surveillance, determining the cause of disease, diagnostic testing, searching for prognostic factors, and testing new treatments.

Because the quality of epidemiologic evidence varies greatly among studies, the scientific community endorses the principles of Sir Austin Bradford Hill, an eminent British statistician, when attempting to identify causal associations. A cause of a specific disease is an antecedent event or characteristic that is necessary for the occurrence of the disease (Box 22.1).

EVIDENCE-BASED MEDICINE

As much as possible, medical decisions should be based on quality evidence. The best evidence is a properly designed randomized controlled trial. Evidence from nonrandomized but well-designed control trials is of lesser quality. Next in reliability is a well-designed cohort or case-control studies, which have been repeated by several investigators. Opinions of respected authorities and extensive clinical experience are least reliable.

Physicians are currently encouraged to practice evidence-based medicine. This means that clinical trial evidence must pass statistically valid tests for conclusions to have meaning. Good science depends on accurate (ie, statistically significant and meaningful) data from clinical trials. The best trials are usually experimental, powered, randomized, and blinded. Patients randomly assigned to a treatment group or a control group must have an equal probability of being assigned to either group. This prevents selection bias (eg, putting healthier or better prognosis patients in one group and those with a poor prognosis or high likelihood of disease risk in another group). Blinding prevents patients, investigators, or statisticians from knowing who is in the control group and experimental group; thus, biased actions are avoided.

Whereas retrospective and observational studies are descriptive and do not involve either an intervention or a manipulation, an experimental study does. A prospective trial poses the

BOX 22.1 Strength of Association

1. Temporality: Exposure must precede the onset of the disease.
2. Dose-response: Risk increases as exposure increases.
3. Replication: The association is observed repeatedly.
4. Coherence: The association is consistent with other scientific knowledge and does not require that established facts be ignored.
5. Exclusion of the role of chance: Appropriate statistical tests demonstrate that the observed association is extremely unlikely to have arisen by chance.

Modified from Hill AB. The environment and disease: association or causation? Proc R Soc Med 1965;58:295.

TABLE 22.1 Mathematical Definitions of Statistical Terms

Terminology	Mathematical Definition
Prevalence rate	Number of persons with disease/Total number in the group
Incidence rate	Number of new cases/Total number at risk per unit of time
Kappa	$(P_{obs} - P_{chance})/(1 - P_{chance})$
Sensitivity	True positive/(True positive + False negative)
Specificity	True negative/(True negative + False positive)
Predictive value positive	True positive/(True positive + False positive)
Predictive value negative	True negative/(True negative + False negative)

question before the data are collected, thus allowing better control of confounding variables, unlike a retrospective study, which poses the question after the data are collected.

MEASURES IN EPIDEMIOLOGY

To describe and compare groups in a meaningful manner, it is important to find and enumerate appropriate denominators and statistical terms (Table 22.1).

- **Incidence rate:** Measures the new cases of a specific disease that develop during a defined period of time and the approximation of the risk for developing the disease. The incidence rate focuses on events. Incidence measures the probability of developing a disease.
- **Kappa coefficient:** Kappa indicates how much observers agree beyond the level of agreement that could be expected by chance. Kappa is estimated as $(P_{obs} - P_{chance})/(1 - P_{chance})$. Thus, the kappa coefficient is the observed agreement, corrected for chance as a fraction of the maximum obtainable agreement, also corrected for chance. Landis and Koch have suggested useful categorizations. Kappa = 0.00 should be taken as representing "poor" agreement, 0.00 ± 0.20 as "slight" agreement, 0.21 ± 0.40 as "fair" agreement, 0.41 ± 0.60 as "moderate" agreement, 0.61 ± 0.80 as "substantial" agreement, and 0.81 ± 0.99 as "almost perfect" agreement. A kappa coefficient of 1 represents perfect agreement.
- **Mean:** The average of a sample of observations
- **Median:** The middle value when the values are arranged in order from the smallest to the largest
- **Meta-analysis:** The statistical process of pooling the results from separate studies concerned with the same treatment or issue is frequently used in the context of medical statistics and provides the quantitative backbone of the evidence-based medicine program. A large number of meta-analyses are undertaken with the broad aim of combining divergent outcomes into a single estimate of treatment effect. For example, the Cochrane Collaboration endeavors to collate and synthesize high-quality evidence on the effects of important health care interventions for a worldwide, multidisciplinary audience and publishes them in the *Cochrane Database of Systematic* Reviews. Meta-analyses increase the statistical power by increasing the sample size, resolve uncertainty when reports do not agree, and improve the estimates of effect size. The bias of publication only of positive results is a concern for those using results of meta-analyses because, if statistically significant or "positive" results are more likely to be published, a meta-analysis based on the resulting literature will be biased. The quality of the studies included is important to the quality of the final result.
- **Pearson's correlation *r*:** The degree to which two variables are related is called correlation. Pearson's correlation is represented by the value *r* and varies between −1 and +1. It is usually presented as a scatter point graph. A value of −1 suggests a perfect negative linear relationship, a value of 0 reflects no linear relationship, and a value of 1 reflects a perfect linear relationship. Values of −1, 0, and +1 are rare.
- **Person time:** The sum of the observation period of risk for the persons in a group being studied.
- **Predictive value positive:** The proportion of positive test results that is truly positive (ie, the probability that someone classified as exposed is truly exposed). This value only refers to positive tests.
- **Predictive value negative:** The proportion of negative test results that is truly negative. The predictive value of a negative test result refers to the proportion of patients with a negative test result who are free of disease.

These values, unlike sensitivity and specificity, indicate the reliability of the test in the determination of presence or absence of disease.

- **Prevalence rate:** The amount of disease in a population. Prevalence measures the proportion of diseased individuals at a particular time and represents a snapshot of the disease. Other commonly used terms are *prevalence proportion* and *point prevalence*. It is a measure of status and includes individuals with newly diagnosed disease and those surviving with disease. The numerator is the number of affected individuals in a specific time period. The denominator is the total number of persons in the group. Prevalence rates range between 0 and 1.
- **Quality-adjusted life year (QALY):** The QALY was developed as an attempt to combine the value length of life and quality of life into a single index number. One year of perfect health is given a value of 1. Death is given a value less than 0. A year of less than perfect health will have a value less than 1. States of health considered worse than death can be argued to have a negative value. The QALY value is

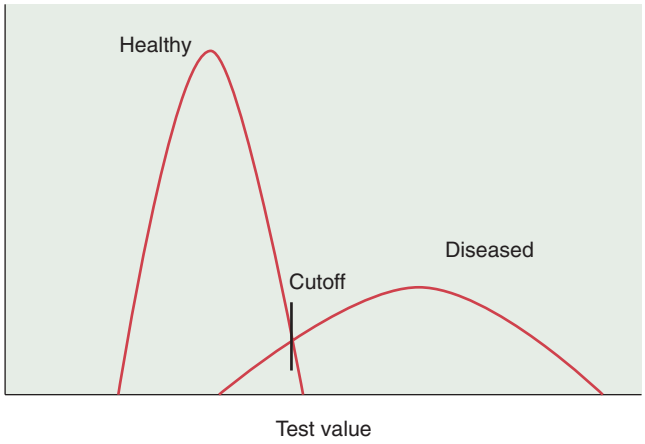

FIGURE 22.1 Effects of shifting cutoff point on sensitivity and specificity.

determined by multiplying the utility value associated with that state of health by the years lived in that state. QALY is a metric used to compare the benefit of health care interventions. Combination of QALYs with the cost of an intervention (Cost/QALY) can provided an economic framework for comparisons of therapies. QALYs have several limitations and should not be used alone in decision making.

- **Sensitivity:** The proportion of truly diseased persons who are classified as diseased by the test. The sensitivity of a test is therefore the probability of a test being positive when the disease is present. The sensitivity of test may also be called the true-positive rate. In Fig. 22.1, it is evident that the cutoff point of a test can affect the sensitivity. If the cutoff point is moved to the left, more diseased persons will be identified. At the same time, more healthy persons will be erroneously classified as sick. However, as the cutoff value for normal is moved to the right, the test will become less sensitive because fewer diseased persons will be classified as such.
- **Specificity:** The proportion of a population of disease-free individuals who are classified as undiseased by a test. In contrast to the sensitivity of a test, the specificity of a test is the probability that a test result will be negative when the disease is absent. The cutoff point of a test for normality influences the specificity. As the value of normality or cutoff moves to the left, the test becomes less specific because fewer health individuals are recognized as such. In contrast, moving the cutoff values to the right increases the specificity (see Fig. 22.1). In the best scenario, a test would be able to discriminate between diseased and healthy individuals without any overlap. **More often, the scenario is as presented in Fig. 22.1, in which there is significant overlap and whatever the cutoff value healthy persons may be classified as diseased and sick persons classified as healthy.** When we set the cutoff point for a test, we must be attentive to the purpose of the test. If the disease is treatable and missing the disease has serious ramifications, then we must favor sensitivity over specificity. Alternatively, if it is more important to correctly identify healthy individuals, then specificity is prioritized. Published reports of the performance of tests usually just provide sensitivity and specificity results. Variations of these measures occur under many conditions and will also produce variations in predictive values.
- **Standard deviation (SD):** A measure of the variability within each group. If there is a normal (bell-shaped curve) distribution, approximately 95% of the values are within 2 SDs on both sides of the average.
- **Tests of heterogeneity:** Before performing a meta-analysis, it is customary to assess evidence of variation in the underlying effects. This variation, termed "heterogeneity," arises because of differences across studies in populations, exposures *or* interventions, outcomes, design, or conduct. A forest plot is useful for visual assessment of consistency of results across studies. A statistic that measures the consistency of findings as the proportion of total variation in point estimates attributable to heterogeneity is now widely used.

ANALYSIS OF CLINICAL TRIALS

- **Null hypothesis:** This hypothesis, symbolized by H0, is a statement claiming that there is no difference between the experimental and population means. The alternative hypothesis (H1) is the opposite of the null hypothesis. Often in research, we need to be able to test for both the positive and adverse outcomes; therefore, a two-tailed hypothesis is chosen even though the expectation of the experiment is in a particular direction.
- **Significance level:** A level of significance termed the alpha value is determined before the study has begun. The alpha value is the likelihood that a difference as large or larger that occurred between the study groups could be determined by chance alone. The alpha level is established by those designing the study and becomes the level of statistical significance. The most typical alpha level is 0.05.
- **One-tail test:** A test to determine a difference in only one direction (eg, to determine if drug A is better than drug B)
- **Two-tail test:** A test to determine any difference between the variable (eg, if either drug A or drug B is superior to the other). It is usually considered that in a two-tailed test, more trust can be placed in the statistically significant results than with a one-tailed test. When in doubt, the two-tailed test is preferred.
- **Confidence interval (CI):** The range of values that is believed to contain the true value within a specific level of certainty.
- **Alpha error:** The rejection of the null hypothesis when it is, in fact, correct; also called a type I error.
- **Beta error:** Failure to reject the null hypothesis when it is, in fact, incorrect; also called a type II error.
- **Power:** The probability that a study will be able to correctly detect a true effect of a specific magnitude. The statistical power refers to the probability of finding a difference when one truly exists or how well the null hypothesis will be rejected. The power is usually specified beforehand in prospective studies. The values of 0.8 (80%) or 0.9 (90%) are typical. The higher the value, the less chance there is of a type II error. A 0.9 value means that a type II error would be avoided 90% of the time.

- **Risk:** The proportion of unaffected individuals who, on average, will contract the disease of interest over a specified period of time. Results of a trial are often expressed as absolute or relative risk reductions. The absolute difference is the actual difference between the units of the difference. In relative risk, the differences are the percentage change. Relative risk reductions often sound much more dramatic than do the absolute values. One must consider the prevalence of a disease when evaluating risk reductions. When there is a low prevalence of a disease process, small risk reductions become unimpressive and must be evaluated in terms of the benefits of a particular mode of therapy.
- **Incremental cost-effectiveness ratio:** The additional cost divided by the incremental benefit compared with an alternate strategy. A strategy was strongly dominated if it was more costly and less effective than another or cost effective if it had an incremental cost-effectiveness ratio of $50,000 to 100,000 per year of life gained relative to an alternate strategy.
- **Odds ratio (OR):** The ratio of the odds that an event will occur in one group compared with the odds that the event will occur in the other group. In an osteoporosis study, if 14 of 22 people who are thin, have fractures, the odds of having a fracture are 14 in 22 or 0.64. If 5 of the 33 nonthin people fracture bone, the odds are 5 in 33 or 0.15. The OR is 0.64 divided by 0.15 or 4.2, meaning that thin people are 4.2 times more likely to receive fractures. An OR of 1 means that both groups have a similar likelihood of having an event.
- **Overall survival (OS):** The interval from the completion of treatment to censoring or death from any cause.
- **Progression-free survival (PFS):** The interval from the date of randomization to the documentation of progression of the illness or death from any cause.
- **Actuarial (life table) survival:** This technique uses grouped information to estimate the survival curve. The data are grouped into fixed time periods (eg, months, years) that include the maximum follow-up. The survival curve is estimated as a continuous curve and gives an estimate of the proportions of a group of patients who will be alive at different times after the initial observation. The group includes patients with incomplete follow-up.
- **Chi square ($\chi 2$):** The primary statistical test used for studying the relationship between variables. This is a test used to compare proportions of categorical variables.
- **Cox proportional hazard regression analysis:** Cox regression analysis is a technique for assessing the association between variables and survival rate. The measure of risk provided for each variable is the risk ratio (RR). An RR of 1 means that the risk is the same for each participant. An RR greater than 1 indicates increased risk; a ratio less than 1 indicates less risk. A ratio of 5.4 means that the patients with a variable are 5.4 times more likely to have the outcome being studied. CIs can also be provided with RRs. This type of analysis is usually presented in a table.
- **Efficacy:** The possibility that an intervention will result in a change (eg, in vaccine trials).
- **Imputation:** In many analytical scenarios, a case is discarded if it is missing data relevant to the analysis. This may introduce a bias, decrease the power of the study, or alter the representativeness of the results. Imputation is the process of substituting missing data. There are numerous techniques to impute data.
- **Multivariate analysis:** A technique of analysis of data that factors many variables. A mathematical model is constructed that simultaneously determines the effect of one variable while evaluating the effect of other factors that may have an influence on the variable being tested. The two most common algorithms developed to accomplish this task are the step-up and step-down procedures. Variables are added to an initial small set or deleted from an initial large set while testing repeatedly to see which new factor makes a statistical contribution to the overall model.
- **Propensity score:** In studies in which randomization is not possible, investigators use this score to adjust for the bias due to confounding variables inherent in treatment selection for groups being compared (eg, in observational trials when the treatment of the participants is not random). Assignment to intervention does not occur by chance but depends on patient characteristics that can influence the effect of the intervention on the outcome. The propensity score is the probability that a patient would receive the treatment of interest based on the characteristics of the patient, clinician, and clinical environment. Several different techniques can be used to balance the groups being compared. The most common strategy is propensity score matching. Propensity score methods are usually better than matching on specific characteristics or stratification because it adjusts for confounding better than other strategies. This is a valuable approach when completion of a randomized trial is not feasible.
- **Receiver operator characteristics (ROCs):** These curves are the best way to demonstrate the relationships between sensitivity and specificity. The curves plot sensitivity (true-positive rate) against the false-positive rate (1 – Specificity) (Fig. 22.2). The closer the curve is to the upper lefthand corner, the more accurate it is because the true-positive rate is closer to 1 and the false-positive rate is closer to 0. Along any particular ROC curve one can observe the impact of compromising the true-positive and false-positive rates. As the requirement that a test has a high true-positive rate increases, the false-positive rate will also increase. The closer the curve is to the 45-degree diagonal of the ROC area under the curve, the less accurate the test (see Fig. 22.2).
- **Sensitivity analysis:** Modeling is a tool that permits the incorporation of data from different sources to predict outcomes that may be likely. This tool allows for various interventions and numerous scenarios. Interpretation of the findings depends on the confidence the operator has in various factors of the model. Sensitivity analysis involves examination of the variation in the outcome as the variables change.
- **One-way sensitivity analysis:** This is the simplest form of sensitivity analysis in which the effectiveness of only one

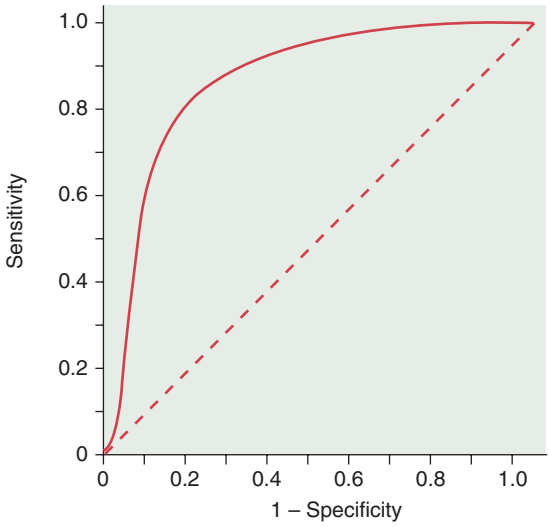

FIGURE 22.2 A hypothetical example of a receiver operating characteristic curve. The *solid line* represents the performance of the diagnostic test of interest; the *dashed diagonal line* serves as a reference of a test with no diagnostic value. (From Greenberg RS, Daniels SR, Flanders WD, et al: *Medical Epidemiology,* 3rd ed. Lange Medical Books/McGraw-Hill, 2001Reproduced by permission of The McGraw-Hill Companies.)

variable in the model is analyzed to assess the range of impact of that variable on the outcome.

- **Univariate analysis:** Analyses may be univariate or multivariate because they examine one or more variables at a time, respectively.

TYPES OF CLINICAL TRIALS

Clinical trials are experiments in which the investigator intervenes rather than observes and is the best test of a cause-and-effect relationship. A properly conducted experiment requires that when the intervention is applied to one group, there is a control group or some other suitable standard by which participants of the clinical experiment or their guardians must give informed consent. The gold standard of clinical trials is the randomized experiment. With randomization, each participant has an equal chance of being in either of the arms of the trials. Randomization is important because it equalizes baseline characteristics of the participants so that the comparison of the treatments is fair. If randomization is not feasible, possible nonrandom standards of comparison must include patients similar to the treated group. Randomization is the current norm for demonstrating efficacy and safety of investigational methods. The advantages of randomization are numerous:

- Decreases investigator's bias in assigning patients to treatment groups
- Permits certain statistical methods to be used in the resulting data
- Allows for blinding of the patient and investigator
- Is the current norm for demonstrating efficacy and safety of investigational medicines

BOX 22.2 Types of Clinical Trials

Single-patient clinical trials
Multicenter trials
National clinical trials
Continuation trials
Compassionate plea trials
Pharmacoeconomic trials
Trials to evaluate medical devices
Pharmacokinetic trials

Unacceptable methods of randomization include the following:

- Alternate assignments
- Alternate day assignments
- Birthday assignments
- Coin tosses
- Initials of a patient

Single-patient clinical trials are indicated only in specific situations. They are generally used to evaluate rare diseases when other types of trials are inappropriate or when only a small percentage of patients respond to a specific treatment. Single-patient clinical trials are useful to determine the response of a particular patient is a result of placebo or if an adverse reaction is related to a specific medication. The disease should be chronic, and the disease severity must be stable during the clinical trial duration. It should be expected that the effect of the treatment should be measurable in a short time, and the effect should be rapidly reversible after the treatment has stopped. The investigator and patient should be blinded, and the patient's condition should return preexisting baselines between treatment legs.

Multicenter trials are advantageous because they offer more rapid patient accrual and allow for greater protocol complexity. Multicenter trials reduce the opportunity for an individual's bias to influence the conduct of the trial; they increase the likelihood for the inclusion of a more representative study population and facilitate a higher standard for data processing and analysis. Disadvantages of multicenter trials are the administrative considerations that underlie the management and administrative arrangements (eg, institutional review board, ethics committees). Considerations must be delineated for criteria for patient enrollment, diagnostic classification, and assessment of treatment outcome. These trials are inherently more costly (Box 22.2).

EVALUATION OF CLINICAL TRIALS

Many factors must be considered when evaluating a clinical trial. The most important is the clinical trial objective or aim. Whether the objectives of the trial are adequately assessed depends on the presence and extent of bias and confounding factors. Bias is a nonrandom error in a study that can alter the outcome. Types of bias to consider when evaluating a manuscript are listed in Table 22.2.

TABLE 22.2 Bias and Confounding Factors: Examination of the Literature in the Field

- Specifying and selecting the clinical trial sample
  - Popularity bias
  - Referral filter bias
  - Diagnostic or access bias
  - Wrong sample size
  - Migrator, nonrespondent, or volunteer bias
- Executing the exposure
- Contamination, withdrawal, or compliance/therapeutic bias
- Information bias
- Observer bias
- Interviewer bias
- Use of nonvalidated instruments
- Active control bias
- Analyzing the data
  - Post hoc significance bias
  - Fishing expeditions
- Interpreting the analysis
- Publishing the results

Specifying the sample size or number of participants in the study needed to detect a difference or an effect of a given magnitude depends on many variables. The most important is the magnitude of the effect desired or expected. Other important considerations are the desired probability of the study to identify the correct outcome (power), the variability of the variables being analyzed, the number of parts of the clinical trial, the magnitude of the placebo effect, and the number of dependent parts of the clinical trials. When determining the sample size, one must consider if the size of the treatment groups will be equal or nonequal (eg, 2:1 ratio). **An advantage of using groups of unequal size is that more information will be gained about patient responses in the larger arm. A disadvantage is the loss in study power; however, this detraction is not usually substantial if the ratios are kept under 3:1.**

Placebo Treatment Groups

Placebo treatment groups control for the psychological aspects of being in a treatment trial. They also control for adverse events being attributed to a medicine when they result from spontaneous changes in the disease or from other causes and allow a stronger interpretation of the data. Placebo treatment groups are considered ethical if the following occur:

- No standard treatment exists.
- The standard treatment has been proven ineffective.
- Standard treatment is inappropriate for the particular clinical trial.
- Placebo has been reported to be effective in treating the condition.
- The disease is mild and lack of treatment is not considered to be medically important.
- The disease process is characterized by frequent spontaneous exacerbations and remissions.

Controls Used in Clinical Trials

Control groups in clinical trials may be obtained by many different methods. Randomized control groups are the most traditional and accepted and only chance should determine who enters any of the study arms. Nonrandom control groups may also be used. Participants in these nonrandom control groups should have similar characteristics to those of the "treatment arm" and may include historical data obtained on the same patients on no therapy, the same therapy, or different therapy. Participants in the control arm may be assigned to a placebo, an active medication, or concurrent use of nontreatment; use a different dose of the same medication; or receive usual care.

Dropouts from clinical trials are inevitable. The simplest reasons may be that the participants declined to participate after enrollment or that the clinical course during the trial required a change in therapy. Whatever the reason for noncompliance or dropout, these participants should be followed because it is essential to analyze the outcomes of the groups as intent to treat. Inclusion of these data provides a conservative estimate of the differences in treatment.

Studies of Therapy

There are many different types of clinical trials; in general, they are categorized into categories or phases. Phase I trials are usually to screen the safety of the intervention or drug. These trials can be inclusive of multiple doses of a new medicine or evaluation of an old medicine in a new therapeutic area. These trials usually consist of 10 to 100 participants.

Phase II trials clarify and establish the protocol and elucidate the experimental conditions that will allow the most important phase of the trial to give a definitive result. These trials are valuable because they establish protocols and the experimental conditions that will allow the final phase of the trial to give a definitive result. They allow for the following:

- The evaluation of a variable related to the clinical pharmacology of a medicine
- Development of clinical experience by research personnel under open-label conditions before initiation of a double-blind trial

Aims of phase II trials are to assess how many people should be included in the final phase of testing, determine the endpoints of the trial, and provide preliminary estimates of effective dose and duration of treatment.

Phase III trials are for comparison to standard therapy or placebo if ethically justifiable. These trials are more commonly randomized and are regarded as the best way to obtain unbiased data.

Blinding

Blind refers to the lack of knowledge of the investigational agent by the patients, investigators, ancillary personnel, data review committees, and statisticians. Blinding is used to decrease the biases that may occur during a clinical trial. An open-label trial indicates that no blind is used. Examples of open-label trials are as follows:

- Pilot trials
- Case studies in life-threatening situations

- Unusual studies in which definitive data may be obtained (eg, coma patients)
- Clinical trials in which ethical considerations do not permit blinding

In single-blind clinical trials, either the patient or investigator is unaware of the treatment received. Single-blind trials provide a degree of control when a double-blind trial is impossible or impractical and provides a degree of assurance of the data's validity compared with open-label trials. In double-blind trials, neither the investigator nor the patient is aware of what treatment the patient is receiving. This allows for strong data interpretation if all other aspects of the trial were properly designed and conducted, the blind remained intact, the protocol was not seriously breached, the power of the trial was adequate, and the patients were compliant. Triple-blind trials are situations in which anyone who interacts with either the patient of physician is blinded. These studies allow for the strongest interpretation of data if the conditions can be met.

If blinding is to be used, then the study should be designed so that it is very difficult to break the blind. Unblinding may occur based on any of the following:

- Adverse reactions
- Lack of efficacy
- Efficacy
- Changes in laboratory values
- Errors in labeling
- Comments from unblinded study personnel
- Information presented in correspondence or reports
- Intentionally looking for clues (Box 22.3)

BOX 22.3 Types of Blinds

Open label
Single blind
Double blind
Full double blind: keeping blind everyone who interacts with the patient
Full triple blind: keeping blind anyone who interacts with the patients and the investigators

When to Stop a Clinical Trial

The decision to stop a clinical trial has many important ramifications. The ethical dilemmas include the needs of the next eligible patient insomuch that a participant should never be randomly assigned to an established inferior treatment. This must be balanced by the collective needs of society that terminating a trial will still result in the correct policy for the future and the need for sufficient data to change clinical practice for the better.

Early termination of a trial has its disadvantages. If the trial is stopped after recruitment of a small number of participants, the results may lack credibility. The assumed treatment difference may be the result of chance and a false-positive result. The early stopping of trials can result in imprecision and wide CIs for treatment effect. Finally, the treatment recommendation that results from stopping a trial early may be unduly enthusiastic.

Statistical stopping guidelines should be determined before the clinical trial begins. A sufficiently small *P* value for treatment difference on a trial's primary endpoint can be a guideline for when it is ethically desirable to stop a trial. It is most acceptable to have a limited number of preplanned interim analyses. Multiple repeated looks at the data can guard against the risk of a false-positive result.

Basic Principles in Gynecologic Radiotherapy

Catheryn M. Yashar, MD, FACR, FACRO

OUTLINE

Introduction to Electromagnetic Radiation
Radiation Units
Radiation Physics
- Energy Deposition
- Sources of Radiation
- Photon Interactions
- Radioactive Decay
- Inverse Square Law
- Depth Dose Characteristics of Radiation

Radiobiology
- Structural Changes
- Radiosensitivity

Radiosensitizers, Hypoxic Cell Sensitizers, and Radioprotectors
- Genetic Effects
- Fetal Effects

Principles of Clinical Radiation Therapy
- External-beam Radiation (Teletherapy)
- Local Radiation (Brachytherapy)
- Normal Tissue Tolerance
- Pelvic Organ Tolerance
- Long-term Effects

New Radiation Modalities
- Protons
- Electrons
- Fast Neutrons
- Negative Pi Mesons and Other Heavy Ions

New Radiation Delivery Technology
- Intraoperative Radiation
- Hyperthermia
- Three-dimensional Conformal Radiation Therapy
- Intensity-modulated Radiation Therapy
- Stereotactic Radiotherapy
- Immune-tagged Radiation Therapy

Glossary

KEY POINTS

1. Radiation therapy is used for the treatment of primary and metastatic gynecologic carcinomas.
2. Radiation therapy depends on the differential susceptibility of tumors to irradiation compared with normal tissues, and research attempts to maximize the therapeutic ratio are ongoing.
3. Photons, a nonparticulate form of radiation, are the primary modality of therapeutic irradiation used in gynecologic carcinomas.
4. Particulate irradiation with electrons and protons are also used in many centers but have specialized indications.
5. Radiation is measured in international system (SI) unit of centigray and Gray. A typical dose for therapeutic irradiation for adjuvant therapy is 45 to 50 Gy and for gross disease, as in cervical carcinoma, is 80 to 85 Gy.
6. Radiation is primarily generated from human-made sources, as in a linear accelerator, called x-rays, or from naturally radioactive decay, termed gamma rays. Therapeutically, these are indistinguishable, although photons or electrons may be the therapeutic source.
7. A variety of DNA lesions are produced by radiation including base damage, DNA–protein crosslinking, single-strand breaks, and double-strand breaks.
8. In general, radiation is delivered in two basic manners. External-beam radiation therapy delivers radiation to the body from an external source. Brachytherapy, a crucial component to the safest and most effective treatment of many gynecologic cancers, delivers radiation from sources that are placed within the body.
9. An important concept, crucial to the delivery of brachytherapy, is that the dose of radiation at a given point is inversely proportional to the square of the distance from the source of radiation (dose $\propto$ 1/ Distance^2). This forms the basis of high therapeutic dose directly to the tumor and safe doses to adjacent critical organs. External methods of delivery cannot duplicate this delivery. A level of expertise is absolutely crucial to the delivery of this modality.
10. Low-dose-rate brachytherapy is being replaced in most centers by high-dose-rate brachytherapy or pulse-dose-rate brachytherapy.
11. Image guidance with computed tomography, magnetic resonance imaging, or positron emission computed tomography scans, in all aspects of radiation therapy (planning, external and brachytherapy), appears to increase the therapeutic ratio.

12. Concurrent therapies (radiosensitizers and protectors) seek to increase this therapeutic ratio, each with its own mechanism of action to be exploited.
13. The short- and long-term effects of irradiation are not trivial, and a risk-to-benefit discussion is crucial to the patient and multidisciplinary oncology team. During and after therapy, a team approach best serves the patient.
14. Intensity-modulated radiation therapy, image-guided radiation therapy, and stereotactic radiation therapy are all tools in an ever increasingly complex toolbox for the radiation oncologist to use for increased local control, survival, and palliation. Ongoing studies evaluate the risk-to-benefit ratio and cost effectiveness of these new and expensive technologies.

A basic understanding of the principles of radiation oncology is essential to gynecologic oncologists. Radiation therapy is used in the curative treatment of locoregionally advanced cervical and vaginal carcinoma. It is often an adjuvant therapy prescribed for uterine or vulvar carcinoma and in inoperable patients may be the only definitive therapy available. Last, it can be used for the palliative treatment of gynecologic carcinomas.

INTRODUCTION TO ELECTROMAGNETIC RADIATION

Radiant energy or radiation is an essential component of life on earth. For example, sunlight provides heat, light, and energy for plant photosynthesis, and radio waves provide a method of communication. This electromagnetic radiation physically consists of photons, or "packets" of energy without mass or charge. The primary difference between the radiations is the energy of the photons. The energy is proportional to frequency ($E = h\nu$, where h is Planck's constant and ν is frequency) and inversely proportional to wavelength (Table 23.1). A common analogy is to compare wavelength to the length of a person's stride when walking; the number of strides per minute is the frequency of the wave.

Photons, a nonparticulate radiation, are only one form of radiation. Another form of radiation is particulate radiation. Particulate radiation consists of subatomic particles such as electrons, protons, α particles, and neutrons.

Radiation is not harmful in ordinary quantities and is actually helpful to life processes. In fact, exposure to radiation is a constant phenomenon (Tables 23.2 and 23.3). However, high-energy, or "ionizing," radiation is not entirely harmless, although it is commonly used for both diagnostic and therapeutic purposes. High-energy radiation can be injurious to biologic material, and its use in oncology depends on the ability of normal tissue to recover from the effects more effectively or efficiently than malignant tissue. Radiation causes both reversible and irreversible changes in normal tissue, and these effects are placed into two categories: acute effects (apparent during or shortly after the radiation course) and long-term effects (apparent from 6 months to years after completion of therapy). Radiation effects may not be initially apparent except by careful chemical or microscopic study. Indeed, the effects may not be apparent for many years or may manifest only in the offspring of the irradiated organism. The accepted position regarding radiation exposure is that incidental environmental radiation, diagnostic tests, and therapeutic radiation can all be detrimental. Although in many cases the chance of injury from diagnostic or environmental radiation is slight, the possibility of damage from a known exposure must always be weighed against the importance of the information to be gained or the effect desired. Incidental exposure must be avoided through control of environmental hazards whenever possible by following the ALARA (as low as reasonably achievable) principle.

There are many forms and sources of radiation, including natural isotopes and human-made radiations. The natural radiation emissions (gamma and beta rays) of isotopes such as iridium, iodine, and cesium are used for therapeutic purposes in many human malignancies (Table 23.4). In addition, during the past 4 decades, increasingly sophisticated machines have been manufactured to produce high-intensity, directed radiation to treat both malignant and benign conditions. Modern machines emit energies greater than 1 million electron volts (1 MeV) and are termed *supervoltage* or *megavoltage machines* (Table 23.5). The most commonly available are called linear accelerators (linacs). Even these have recently become more sophisticated to allow increasingly precise delivery of radiation in the form of intensity-modulated radiation therapy (IMRT). The newest generation models allow for real-time computed tomography (CT) for position verification, termed image-guided radiation therapy, or IGRT. Image guidance is also more

TABLE 23.1 Electromagnetic Spectrum

	Wavelength (M)	Frequency (Hz)	Energy (J)
Radio	$>1 \times 10^{-1}$	$<3 \times 10^{9}$	$<2 \times 10^{-24}$
Microwave	$1 \times 10^{-3} - 1 \times 10^{-1}$	$3 \times 10^{9} - 3 \times 10^{11}$	$2 \times 10^{-24} - 2 \times 10^{-22}$
Infrared	$7 \times 10^{-7} - 1 \times 10^{-3}$	$3 \times 10^{11} - 4 \times 10^{14}$	$2 \times 10^{-22} - 3 \times 10^{-19}$
Visible	$4 \times 10^{-7} - 7 \times 10^{-7}$	$4 \times 10^{14} - 7.5 \times 10^{14}$	$3 \times 10^{-19} - 5 \times 10^{-19}$
Ultraviolet	$1 \times 10^{-8} - 4 \times 10^{-7}$	$7.5 \times 10^{14} - 3 \times 10^{16}$	$5 \times 10^{-19} - 2 \times 10^{-17}$
X-ray	$1 \times 10^{-11} - 1 \times 10^{-8}$	$3 \times 10^{16} - 3 \times 10^{19}$	$2 \times 10^{-17} - 2 \times 10^{-14}$
Gamma ray	$<1 \times 10^{-11}$	$>3 \times 10^{19}$	$>2 \times 10^{-14}$

TABLE 23.2 General Population Radiation Exposure

Radiation Source	Average Annual Whole-Body Dose (millirem/yr)
Natural: cosmic	29
Terrestrial	29
Radon	200
Internal (eg, ^{40}K, ^{14}C)	40
Human made (diagnostic radiography, nuclear medicine, consumer products such as smoke detectors)	64
All others (fallout, air travel, occupational)	2
Average annual total	360\
Tobacco smokers: add ~280 mrem	

TABLE 23.3 Radiation Associated With Common Activities

Activity	Typical Radiation Dose
Smoking	280 mrem/yr
Chest radiography	8 mrem/single radiograph
Drinking water	5 mrem/yr
Cross-country airplane trip	5 mrem/yr

TABLE 23.4 Radioactive Isotopes Used in Radiation Oncology

Element	Isotope	E_{max} (MeV)	$T_{1/2}$	Clinical Use
Radium	^{236}Ra	3.26	1600 yr	Historical
Cesium	^{137}Cs	0.514, 1.17	30 yr	Temporary intracavitary implants
Iridium	^{192}Ir	0.38_{ave}	74.2 d	Temporary interstitial implants and source for high dose rate machine
Iodine	^{125}I	0.028_{ave}	60.2 d	Permanent interstitial implants
Phosphorus	^{32}P	None	14.3 d	Permanent intracavitary placement
Palladium	^{103}Pd	20KV	17 d	Permanent prostate seed implant

TABLE 23.5 Radiation Delivery by Energy

Modality	Voltage	Source
Low voltage (superficial)	85–150 keV	X-ray
Medium voltage (orthovotage)	180–400 keV	X-ray
Supervoltage	500 keV–8 MeV	Linear accelerator, ^{60}Co machine
Megavoltage	Above supervoltage energy	Betatron, linear accelerator

TABLE 23.6 Historical and International System (SI) Units of Radiation

Quantity	Historical Unit	SI Unit	Conversion Factor
Exposure	R	C/kg	2.58×10^{-4} C/kg/R
Absorbed dose	Rad	Gray (Gy)	10^{-2} Gy/rad
Dose equivalent (used in radiation protection)	Rem	Seivert (Sv)	10^{-2} Sv/rem
Activity	Curie (Ci)	Becquerel (Bq)	3.7×10^{10} Bq/Ci

commonly used in brachytherapy, which historically used only two-dimensional imaging. With the advent of CT- and magnetic resonance imaging (MRI)–compatible brachytherapy applicators, imaging modalities are used to more precisely direct the radiation to the tissues at risk while simultaneously avoiding normal, uninvolved tissues. The acceleration in technology has paralleled the advances in computer technology. In addition, simulations that combine radiation delivery planning with positron emission tomography (PET) and MRI are currently being used at several centers.

RADIATION UNITS

Those in training and in practice must familiarize themselves with the international system (SI) of weights and measures used today. The SI units and appropriate conversions are shown in Table 23.6.

When a radiation exposure occurs, the resultant ionizations deposit energy in the air. **If a patient lies in the path of the beam, energy will be deposited in the patient. This deposition of energy by radiation exposure is called *r*adiation-*a*bsorbed *d*ose, measured in the acronym rad. One rad is equivalent to the deposition of 100 ergs of energy into each gram of the irradiated object. The SI unit of radiation absorbed dose is the gray (Gy), and 1 Gy = 1 cGy =100 rads = 1 joule/kg. The erg and joule are units of energy.**

RADIATION PHYSICS

Energy Deposition

Radiation energy is deposited into the tissue in one of two ways: direct or indirect ionization. Ionization is when an outer shell electron is stripped from an atom, leaving a positive charge. Direct ionization is the predominant mechanism of action of particles that possess charge, but photons can also cause direct ionization. Examples of directly ionizing particles include particulate radiation such as protons and neutrons. Indirect ionization produces free radicals of other molecules, namely water, which diffuse and damage critical targets (Fig. 23.1). A free radical has an unpaired outer shell electron that is chemically unstable and very reactive. The hydroxyl free radical (made by the lysis of H_20) diffuses only about 1 nm and breaks the chemical bonds in cellular proteins and other key substances such as DNA. Either form of energy deposition results in ionization of

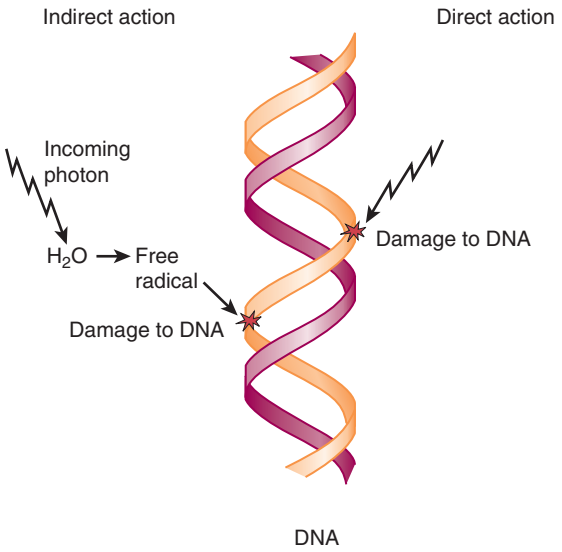

FIGURE 23.1 Direct and indirect actions of radiation. DNA, the most lethal target of radiation is schematically shown in the center. In direct action, the incident photon displaces an electron from the target (DNA) molecule. In indirect action, another molecule, such as water, is ionized, and the displaced electron diffuses to the target and damages the DNA.

target molecules. Scientists estimate that about two-thirds of cell biologic damage is from indirect action by ionizing radiation, from sources such as x-rays and gamma rays.

The electrons generated by penetrating photons lose their energy slowly, resulting in a low energy deposition along the electron track, or low linear energy transfer (LET; defined as energy transferred per unit length of track, or keV/μm). High LET radiations (neutrons, negative p mesons, or alpha particles) deposit more energy per unit length, are more commonly directly ionizing, and are less susceptible to perturbations such as oxygen tension. This means that for the same reaction produced in healthy cells by all radiation modalities, high LET radiation has a higher probability (1.5 to 2.5 times that of x-rays) of killing those cells in less than ideal circumstances (ie, hypoxic tumor cells, cells in a resistant part of the cell cycle).

Sources of Radiation

Gamma rays are the photons emitted from the atomic nuclear decay of radioactive isotopes—for example, ^{137}Cs (cesium) or ^{60}Co (cobalt). *X-rays* are photons electrically generated by bombarding a target such as tungsten with electrons (how a linear accelerator works). When these fast-moving electrons approach the tungsten nuclear field, they are attracted to the nucleus and thus veer from their original path. This change in direction causes deceleration and kinetic energy is converted to x-rays in the form of bremsstrahlung photons. These emitted x-rays, or photons, vary in energy from zero to a maximum determined by the kinetic energy of the bombarding electrons. Machines such as the betatron and linear accelerator generate electrons with high kinetic energy and thus produce high-energy x-rays. In addition to bremsstrahlung photons, characteristic photons are also produced as atoms seek to fill electron orbital vacancies (see later discussion). Gamma rays and x-rays can be collectively called *photons*, and what is of medical importance is the energy and delivery of the photon, not the source.

Photon Interactions

The interaction of photons with matter is accomplished through six mechanisms: **(1) Compton scattering, (2) photoelectric absorption, (3) pair production, (4) triplet production, (5) photodisintegration, and (6) coherent scattering (no energy transfer).** The Compton effect is the major interaction of photons in tissue used in modern radiotherapy (Fig. 23.2). When the photon from the linear accelerator interacts with outer orbital atomic electrons, part of the photon energy transfers to the electron as kinetic energy. The photon is deflected with reduced energy. The ejected electron is propelled forward and sets up a cascade of increasing energy deposition by displacing more electrons. As a result of this initiation and subsequent *buildup effect*, megavoltage photon beams have a skin-sparing effect not seen in older machines and therefore produce less superficial tissue change.

The photoelectric effect is seen at lower energies. This effect is the most important in diagnostic radiology. In this interaction, the incident photon is absorbed completely by an inner shell electron. The inner shell electron is ejected with kinetic energy equal to the incident photon energy less the electron-binding energy. An outer shell electron then drops into the vacancy. As this electron changes orbit, its energy is reduced, and the excess energy is given off in the form of a photon, called a "characteristic photon."

In pair production, photon energies greater than 1.02 MeV interact with the strong electric field of the nucleus and lose all incident energy. The incident photon energy is converted into matter in the form of a positron–electron pair. If this happens in the field of an orbital electron, three particles are produced in the interaction, and the interaction is called triplet production.

Last, in photodisintegration, the high-energy photon enters the nucleus and ejects a neutron, proton, or alpha particle. This is important for shielding considerations in linear accelerators that operate at energies above 15 MeV.

Radioactive Decay

Naturally radioactive substances decay to more stable substances by several methods: (1) beta decay (^{32}P, ^{18}F), (2) electron capture (^{125}I), (3) alpha decay (^{226}Ra), and (4) isomeric transition (gamma emission and internal conversion). "Decay" is the manner in which an isotope releases, or gains, matter, or energy to become a more stable substance. The rate of decay of a radionuclide is exponential and is termed the "activity." The old unit for activity was the Curie (Ci). The SI unit is the becquerel (Bq) defined by 1 Bq = 1 dps (disintegration per second). The half-life ($T^{1/2}$) is the time required to disintegrate to half the original activity. $T^{1/2}$ of commonly used radioactive substances is in Table 23.4.

^{137}Cs (Cesium-137), used in low dose rate (LDR) applications, is a byproduct of the fission process in a nuclear reactor and decays via beta and gamma emission. In beta decay, a neutron from the nucleus converts into a proton (positively

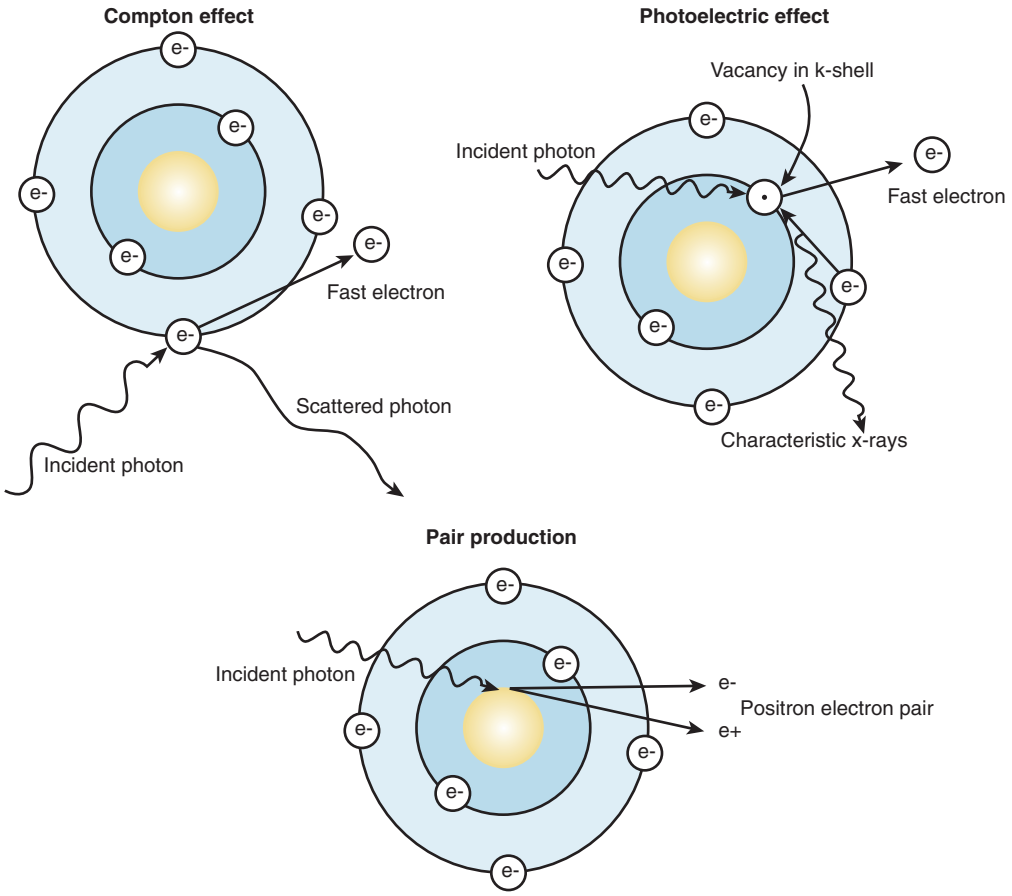

FIGURE 23.2 The major photons interactions important in therapeutic and diagnostic radiation oncology.

charged) and an electron. Again, to increase stability, a photon is released, and the ^{127}Cs becomes the more stable ^{137}Ba (Fig. 23.3). ^{137}Cs decays approximately 2%/year.

^{192}Ir (iridium 192) is also produced in a nuclear reactor and decays via beta decay (see earlier) and electron capture. In electron capture, the nucleus "captures" an orbital electron and converts a proton into a neutron. ^{192}Ir then becomes the excitable ^{192m}Pt and ^{192m}Os, which release gamma rays to stabilize. ^{192}Ir is the primary isotope used for high dose rate (HDR) applications and interstitial implants. It decays approximately 1%/day.

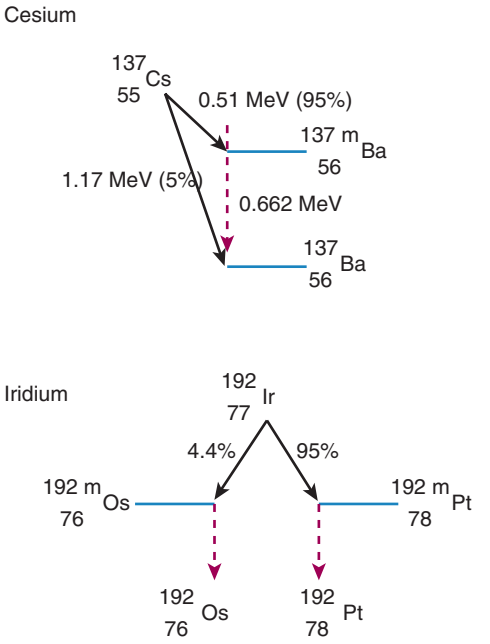

FIGURE 23.3 Decay diagram of ^{137}Cs and ^{192}Ir.

Inverse Square Law

Another important physics concept in radiotherapy is the inverse square law. This law states that the dose of radiation at a given point is inversely proportional to the square of the distance from the source of radiation (dose ∝ 1/distance^2). This rapid decrease in dose is very important in brachytherapy. It underscores why the bladder and rectum can be relatively protected from the high intracavitary doses of radiation, especially with good vaginal packing to maximize the distance from the source to the normal organ. It also underscores why good geometry is critical when performing implants. Last, it explains the reasoning behind standing at the door (increasing the distance) while conversing with a brachytherapy patient. As a

simplistic example, consider the following. The dose at point A is 4. Two feet away the dose would be 4 divided by the square of the distance (2^2) or 4/4 = 1. Another 2 feet away, the dose would be 1/4 ($4/4^2 = 4/16 = 1/4$).

Depth Dose Characteristics of Radiation

The last physics concept to master is variation in radiation beam characteristics based on energy. **To that end, it is important to realize that the energy and penetrating power of ionizing radiation increase as the photon frequency increases and wavelength decreases.** In addition, as energy increases, the depth of maximum dose increases (D_{max}; remember the *buildup effect* discussed earlier). For low energies, such as 250 keV, the maximum dose is at the skin surface. For a 4-MeV (4 million electron volts) accelerator, the D_{max} is approximately 1 cm; for 6 MeV, D_{max} is at 1.5 cm; for 22 MeV, D_{max} is at 3.5 cm; and so on. Knowing this, one can see why higher energy beams are more suited to treat deeply seated tumors, such as in the uterine or cervix. These higher energy beams differentially spare more superficial tissues. Depths of maximum dose curves and isodose distributions (areas receiving similar dose) for various energies are shown in Fig. 23.4.

The reduced effect on skin of supervoltage radiation, compared with orthovoltage (keV range) radiation, is based on a physical characteristic of radiation. With higher energy, forward movement of the energy cascade (in the direction of the primary beam) is greater with reduced lateral scattering. As the energy increases, it becomes more penetrating, and the photons and resultant liberated electrons travel a greater distance into the absorbing material. Therefore, the percentage of radiation at any specific depth, compared with the surface dose, increases as the energy increases.

In summary, above the energy of 400 to 800 keV, the advantages to higher energy photons are less damage to the skin at the portal of entry, greater radiation at depth relative to the surface, and reduced lateral scatter of radiation in the tissues. In addition, there is less photoelectric effect at higher energies and therefore less absorption in bone.

RADIOBIOLOGY

The selective destruction of tissues forms the basis of therapeutic radiation. Neoplastic cells are preferentially killed by radiation compared with the surrounding normal tissues, primarily as a result of differences in repair capabilities. This differential radiosensitivity between normal and cancerous tissues determines in large part whether a radiated neoplasm is eradicated. **The ratio that defines the dose necessary to effect tumor kill**

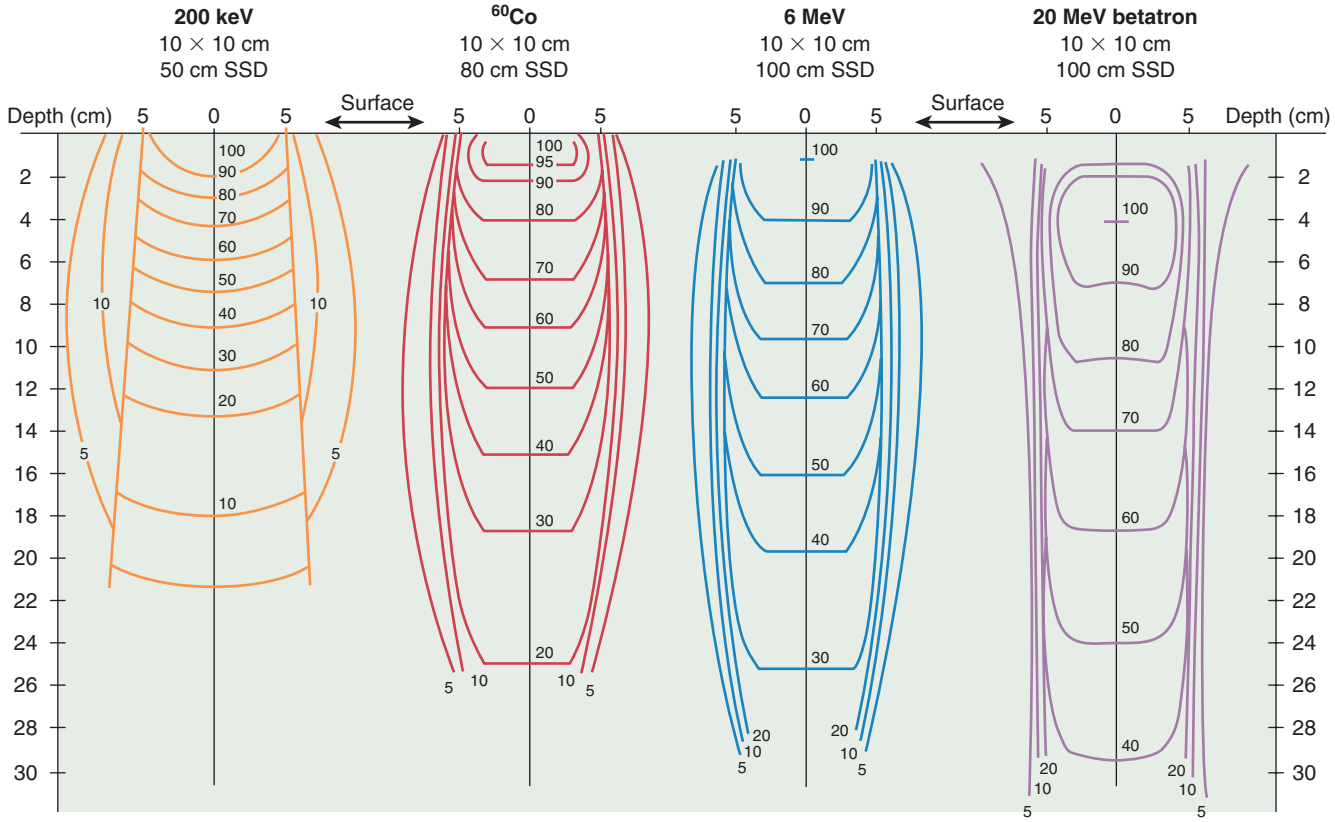

FIGURE 23.4 Comparison isodose curves and depth-dose distribution through a single field. Each machine is delivering photons of different energies. Note that higher energy machines deliver radiation to a greater depth for the same surface dose. Note also the skin sparing with 6- and 20-MV equipment. Last, note the difference in lateral scattering—higher energy photons are more "forward moving" with less lateral scatter.

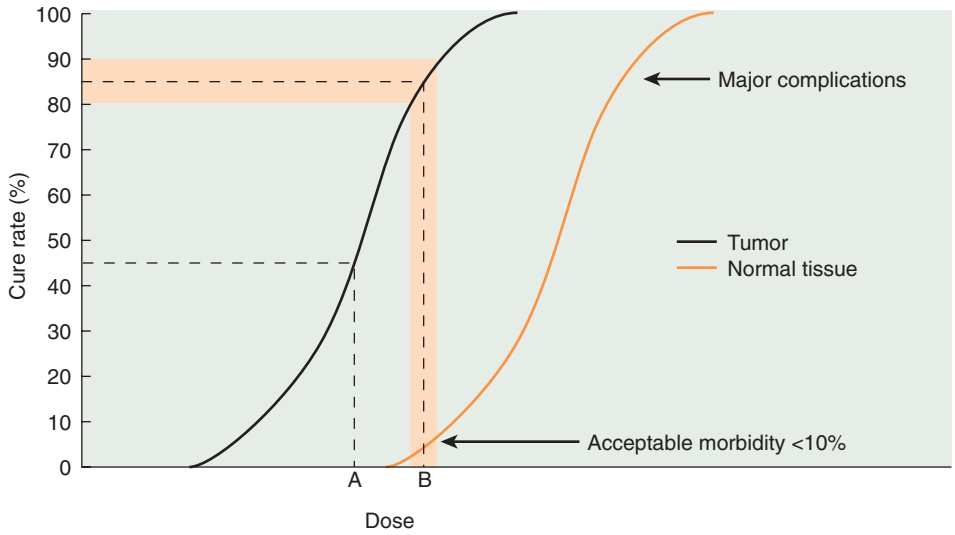

FIGURE 23.5 Therapeutic ratio. Diagrammatic representation of a parallel tumor response and normal tissue tolerance curve demonstrating the relationship between increasing dose, increasing cure rate, and increasing morbidity. Under ideal circumstances *(B),* an 80% to 90% cure rate can be achieved with 5% to 10% morbidity. Pushing the cure rate carries with it an increase in morbidity. However, attempts to avoid all morbidity *(A)* significantly reduce the ability to cure. Although the shape of these curves varies for various tumor types and dose rates, general concepts are valid whenever radiotherapy is used to treat malignant lesions.

with the dose likely to cause normal tissue damage is the therapeutic ratio, and modern radiotherapy is striving to maximize this ratio (Fig. 23.5).

Structural Changes

Deposition of radiation energy in the cell can lead to a variety of changes that alter normal function. Degradation, or breaking into smaller units, and cross-linking are examples of structural damage that can affect proteins, enzymes, and nucleic acids. The initial chemical change occurs in a fraction of a second and is rarely detected directly. Some changes are repaired almost immediately, but others can never be repaired. Although various morphologic and functional changes occur in irradiated cells, the bulk of direct and indirect evidence suggests that the biologic effects of radiation result principally from DNA damage. For example, it has been calculated that 1 million cGy is required to inactivate cell cytoplasmic enzyme systems, and doses of 1000 cGy are required to damage cell membranes. In contrast, chromosomal aberrations and mutations can be produced by very low doses of radiation. Because only a few hundred cGy are needed to produce a high degree of lethality in cell tissue culture, it seems logical that nuclear changes are responsible for cell death.

Radiation-induced DNA damage destroys the cell by one of several mechanisms. It may stimulate cell apoptosis, called interphase death, which is visible by several methods, including light microscopy and Western blot. Radiation may also cause mitotic death. In this form of damage, the cell outwardly appears normal but is sufficiently damaged so that cell division is not possible. Actual death of the cell does not occur, however, until cell division is attempted. This is why tumors may continue to regress after completion of radiation.

A variety of DNA lesions are produced by radiation including base damage, DNA–protein crosslinking, single-strand breaks, and double-strand breaks (DSBs). Repairing even a single nucleotide requires many genes and a series of steps. The most toxic cellular lesion inflicted by ionizing radiation is the DSB. In fact, the proficiency of repair of DSB correlates well with radiation-induced lethality. The repair of DSB can occur by several mechanisms. Religation of complementary DSB ends, homologous recombination (HR), is efficient, and cells can usually survive. The Mre11 protein is attracted when a DSB occurs and may be the first sensor of the break and primarily involved in repair through nuclease activity, unwinding DNA, or removing hairpin loops. When the ends are not complementary, nonhomologous end joining (NHEJ) is used and can be complicated by small DNA deletions or insertions. These errors in turn can lead to cell death or mutation. Some of the necessary proteins for NHEJ are Ku70, Ku80, DNA ligase IV, and XRCC4. The Ku70/Ku80 complex binds to the DSB and unwinds the strand while the DNA ligase IV/XRCC4 complex repairs DSBs. Mammalian cells seem to repair more by NHEJ than HR.

Radiosensitivity

Radiosensitivity is the response of the tumor to irradiation that can be measured by the extent of regression, rapidity of response, and response durability. Radiosensitivity depends on several factors. These factors include the ability to repair damage, hypoxia, cell cycle position, and growth fraction. In addition, the volume of the initial tumor has been demonstrated to influence the ability to eradicate tumors.

Understanding that radiosensitivity and radiocurability are not identical in meaning is essential. Relatively radioresistant tumors accessible to high-dose local radiation therapy can be

cured, but radiosensitive tumors that are widely metastatic can only be controlled locally. An excellent example of a relatively radioresistant tumor is squamous cell carcinoma of the cervix; however, this malignancy remains one of the most curable tumors in humans because of its accessibility to high-dose irradiation and the relatively radioresistant nature of the hosting normal tissues (eg, cervix and vagina). The ability to place radium or cesium in juxtaposition to the malignancy within dose ranges tolerable to the surrounding normal tissue is the key to success.

Many attempts have been made to develop an assay to predict tumor radiosensitivity. However, no assay yet developed accurately predicts the outcome in a given tumor. **This is likely secondary to tumors containing mixed cell populations with differing sensitivities to chemotherapy and radiation. Sensitive cells are eliminated, but resistant cells continue to grow. This explains why many tumors initially respond to therapy but are ultimately incurable.**

In vitro models have been developed to predict and study tumor cell radiosensitivity. Cellular radiosensitivity is generally quantified by measuring the loss of reproductive capacity, which can be plotted in a survival curve. Survival curves are characterized by an initial slope, α, and the terminal slope, β. α represents irreparable damage to the cell, and β represents the repairable damage (Fig. 23.6). The α/β ratio is the dose at which the contribution from alpha equals the contribution from beta and is a measure of radiosensitivity. Large ratios are seen with rapidly dividing cells and help predict the response of tumors and the early effects of radiation. Low ratios characterize late responding tissues.

In addition, the size of the shoulder (Dq) on a survival curve relays valuable information because it represents the magnitude of repair of sublethal damage (SLD). Broad shoulders have small α/β ratios and good repair of SLD. This repair of sublethal damage takes several hours (2–6 hours) to complete. The ability of cells to repair SLD forms the basis for the use of fractionated doses in clinical radiation therapy, in which differential capacities between normal tissue and tumor to repair a sublethal injury can be exploited (Fig. 23.7). This differential repair capacity also forms the basis for accelerated fractionation or hyperfractionation in which the dose is given twice a day. This approach works very well with rapidly growing tumors. Treated twice a day, the normal tissues have sufficient time to repair, but the tumor tissues, which are less organized, efficient, and accurate, are differentially killed. Some cells have almost no shoulder, indicating a limited ability to repair sublethal damage, and these cells can be eradicated with relatively low doses of radiation. For example, dysgerminomas are highly curable with relatively low doses of radiation (20–30 Gy) compared with cervical cancer tumors, which may require more than 70 Gy to obtain cure.

The availability of oxygen is of vital importance to the radiosensitivity of the cell also. As radiation enters the cell, it interacts with organic molecules (DNA). This molecule may repair itself unless an oxygen molecule becomes attached, thereby "fixing" the damage. The addition of O_2 will enhance low LET radiation (photons) but does not similarly affect high LET radiation. The ability of oxygen to enhance radiation is measured by the oxygen enhancement ratio, or oxygen enhancement ratio (OER) (OER = Dose of XRT without O_2 for a given effect/Dose of XRT with O_2 for the same effect). It takes at least 2% (17 mm Hg) tissue O_2 to see the full oxygen effect.

Tumor cells with potentially unlimited capacity for growth are limited as they outgrow the blood supply. In fact, tumors above 200 μm have necrotic cores secondary to a limited diffusion distance for oxygen. Oxygen may effectively penetrate approximately 70 μm from the blood vessel (Fig. 23.8). Outside this distance, tumor cells become deficient and enter a noncycling phase. They may become hypoxic or even anoxic and necrotic.

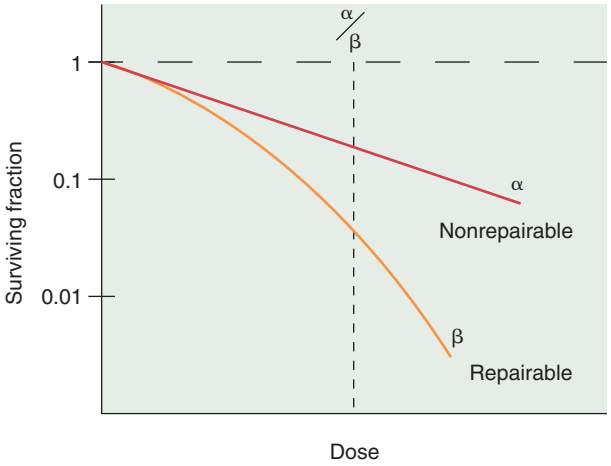

FIGURE 23.6 Cell survival curve. The initial slope, α, represents irreparable damage, and the terminal slope, β, represents reparable damage. The α/β ratio is the point on the curve where the two are equal.

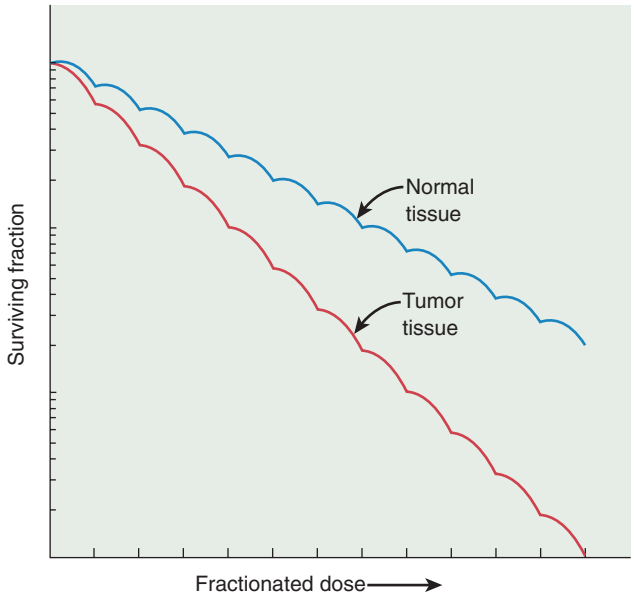

FIGURE 23.7 Different capacities between normal tissue and tumor to accumulate and repair sublethal injury from fractionated doses result in differential survival. The normal tissue is able to repair more efficiently and effectively.

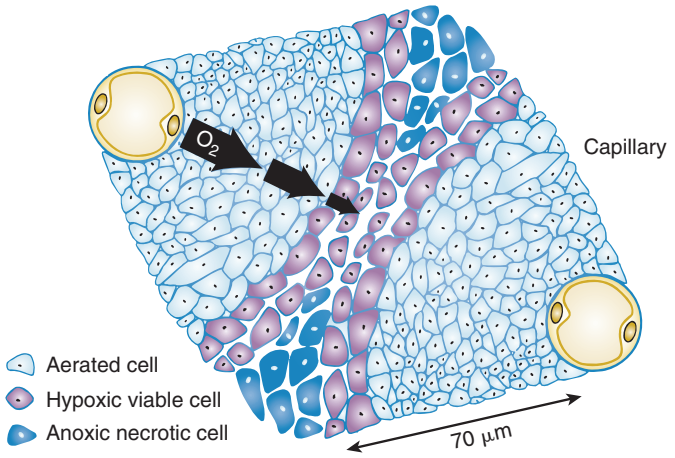

FIGURE 23.8 As the distance from the blood supply increases, cells become hypoxic and even anoxic. Hypoxic cells are more radioresistant and therefore harder to sterilize. Oxygen diffuses about 70 μm from the capillary.

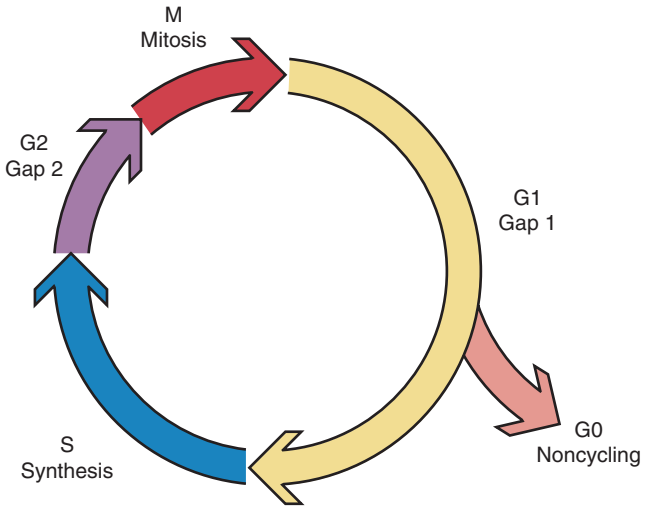

FIGURE 23.9 Cell cycle.

This is important from a radiobiologic standpoint because noncycling cells exhibit a greater capacity to repair radiation injury. Hypoxic cells are more resistant to the effects of radiation than are cells with normal oxygen tension. Thus large tumors can be difficult to control with radiation therapy, not only because there is a greater number of cells to sterilize but also because a proportion of these cells are hypoxic, noncycling, and radioresistant. As a clinical example, experience notes that exophytic friable cervical lesions that hemorrhage easily on contact respond better and more quickly than infiltrative lesions. The blood supply and oxygenation vary considerably between these two lesions, with the friable lesion better vascularized and oxygenated and therefore more radiosensitive. Unfortunately, attempts to overcome this differential sensitivity by mechanisms such as hyperbaric oxygen and radiosensitizers have been less than optimal to date.

Another factor important in radiosensitivity is the proportion of mitotic or clonogenic cells in the tumor. Cycling cells are more radiosensitive. In fact, mitotic counts have been shown to correlate with the prognosis in many tumors. The position in the cell cycle is also important (Fig. 23.9). Cells in late G2 and mitosis (M-phase) are the most sensitive to radiation, and cells in late synthesis (S-phase) are the most resistant (Fig. 23.10). This is exploited with chemotherapies such as paclitaxel, which arrests cells in mitosis and is a profound radiation sensitizer.

Finally, the initial tumor volume greatly influences the ability to sterilize a site. **Generally, the smaller the tumor volume, the less radiation is required to destroy all cells. As the volume increases, the dose to obtain local control is increased.** The concept of treating with "shrinking" fields is to serially reduce the size of the radiation portals to give a higher dose of radiation therapy to the central portion of the tumor, where presumably more hypoxic, radioresistant cells are present.

Historically, clinicians attempted to correlate radiation tumor response and local tumor control. Generally, the faster and more complete the tumor response at the completion of the therapy, the greater long-term control, assuming that no distant metastasis occurs. Although this is not uniformly true, it has been shown in cervical cancer that there is a good correlation between local tumor control and complete or partial regression of the cancer at the completion of radiation. In addition, Grigsby and associates have correlated posttreatment PET tumor response (which measures glucose metabolism) with survival.

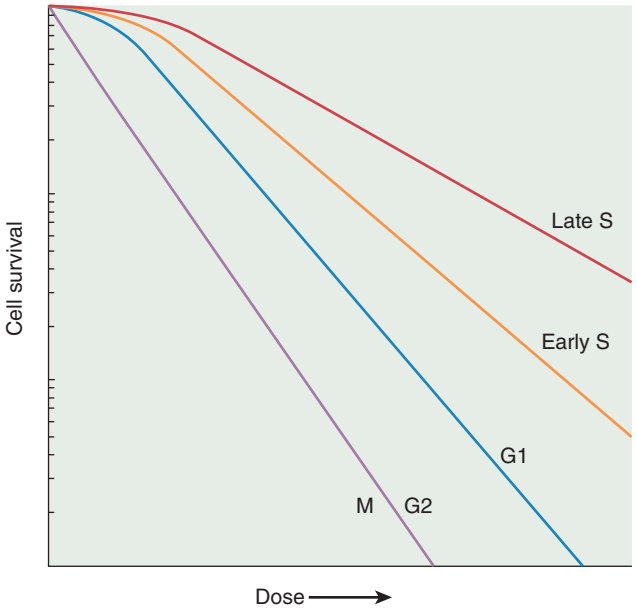

FIGURE 23.10 The survival curve for cells in mitosis, and G2 is steep and has no shoulder. The curve for cells late in S phase is shallower and has a large shoulder. G1 and early S are intermediate in sensitivity.

Another factor limiting radiocurability is the normal tissue toxicity with increasing radiation doses. Normal tissue effects depend on total dose, dose fraction size, volume, and inherent tissue radiosensitivity. The ultimate goal is to obtain maximal

curability with minimal side effects. Combining radiation therapy with surgery or chemotherapy decreases normal tissue tolerance to a given dose. Well-established port size, total dose, and fractionation schemes have been identified but cannot remain static. Variations are being investigated to increase curability and decrease complications, including new chemotherapeutic radiosensitizers, technological advances in the delivery of radiation such as IMRT, and radioprotectors such as Ethyol.

RADIOSENSITIZERS, HYPOXIC CELL SENSITIZERS, AND RADIOPROTECTORS

Radiation sensitizers and protectors are being actively investigated to increase the effectiveness of radiation or allow dose escalation while minimizing side effects. **Radiation sensitizers increase the ability of radiation to cause permanent, lethal damage.** This therapeutic gain may be from a variety of mechanisms, including selective uptake, targeting, or activation. To be effective, sensitizers must have acceptable normal tissue side effects. Known radiation sensitizers include chemotherapeutic agents such as cisplatin, 5-fluorouracil, paclitaxel, Adriamycin, and gemcitabine. Hypoxic cell sensitizers include the imidazole drugs such as misonidazole and bioreductive agents such as tirapazamine. Endogenous sulfhydryl compounds and Ethyol afford radioprotection to normal tissues.

The advantages afforded by chemoradiation can be by several mechanisms. Some agents (eg, cisplatin) inhibit the repair of radiation damage, but others (eg, paclitaxel) block cells in a radiosensitive cell cycle phase. Adriamycin, docetaxel, and paclitaxel have unique effects when combined serially with radiation because "radiation recall" is an uncommon but distressing phenomenon. After a course of radiation, the normal tissue sensitization can be "recalled" when the chemotherapy is initiated—this phenomenon is a reemergence of a prior radiation burn that conforms exactly to the prior radiation portal. The mechanism of this is unknown but well described for these chemotherapies.

The nitroimidazoles such as metronidazole, misonidazole, etanidazole, and nimorazole are electron affinic and increase the sensitivity of radioresistant hypoxic cells to XRT. They mimic oxygen and can diffuse into hypoxic areas. Unfortunately, clinical studies to date have demonstrated significant toxicity and little clinical utility with these drugs.

Tirapazamine is entering clinical trials as an adjunct to radiotherapy. Gynecologic Oncology Group (GOG) trial 219 randomized chemoradiation for cervical cancer with and without tirapazamine. Tirapazamine is bioactivated intracellularly to a cytotoxic, active free radical that causes extensive chromosomal breaks and inhibits DNA repair. The reaction is driven by low tissue oxygen tension and when combined with radiation may allow more effective destruction of tumors with hypoxic cores. The GOG published a phase II trial for advanced or recurrent cervical carcinoma using tirapazamine and cisplatin and concluded that the combination was fairly well tolerated. A subsequent phase III trial randomizing stages Ib2 to IVa between standard cisplatin and radiation versus cisplatin, radiation, and tirapazamine was opened but closed for accrual in 2009.

Radioprotection has been proved in several sites with the use of Ethyol. Amifostine (Ethyol; WR-2721) is an organic thiophosphate extensively studied by the Walter Reed Army Institute of Research. Normal tissues noted to be protected included the salivary glands, bone marrow, immune system, skin, oral mucosa, esophagus, intestinal mucosa, kidney, and testes. It is dephosphorylated to the active metabolite (WR-1065) in the tissues.

It is believed that tissue versus tumor alkaline phosphatase concentration variations provide the differential protective effect. In addition, tissue pH differences afford selective tissue versus tumor uptake of Ethyol. When given intravenously, the plasma half-life is less than 10 minutes, but there is prolonged retention of the drug in normal tissue. In the first 30 minutes, drug uptake into normal tissues has been shown to be 100 times that of tumor tissues. When inside the cell, the metabolite scavenges oxygen free radicals and provides an alternative target for alkylating agents, such as cisplatin.

There have been numerous studies of the protective effect of Ethyol with no reported decrease in antitumor efficacy. A phase III trial in head and neck cancer unequivocally established its role in salivary gland protection, confirming earlier studies. Other clinical trials have shown Ethyol protects from cisplatin-induced renal, neurologic, and bone marrow toxicity. Liu published a phase III randomized trial in rectal cancer patients treated with pelvic radiation with and without Ethyol (340 mg/m^2). The toxicity in the mucous membranes and genitourinary (GU) and gastrointestinal (GI) tracts was reduced by 50% in the Ethyol arm. Moderate to severe late toxicities were seen in 14% of those treated without Ethyol compared with zero in the Ethyol-treated patients.

Athanassiou and colleagues randomly assigned 205 patients with pelvic radiation plus or minus Ethyol and demonstrated a significant decrease in bladder and GI toxicity. Complete responses to therapy and median survival were not significantly different between the arms. The RTOG (Radiation Therapy Oncology Group 0116) completed a two-arm trial using Ethyol with chemoradiation for pelvic and paraaortic radiation with concomitant cisplatin in cervical carcinoma. Arm 1 consisted of cisplatin chemotherapy concomitant with paraaortic radiation and demonstrated significant acute and late toxicity. Arm 2 again demonstrated significant acute and long-term toxicity, with no significant benefit demonstrated with the addition of Ethyol, although compliance to the medication was disappointing. Ethyol has been found to be useful in reducing early and late toxicity with hypofractionated accelerated conformal radiation by Koukourakis. Toxicities with intravenous administration include hypotension and nausea. Data on subcutaneous administration demonstrate less hypotension but treatable nausea and skin effects persist. There have been rare reports of Stevens-Johnson syndrome.

Genetic Effects

It is not possible to generalize and assign a specific mutation rate to a given radiation dose. Gene loci differ greatly in their

mutability, and the random damage exerted by irradiation on any particular chromosome makes predictability impossible. The mitotic stage, cell type, sex, species, and dose rate influence the mutation rate as studied in lower animals and bacteria. Data from lower animals are difficult to extrapolate to humans, and therefore prediction of mutation rates cannot be expected from the evidence that has been accumulated from various types of radiation exposure. Direct evidence of radiation-induced mutation in humans is lacking, although there is strong anecdotal evidence for carcinogenesis in those exposed to radiation. A few examples are excess skin cancers seen in those exposed to x-rays before safety standards were established, lung cancer in pitchblende miners, bone tumors in radium dial painters, and liver tumors in those exposed to Thorotrast contrast. The largest groups of humans available for study are survivors and descendants of those exposed in Hiroshima and Nagasaki. Although there has been no detectable effect on the frequency of prenatal or neonatal deaths or on the frequency of malformations in subsequent generations, this does not mean that no hereditary effects were produced. The number of exposed parents was small, and dosages were so low that it would have been surprising if an increase in mutation had been detected in such a brief period. There has not been sufficient time for the several generations needed to reveal recessive damage.

Radiation does not produce new and unique mutations but increases the incidence of spontaneous mutations. Based largely on experiments in mice, it is estimated that the doubling dose (ie, the dose that will double the spontaneous mutation rate) for humans is probably 100 cGy. Between 1% and 6% of spontaneous mutations in humans can be ascribed to background radiation. With the use of image intensifiers, improved radiographic film, and appropriate shielding to prevent scatter, it is possible to attain satisfactory radiographic visualization of internal structures with reduced exposure. The average dose of irradiation to the gonads of some common diagnostic techniques is given in Table 23.7. The use of diagnostic radiographs and CT scans has increased and fueled concerns that toxic radiation effects may emerge, especially among children exposed to increased diagnostic medical irradiation. Current recommendations stress the use of ionizing radiation only when necessary and substitution of alternate sources of imaging, such as MRI, which relies on magnetic fields, when possible.

In general, most mutations are harmful, and there is no known threshold dose for the genetic effect. Permanent sterility in females is estimated to have a threshold of 250 to 600 cGy to acute exposure and 0.2 Gy/year for protracted exposure. The threshold dose for sterility varies based on the age of the patient, with younger patients being more resistant to the deleterious effect.

Fetal Effects

The classic effects of radiation on the mammalian embryo are as follows: (1) intrauterine and extrauterine growth restriction; (2) embryonic, fetal, or neonatal death; and (3) gross congenital malformations. Dose, gestational age, and dose rate are all important factors influencing radiation damage. The recommendation for fetal dose during the entire gestation is 0.5 rem or less (roughly 0.5 cGy). Monthly exposures should not exceed 0.05 rem. If a pregnant patient receives 10 cGy in the sensitive period of 10 days to 26 weeks, therapeutic abortion should be considered to avoid radiation effects, including malformations, microcephaly, and mental retardation.

TABLE 23.7 Radiation Doses to Low Pelvis From Diagnostic Scans

Examination	Dose to Fetus (First Trimester) and Maternal Gonads (mcGy)
Lower extremity radiography	1
Cervical spine radiography	2
Chest radiography	8
Chest fluoroscopy	70
Lumbar spine radiography	275
Hip radiography	100
IVP	585
Upper GI	330
Lower GI	465
Chest CT	8
Abdominal CT	800
Pelvic CT	2300

CT, Computed tomography; *GI,* gastrointestinal; *IVP,* intravenous pyelography.
Modified from DiSaia PJ. In Scott JR, DiSaia PJ, Hammond CB, Spellacy WN, eds. *Danforth's Obstetrics and Gynecology,* 8th ed. Philadelphia, 1999, JB Lippincott.

The peak incidence of gross malformations occurs during early organogenesis (10–40 days of gestation in humans), although cellular, tissue, and organ hypoplasia can be produced by radiation throughout the fetal and neonatal period with sufficient dose. Diagnostic x-ray procedures should be avoided in the pregnant woman unless there is overwhelming urgency. In women of childbearing age, possible damage to an early conceptus can be prevented by performing tests immediately after the commencement of a menstrual period and obtaining a negative pregnancy test result. Compelling evidence that radiation may be a causative agent in childhood cancer after prenatal exposure comes from several studies in Great Britain and the United States.

Some concrete information is available from the Japanese survivors of the atom bomb attacks in 1945. Examination of children born to survivors demonstrates the primary effect from in utero radiation was microcephaly and mental retardation. **The most sensitive phase for mental retardation was from 8 to 15 weeks of gestation.** In addition, permanent growth restriction was also observed, especially in embryos exposed less than 1500 m from the center of the explosion. Hall reached the following conclusions:

1. Moderately large doses of radiation (>200 cGy) delivered to human embryos before 2 to 3 weeks of gestation are unlikely to produce severe abnormalities in most children born, although a considerable number of embryos may be reabsorbed or aborted (all-or-none phenomenon).

2. Significant irradiation between 4 and 11 weeks of gestation leads to severe abnormalities in many organs.
3. Irradiation between 11 and 16 weeks of gestation may produce some eye, skeletal, and genital organ abnormalities; however, stunted growth, microcephaly, and mental retardation are often present.
4. Irradiation of fetuses between 16 and 20 weeks of gestation may lead to a mild degree of microcephaly, mental retardation, and stunting of growth.
5. Irradiation after 30 weeks of gestation is unlikely to produce gross structural abnormalities leading to a serious disability but could cause functional disabilities.

PRINCIPLES OF CLINICAL RADIATION THERAPY

The technical modalities used in modern radiation therapy may be divided into two major categories:

1. **External irradiation:** This applies to irradiation from sources at a distance from the body (eg, teletherapy with ^{60}Co, linear accelerator, betatron, or orthovoltage radiograph machines).
2. **Local irradiation** (brachytherapy): This applies to irradiation from sources in direct proximity to the tissue or tumor. Brachytherapy can be delivered with either an LDR system or an HDR system. LDR systems require hospital admission to a shielded room and dose delivery at roughly 50 to 100 cGy/h. HDR systems are commonly done on an outpatient basis and deliver doses of 120 cGy/h.
   a. **Intracavitary irradiation** is done with applicators loaded with radioactive materials such as cesium or iridium (eg, vaginal ovoids, vaginal cylinder, intrauterine tandem, tandem and ring, or, historically, Heyman capsules).
   b. **Interstitial irradiation** (endocurie therapy) is usually delivered in the form of removable needles containing cesium or iridium. The term also applies to permanent isotope implants, such as ^{125}I (iodine) seeds or ^{103}Pd (palladium).
   c. **Direct therapy** was historically delivered by means of cones from an orthovoltage machine (eg, transvaginal) but is rarely available today.
   d. **Intraperitoneal or intrapleural** instillation of radioactive colloids, such as ^{32}P, is yet another local therapy but is infrequently used.

External-beam Radiation (Teletherapy)

External radiation is radiation therapy that is delivered from outside the body. It is most commonly delivered with photons, electrons, or protons. Machinery to deliver the radiation includes ^{60}Co units, orthovoltage machines, and linear accelerators, although linear accelerators are the overwhelming majority. Except in the developing world, ^{60}Co units are unusual. Typically, a patient will need planning done before initiation of radiation, called simulation. Marks or permanent tattoos are applied to the skin to allow for daily setup and, commonly, a planning CT is performed replacing the traditional fluoroscopic simulation. The use of MRI, CT, or PET images to fuse with treatment planning CT data is widely available to better delineate tumor targets and normal tissue and in many centers is part of the standard simulator machine. Three areas must be targeted. The gross tumor volume requires the highest radiation dose. Microscopic extensions into surrounding tissues must be targeted but generally require a lesser dose for sterilization. Subclinical disease presumed to be present in postoperative beds or regional nodes must also be treated to prevent marginal failures.

Local Radiation (Brachytherapy)

Local application of radiation (also known as brachytherapy) permits very high doses to restricted tissue volumes. In this situation, the physical principle (inverse square law) that the intensity of irradiation rapidly decreases with distance from the radiation source is used to advantage. Brachytherapy is well suited to treat small tumors with well-defined limits and a clinical situation in which it is desirable to restrict the volume of tissue irradiated. Larger volumes of tissue that need radiation therapy are best treated with external irradiation. Historically, radium (^{226}Ra) had been the most common isotope used for local application, but because of storage, risk of leaks, and extremely long half-life, it is rarely used in the United State. Sources used today are often converted to mg-Ra-equivalents. Brachytherapy sources such as ^{125}I, ^{137}Cs, ^{192}Ir, and ^{103}Pd are more commonly used today (see Table 23.4).

Although conventional LDR intracavitary brachytherapy has produced very good results in cervical cancer, remote afterloading HDR intracavitary brachytherapy is becoming more widespread. The treatment results of LDR and HDR appear to be similar both for local control and survival, although there are no large American randomized trials. Retrospective studies, however, mirror the results of the randomized studies. There remain concerns over potential differences in late complications resulting from the different biologic mechanisms between the continuous low dose rate of LDR and the intermittent high dose rate of HDR. The increased interest in HDR arises from cost of inpatient hospitalization, the risks of prolonged bed rest, and radiation exposure to medical personnel with LDR systems. In both LDR and HDR, it is very important to keep the doses to normal tissues as low as possible by proper placement of radiation carriers and the use of shielding and packing or retraction techniques. HDR units use computer technology to "optimize" the dwell time of a single source to give the required distribution. The American Brachytherapy Society has published consensus guidelines on the administration of HDR for both cervical and uterine carcinomas. Also in use as an alternative to LDR or HDR is pulsed dose rate (PDR), although randomized trials on this method are lacking, and published reports are few but increasing.

The term *dosimetry* is applied to the measurement and calculation of dose that the patient receives. In brachytherapy, as radiation intensity rapidly decreases with increasing distance from the source, tissue adjacent to the radiation source is treated to a high dose while relatively sparing surrounding tissue. The effectiveness of this distribution of irradiation depends on meticulous application of these sources. Interstitial application

of radioactive sources is more difficult than intracavitary application. It is essential that the gynecologic oncologist be able to critically assess the placement of tandem and ovoids, cylinder, and ring to assess the optimal placement of brachytherapy sources (Figs. 23.11 and 23.12). Increased use of computer planning to optimize the dose to the tumor and minimize the dose to the normal tissues is under active clinical investigation and is likely to replace the current two-dimensional dosing guidelines and restrictions based on calculated doses to points (eg, points A, B, and bladder and rectal points) with three-dimensional, volume-directed, image-guided brachytherapy (IGBT). The European collaborative group Groupe Européen de Curiethérapie and the European Society for Therapeutic Radiology and Oncology (GEC-ESTRO) have published extensive work on this subject and an international trial. EMBRACE (Mri-guided BRachytherapy in CErvical cancer) is open to test the utility and applicability of the new guidelines.

Normal Tissue Tolerance

The tolerance of any tissue (normal or tumor) to irradiation therapy depends on several characteristics of radiation, including (1) fractionation technique, (2) field arrangement, (3) total dose, (4) dose rate, and (5) volume irradiated.

Fractionation is the number of treatments needed to deliver the total dose. Pelvic radiation delivered to a patient for a total dose of 5000 cGy given in five daily fractions of 200 cGy each week for 5 weeks is well tolerated in most cases. However, if that same total dose of 5000 cGy were given in five fractions of 1000 cGy every Monday for 5 consecutive weeks, tolerance would be low.

In addition, multiple fields are used to minimize toxicity by dividing the exposure of normal tissue into multiple different regions. Three-dimensional conformal therapy (3DCF), IMRT, and IGRT are areas of active investigation to further maximize dose to tumor and minimize toxicity to the surrounding normal tissues (Fig. 23.13). With external irradiation, the patient is treated to all fields 5 days/week.

As is seen in LDR brachytherapy versus HDR brachytherapy, dose rate affects tolerance. The final dose in HDR is necessarily lower to compensate for normal tissue tolerance concerns with the markedly higher dose rate in HDR. Conversion of doses to a 2-Gy dose equivalent is recommended by the Groupe Euro-Péen de Curiethérapie-European for Radiotherapy and Oncology (GECT-ESTRO) guidelines and is becoming more common (see later).

Finally, the volume of tissue irradiated is also an integral factor in tolerance. For example, a 1-cm circular field of skin would easily tolerate the fractionation and dose rate of 1000 cGy each Monday for 5 consecutive weeks. However, for a larger volume, such as whole-pelvis radiation, such a treatment plan is intolerable.

Patient factors also affect normal tissue tolerance. Previous surgery affects the morbidity of radiation therapy. In both cervical and uterine cancer, surgery identifies adverse surgical pathologic findings that direct radiation therapy. In cervical cancer, surgical evaluation of possible lymph node metastases, particularly in advanced cancers, may be done, or a radical hysterectomy may be aborted because on inspection, the tumor is more advanced than originally indicated. Transperitoneal lymph node dissection followed by pelvic and possibly paraaortic radiation increases radiation-induced complications, particularly to the bowel. Radiation complications can be severe, including fistula formation, bowel obstruction, and perforation. The retroperitoneal approach to lymph node dissection has a decreased complication rate and is the preferred method of surgically evaluating lymph node status in cervical cancer. Medical conditions that affect blood flow such as diabetes, hypertension, and peripheral vascular disease can also decrease normal tissue tolerance.

Pelvic Organ Tolerance

Irradiation tolerance of the normal organs of the pelvis varies from one patient to another and is subject to the factors previously mentioned, such as volume, fractionation, and total dose of irradiation. As is illustrated in many areas of oncology, the more advanced lesions require higher doses for tumor eradication, and hence the possibility of morbidity increases. This, combined with the fact that advanced cancer often already compromises the integrity of the bladder and rectum, means that serious sequelae can develop in patients with advanced cervical, vaginal, and corpus lesions when curative therapy is sought. New advances in radiation delivery will, hopefully, decrease these adverse effects.

The normal tissues of the cervix and the corpus of the uterus can tolerate very high doses of radiation. In fact, they withstand higher doses better than any other comparable volume of tissue in the body; surface doses of 20,000 to 30,000 cGy in about 2 weeks are tolerated. This remarkable tolerance level permits a large tumor dose and allows a very high percentage of central control of cervical cancer. **The unusual radiation tolerance of the uterus and the vagina, stemming from an unusual ability to recover from radiation injury, accounts for the success of brachytherapy in the treatment of cervical lesions.**

In contrast, the sigmoid, rectosigmoid, and rectum are more susceptible to radiation injury than are other pelvic organs. The frequency of injury to the large bowel often depends on the total dose administered by both the external beam and the intracavitary system. With external-beam radiation alone, the large bowel is the most sensitive of the pelvic structures. The bladder tolerates slightly more radiation than does the rectosigmoid, according to most authorities. Acceptable maximal point doses are 75 Gy and 70 Gy to the bladder and rectum, respectively. Fletcher proposed a rule that gives the upper limits of pelvic irradiation and indirectly gives the tolerance of the bladder and rectum. The guidelines limit the sum of the central dose, stating that external-beam radiation dose plus the number of milligram-hours of cesium administered by brachytherapy should never exceed 10,000. There is a parallel time guideline also critical to this limit. This is a necessary safety to prevent compact systems from exceeding vaginal or cervical tolerance. This guideline is valid only when the Fletcher-Suit brachytherapy systems are used. Most of this is applicable to therapy for the uterus, cervix, and vagina. In general, if a large dose of intracavitary irradiation is applied centrally for a small lesion, the amount of external beam applied centrally

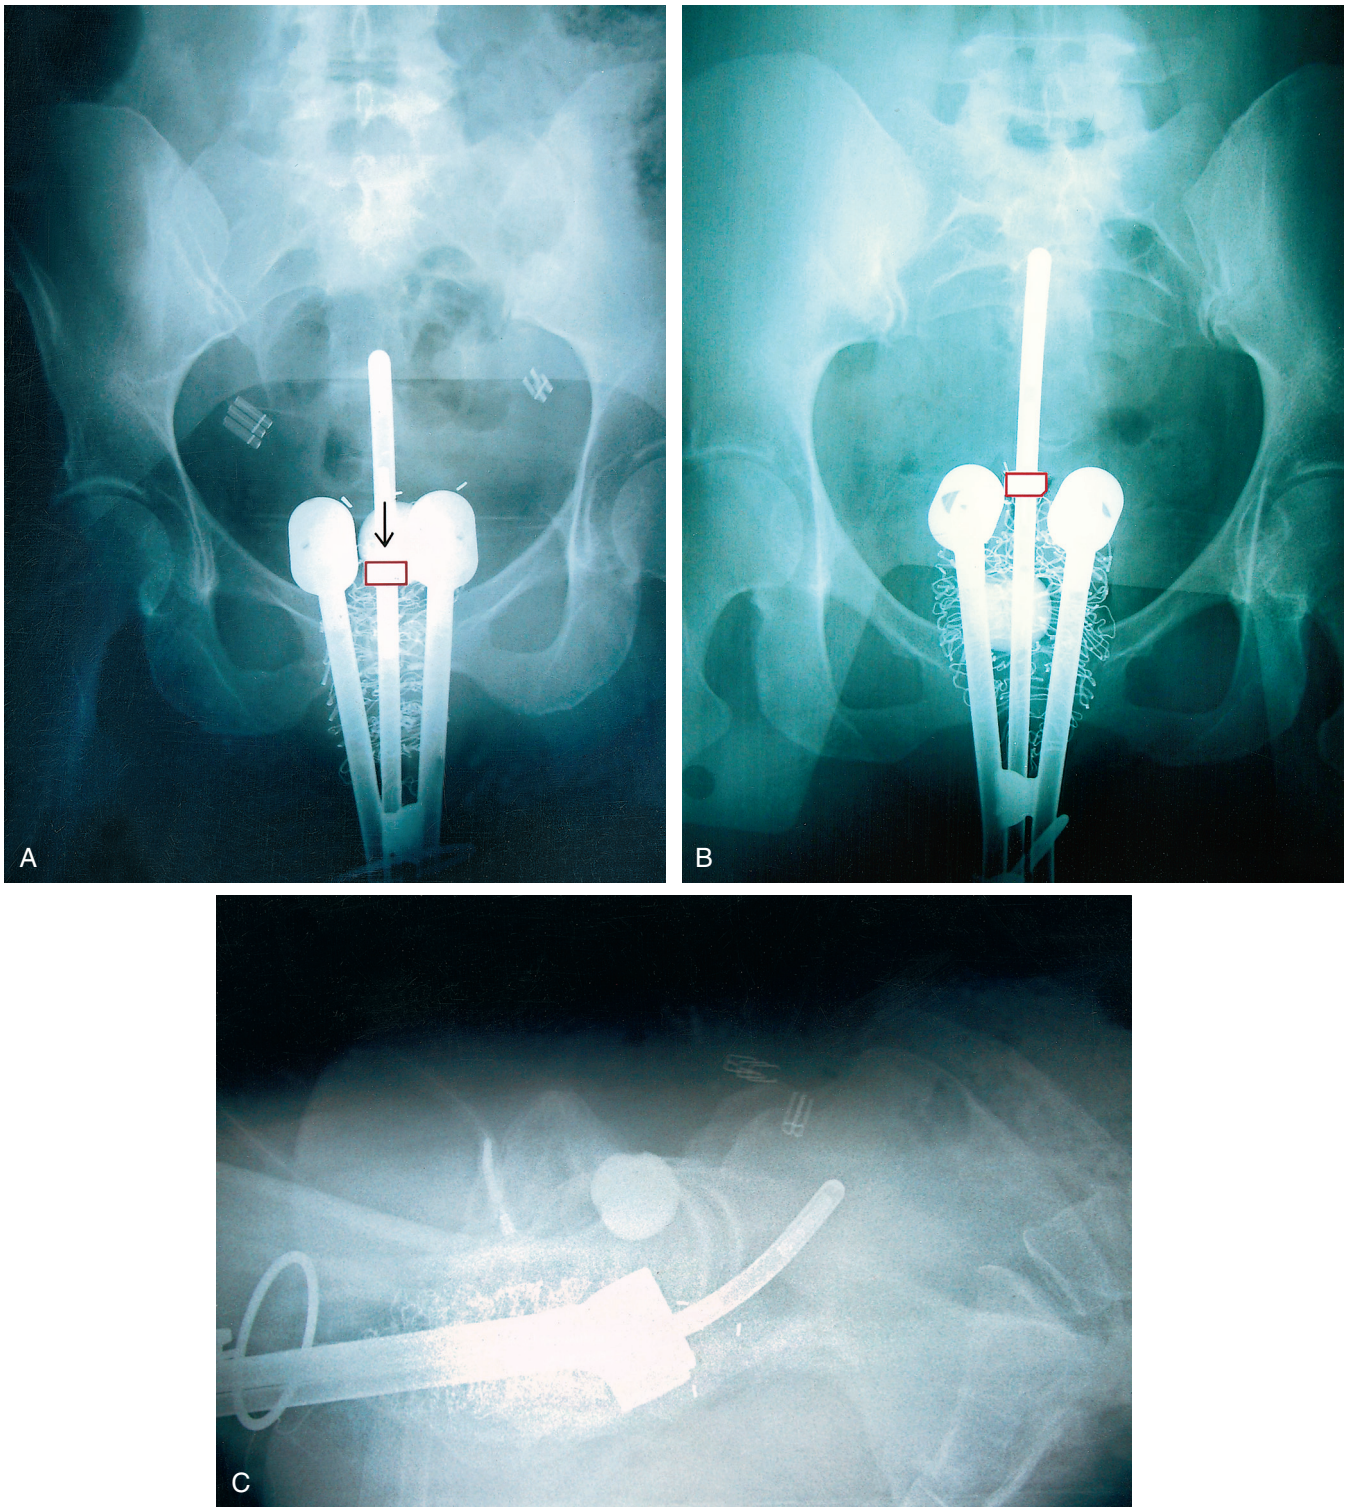

FIGURE 23.11 Assessing proper placement of tandem and ovoids. In both photos, small interstitial silver seeds mark the cervix. Note that in **A,** the cervical stop, outlined in *red,* has dropped away from the cervix, compromising the dose delivery to the tumor and increasing the complications. In **B,** this has been corrected. Also note that the vaginal packing (delineated by radiopaque string) lies below the ovoids and that the tandem is midline and bisects the ovoids. In **C,** a lateral radiograph, the tandem again bisects the ovoids and lies beneath the bladder (the Foley balloon is filled with contrast material) and does not lie too close to the sacrum.

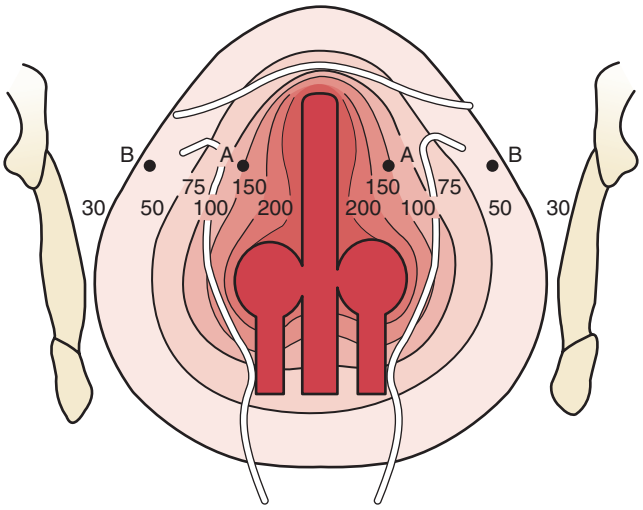

FIGURE 23.12 Isodose curves surrounding a typical Fletcher-Suit intracavitary application (tandem plus ovoids) for cervical cancer. Note the location of points *A* and *B* and the relative dose rates at distances from the system.

must be reduced. Conversely, if a lesion is large and the vaginal geometry is poor, a smaller intracavitary dose can be given and the dose administered by external beam may be raised (6000–7000 cGy).

GEC-ESTRO dose/volume guidelines limit the bladder to 90 Gy_{EQD2} and rectum/sigmoid to 70 to 75 Gy_{EQD2} for a calculated 2-cc volume combining doses from both external-beam irradiation and brachytherapy. In this system, doses from HDR brachytherapy are converted by a formula to a 2-Gy equivalent to allow the doses to be added (EQD2, or equivalent dose at 2 Gy). The formula for conversion is $EQD2 = D \times [(d + \alpha/\beta)/2 + \alpha/\beta]$, where D is total dose, d is dose/fraction, and α/β is 3 for late-responding tissues and 10 for tumor/acute-responding tissues. Certain assumptions are made in this model, such as the same 2 cc of bladder, rectum, and sigmoid receive the maximal amount of irradiation with each fraction of brachytherapy. Especially in the mobile sigmoid colon, this assumption may be erroneous but models the worst-case scenario. A recent paper by Georg and colleagues demonstrated that the 5-year actuarial rectal toxicity rate was 20% if the dose exceeded 75 Gy_{EQD2} and 5% if the 2-cc dose remained below 75 Gy_{EQD2}. For the bladder, the 5-year actuarial toxicity rate was 13% versus 9% if a value of 100 Gy_{EQD2} was used. Insufficient events occurred in the sigmoid colon in this study for definitive analysis, but recommendations remain to keep the sigmoid less than 70 to 75 Gy_{EQD2}. It is hoped that further study will refine these guidelines.

Pelvic radiation spares a significant portion of the small bowel because bowel is normally in episodic motion. This tends to prevent any one segment from receiving an excessive dose. However, if loops of small bowel are immobilized as a result of adhesions caused by previous surgery, they may be held directly in the path of the radiation beam and thus injured (Fig. 23.14). The result of such an injury is usually not manifested for at least 6 months or longer after completion of radiation. Studies demonstrate that the use of IMRT in the postoperative setting can decrease the acute effects of irradiation on the bladder and bowel, but definitive randomized studies are not available to date (see later).

Long-term Effects

Finally, it is important to understand the permanent nature of radiation injury. When any area of the body is subjected to tumoricidal doses of radiation, the normal tissues of that area sustain an injury that is only partially repaired. The tumor tissue disappears, but the normal tissue bed remains, and residual radiation changes must be seriously considered if other disease processes ensue. Radiobiologists estimate that in the case of injury to normal tissues, only 5% to 20% of the damage is repaired. If a second malignant neoplasm arises in that same area many years later, additional tumoricidal radiation is frequently impossible because of permanent radiation changes. In addition, any surgical procedures performed within a previously irradiated field are at higher risk for poor healing, fistula formation, and so forth.

Radiation-induced soft tissue necrosis can be a significant complication. This is usually a result of a progressive obliterative endarteritis that leads to decreased blood flow and a resultant hypoxic tissue bed. This causes increased fibrosis, poor healing, and chronic ulceration. Local conservative management (eg, hydrogen peroxide douche, estrogen therapy) resolves the problem in many cases. A small group of patients has significant tissue breakdown that may be painful and may lead to fistula formation. The use of hyperbaric oxygen has been shown to enhance healing in these radiation-induced injuries. Treatment with hyperbaric oxygen requires entering a tank where one breathes 100% oxygen at an increased atmospheric pressure. This increases the oxygen concentration in all body tissues up to 20 times normal. This treatment is done daily for 6 to 8 weeks. Side effects include nausea, claustrophobia, painful pressure on the ears—similar to the changes experienced with airline pressure changes—pneumothorax, and oxygen toxicity.

Permanent changes to the GU and GI tract can cause signs and symptoms such as decreased bladder capacity, hematuria, ureteral or urethral stricture, hematochezia, bowel obstruction, chronic diarrhea, tenesmus, fecal incontinence, and fistula formation. Gynecologic changes include dryness and shortening of the vagina, dyspareunia, and decreased orgasm. All of these long-term effects should be addressed by the oncology team to maximize the patient's quality of life.

NEW RADIATION MODALITIES

Protons

Protons result in an excellent physical dose distribution. The dose increases slowly with depth and reaches a sharp maximum near the end of the particle's range called the Bragg peak. This sharp dose peak allows for extremely precise, circumscribed delivery. Other than the physical distribution advantage, protons have biologic properties similar to x-rays. Protons are ideal for specific clinical situations, such as spinal cord tumors and eye melanomas, in which a sharp dose delivery is critical to avoid normal tissue damage. Reports also describe the utility in more common tumors, such as prostate cancer. Although useful in

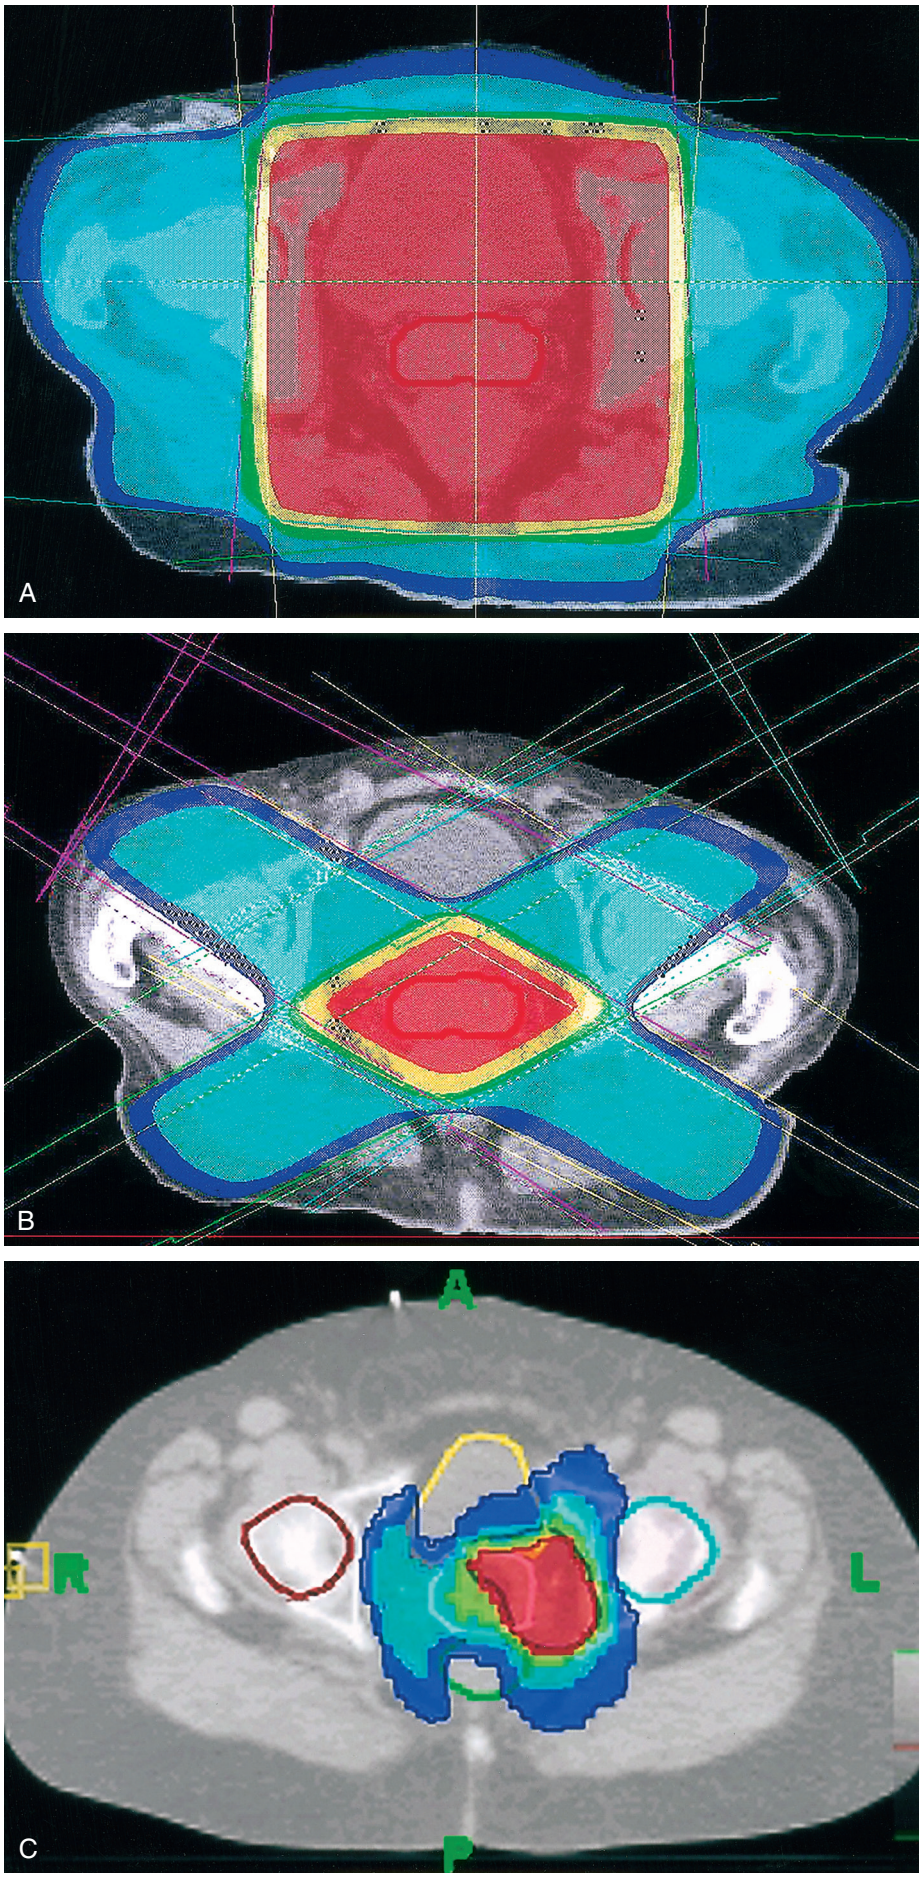

FIGURE 23.13 Comparison of normal tissue irradiated with four field box technique (**A**), three-dimensional conformal therapy (**B**), and intensity-modulated radiation therapy (**C**). The *red* represents areas that receive 100% of the prescription dose, *yellow* 90%, *green* 50%, and *blue* 40%. Notice how the normal tissue volume receives less dose as the treatment is delivered more conformally.

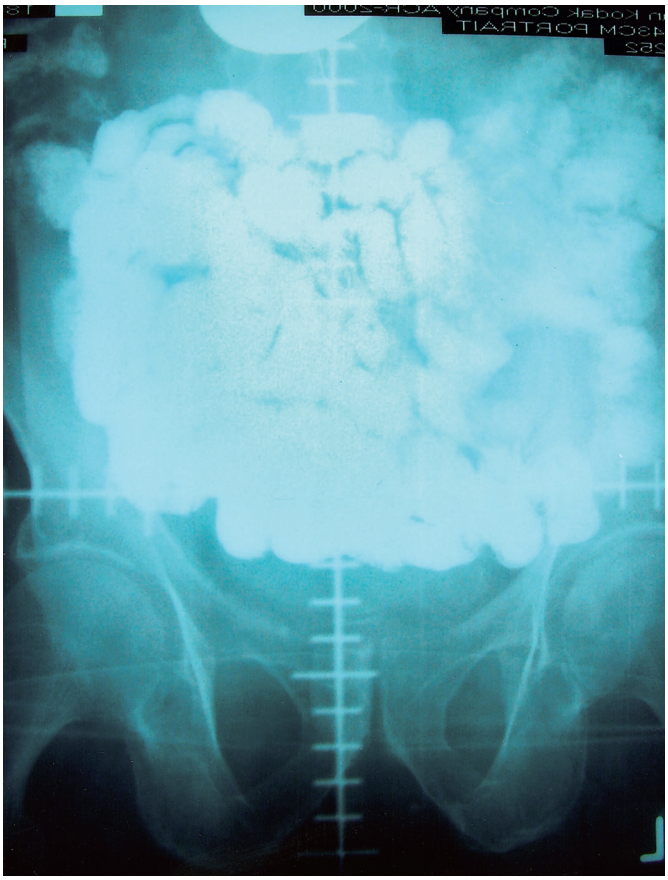

FIGURE 23.14 Small bowel in the pelvis demonstrated by small bowel contrast.

several clinical situations, the cost of delivery from a cyclotron or special linear accelerator makes it currently available in a few cities, although interest is mounting and new centers are being built or contemplated in other areas.

Electrons

Most modern linear accelerators can produce high-energy electron beams. Electrons lose energy rapidly as they travel in tissue and interact with tissue atoms, and ultimately their kinetic energy is reduced to zero. Therefore, unlike photons, electrons have a specific range dependent on energy and the tissue traversed. Transvaginal electron irradiation can be used for a copiously bleeding exophytic cervical lesion to induce hemostasis. The dosimetry is such that most of the energy delivered transvaginally is absorbed into the malignant lesions itself. Lesions of the vulva and inguinofemoral lymph nodes are also treated with electron beams in many institutions. The limitations of electron therapy are related to the strengths. Because it loses energy rapidly, it cannot be used for deep-seated tumors, and the applicator must rest very close to the tumor itself, so only fairly superficial, shallow lesions are appropriately treated with electrons.

Fast Neutrons

Neutrons interact in tissue to produce recoil protons, α particles, and other nuclear particles. Their potential usefulness stems from a reduced OER (this translates into decreased hypoxic cell resistance), reduced differential killing by cell cycle, reduced ability for cells to repair sublethal damage, and higher effectiveness for slowly cycling tumors.

Although randomized controlled trials demonstrated that neutron therapy provided improved local control in some tumors, its utility was limited by higher morbidity and cost. Overall, use is limited by the cost of the cyclotron, limited depth penetrations, high surface entrance dose, lack of sharp beam boundaries, and variable intensity modulation.

Negative Pi Mesons and Other Heavy Ions

Negative pi mesons, or pions, are negatively charged particles that have a mass 273 times that of an electron. These are produced in a cyclotron or linear accelerator using 400 to 800 MeV protons that bombard a beryllium target. Pions exhibit a Bragg peak produced by elicited protons, neutrons, and α particles. Other heavy ions such as neon, argon, and carbon have been studied, but equipment to produce these special particles is expensive and not widely available. Use is limited to experimental therapy only. As with neutrons, these forms of radiation have a high biologic effectiveness and a low dependence on oxygen.

NEW RADIATION DELIVERY TECHNOLOGY

Intraoperative Radiation

Several centers throughout the world are investigating the utility of large-fraction intraoperative external irradiation. Patients are subjected to operative procedures in which the area of involvement is carefully defined, and radiation fractions of 1500 to 2500 cGy are delivered directly to the area identified. Applications of this technique in gynecologic oncology have been in the treatment of biopsy-proven positive paraaortic or pelvic nodes and marginally resectable recurrences. Electron beam radiation is delivered with one high-dose fraction with the bowel and other sensitive normal tissues packed to the side, thus minimizing the probability of visceral injuries. For best results, external-beam radiation is often combined with intraoperative therapy. Because the intraoperative accelerators only deliver electrons, it is subject to the same limitations as all electron beams (see previous discussion). Experience in both primary and recurrent tumors has been reported. The results are limited but have shown increased local control when used selectively. The role of intraoperative radiation in gynecology is not widespread and is limited to a few institutions that are capable of providing this specialized therapy. New techniques involving intraoperative low-energy radiation sources in the kV range are being investigated in other sites such as breast, but there are no reports of use in gynecologic cancers as yet.

Hyperthermia

As discussed previously, solid tumor masses often have hypovascular centers, which are poorly penetrated by antineoplastic drugs and have hypoxic, radioresistant cell fractions. Hyperthermia is another method used to overcome these relatively radioresistant tumors. Although several anecdotal clinical observations have been made, current interest in hyperthermia is based

mainly on careful biologic studies on cells and transplantable tumors performed in the 1980s. Although there is no evidence that tumor cells are consistently more sensitive to heat than normal cells, several factors may contribute to a therapeutic gain. Tumor hypoxic cell populations have an acidic pH and are nutritionally deprived. These factors increase sensitivity to heat. Therapeutic gain is also derived from selective heat retention in the tumor. The hypoxic core is maintained at a higher temperature than the normal tissues, which more efficiently remove heat secondary to better-organized vasculature. Ultimately, cell death is dependent on the temperature achieved and is time dependent. Hyperthermia is combined with radiation as each modality preferentially kills a separate part of the tumor; in addition, heat increases the cell kill of external radiation by inhibiting sublethal and potentially lethal damage repair. Late S phase is the most sensitive phase to hyperthermia but the most resistant to low LET (photon) radiation, and thus the two modalities complement one another. The first notable use of hyperthermia in gynecologic oncology has been with interstitial hyperthermia for deep tumors of the pelvis. Increased survival has been demonstrated, although reports are mixed and the therapy is not commonly available.

Three-dimensional Conformal Radiation Therapy

Three-dimensional conformal radiation therapy is linked to a multiplicity of imaging modalities, especially CT. Beam placement using a CT simulator replaces the conventional simulator (fluoroscopic planning machine) for plan design to the extent that the term "virtual simulation" is used to describe it. The digitally reconstructed radiographs link the plan to the treatment unit in a manner that is rapidly replacing the conventional simulator. Three dimensional conformal therapy (3DCF) entails shaping of the beam to conform to the target as seen by CT imaging. The physician arranges the beams to maximize dose to the tumor and minimize dose to normal tissues. Patient, tumor, and normal target movement demand patient immobilization and that adequate margin be placed around the targets to prevent a "marginal miss."

Intensity-modulated Radiation Therapy

Intensity-modulated radiation therapy, compared with 3DCF therapy, uses the power of computers to perform hundreds to thousands of iterations of planning to maximize and shape tumor dose and minimize normal tissue dose (Fig. 23.15). This form of planning, called forward planning, gives the computer instructions on what dose to deliver to the targets and sets limitations on normal structures. Both 3DCF therapy and IMRT use small collimator "leaves" to finely shape the beam. These "leaves" are mobile and block portions of the generated x-rays. If the collimator "leaves" move while the radiation beam is on and vary the beam intensity, areas of tumor and normal tissue can receive a spectrum of doses, hence the term *intensity modulated*. These collimator "leaves" also allow for irregular shapes to be treated. This technology has demonstrated similar local control with reduced complications in several sites such as prostate and head and neck. In gynecologic cancer, decreased radiation to normal tissues, including bowel, bladder, and bone marrow, has been demonstrated, especially in the postoperative setting. Papers have been published on the use of IMRT in postoperative uterine and cervical carcinoma, vulvar carcinoma, whole abdominal radiotherapy, vaginal carcinoma, and intact cervical carcinoma. Because of the daily variation in bladder and rectal filling, the mobility of the upper vagina and cervix, and the change in cervical volume over the span of treatment in intact cervical cancer, use of IMRT should be undertaken with extreme caution and special attention should be given to assure that the target is accurately delineated and treated with each fraction. Randomized, prospective trials evaluating IMRT are anticipated, and consensus guidelines for clinical target volume delineation have been recently published by Lim and colleagues. Introduction of new technology such as tomotherapy (a linear accelerator linked to an online CT scanner), CyberKnife (a linear accelerator capable of fiducial imaging to target radiation), and cone-beam CT (CT scan mounted to the linear accelerator) for image-guided radiotherapy assists in daily target and normal tissue localization but in gynecologic cancer is still investigational. Other concerns regarding this technology include the enormous physician and physics time used for planning, increased cost, and the unknown long-term consequences of lower dose but increased volume of tissue exposed to radiation.

Stereotactic Radiotherapy

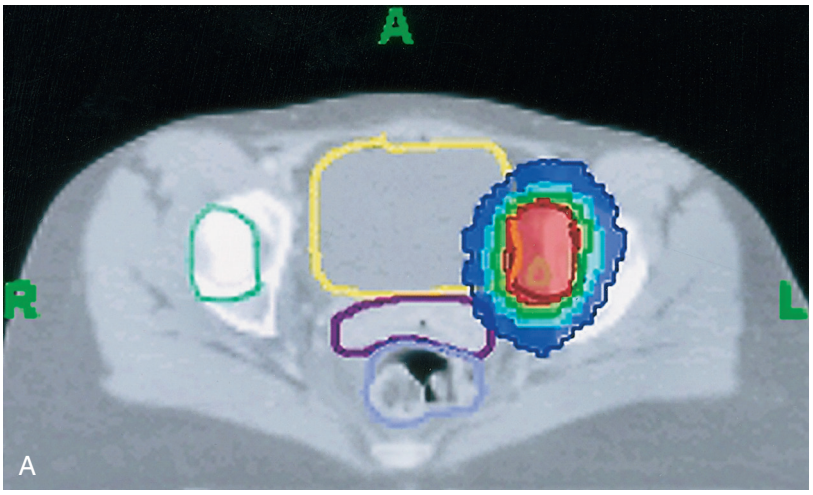
Stereotactic radiation and gamma knife radiation are similar to IMRT and 3DCF radiation because they allow precise, high-dose delivery of external radiation. It is commonly used for both primary and metastatic brain tumors, small lung tumors, and an increasing number of other sites. Whereas stereotactic radiation uses a modification of the linear accelerator, gamma knife is a separate machine with 201 separate ^{60}Co sources used to focus on the target.

Immune-tagged Radiation Therapy

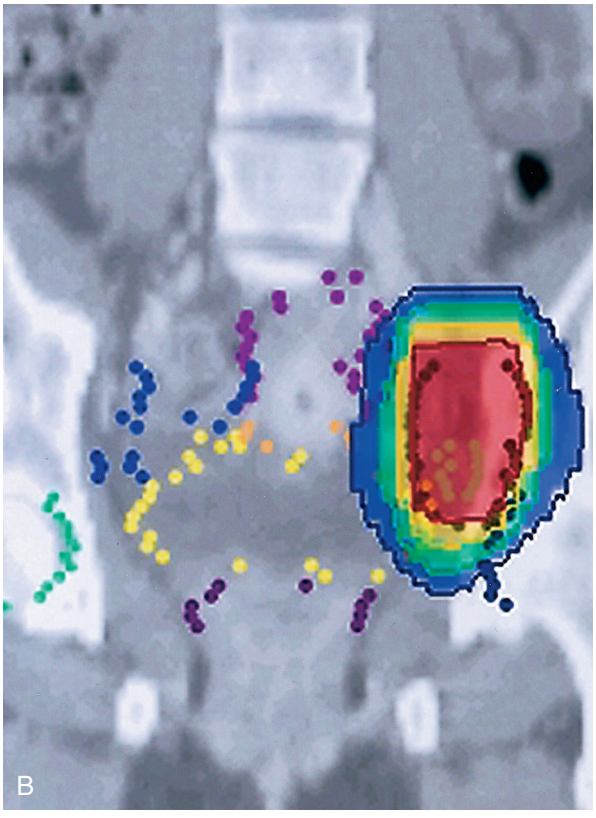
Recently, several products that tag a radioisotope to a monoclonal antibody have entered the market. This modality of radiation allows delivery of the radioactive isotope to the unique antibody target. It has been used successfully in lymphomas and awaits the identification of a unique target before development for a gynecologic use.

GLOSSARY

absorbed dose The energy imparted to matter by ionizing radiation per unit mass of irradiated material. The unit is the gray (Gy), defined to be an energy absorption of 1 joule/kg. The old unit was the rad, which was defined as an energy absorption of 100 ergs/g.



brachytherapy Treatment of malignant tumors by radioactive sources that are implanted close to (intracavitary) or within (interstitial) the tumor.



dosimetry The term applied to the measurement and calculation of dose that the patient receives.

electron volt (eV) The energy of motion acquired by an electron accelerated through a potential difference of 1 volt.

excitation The moving of an electron to a more distant orbit within the same atom.

gamma rays Electromagnetic irradiation (originating inside the nucleus) emitted by excited nuclei. The gamma rays from an isotope will have one or several sharply defined energies.

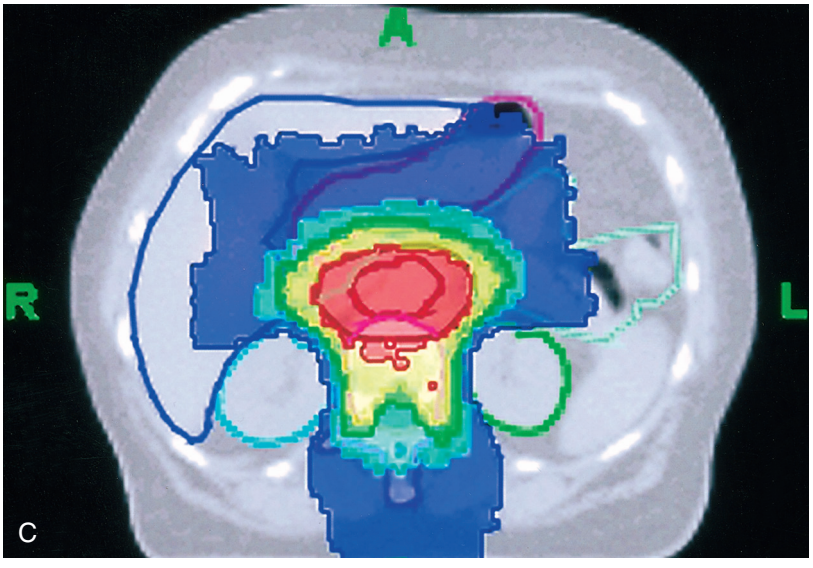


FIGURE 23.15 In **A** and **B,** note how little normal tissue is treated to accomplish the sidewall nodal boost. In **C,** note how the renal parenchyma and spinal cord are relatively spared in treating the paraaortic recurrence.

Gray (Gy) The special name for the unit of absorbed dose and specific energy impacted; 1 Gy = 1 joule/kg = 100 rads.

half-life The time in which half the atoms of a radioactive species disintegrate.

image-guided brachytherapy (IGBT) The use of imaging for three-dimensional, volume directed planning.

image-guided radiation therapy (IGRT) The use of images taken before, during, or after treatment while in the treatment room to allow visualization of target, fiducial markers, or organs at risk.

intensity modulated radiation therapy (IMRT) Computer technology that allows variable fluence across the beam and increased conformance to target relative to normal tissues.

inverse square law The intensity of radiation from a point varies inversely as the square of the distance from the source. Thus, the dose rate at 2 cm from a source is one fourth that at 1 cm. At 3 cm, the dose rate is one-ninth that at 1 cm.

ionization The removal of an electron from an atom, leaving a positively charged ion.

ionizing radiation Radiation capable of causing ionization.

isotope Nuclides having an equal number of protons but a different number of neutrons (excitable situation).

keV 1000 eV.

linear energy transfer (LET) The energy lost by the particle or photon per micron of path depth. High LET radiations are more effective against hypoxic cells.

meV 1,000,000 eV.

oxygen enhancement ratio (OER) The ratio of the dose required for a given level of cell killing under hypoxic conditions compared with the dose needed in air.

penumbra The radiation outside the full beam, which is often caused by scatter or incomplete collimation.

rad A unit-absorbed dose of ionizing radiation equivalent to the absorption of 100 erg per gram of irradiated material.

relative biologic effectiveness (RBE) A ratio of the absorbed dose of a reference radiation to the absorbed dose of a test radiation to produce the same level of biologic effect, other conditions being equal.

rem The old unit of dose equivalent. It is the product of the absorbed dose in rads and modifying factor and is being replaced by the sievert.

roentgen (R) An internationally accepted unit of radiation quantity: It is the quantity of "x-ray or gamma irradiation such that the associated corpuscular emission per 0.001293 g of air produces, in air, ions carrying 1 esu of quantity of electricity of either sign." X-rays originate outside the nucleus.

Sievert (SU): The unit of dose equivalent in the SI system (1 Sv = 100 rem).

x-rays: Rays emitted by a particular generator will emit a spectrum of energies.

A APPENDIX

Staging: Staging of Cancer at Gynecologic Sites

ABSTRACT

For complete details of anatomy, staging classification, and rules for classification by sites of malignant tumors of the female pelvis, please, go to expertconsult.com. To access your account, look for your activation instructions on the inside front cover of this book.

CERVIX UTERI, CORPUS UTERI, OVARY, VAGINA, VULVA, GESTATIONAL TROPHOBLASTIC TUMORS, AND FALLOPIAN TUBE

In 1976, the American Joint Committee adopted the classification of the International Federation of Gynecology and Obstetrics (FIGO), which is the format used in the *Annual Report on the Results of Treatment in Carcinoma of the Uterus, Vagina and Ovary*, which is published every 3 years. This report has used the FIGO classification with periodic modifications since 1937, the last being 2009. Numerous institutions throughout the world contribute their statistics for inclusion in this voluntary collaborative presentation of data.

The cervix and corpus uteri were among the first anatomic sites to be classified by the TNM system. This uses extent of primary tumor (T), nodal metastasis (N), and distant metastasis (M) status to stage cancers. This system has been approved by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC). FIGO has worked closely for many years with the AJCC and UICC in the classification of cancer at gynecologic sites. Staging of malignant tumors is essentially the same, and stages are comparable in the two (FIGO and TNM) systems regarding categories and details.

APPENDIX A

Staging: Staging of Cancer at Gynecologic Sites

CERVIX UTERI, CORPUS UTERI, OVARY, VAGINA, VULVA, GESTATIONAL TROPHOBLASTIC TUMORS, AND FALLOPIAN TUBE

In 1976, the American Joint Committee adopted the classification of the International Federation of Gynecology and Obstetrics (FIGO), which is the format used in the *Annual Report on the Results of Treatment in Carcinoma of the Uterus, Vagina and Ovary*, which is published every 3 years. This report has used the FIGO classification with periodic modifications since 1937, the last being 2009. Numerous institutions throughout the world contribute their statistics for inclusion in this voluntary collaborative presentation of data.

The cervix and corpus uteri were among the first anatomic sites to be classified by the TNM system. This uses extent of primary tumor (T), nodal metastasis (N), and distant metastasis (M) status to stage cancers. This system has been approved by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC). FIGO has worked closely for many years with the AJCC and UICC in the classification of cancer at gynecologic sites. Staging of malignant tumors is essentially the same, and stages are comparable in the two (FIGO and TNM) systems regarding categories and details.

ANATOMY AND CLASSIFICATION BY SITES OF MALIGNANT TUMORS OF THE FEMALE PELVIS

Cervix Uteri

Anatomy

1. *Primary site:* The cervix is the lower third of the uterus. It is roughly cylindrical in shape, projects through the upper anterior vaginal wall, and communicates with the vagina through an orifice called the external os. Cancer of the cervix may originate on the vaginal surface or in the canal.
2. *Nodal stations*: The cervix is drained by preureteral, postureteral, and uterosacral routes into the following first station nodes: parametrial, hypogastric (obturator), external iliac, presacral, and common iliac. Paraaortic nodes are second station and are considered metastases.
3. *Metastatic sites:* The most common sites of distant spread include the aortic and mediastinal nodes, the lungs, and the skeleton.

Rules for Classification

1. *Clinical-diagnostic staging:* Staging of cervical cancer is based on clinical evaluation; therefore, careful clinical examination should be performed in all cases by an experienced examiner, preferably with the patient under anesthesia. The clinical staging must not be changed because of subsequent findings. When there is doubt as to which stage a particular cancer should be allocated, the earlier stage is mandatory. The following examinations are permitted: palpation, inspection, colposcopy, endocervical curettage, hysteroscopy, cystoscopy, proctoscopy, intravenous urography, and radiographic examination of the lungs and skeleton. Suspected bladder or rectal involvement should be confirmed by biopsy and histologic evidence. Findings of optional examinations, such as lymphangiography, arteriography, venography, laparoscopy, computed tomography (CT) scan, and magnetic resonance imaging are valuable for planning therapy; however, because these are not generally available and the interpretation of results varies, the findings of such studies should not be the basis for changing the clinical staging.
2. *Surgical-evaluative staging:* Surgical evaluation is applicable only after laparotomy or laparoscopy and examination of tumor and nodes. Fine-needle aspiration (FNA) of scan-detected suspicious lymph nodes may be helpful when planning treatment. Conization or amputation of the cervix is regarded as a clinical examination. Invasive cancers thus identified should be included in the reports (see no. 4 below).
3. *Postsurgical treatment—pathologic staging:* In patients treated with surgical procedures, the pathologist's findings in the removed tissues can be the basis for extremely accurate statements on the extent of disease. The findings should not be allowed to change the clinical staging but should be recorded in the manner described for the pathologic staging of disease. The TNM nomenclature is appropriate for this purpose. Infrequently, it happens that hysterectomy is carried out in the presence of unsuspected extensive invasive cervical carcinoma. Such cases cannot be clinically staged or included in therapeutic statistics, but it is desirable that

they be reported separately. Only if the rules for clinical staging are strictly observed will it be possible to present comparable results between clinics and by differing modes of therapy.

4. *Retreatment staging:* Complete examination using the procedures cited in no. 2, including a search for distant metastases, is recommended in cases known or suspected to recur. Biopsy and histologic confirmation are particularly desirable when induration and fibrosis from previously treated disease are present.
5. Only if the rules for clinical staging are strictly observed will it be possible to compare results among clinics and by differing modes of therapy.

Staging Classification

FIGO Nomenclature

Stage I	The carcinoma is strictly confined to the cervix (extension to the corpus would be disregarded).
Stage IA	Invasive carcinoma that can be diagnosed only by microscopy. All macroscopically visible lesions—even with superficial invasion—are allotted stage IB carcinomas. Invasion is limited to a measured stromal invasion with a maximal depth of 5 mm and a horizontal extension of no more than 7 mm. Depth of invasion should not be more than 5 mm related to the basis of the epithelium of the original tissue (superficial or glandular). The involvement of vascular spaces—venous or lymphatic—should not change the stage allotment.
Stage IA1	Measured stromal invasion of no more than 3 mm in depth and extension of no more than 7 mm
Stage IA2	Measured stromal invasion of more than 3 mm and no more than 5 mm with an extension of no more than 7 mm
Stage IB	Clinically visible lesions limited to the cervix, uteri, or preclinical cancers greater than stage IA
Stage IB1	Clinically visible lesions no larger than 4 cm
Stage IB2	Clinically visible lesions larger than 4 cm
Stage II	The carcinoma extends beyond the cervix but has not extended to the pelvic wall or to the lower third of the vagina.
Stage IIA	No obvious parametrial involvement
Stage IIA_1	Clinically visible lesion ≤4.0 cm in greatest dimension
Stage IIA_2	Clinically visible lesion >4.0 cm in greatest dimension
Stage IIB	Obvious parametrial involvement
Stage III	The carcinoma has extended to the pelvic wall. On rectal examination, there is no cancer-free space between the tumor and the pelvic wall and/or involves the lower third of the vagina and/or causes hydronephrosis or nonfunctioning kidney.
Stage IIIA	No extension to the pelvic wall
Stage IIIB	Extension to the pelvic wall and/or hydronephrosis or a nonfunctioning kidney
Stage IV	The carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum. A bullous edema as such does not permit a case to be allotted to stage IV.
Stage IVA	Spread of the growth to adjacent organs
Stage IVB	Spread to distant organs

FIGO, International Federation of Gynecology and Obstetrics.

Notes About the Staging

All macroscopically visible lesions, even with superficial invasion, are allotted to stage IB carcinomas. The diagnosis of stages IA_1 and IA_2 should be based on microscopic examination of removed tissue, preferably a cone, which must include the entire lesion. The depth of invasion should not be more than 5 mm, taken from the base of the epithelium—either surface or glandular—from which it originates. The second dimension, the horizontal spread, must not exceed 7 mm. Vascular space involvement, either venous or lymphatic, should not alter the staging but should be specifically recorded because it may affect treatment decisions in the future. Larger lesions should be staged as IB. As a rule, it is impossible to estimate clinically if a cancer of the cervix has extended to the corpus. Extension to the corpus should therefore be disregarded.

A patient with a growth fixed to the pelvic wall by a short and indurated but not nodular parametrium should be allotted to stage IIB. It is impossible at clinical examination to decide whether a smooth and indurated parametrium is truly cancerous or only inflammatory. Therefore, the case should be placed in stage III only if the parametrium is nodular to the pelvic wall or if the growth itself extends to the pelvic wall.

The presence of hydronephrosis or nonfunctioning kidney resulting from stenosis of the ureter by cancer permits a case to be allotted to stage III even if according to the other findings the case should be allotted to stages I or II.

The presence of bullous edema, as such, should not permit a case to be allotted to stage IV. Ridges and furrows into the bladder wall should be interpreted as signs of submucous involvement of the bladder if they remain fixed to the growth at palposcopy (ie, examination from the vagina or the rectum during cystoscopy). Finding malignant cells in cytologic washings from the urinary bladder requires further examination and a biopsy from the wall of the bladder.

Histopathology

Cases should be classified as carcinomas of the cervix if the primary growth is in the cervix. All histologic types must be included. Grading by any of several methods is encouraged but is not a basis for modifying the stage groupings. When surgery is the primary treatment, the histologic findings permit the case to have pathologic staging as described in Rules for Classification, no. 2. All tumors are to be microscopically verified.

Histopathologic Types

Squamous cell carcinoma in situ
Squamous cell carcinoma
- Keratinizing
- Nonkeratinizing

Verrucous
Adenocarcinoma in situ
Adenocarcinoma in situ, endocervical type
Endometrioid adenocarcinoma
Clear cell adenocarcinoma
Adenosquamous carcinoma
Adenoid cystic carcinoma
Small cell carcinoma
Undifferentiated carcinoma

Histopathologic Grade

G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated

Corpus

Anatomy

1.1 **Primary site:** The upper two-thirds of the uterus above the level of the internal cervical os is called the *corpus.* The fallopian tubes enter at the upper lateral corners of a pear-shaped body. The portion of the muscular organ that is above a line joining the tubouterine orifices is often referred to as the *fundus.*

1.2 **Nodal stations:** The major lymphatic trunks are the utero-ovarian (infundibulopelvic), parametrial, and presacral, which drain into the hypogastric, external iliac, common iliac, presacral, and paraaortic nodes.

1.3 **Metastatic sites:** The vagina and lung are the common metastatic sites.

Rules for Classification

The FIGO committee on gynecologic oncology agreed on the system for surgical staging for carcinoma of the corpus uteri at the meeting in Rio de Janeiro in October 1988 with modification made in 2009.

Surgical Staging Classification

FIGO Nomenclature

Stage I		Cancer confined to the corpus uteri, including carcinosarcoma
Stage IA	G123	No or less than half myometrial invasion
Stage IB	G123	Invasion equal to or more than half of the myometrium
Stage II	G123	Tumor invades cervical stroma but does not extend beyond the uterus (endocervical glandular involvement only should be considered as stage I)
Stage III	G123	Local and/or regional spread of the tumor
Stage IIIA	G123	Tumor invades serosa of the corpus uteri and/or adnexa
Stage IIIB	G123	Vaginal metastases and/or parametrial involvement
Stage IIIC	G123	Metastases to pelvic and/or paraaortic lymph nodes

Stage IIIC1		Positive pelvic node
Stage IIIC2		Positive paraaortic lymph nodes with or without positive pelvic lymph nodes
Stage IV	G123	Tumor invades bladder and/or bowel mucosa and/or distant metastases
Stage IVA	G123	Tumor invasion of bladder and/or bowel mucosa
Stage IVB		Distant metastases, including intraabdominal metastases and/or inguinal lymph nodes

FIGO, International Federation of Gynecology and Obstetrics.

Notes: Tumor grade, cell type, and presence or absence of malignant cytology in pelvic washings should be reported along with stage.

Abdominal and pelvic peritoneal metastases are stage IVB.

Notes About the Staging

Histopathology—degree of differentiation. Cases of carcinoma of the corpus should be grouped with regard to the degree of differentiation of the adenocarcinoma as follows:

G1: ≤5% of a nonsquamous or nonmorular solid growth pattern

G2: 6% to 50% of a nonsquamous or nonmorular solid growth pattern

G3: >50% of a nonsquamous or nonmorular solid growth pattern

Notes on Pathologic Grading

1. Notable nuclear atypia, inappropriate for the architectural grade, raises the grade of a grade 1 or 2 tumor by 1.
2. In serous and clear cell adenocarcinomas, nuclear grading takes precedence.
3. Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

Rules Related to Staging

1. Because corpus cancer is now surgically staged, procedures previously used for determination of stages are no longer applicable, such as the finding of fractional dilatation and curettage (D&C) to differentiate between stages I and II.
2. It is understood that there may be a few patients with corpus cancer who will be treated primarily with radiation therapy. If that is the case, the clinical staging adopted by FIGO in 1971 would still apply, but designation of that staging system would be noted.
3. Ideally, the width of the myometrium should be measured along with the width of tumor invasion.

Histopathology

The histopathologic types are:

- Endometrioid carcinoma
- Adenocarcinoma
- Adenocanthoma (adenocarcinoma with squamous metaplasia)
- Adenosquamous carcinoma (mixed adenocarcinoma and squamous cell carcinoma)
- Mucinous adenocarcinoma
- Serous adenocarcinoma
- Clear cell adenocarcinoma
- Squamous cell adenocarcinoma
- Undifferentiated adenocarcinoma

Ovary, Fallopian Tube, and Peritoneal

Anatomy

1.1 **Primary site:** Ovaries are a pair of solid bodies, flattened ovoids that are 2 to 4 cm in diameter; they are connected by a peritoneal fold to the broad ligament and by the infundibulopelvic ligament to the lateral wall of the pelvis.

1.2 **Nodal stations:** The lymphatic drainage occurs by the utero-ovarian and round ligament trunks and an external iliac accessory route into the following regional nodes: external iliac; common iliac; hypogastric; lateral sacral; and paraaortic nodes; and, rarely, inguinal nodes.

1.3 **Metastatic sites:** The peritoneum, including the omentum and pelvic and abdominal viscera, is a common site for seeding. Diaphragmatic involvement and liver metastases are common. Pulmonary and pleural involvement is often seen.

Rules for Classification

Ovarian cancer is surgically staged. Operative findings before tumor debulking determine the stage, which may be modified by histopathologic as well as clinical or radiologic evaluation. Laparotomy and resection of the ovarian mass, as well as hysterectomy, form the basis for staging. Biopsies of all suspicious sites, such as the omentum, mesentery, liver, diaphragm, pelvic, and paraaortic nodes, are required. The final histologic findings after surgery (and cytologic ones when available) should be considered in the staging. Clinical studies, if carcinoma of the ovary is diagnosed, include routine radiology of the chest. CT scanning may be helpful in initial staging and follow-up of tumors.

1. *Clinical-diagnostic staging:* Although clinical studies similar to those for other sites may be used, the establishment of a diagnosis most often requires a laparotomy, which is most widely accepted in surgical-pathologic staging. Clinical studies, if carcinoma of the ovary is diagnosed, include routine radiography of the chest and abdomen, liver studies, and hemograms.
2. *Surgical-evaluative staging:* Laparotomy and biopsy of all suspected sites of involvement provide the basis for this type of staging; this staging is often identical to postsurgical staging. Histologic and cytologic data are required.
3. *Postsurgical treatment—pathologic staging:* This treatment should include laparotomy and resection of ovarian masses as well as a hysterectomy. Biopsies of all suspicious sites, such as the omentum, mesentery, liver, diaphragm, and pelvic and paraaortic nodes, are required. Pleural effusions should be documented by cytology.
4. *Retreatment staging:* Second-look laparotomies and laparoscopy are being evaluated because of the limitation of routine pelvic and abdominal examinations in detecting early recurrence. Other optional and investigative procedures include ultrasonography and CT scanning. All suspected recurrences need biopsy confirmation.

Staging Classification

Staging is based mainly on findings seen at surgical exploration. Clinical evaluation and imaging studies should be done when appropriate. These findings may affect final staging. The histology is to be considered in the staging, as is cytology as far as effusions are concerned. It is desirable that a biopsy be taken from suspicious areas outside of the pelvis.

Stage I	Growth limited to the ovaries
Stage IA	Growth limited to one ovary; no ascites present containing malignant cells; no tumor on the external surface; capsule intact
Stage IB	Growth limited to both ovaries; no ascites present containing malignant cells; no tumor on the external surfaces; capsules intact
Stage IC*	Tumor stage IA or IB but with tumor on the surface of one or both ovaries or with capsule ruptured or with ascites present containing malignant cells or with positive peritoneal washings. 1C1 Surgical spill IC2 Tumor rupture before surgery or tumor on the serosal surface 1C3 Malignant cell in the ascites or peritoneal washings
Stage II	Growth involving one or both ovaries with pelvic extension
Stage IIA	Extension and/or metastases to the uterus and/or tubes
Stage IIB	Extension to other pelvic tissues
Stage III	Tumor involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes; superficial liver metastases equal to stage III; tumor limited to the true pelvis but with histologically proven malignant extension to the small bowel or omentum
Stage IIIA	Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of the abdominal peritoneal surfaces and/or retroperitoneal positive retroperitoneal nodes IIIA1 Positive retroperitoneal nodes only IIIA1(i) Metastasis ≤10 mm IIIA1(ii) Metastasis >10 mm IIIA2 Microscopic, extrapelvic peritoneal involvement plus or minus positive retroperitoneal nodes
Stage IIIB	Tumor of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter, plus or minus nodes

Stage IIIC	Abdominal implants >2 cm in diameter and/or positive retroperitoneal or inguinal nodes. Includes extension to the capsule of the liver or spleen
Stage IV	Growth involving one or both ovaries with distant metastases. If pleural effusion is present, there must be positive cytology to allot a case to stage IV. Parenchymal liver metastasis equals stage IV.
	IVA Pleural effusion only with positive cytology
	IVB Hepatic and or splenic parenchymal metastasis, metastasis to extraabdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)

*To evaluate the impact on prognosis of the different criteria for allotting cases to stages IC or IIC, it would be useful to know whether rupture of the capsule was spontaneous or caused by the surgeon and if the source of malignant cells was peritoneal washings or ascites.

Primary peritoneal cancer is staged similarly.

Histopathology

The task force of the AJCC endorses the histologic typing of ovarian tumors, as presented in the World Health Organization publication no. 9, 1973, and recommends that all ovarian epithelial tumors be subdivided according to a simplified version. The types recommended are as follows: serous tumors, mucinous tumors, endometrioid tumors, clear cell (mesonephroid) tumors, undifferentiated tumors, and unclassified tumors.

- Serous tumors
- Benign serous cystadenomas
- Of borderline malignancy: serous cystadenomas with proliferating activity of the epithelial cells and nuclear abnormalities but with no infiltrative destructive growth (carcinomas of low potential malignancy)
- Serous cystadenocarcinomas
- Mucinous tumors
- Benign mucinous cystadenomas of borderline malignancy: mucinous cystadenomas with proliferating activity of the epithelial cells and nuclear abnormalities but with no infiltrative destructive growth (carcinomas of low potential malignancy)
- Mucinous cystadenocarcinomas
- Endometrioid tumors
- Benign endometrioid cystadenomas
- Endometrioid tumors with proliferating activity of the epithelial cells and nuclear abnormalities but with no infiltrative destructive growth (carcinomas of low potential malignancy)
- Endometrioid adenocarcinomas
- Clear cell tumors
- Benign clear cell tumors
- Clear cell tumors with proliferating activity of the epithelial cells and nuclear abnormalities but with no infiltrative destructive growth (low potential malignancy)
- Clear cell cystadenocarcinomas
- Brenner
- Benign Brenner
- Borderline malignancy
- Malignant
- Transitional cell
- Undifferentiated carcinomas
- A malignant tumor of epithelial structure that is too poorly differentiated to be placed in any other group
- Mixed epithelial tumors

These tumors consist of two or more of the five major cell types of common epithelial tumors (types should be specified).

Cases with intraperitoneal carcinoma in which the ovaries appear to be incidentally involved and not the primary origin should be labeled as extraovarian peritoneal carcinoma.

Histopathologic Grade (G)

- Borderline
- Well differentiated
- Moderately differentiated
- Poorly differentiated or undifferentiated

Fallopian Tube

The fallopian tube extends from the posterior superior aspect of the uterine fundus laterally and anteriorly to the ovary. Its length is approximately 10 cm. The lateral end opens to the peritoneal cavity. Carcinoma of the oviduct can metastasize to the regional lymph nodes, including the paraaortic nodes. Direct extension to surrounding organs, as well as intraperitoneal seeding, often occurs. Peritoneal implants may occur with an intact tube.

1. Carcinoma in situ of the fallopian tube is a defined entity; therefore, it is included in the staging under stage 0.
2. Because the fallopian tube is a hollow viscus and because extension into the submucosa or muscularis to and beyond the serosa can be defined (a concept similar to that of Dukes'

classification for colon cancer), these are taken into consideration in stage IA, IB, and IC in addition to laterality, as well as the presence or absence of ascites. As in ovarian carcinoma, peritoneal washings positive for malignant cells or malignant ascites are placed in stage IC.

3. In stage III, the classification of the tumor is based on the size of the findings at the time of entry into the abdominal cavity and does *not* depend on the residual at the end of the debulking. In addition, surface involvement of the liver is in stage III, as is inguinal node metastasis. As in ovarian cancer, pleural effusion must have malignant cells to be called stage IV.

Laparotomy and resection of tubal masses, as well as hysterectomy, form the basis for staging. Biopsies of all suspicious sites (eg, the omentum, mesentery, liver, diaphragm, and pelvic and para-aortic nodes) are required. The final histologic findings after surgery (and cytologic ones when available) are to be considered in the staging.

Clinical studies, if carcinoma of the tube is diagnosed, include routine radiography of chest. CT scanning may be helpful in the initial staging and follow-up of tumors.

FIGO Staging for Fallopian Tube Carcinoma

Staging for the fallopian tube is by the surgical pathologic system. Operative findings before tumor debulking may be modified by histopathologic as well as clinical or radiologic evaluation.

Stage I: Tumor confined to the fallopian tubes

- IA — Tumor limited to 1 tube, serosa intact, no tumor on surface, negative washings
- IB — Tumor involves both tubes; otherwise, like IA
- IC — Tumor limited to 1 or both tubes
  - IC1 — Surgical spill
  - IC2 — Tumor rupture before surgery or tumor on serosal surface
  - IC3 — Malignant cells in the ascites or peritoneal washings

Stage II: Tumor involves 1 or both tubes with pelvic extension (below the pelvic brim) or primary peritoneal cancer

- IIA — Extension and/or implant on uterus and/or ovaries
- IIB — Extension to other pelvic intraperitoneal tissues

Stage III: Tumor involves one or both tubes with confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes

- IIIA Positive retroperitoneal lymph nodes and/or microscopic metastasis beyond the pelvis
- IIIA1 — Positive retroperitoneal lymph nodes only
  - IIIA1(i) — Metastasis ≤10 mm
  - IIIA1(ii) — Metastasis >10 mm
- IIIA2 — Microscopic, extrapelvic (above the brim) peritoneal involvement ± positive retroperitoneal lymph nodes
- IIIB — Macroscopic, extrapelvic, peritoneal metastasis ≤ 2 cm ± positive retroperitoneal lymph nodes; includes extension to the capsule of the liver or spleen
- IIIC — Macroscopic, extrapelvic, peritoneal metastasis >2 cm ± positive retroperitoneal lymph nodes; includes extension to the capsule of the liver or spleen.

Stage IV: Distant metastasis excluding peritoneal metastasis

- IVA — Pleural effusion with positive cytology
- IVB — Hepatic and/or splenic parenchymal metastasis, metastasis to extraabdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)

Uterine Sarcoma

Before this time, uterine sarcomas were staged as endometrial cancers. This was not reflective of survival. The committee has established a sarcoma staging system based on the criteria used in other soft tissue sarcomas. This is, in a sense, a best-guess staging system. Data will need to be collected until the system can be revised.

Staging of Uterine Sarcomas (Leiomyosarcomas, Endometrial Stromal Sarcomas, and Adenosarcomas)

Stage I	Tumor limited to the uterus (two different substagings for LMS/ESS and adenocarcinomas)
Stage IA	<5 cm
Stage IB	≥5 cm (1-2)
Stage II	Tumor extends to the pelvis
Stage IIA	Adnexal involvement
Stage IIB	Tumor extends to extrauterine pelvic tissue
Stage III	Tumor invades abdominal tissues (not just protruding into the abdomen)
Stage IIIA	One site
Stage IIIB	More than one site
Stage IIIC	Metastasis to pelvic and/or paraaortic lymph nodes
Stage IV	Tumor invades bladder and/or rectum and/or distant metastasis
Stage IVA	Tumor invades bladder and/or rectum
Stage IVB	Distant metastasis

ESS, endometrial stromal sarcoma; *LMS,* leiomyosarcoma.

Endometrial Stromal Sarcomas

Simultaneous tumors of the uterine corpus and ovary or pelvis in association with ovarian or pelvic endometriosis should be classified as independent primary tumors.

Adenosarcomas

Stage I	Tumor limited to uterus (two different substagings for LMS/ESS and adenosarcomas)
Stage IA	Tumor limited to endometrium or endocervix (without myometrial invasion)
Stage IB	Tumor invades up to less than half of myometrium
Stage IC	Tumor invades to more than one half of myometrium (4)
Stage II	Tumor extends to the pelvis
Stage IIA	Adnexal involvement
Stage IIB	Tumor extends to extrauterine pelvic tissue
Stage III	Tumor invades abdominal tissues (not just protruding into the abdomen)
Stage IIIA	One site
Stage IIIB	More than one site
Stage IIIC	Metastasis to pelvic and/or paraaortic lymph nodes
Stage IV	Tumor invades bladder and/or rectum and/or distant metastasis
Stage IVA	Tumor invades bladder and/or rectum
Stage IVB	Distant metastasis

Carcinosarcomas

Carcinosarcomas should be staged as carcinomas of the corpus uteri.

Prat J: FIGO staging for uterine sarcomas, *Int J Gynaecol Obstet* 104(3):177–178, 2009.

Vagina

Classification by Site

Cases should be classified as carcinoma of the vagina when the primary site of the growth is in the vagina. Tumors present in the vagina as secondary growths from genital or extragenital

sites should be excluded. A growth that has extended to the portio and reached the area of the external os should always be allotted to carcinoma of the cervix. A growth limited to the urethra should be classified as carcinoma of the urethra. There should be histologic verification of the disease. The vagina is drained by lymphatics toward the pelvic nodes in its upper two-thirds and toward the inguinal nodes in the lower third. The rules for staging are similar to those for carcinoma of the cervix.

Staging Classification

FIGO Nomenclature

Stage 0	Carcinoma in situ and intraepithelial carcinoma are present.
Stage I	The carcinoma is limited to the vaginal wall.
Stage II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall.
Stage III	The carcinoma has extended to the pelvic wall.
Stage IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum; bullous edema as such does not permit a case to be allotted to stage IV.
Stage IVA	The growth spreads to adjacent organs and/or direct extension beyond the true pelvis.
Stage IVB	The growth spreads to distant organs.

FIGO, International Federation of Gynecology and Obstetrics.

BIBLIOGRAPHY

Current FIGO staging for cancer of the vagina, fallopian tube, ovary, and gestational trophoblastic neoplasia, *Int J Gynaecol Obstet* 105(1):3–4, 2009.

Vulva

Cases should be classified as carcinoma of the vulva when the primary site of growth is in the vulva. Tumors present in the vulva as secondary growths from a genital or extragenital site should be excluded. Malignant melanoma should be reported separately. A carcinoma of the vulva that extends into the vagina should be considered as a carcinoma of the vulva. There should be histologic confirmation of the cancer. The femoral, inguinal, external iliac, and hypogastric nodes are the sites of regional spread. Involvement of pelvic lymph nodes (eg, external, internal, and common iliac) is considered as distant metastasis.

Staging Classification

Definitions of the clinical stages in carcinoma of the vulva follow:

Carcinoma of the Vulva

Stage I	Tumor confined to the vulva with negative notes
Stage IA	Lesions ≤2 cm in size confined to the vulva or perineum and with stromal invasion no ≤1 mm*
Stage IB	Lesions >2 cm in size confined to the vulva or perineum or with stromal invasion greater than 1 mm
Stage II	Tumor of any size with extension to adjacent perineal structures (one third lower urethra, one third lower vagina, and/or extension to the anus) with negative nodes
Stage III	Tumor of any size with or without adjacent spread to the lower one third urethra, one third lower vagina, or the anus with positive inguinofemoral lymph node metastasis
Stage IIIA (i)	One lymph node metastasis ≥5 mm
Stage IIIA (ii)	One to three lymph node metastasis(es) of <5 mm
Stage IIIB (i)	Two or more lymph node metastasis ≥5 mm
Stage IIIB (ii)	Three or more lymph node metastasis <5 mm
Stage III	Positive node(s) with extracapsular spread
Stage IV	Tumor invades other regional (two-thirds of the upper urethra, greater than or equal to two-thirds of the upper vagina) or distant structures
Stage IVA (i)	Tumor invades any of the following: upper urethra and/or vaginal mucosa, or fixated to boney pelvic structures, bladder mucosa, or rectal mucosa
Stage IVB (ii)	Fixed or ulcerated inguinofemoral lymph nodes
Stage IVB	Any distant metastasis, including pelvic lymph nodes

*The depth of invasion is defined as the measurement of the tumor from the epithelial–stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

Rules for Staging

T1B T	Primary tumor
Tis	Preinvasive carcinoma (carcinoma in situ)
T1	Tumor confined to the vulva and/or perineum; ≤2 cm in greatest dimension
T1A	and with stromal invasion no greater than 1 mm
T1B	and with stromal invasion greater than 1 mm
T2	Tumor confined to the vulva and/or perineum; >2 cm in greatest dimension
T3	Tumor of any size with adjacent spread to the urethra and/or vagina and/or the anus
T4	Tumor of any size infiltrating the bladder mucosa and/or the rectal mucosa, including the upper part of the urethral mucosa and/or fixed to the bone
N	Regional lymph nodes
N0	No lymph node metastasis
N1	Unilateral regional lymph node metastasis
N2	Bilateral regional lymph node metastasis
M	Distant metastasis; no clinical metastasis (M0)
M0	No distant metastasis
M1	Distant metastasis (including pelvic lymph node metastasis)

Gestational Trophoblastic Tumors

In 1991, FIGO added nonsurgical-pathologic prognostic risk factors to the classic anatomic staging system. These include β-human chorionic gonadotropin (hCG) levels of greater than 10^5 and the duration of an antecedent pregnancy for longer than 6 months.

Because gestational trophoblastic tumors have a very high cure rate in almost all patients, the ultimate goal of staging is to differentiate patients who are likely to respond to less intensive chemotherapeutic protocols from those who require more intensive chemotherapy to achieve remission.

Staging should be based on history, clinical examination, and appropriate laboratory and radiologic studies. Because β-hCG titers accurately reflect clinical disease, histologic verification is not required for a diagnosis, although it may aid in therapy.

FIGO Staging for Trophoblastic Tumors

Stage IIIB Stage I	Disease confined to the uterus
Stage IA	Disease confined to the uterus with no risk factors
Stage IB	Disease confined to the uterus with one risk factor
Stage IC	Disease confined to the uterus with two risk factors
Stage II	GTT extends outside of the uterus but is limited to the genital structures (adnexa, vagina, broad ligament)
Stage IIA	GTT involving genital structures without risk factors
Stage IIB	GTT extends outside of the uterus but is limited to genital structures with one risk factor
Stage IIC	GTT extends outside of the uterus but is limited to the genital structures with two risk factors
Stage III	GTT extends to the lungs, with or without known genital tract involvement
Stage IIIA	GTT extends to the lungs, with or without genital tract involvement and with no risk factors
Stage IIIB	GTT extends to the lungs, with or without genital tract involvement and with one risk factor
Stage IIIC	GTT extends to the lungs, with or without genital tract involvement and with two risk factors
Stage IV	All other metastatic sites
Stage IVA	All other metastatic sites, without risk factors

Stage IVB	All other metastatic sites, with one risk factor
Stage IVC	All other metastatic sites, with two risk factors

GTT, Gestational trophoblastic neoplasia.

1. hCG >100,000 U/mL
2. Duration of disease >6 months from termination of the antecedent pregnancy

The following factors should be considered and noted in reporting:

1. Prior chemotherapy for known gestational trophoblastic neoplasia
2. Placental site tumors should be reported separately
3. Histologic verification of disease is not required

Gestational Trophoblastic Neoplasia: World Health Organization Risk Scoring

Factor \ Points	0	1	2	4
Age (yr)	<40	>40		
Antecedent pregnancy	Hydatidiform mole	Abortion	Term pregnancy	
Interval months from index pregnancy	<4	4–6	7–12	>12
Pretreatment hCG (milli Iu/mL)	$<10^3$	10^3–10^4	$>10^4$–10^5	$>10^5$
Largest tumor size, including uterus		3–4 CM	≥5 CM	
Site of metastases		Spleen or kidney	GI tract	Brain or liver
Number of metastases identified		1–4	5–8	>8
Prior failed chemotherapy			Single drug	Two or more drugs

CM, cerebral metastasis; *GI,* gastrointestinal; *hCG,* human chorionic gonadotropin.

Modified From Common Terminology Criteria for Adverse Events (Common Terminology Criteria for Adverse Events)*

(version 4.0)
U.S. Department of Health and Human Services
National Institutes of Health, National Cancer Institute
Published May 28, 2009 (v4.03: June 14, 2010)

For the complete table containing common terminology criteria for adverse events, please go to expertconsult.com. To access your account, look for your activation instructions on the inside front cover of this book.

QUICK REFERENCE

The National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events is a descriptive terminology that can be used for adverse event (AE) reporting. A grading (severity) scale is provided for each AE term.

COMPONENTS AND ORGANIZATION

System Organ Class

System Organ Class (SOC), the highest level of the Medical Dictionary for Regulatory Activities (MedDRA) hierarchy, is identified by anatomic or physiologic system, etiology, or purpose (eg, SOC investigations for laboratory test results). CTCAE terms are grouped by MedDRA Primary SOCs. Within each SOC, AEs are listed and accompanied by descriptions of severity (grade).

CTCAE Terms

An AE is any unfavorable and unintended sign (including an abnormal laboratory finding), symptom, or disease temporally associated with the use of a medical treatment or procedure that may or may *not* be considered related to the medical treatment or procedure. An AE is a term that is a unique representation of a specific event used for medical documentation and scientific analyses. Each CTCAE v4.0 term is a MedDRA LLT (lowest level term).

Definitions

A brief definition is provided to clarify the meaning of each AE term.

Grades

Grade refers to the severity of the AE. The CTCAE displays grades 1 through 5 with unique clinical descriptions of severity for each AE based on this general guideline.

*CTCAE v4.0 incorporates certain elements of the MedDRA terminology. For further details on MedDRA, refer to the MedDRA MSSO website (http://www.meddramsso.com).

QUICK REFERENCE

The National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events is a descriptive terminology that can be used for adverse event (AE) reporting. A grading (severity) scale is provided for each AE term.

COMPONENTS AND ORGANIZATION

System Organ Class

System Organ Class (SOC), the highest level of the Medical Dictionary for Regulatory Activities (MedDRA) hierarchy, is identified by anatomic or physiologic system, etiology, or purpose (eg, SOC investigations for laboratory test results). CTCAE terms are grouped by MedDRA Primary SOCs. Within each SOC, AEs are listed and accompanied by descriptions of severity (grade).

CTCAE Terms

An AE is any unfavorable and unintended sign (including an abnormal laboratory finding), symptom, or disease temporally associated with the use of a medical treatment or procedure that may or may *not* be considered related to the medical treatment or procedure. An AE is a term that is a unique representation of a specific event used for medical documentation and scientific analyses. Each CTCAE v4.0 term is a MedDRA LLT (lowest level term).

Definitions

A brief definition is provided to clarify the meaning of each AE term.

Grades

Grade refers to the severity of the AE. The CTCAE displays grades 1 through 5 with unique clinical descriptions of severity for each AE based on this general guideline.

1. Grade 1: Mild; asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated.
2. Grade 2: Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs.†
3. Grade 3: Severe or medically significant but not immediately life threatening; hospitalization or prolongation of hospitalization indicated; disabling; limiting self-care ADLs.‡
4. Grade 4: Life-threatening consequences; urgent intervention indicated.
5. Grade 5: Death related to AE

A semicolon indicates "or" within the description of the grade.

A single dash (—) indicates a grade is not available.

Not all grades are appropriate for all AEs. Therefore, some AEs are listed with fewer than five options for grade selection.

Grade 5

Grade 5 (death) is not appropriate for some AEs and therefore is not an option.

*CTCAE v4.0 incorporates certain elements of the MedDRA terminology. For further details on MedDRA, refer to the MedDRA MSSO website (http://www.meddramsso.com).

†Instrumental ADLs refer to preparing meals, shopping for groceries or clothes, using the telephone, managing money, and so on.

‡Self-care ADLs refer to bathing, dressing and undressing, feeding self, using the toilet, taking medications, and not being bedridden.

Activities of Daily Living

Blood and Lymphatic System Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Anemia	Hgb <LLN–10.0 g/dL; <LLN–6.2 mmol/L; <LLN–100 g/L	Hgb <10.0–8.0 g/dL; <6.2–4.9 mmol/L; <100–80 g/L	Hgb <8.0 g/dL; <4.9 mmol/L; <80 g/L; transfusion indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a reduction in the amount of hemoglobin in 100 mL of blood. Signs and symptoms of anemia may include pallor of the skin and mucous membranes, shortness of breath, palpitations of the heart, soft systolic murmurs, lethargy, and fatigability.					
Bone marrow hypocellular	Mildly hypocellular or ≤25% reduction from normal cellularity for age	Moderately hypocellular or >25%–<50% reduction from normal cellularity for age	Severely hypocellular or >50%–≤75% reduction cellularity from normal for age	Aplastic persistent for >2 weeks	Death
Definition: A disorder characterized by the inability of the bone marrow to produce hematopoietic elements					
Disseminated intravascular coagulation	—	Laboratory findings with no bleeding	Laboratory findings and bleeding	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by systemic pathologic activation of blood clotting mechanisms that result in clot formation throughout the body. There is an increase in the risk of hemorrhage as the body is depleted of platelets and coagulation factors.					
Febrile neutropenia	—	—	ANC <1000/mm^3 with a single temperature of >38.3°C (101°F) or a sustained temperature of ≥38°C (100.4°F) for >1 hour	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an ANC <1000/mm^3 and a single temperature of >38.3°C (101°F) or a sustained temperature of ≥38°C (100.4°F) for >1 hour					
Hemolysis	Laboratory evidence of hemolysis only (eg, direct antiglobulin test; DAT; Coombs; schistocytes; decreased haptoglobin)	Evidence of hemolysis and ≥2 g decrease in hemoglobin.	Transfusion or medical intervention indicated (eg, steroids)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by laboratory test results that indicate widespread erythrocyte cell membrane destruction					
Hemolytic uremic syndrome	Evidence of RBC destruction (schistocytosis) without clinical consequences	—	Laboratory findings with clinical consequences (eg, renal insufficiency, petechiae)	Life-threatening consequences (eg, CNS hemorrhage or thrombosis or embolism, renal failure)	Death
Definition: A disorder characterized by a form of thrombotic microangiopathy with renal failure, hemolytic anemia, and severe thrombocytopenia					
Leukocytosis	—	—	>100,000/mm^3	Clinical manifestations of leukostasis; urgent intervention indicated	Death
Definition: A disorder characterized by laboratory test results that indicate an increased number of white blood cells in the blood					
Lymph node pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in a lymph node					
Spleen disorder	Incidental findings (eg, Howell-Jolly bodies); mild degree of thrombocytosis and leukocytosis	Prophylactic antibiotics indicated	—	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder of the spleen					
Thrombotic thrombocytopenic purpura	Evidence of RBC destruction (schistocytosis) without clinical consequences	—	Laboratory findings with clinical consequences (eg, renal insufficiency, petechiae)	Life-threatening consequences (eg, CNS hemorrhage or thrombosis or embolism, renal failure)	Death
Definition: A disorder characterized by the presence of microangiopathic hemolytic anemia, thrombocytopenic purpura, fever, renal abnormalities, and neurologic abnormalities such as seizures, hemiplegia, and visual disturbances. It is an acute or subacute condition.

Blood and Lymphatic System Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Blood and lymphatic system disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *ANC,* absolute neutrophil count, *CNS,* central nervous system, *DAT,* direct antiglobulin test, *Hgb,* hemoglobin, *LLN,* lower limit of normal, *RBC,* red blood cell.

Cardiac Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Acute coronary syndrome	—	Symptomatic, progressive angina; cardiac enzymes normal; hemodynamically stable	Symptomatic, unstable angina or acute myocardial infarction, cardiac enzymes abnormal, hemodynamically stable	Symptomatic, unstable angina or acute myocardial infarction, cardiac enzymes abnormal, hemodynamically unstable	Death
Definition: A disorder characterized by signs and symptoms related to acute ischemia of the myocardium secondary to coronary artery disease. The clinical presentation covers a spectrum of heart diseases from unstable angina to myocardial infarction.					
Aortic valve disease	Asymptomatic valvular thickening with or without mild valvular regurgitation or stenosis by imaging	Asymptomatic; moderate regurgitation or stenosis by imaging	Symptomatic; severe regurgitation or stenosis by imaging; symptoms controlled with medical intervention	Life-threatening consequences; urgent intervention indicated (eg, valve replacement, valvuloplasty)	Death
Definition: A disorder characterized by a defect in aortic valve function or structure					
Asystole	Periods of asystole; non-urgent medical management indicated	—	—	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia without cardiac electrical activity. Typically, this is accompanied by cessation of the pumping function of the heart.					
Atrial fibrillation	Asymptomatic; intervention not indicated	Non-urgent medical intervention indicated	Symptomatic and incompletely controlled medically, or controlled with device (eg, pacemaker), or ablation	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia without discernible P waves and an irregular ventricular response resulting from multiple reentry circuits. The rhythm disturbance originates above the ventricles.					
Atrial flutter	Asymptomatic; intervention not indicated	Non-urgent medical intervention indicated	Symptomatic and incompletely controlled medically, or controlled with device (eg, pacemaker), or ablation	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia with organized rhythmic atrial contractions with a rate of 200 to 300 beats/min. The rhythm disturbance originates in the atria.					

Cardiac Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
AV block complete	—	Non-urgent intervention indicated	Symptomatic and incompletely controlled medically, or controlled with device (eg, pacemaker)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia with complete failure of atrial electrical impulse conduction through the AV node to the ventricles.					
AV block, first degree	Asymptomatic; intervention not indicated	Non-urgent intervention indicated	—	—	—
Definition: A disorder characterized by a dysrhythmia with a delay in the time required for the conduction of an electrical impulse through the AV node beyond 0.2 seconds; prolongation of the PR interval greater than 200 msec.					
Cardiac arrest	—	—	—	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by cessation of the pumping function of the heart					
Chest pain—cardiac	Mild pain	Moderate pain; limiting instrumental ADLs	Pain at rest; limiting self-care ADLs	—	—
Definition: A disorder characterized by substernal discomfort caused by insufficient myocardial oxygenation					
Conduction disorder	Mild symptoms; intervention not indicated	Moderate symptoms	Severe symptoms; intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by pathologic irregularities in the cardiac conduction system					
Constrictive pericarditis	—	—	Symptomatic heart failure or other cardiac symptoms, responsive to intervention	Refractory heart failure or other poorly controlled cardiac symptoms	Death
Definition: A disorder characterized by a thickened and fibrotic pericardial sac; these fibrotic changes impede normal myocardial function by restricting myocardial muscle action					
Heart failure	Asymptomatic with laboratory (eg, BNP) or cardiac imaging abnormalities	Symptoms with mild to moderate activity or exertion	Severe with symptoms at rest or with minimal activity or exertion; intervention indicated	Life-threatening consequences; urgent intervention indicated (eg, continuous IV therapy or mechanical hemodynamic support)	Death
Definition: A disorder characterized by the inability of the heart to pump blood at an adequate volume to meet tissue metabolic requirements or the ability to do so only at an elevation in the filling pressure					
Left ventricular systolic dysfunction	—	—	Symptomatic because of drop in ejection fraction; responsive to intervention	Refractory or poorly controlled heart failure caused by drop in ejection fraction; intervention such as ventricular assist device, IV vasopressor support, or heart transplant indicated	Death
Definition: A disorder characterized by failure of the left ventricle to produce adequate output despite an increase in distending pressure and in end-diastolic volume. Clinical manifestations may include dyspnea, orthopnea, and other signs and symptoms of pulmonary congestion and edema.					
Mitral valve disease	Asymptomatic valvular thickening with or without mild valvular regurgitation or stenosis by imaging	Asymptomatic; moderate regurgitation or stenosis by imaging	Symptomatic; severe regurgitation or stenosis by imaging; symptoms controlled with medical intervention	Life-threatening consequences; urgent intervention indicated (eg, valve replacement, valvuloplasty)	Death
Definition: A disorder characterized by a defect in mitral valve function or structure					
Mobitz (type) II atrioventricular block	Asymptomatic; intervention not indicated	Symptomatic; medical intervention indicated	Symptomatic and incompletely controlled medically or controlled with device (eg, pacemaker)	Life-threatening consequences; urgent intervention indicated	Death

Continued

Cardiac Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Definition: A disorder characterized by a dysrhythmia with relatively constant PR interval before the block of an atrial impulse. This is the result of intermittent failure of atrial electrical impulse conduction through the AV node to the ventricles.					
Mobitz type I	Asymptomatic; intervention not indicated	Symptomatic; medical intervention indicated	Symptomatic and incompletely controlled medically, or controlled with device (eg, pacemaker)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia with a progressively lengthening PR interval before the blocking of an atrial impulse. This is the result of intermittent failure of atrial electrical impulse conduction through the AV node to the ventricles.					
Myocardial infarction	—	Asymptomatic and cardiac enzymes minimally abnormal; no evidence of ischemic ECG changes	Severe symptoms; cardiac enzymes abnormal; hemodynamically stable; ECG changes consistent with infarction	Life-threatening consequences; hemodynamically unstable	Death
Definition: A disorder characterized by gross necrosis of the myocardium; this is caused by an interruption of blood supply to the area					
Myocarditis	Asymptomatic with laboratory (eg, BNP[) or cardiac imaging abnormalities	Symptoms with mild to moderate activity or exertion	Severe with symptoms at rest or with minimal activity or exertion; intervention indicated	Life-threatening consequences; urgent intervention indicated (eg, continuous IV therapy or mechanical hemodynamic support)	Death
Definition: A disorder characterized by inflammation of the muscle tissue of the heart					
Palpitations	Mild symptoms; intervention not indicated	Intervention indicated	—	—	—
Definition: A disorder characterized by an unpleasant sensation of irregular or forceful beating of the heart					
Paroxysmal atrial tachycardia	Asymptomatic; intervention not indicated	Symptomatic; medical management indicated	IV medication indicated	Life-threatening consequences; incompletely controlled medically; cardioversion indicated	Death
Definition: A disorder characterized by a dysrhythmia with abrupt onset and sudden termination of atrial contractions with a rate of 150 to 250 beats/min. The rhythm disturbance originates in the atria.					
Pericardial effusion	—	Asymptomatic; effusion size small to moderate	Effusion with physiologic consequences	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by fluid collection within the pericardial sac, usually caused by inflammation					
Pericardial tamponade	—	—	—	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an increase in intrapericardial pressure resulting from the collection of blood or fluid in the pericardium					
Pericarditis	Asymptomatic; ECG or physical findings (eg, rub) consistent with pericarditis	Symptomatic pericarditis (eg, chest pain)	Pericarditis with physiologic consequences (eg, pericardial constriction)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by irritation to the layers of the pericardium (the protective sac around the heart)					
Pulmonary valve disease	Asymptomatic valvular thickening with or without mild valvular regurgitation or stenosis by imaging	Asymptomatic; moderate regurgitation or stenosis by imaging	Symptomatic; severe regurgitation or stenosis by imaging; symptoms controlled with medical intervention	Life-threatening consequences; urgent intervention indicated (eg, valve replacement, valvuloplasty)	Death
Definition: A disorder characterized by a defect in pulmonary valve function or structure					

Cardiac Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Restrictive cardiomyopathy	—	—	Symptomatic heart failure or other cardiac symptoms, responsive to intervention	Refractory heart failure or other poorly controlled cardiac symptoms	Death
Definition: A disorder characterized by an inability of the ventricles to fill with blood because the myocardium (heart muscle) stiffens and loses its flexibility					
Right ventricular dysfunction	Asymptomatic with laboratory (eg, BNP) or cardiac imaging abnormalities	Symptoms with mild to moderate activity or exertion	Severe symptoms, associated with hypoxemia, right heart failure; oxygen indicated	Life-threatening consequences; urgent intervention indicated (eg, ventricular assist device); heart transplant indicated	Death
Definition: A disorder characterized by impairment of right ventricular function associated with low ejection fraction and a decrease in motility of the right ventricular wall.					
Sick sinus syndrome	Asymptomatic; intervention not indicated	Non-urgent intervention indicated	Severe, medically significant; medical intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia with alternating periods of bradycardia and atrial tachycardia accompanied by syncope, fatigue, and dizziness					
Sinus bradycardia	Asymptomatic; intervention not indicated	Symptomatic, medical intervention indicated	Severe, medically significant, medical intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia with a heart rate less than 60 beats/min that originates in the sinus node					
Sinus tachycardia	Asymptomatic; intervention not indicated	Symptomatic; non-urgent medical intervention indicated	Urgent medical intervention indicated	—	—
Definition: A disorder characterized by a dysrhythmia with a heart rate greater than 100 beats/min that originates in the sinus node					
Supraventricular tachycardia	Asymptomatic; intervention not indicated	Non-urgent medical intervention indicated	Medical intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia with a heart rate greater than 100 beats/min that originates above the ventricles					
Tricuspid valve disease	Asymptomatic valvular thickening with or without mild valvular regurgitation or stenosis	Asymptomatic; moderate regurgitation or stenosis by imaging	Symptomatic; severe regurgitation or stenosis; symptoms controlled with medical intervention	Life-threatening consequences; urgent intervention indicated (eg, valve replacement, valvuloplasty)	Death
Definition: A disorder characterized by a defect in tricuspid valve function or structure					
Ventricular arrhythmia	Asymptomatic; intervention not indicated	Non-urgent medical intervention indicated	Medical intervention indicated	Life-threatening consequences; hemodynamic compromise; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia that originates in the ventricles					
Ventricular fibrillation	—	—	—	Life-threatening consequences; hemodynamic compromise; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia without discernible QRS complexes caused by rapid repetitive excitation of myocardial fibers without coordinated contraction of the ventricles					

Continued

Cardiac Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Ventricular tachycardia	—	Non-urgent medical intervention indicated	Medical intervention indicated	Life-threatening consequences; hemodynamic compromise; urgent intervention indicated	Death
Definition: A disorder characterized by a dysrhythmia with a heart rate greater than 100 beats/min that originates distal to the bundle of His					
Wolff-Parkinson-White syndrome	Asymptomatic; intervention not indicated	Non-urgent medical intervention indicated	Symptomatic and incompletely controlled medically or controlled with procedure	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by the presence of an accessory conductive pathway between the atria and the ventricles that causes premature ventricular activation					
Cardiac disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *AV,* atrioventricular; *BNP,* B-natriuretic peptide; *ECG,* electrocardiography; *IV,* intravenous.

Congenital, Familial, and Genetic Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Congenital, familial, and genetic disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living.

Ear and Labyrinth Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Ear pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the ear					
External ear inflammation	External otitis with erythema or dry desquamation	External otitis with moist desquamation, edema, enhanced cerumen or discharge; tympanic membrane perforation; tympanostomy	External otitis with mastoiditis; stenosis, or osteomyelitis; necrosis of soft tissue or bone	Urgent operative intervention indicated	Death
Definition: A disorder characterized by inflammation, swelling, and redness to the outer ear and ear canal					

Ear and Labyrinth Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
External ear pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the external ear region					
Hearing impaired	Adults enrolled on a monitoring program (on a 1-, 2-, 3-, 4-, 6- and 8-kHz audiogram): Threshold shift of 15–25 dB averaged at two contiguous test frequencies in at least one ear Adults not enrolled in monitoring program: subjective change in hearing in the absence of documented hearing loss Pediatric (on a 1-, 2-, 3-, 4-, 6- and 8-kHz audiogram): threshold shift >20 dB at 8 kHz in at least one ear	Adults enrolled in monitoring program (on a 1-, 2-, 3-, 4-, 6- and 8-kHz audiogram): Threshold shift of >25 dB averaged at two contiguous test frequencies in at least one ear. Adults not enrolled in monitoring program: hearing loss but hearing aid or intervention not indicated; limiting instrumental ADLs Pediatric (on a 1-, 2-, 3-, 4-, 6- and 8-kHz audiogram): threshold shift >20 dB at 4 kHz and above in at least one ear	Adults enrolled in monitoring program (on a 1-, 2-, 3-, 4-, 6- and 8-kHz audiogram): Threshold shift of >25 dB averaged at three contiguous test frequencies in at least one ear; therapeutic intervention indicated Adults not enrolled in monitoring program: hearing loss with hearing aid or intervention indicated; limiting self-care ADLs Pediatric (on a 11-, 2-, 3-, 4-, 6- and 8-kHz audiogram): hearing loss sufficient to indicate therapeutic intervention, including hearing aids; threshold shift >20 dB at 3 kHz and above in at least one ear; additional speech-language–related services indicated	Adults: decrease in hearing to profound bilateral loss (absolute threshold >80 dB HL at 2 kHz and above); nonservicable hearing Pediatric: audiologic indication for cochlear implant and additional speech-language–related services indicated	—
Definition: A disorder characterized by partial or complete loss of the ability to detect or understand sounds resulting from damage to ear structures					
Middle ear inflammation	Serous otitis	Serous otitis, medical intervention indicated	Mastoiditis; necrosis of canal soft tissue or bone	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation (physiologic response to irritation), swelling, and redness to the middle ear					
Tinnitus	Mild symptoms; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by noise in the ears, such as ringing, buzzing, roaring, or clicking					
Vertigo	Mild symptoms	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation as if the external world were revolving around the patient (objective vertigo) or as if he himself were revolving in space (subjective vertigo).					
Vestibular disorder	—	Symptomatic; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by dizziness, imbalance, nausea, and vision problems					
Ear and labyrinth disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *HL,* hearing loss.

Endocrine Disorders

Adverse Event	Grade 1	2	3	4	5
Adrenal insufficiency	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; medical intervention indicated	Severe symptoms; hospitalization indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder that occurs when the adrenal cortex does not produce enough of the hormone cortisol and in some cases, the hormone aldosterone. It may be caused by a disorder of the adrenal cortex as in Addison disease or primary adrenal insufficiency.					
Cushingoid	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	Severe symptoms, medical intervention or hospitalization indicated	—	—
Definition: A disorder characterized by signs and symptoms that resemble Cushing disease or syndrome: buffalo hump obesity, striations, adiposity, hypertension, diabetes, and osteoporosis, usually caused by exogenous corticosteroids					
Delayed puberty	—	No breast development by age 13 yr for females; testes volume of <3 cc or no Tanner stage 2 development by age 14.5 yr for males	No breast development by age 14 yr for females; no increase in testes volume or no Tanner stage 2 by age 16 yr for males; hormone replacement indicated	—	—
Definition: A disorder characterized by unusually late sexual maturity.					
Growth accelerated	—	≥ +2 SD above mid parental height or target height	—	—	—
Definition: A disorder characterized by greater growth than expected for age					
Hyperparathyroidism	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	—	—	—
Definition: A disorder characterized by an increase in production of parathyroid hormone by the parathyroid glands. This results in hypercalcemia (abnormally high levels of calcium in the blood).					
Hyperthyroidism	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; thyroid suppression therapy indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; hospitalization indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by excessive levels of thyroid hormone in the body. Common causes include an overactive thyroid gland or thyroid hormone overdose.					
Hypoparathyroidism	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; medical intervention indicated	Severe symptoms; medical intervention or hospitalization indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a decrease in production of parathyroid hormone by the parathyroid glands					
Hypothyroidism	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; thyroid replacement indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; hospitalization indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a decrease in production of thyroid hormone by the thyroid gland					
Precocious puberty	Physical signs of puberty with no biochemical markers for females <8 yr and males <9 yr	Physical signs and biochemical markers of puberty for females <8 yr and males <9 yr	—	—	—
Definition: A disorder characterized by unusually early development of secondary sexual features; the onset of sexual maturation begins usually before age 8 yr for girls and before age 9 yr for boys					
Virilization	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	—	—	—
Definition: A disorder characterized by inappropriate masculinization occurring in a female or prepubertal male					

Endocrine Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Endocrine disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *SD,* standard deviation.

Eye Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Blurred vision	Intervention not indicated	Symptomatic; limiting instrumental ADLs	Limiting self-care ADLs	—	—
Definition: A disorder characterized by visual perception of unclear or fuzzy images					
Cataract	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; moderate decrease in visual acuity (20/40 or better)	Symptomatic with marked decrease in visual acuity (worse than 20/40 but better than 20/200); operative intervention indicated (eg, cataract surgery)	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by partial or complete opacity of the crystalline lens of one or both eyes. This results in a decrease in visual acuity and eventual blindness if untreated.					
Conjunctivitis	Asymptomatic or mild symptoms; intervention not indicated	Symptomatic; topical intervention indicated (eg, antibiotics); limiting instrumental ADLs	Limiting self-care ADLs	—	—
Definition: A disorder characterized by inflammation, swelling, and redness to the conjunctiva of the eye					
Corneal ulcer	—	Symptomatic; medical intervention indicated (eg, topical agents); limiting instrumental ADLs	Limiting self-care ADLs; declining vision (worse than 20/40 but better than 20/200)	Perforation or blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by an area of epithelial tissue loss on the surface of the cornea. It is associated with inflammatory cells in the cornea and anterior chamber.					
Dry eye	Asymptomatic; clinical or diagnostic observations only; mild symptoms relieved by lubricants	Symptomatic; multiple agents indicated; limiting instrumental ADLs	Decrease in visual acuity (<20/40); limiting self-care ADLs	—	—
Definition: A disorder characterized by dryness of the cornea and conjunctiva					
Extraocular muscle paresis	Asymptomatic; clinical or diagnostic observations only	Symptomatic; limiting instrumental ADLs	Limiting self-care ADLs; disabling	—	—
Definition: A disorder characterized by incomplete paralysis of an extraocular muscle					
Eye pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the eye					
Eyelid function disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; nonoperative intervention indicated; limiting instrumental ADLs	Limiting self-care ADLs; operative intervention indicated	—	—
Definition: A disorder characterized by impaired eyelid function					

Continued

Eye Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Flashing lights	Symptomatic but not limiting ADLs	Limiting instrumental ADLs	Limiting self-care ADLs	—	—
Definition: A disorder characterized by a sudden or brief burst of light					
Floaters	Symptomatic but not limiting ADLs	Limiting instrumental ADLs	Limiting self-care ADLs	—	—
Definition: A disorder characterized by an individual seeing spots before his or her eyes. The spots are shadows of opaque cell fragments in the vitreous humor or lens.					
Glaucoma	EIOP with single topical agent for intervention; no visual field deficit	EIOP causing early visual field deficits; multiple topical or oral agents indicated; limiting instrumental ADLs	EIOP causing marked visual field deficits (eg, involving both superior and inferior visual fields); operative intervention indicated; limiting self-care ADLs	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by an increase in pressure in the eyeball due to obstruction of the aqueous humor outflow					
Keratitis	—	Symptomatic; medical intervention indicated (eg, topical agents); limiting instrumental ADLs	Decline in vision (worse than 20/40 but better than 20/200); limiting self-care ADLs	Perforation or blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by inflammation to the cornea of the eye					
Night blindness	Symptomatic but not limiting ADLs	Limiting instrumental ADLs	Limiting self-care ADLs	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by an inability to see clearly in dim light					
Optic nerve disorder	Asymptomatic; clinical or diagnostic observations only	Limiting vision of the affected eye (20/40 or better)	Limiting vision in the affected eye (worse than 20/40 but better than 20/200)	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by involvement of the optic nerve (second cranial nerve)					
Papilledema	Asymptomatic; no visual field defects	Symptomatic decline in vision; visual field defect present sparing the central 20 degrees	Marked visual field defect (worse than 20/40 but better than 20/200)	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by swelling around the optic disc					
Photophobia	Symptomatic but not limiting ADLs	Limiting instrumental ADLs	Limiting self-care ADLs	—	—
Definition: A disorder characterized by fear and avoidance of light					
Retinal detachment	Asymptomatic	Exudative and visual acuity 20/40 or better	Rhegmatogenous or exudative detachment; operative intervention indicated; decline in vision (worse than 20/40 but better than 20/200)	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by the separation of the inner retina layers from the underlying pigment epithelium					
Retinal tear	—	Laser therapy or pneumopexy indicated	Vitreoretinal surgical repair indicated	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by a small laceration of the retina, this occurs when the vitreous separates from the retina. Symptoms include flashes and floaters.					
Retinal vascular disorder	—	Topical medication indicated	Intravitreal medication; operative intervention indicated	—	—
Definition: A disorder characterized by pathologic retinal blood vessels that adversely affects vision					

Eye Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Retinopathy	Asymptomatic; clinical or diagnostic observations only	Symptomatic with moderate decrease in visual acuity (20/40 or better); limiting instrumental ADLs	Symptomatic with marked decrease in visual acuity (worse than 20/40); disabling; limiting self-care ADLs	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder involving the retina					
Scleral disorder	Asymptomatic; clinical or diagnostic observations only	Symptomatic, limiting instrumental ADLs; moderate decrease in visual acuity (20/40 or better)	Symptomatic, limiting self-care ADLs; marked decrease in visual acuity (worse than 20/40)	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by involvement of the sclera of the eye					
Uveitis	Asymptomatic; clinical or diagnostic observations only	Anterior uveitis; medical intervention indicated	Posterior or pan-uveitis	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by inflammation to the uvea of the eye					
Vitreous hemorrhage	Asymptomatic or mild symptoms; clinical or diagnostic observations only	Symptomatic; limiting instrumental ADLs	Limiting self-care ADLs; vitrectomy indicated	Blindness (20/200 or worse) in the affected eye	—
Definition: A disorder characterized by blood extravasation into the vitreous humor					
Watering eyes	Intervention not indicated	Intervention indicated	Operative intervention indicated	—	—
Definition: A disorder of excessive tearing in the eyes; it can be caused by overproduction of tears or impaired drainage of the tear duct					
Eye disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately sight-threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Sight-threatening consequences; urgent intervention indicated; blindness (20/200 or worse) in the affected eye	—

ADL, Activity of daily living; *EIOP,* elevated intraocular pressure.

Gastrointestinal Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Abdominal distention	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; limiting instrumental ADLs	Severe discomfort; limiting self-care ADLs	—	—
Definition: A disorder characterized by swelling of the abdomen					
Abdominal pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the abdominal region					
Anal fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding, TPN, or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the opening in the anal canal to the perianal skin					

Continued

Gastrointestinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Anal hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the anal region					
Anal mucositis	Asymptomatic or mild symptoms; intervention not indicated	Symptomatic; medical intervention indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation of the mucous membrane of the anus					
Anal necrosis	—	—	TPN or hospitalization indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the anal region					
Anal pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the anal region					
Anal stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Symptomatic and severely altered GI function; nonemergent operative intervention indicated; TPN or hospitalization indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the anal canal					
Anal ulcer	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; TPN indicated; elective operative or endoscopic intervention indicated; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a circumscribed, inflammatory, and necrotic erosive lesion on the mucosal surface of the anal canal					
Ascites	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; invasive intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by accumulation of serous or hemorrhagic fluid in the peritoneal cavity					
Bloating	No change in bowel function or oral intake	Symptomatic, decreased oral intake; change in bowel function	—	—	—
Definition: A disorder characterized by subject-reported feeling of uncomfortable fullness of the abdomen					
Cecal hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the cecum					
Cheilitis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; intervention indicated	—	—
Definition: A disorder characterized by inflammation of the lip					
Colitis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Abdominal pain; mucus or blood in stool	Severe abdominal pain; change in bowel habits; medical intervention indicated; peritoneal signs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation of the colon					

Gastrointestinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Colonic fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; bowel rest, TPN or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the large intestine and another organ or anatomic site					
Colonic hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the colon					
Colonic obstruction	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Hospitalization indicated; elective operative intervention indicated; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by blockage of the normal flow of the intestinal contents in the colon					
Colonic perforation	—	Symptomatic; medical intervention indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a rupture in the colonic wall					
Colonic stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the colon					
Colonic ulcer	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; TPN indicated; elective operative or endoscopic intervention indicated; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a circumscribed, inflammatory and necrotic erosive lesion on the mucosal surface of the colon					
Constipation	Occasional or intermittent symptoms; occasional use of stool softeners, laxatives, dietary modification, or enema	Persistent symptoms with regular use of laxatives or enemas; limiting instrumental ADLs	Obstipation with manual evacuation indicated; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by irregular and infrequent or difficult evacuation of the bowels					
Dental caries	One or more dental caries, not involving the root	Dental caries involving the root	Dental caries resulting in pulpitis or periapical abscess or resulting in tooth loss	—	—
Definition: A disorder characterized by the decay of a tooth, in which it becomes softened, discolored or porous					
Diarrhea	Increase of <4 stools per day over baseline; mild increase in ostomy output compared with baseline	Increase of 4–6 stools per day over baseline; moderate increase in ostomy output compared with baseline	Increase of ≥7 stools per day over baseline; incontinence; hospitalization indicated; severe increase in ostomy output compared with baseline; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by frequent and watery bowel movements					

Continued

Gastrointestinal Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Dry mouth	Symptomatic (eg, dry or thick saliva) without significant dietary alteration; unstimulated saliva flow >0.2 mL/min	Moderate symptoms; oral intake alterations (eg, copious water, other lubricants, diet limited to purees or soft, moist foods); unstimulated saliva 0.1–0.2 mL/min	Inability to adequately aliment orally; tube feeding or TPN indicated; unstimulated saliva <0.1 mL/min	—	—
Definition: A disorder characterized by reduced salivary flow in the oral cavity					
Duodenal fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding, TPN or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the duodenum and another organ or anatomic site					
Duodenal hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the duodenum					
Duodenal obstruction	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Hospitalization or elective operative intervention indicated; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by blockage of the normal flow of stomach contents through the duodenum					
Duodenal perforation	—	Symptomatic; medical intervention indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a rupture in the duodenal wall					
Duodenal stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding; hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the duodenum					
Duodenal ulcer	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; medical intervention indicated; limiting instrumental ADLs	Severely altered GI function; TPN indicated; elective operative or endoscopic intervention indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a circumscribed, inflammatory, and necrotic erosive lesion on the mucosal surface of the duodenal wall					
Dyspepsia	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	Severe symptoms; surgical intervention indicated	—	—
Definition: A disorder characterized by an uncomfortable, often painful feeling in the stomach, resulting from impaired digestion. Symptoms include burning stomach, bloating, heartburn, nausea, and vomiting.					
Dysphagia	Symptomatic, able to eat regular diet	Symptomatic and altered eating or swallowing	Severely altered eating or swallowing; tube feeding, TPN, or hospitalization indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by difficulty in swallowing					

Gastrointestinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Enterocolitis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Abdominal pain; mucus or blood in stool	Severe or persistent abdominal pain; fever; ileus; peritoneal signs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation of the small and large intestines					
Enterovesical fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; noninvasive intervention indicated	Severe, medically significant; medical intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the urinary bladder and the intestine					
Esophageal fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding, TPN or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the esophagus and another organ or anatomic site					
Esophageal hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the esophagus					
Esophageal necrosis	—	—	Inability to aliment adequately by GI tract; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the esophageal wall					
Esophageal obstruction	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; limiting instrumental ADLs	Hospitalization indicated; elective operative intervention indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by blockage of the normal flow of the contents in the esophagus					
Esophageal pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the esophageal region					
Esophageal perforation	—	Symptomatic; medical intervention indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a rupture in the wall of the esophagus					
Esophageal stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding; hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the esophagus					
Esophageal ulcer	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; limiting instrumental ADLs	Severely altered GI function; TPN indicated; elective operative or endoscopic intervention indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a circumscribed, inflammatory, and necrotic erosive lesion on the mucosal surface of the esophageal wall

Gastrointestinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Esophageal varices hemorrhage	—	Self-limited; intervention not indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from esophageal varices					
Esophagitis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered eating or swallowing; oral supplements indicated	Severely altered eating or swallowing; tube feeding, TPN, or hospitalization indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by inflammation of the esophageal wall					
Fecal incontinence	Occasional use of pads required	Daily use of pads required	Severe symptoms; elective operative intervention indicated	—	—
Definition: A disorder characterized by inability to control the escape of stool from the rectum					
Flatulence	Mild symptoms; intervention not indicated	Moderate; persistent; psychosocial sequelae	—	—	—
Definition: A disorder characterized by a state of excessive gas in the alimentary canal					
Gastric fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; bowel rest; tube feeding, TPN or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the stomach and another organ or anatomic site					
Gastric hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the gastric wall					
Gastric necrosis	—	—	Inability to aliment adequately by GI tract; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the gastric wall					
Gastric perforation	—	Symptomatic; medical intervention indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a rupture in the stomach wall					
Gastric stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding; hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the stomach					
Gastric ulcer	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; medical intervention indicated; limiting instrumental ADLs	Severely altered GI function; TPN indicated; elective operative or endoscopic intervention indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a circumscribed, inflammatory, and necrotic erosive lesion on the mucosal surface of the stomach					

Gastrointestinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Gastritis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; medical intervention indicated	Severely altered eating or gastric function; TPN or hospitalization indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by inflammation of the stomach					
Gastroesophageal reflux disease	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	Severe symptoms; surgical intervention indicated	—	—
Definition: A disorder characterized by reflux of the gastric or duodenal contents into the distal esophagus. It is chronic in nature and usually caused by incompetence of the lower esophageal sphincter. It may result in injury to the esophageal mucosal. Symptoms include heartburn and acid indigestion.					
GI fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding, TPN, or hospitalization indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between any part of the GI system and another organ or anatomic site					
Gastrointestinal pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the GI region					
Gastroparesis	Mild nausea, early satiety and bloating, able to maintain caloric intake on regular diet	Moderate symptoms; able to maintain nutrition with dietary and lifestyle modifications; may need pharmacologic intervention	Weight loss; refractory to medical intervention; unable to maintain nutrition orally	—	—
Definition: A disorder characterized by an incomplete paralysis of the muscles of the stomach wall resulting in delayed emptying of the gastric contents into the small intestine					
Gingival pain	Mild pain	Moderate pain interfering with oral intake	Severe pain; inability to aliment orally	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the gingival region					
Hemorrhoidal hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the hemorrhoids					
Hemorrhoids	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; banding or medical intervention indicated	Severe symptoms; radiologic, endoscopic or elective operative intervention indicated	—	—
Definition: A disorder characterized by the presence of dilated veins in the rectum and surrounding area					
Ileal fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; TPN or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the ileum and another organ or anatomic site					
Ileal hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the ileal wall					
Ileal obstruction	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; limiting instrumental ADLs	Hospitalization indicated; elective operative intervention indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by blockage of the normal flow of the intestinal contents in the ileum

Gastrointestinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Ileal perforation	—	Symptomatic; medical intervention indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a rupture in the ileal wall					
Ileal stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the ileum					
Ileal ulcer	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; TPN indicated; elective operative or endoscopic intervention indicated; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a circumscribed, inflammatory and necrotic erosive lesion on the mucosal surface of the ileum					
Ileus	—	Symptomatic; altered GI function; bowel rest indicated	Severely altered GI function; TPN indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by failure of the ileum to transport intestinal contents.					
Intraabdominal hemorrhage	—	Medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding in the abdominal cavity					
Jejunal fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; TPN or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the jejunum and another organ or anatomic site					
Jejunal hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the jejunal wall					
Jejunal obstruction	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; limiting instrumental ADLs	Hospitalization indicated; elective operative intervention indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by blockage of the normal flow of the intestinal contents in the jejunum					
Jejunal perforation	—	Symptomatic; medical intervention indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a rupture in the jejunal wall					
Jejunal stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the jejunum					

Gastrointestinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Jejunal ulcer	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; TPN indicated; elective operative or endoscopic intervention indicated; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a circumscribed, inflammatory, and necrotic erosive lesion on the mucosal surface of the jejunum					
Lip pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort of the lip.					
Lower GI hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the lower GI tract (small intestine, large intestine, and anus)					
Malabsorption	—	Altered diet; oral intervention indicated	Inability to aliment adequately; TPN indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inadequate absorption of nutrients in the small intestine. Symptoms include abdominal marked discomfort, bloating, and diarrhea.					
Mucositis oral	Asymptomatic or mild symptoms; intervention not indicated	Moderate pain; not interfering with oral intake; modified diet indicated	Severe pain; interfering with oral intake	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation of the oral mucosal					
Nausea	Loss of appetite without alteration in eating habits	Oral intake decreased without significant weight loss, dehydration, or malnutrition	Inadequate oral caloric or fluid intake; tube feeding, TPN, or hospitalization indicated	—	—
Definition: A disorder characterized by a queasy sensation or the urge to vomit					
Obstruction gastric	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; limiting instrumental ADLs	Hospitalization indicated; elective operative intervention indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by blockage of the normal flow of the contents in the stomach					
Oral cavity fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; TPN or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the oral cavity and another organ or anatomic site					
Oral dysesthesia	Mild discomfort; not interfering with oral intake	Moderate pain; interfering with oral intake	Disabling pain; tube feeding or TPN indicated	—	—
Definition: A disorder characterized by a burning or tingling sensation on the lips, tongue, or entire mouth					
Oral hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the mouth					
Oral pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the mouth, tongue, or lips

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Pancreatic duct stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the pancreatic duct					
Pancreatic fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding, TPN, or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the pancreas and another organ or anatomic site					
Pancreatic hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the pancreas					
Pancreatic necrosis	—	—	Tube feeding or TPN indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the pancreas					
Pancreatitis	—	Enzyme elevation or radiologic findings only	Severe pain; vomiting; medical intervention indicated (eg, analgesia, nutritional support)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation of the pancreas					
Periodontal disease	Gingival recession or gingivitis; limited bleeding on probing; mild local bone loss	Moderate gingival recession or gingivitis; multiple sites of bleeding on probing; moderate bone loss	Spontaneous bleeding; severe bone loss with or without tooth loss; osteonecrosis of maxilla or mandible	—	—
Definition: A disorder in the gingival tissue around the teeth					
Peritoneal necrosis	—	—	Tube feeding or TPN indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the peritoneum					
Proctitis	Rectal discomfort, intervention not indicated	Symptoms (eg, rectal discomfort, passing blood or mucus); medical intervention indicated; limiting instrumental ADLs	Severe symptoms; fecal urgency or stool incontinence; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation of the rectum					
Rectal fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; TPN or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the rectum and another organ or anatomic site					
Rectal hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the rectal wall and discharged from the anus					

Gastrointestinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Rectal mucositis	Asymptomatic or mild symptoms; intervention not indicated	Symptomatic; medical intervention indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by inflammation of the mucous membrane of the rectum					
Rectal necrosis	—	—	Tube feeding or TPN indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the rectal wall					
Rectal obstruction	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; limiting instrumental ADLs	Hospitalization indicated; elective operative intervention indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by blockage of the normal flow of the intestinal contents in the rectum					
Rectal pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the rectal region					
Rectal perforation	—	Symptomatic; medical intervention indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a rupture in the rectal wall					
Rectal stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the rectum					
Rectal ulcer	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function (eg, altered dietary habits, vomiting, diarrhea)	Severely altered GI function; TPN indicated; elective operative or endoscopic intervention indicated; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a circumscribed, inflammatory, and necrotic erosive lesion on the mucosal surface of the rectum					
Retroperitoneal hemorrhage	—	Self-limited; intervention indicated	Transfusion, medical, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the retroperitoneal area					
Salivary duct inflammation	Slightly thickened saliva; slightly altered taste (eg, metallic)	Thick, ropy, sticky saliva; markedly altered taste; alteration in diet indicated; secretion-induced symptoms; limiting instrumental ADLs	Acute salivary gland necrosis; severe secretion-induced symptoms (eg, thick saliva/oral secretions or gagging); tube feeding or TPN indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation of the salivary duct					
Salivary gland fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; tube feeding indicated	Severely altered GI function; hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between a salivary gland and another organ or anatomic site

Gastrointestinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Small intestinal mucositis	Asymptomatic or mild symptoms; intervention not indicated	Symptomatic; medical intervention indicated; limiting instrumental ADLs	Severe pain; interfering with oral intake; tube feeding, TPN, or hospitalization indicated; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation of the mucous membrane of the small intestine					
Small intestinal obstruction	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; limiting instrumental ADLs	Hospitalization indicated; elective operative intervention indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by blockage of the normal flow of the intestinal contents					
Small intestinal perforation	—	Symptomatic; medical intervention indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a rupture in the small intestine wall					
Small intestinal stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Symptomatic and severely altered GI function; tube feeding, TPN, or hospitalization indicated; non-emergent operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the small intestine					
Small intestine ulcer	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; limiting instrumental ADLs	Severely altered GI function; TPN indicated; elective operative or endoscopic intervention indicated; limiting self-care ADLs; disabling	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a circumscribed, inflammatory, and necrotic erosive lesion on the mucosal surface of the small intestine					
Stomach pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the stomach					
Tooth development disorder	Asymptomatic; hypoplasia of tooth or enamel	Impairment correctable with oral surgery	Maldevelopment with impairment not surgically correctable; disabling	—	—
Definition: A disorder characterized by a pathologic process of the teeth occurring during tooth development					
Tooth discoloration	Surface stains	—	—	—	—
Definition: A disorder characterized by a change in tooth hue or tint					
Toothache	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the tooth					
Typhlitis	—	—	Symptomatic (eg, abdominal pain, fever, change in bowel habits with ileus); peritoneal signs	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by inflammation of the cecum					
Upper gastrointestinal hemorrhage	Mild; intervention not indicated	Moderate symptoms; medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the upper GI tract (oral cavity, pharynx, esophagus, and stomach)					

Gastrointestinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Vomiting	1–2 episodes (separated by 5 min) in 24 h	3–5 episodes (separated by 5 min) in 24 h	≥6 episodes (separated by 5 min) in 24 h; tube feeding, TPN, or hospitalization indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by the reflexive act of ejecting the contents of the stomach through the mouth					
GI disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *GI,* gastrointestinal; *TPN,* total parenteral nutrition.

General Disorders and Administration Site Conditions

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Chills	Mild sensation of cold; shivering; chattering of teeth	Moderate tremor of the entire body; narcotics indicated	Severe or prolonged, not responsive to narcotics	—	—
Definition: A disorder characterized by a sensation of cold that often marks a physiologic response to sweating after a fever					
Death neonatal	—	—	—	—	Death
Definition: A disorder characterized by cessation of life occurring during the first 28 days of life.					
Death NOS	—	—	—	—	Death
Definition: A cessation of life that cannot be attributed to a CTCAE term associated with grade 5					
Edema face	Localized facial edema	Moderate localized facial edema; limiting instrumental ADLs	Severe swelling; limiting self-care ADLs	—	—
Definition: A disorder characterized by swelling due to excessive fluid accumulation in facial tissues					
Edema limbs	5%–10% interlimb discrepancy in volume or circumference at point of greatest visible difference; swelling or obscuration of anatomic architecture on close inspection	>10%–30% interlimb discrepancy in volume or circumference at point of greatest visible difference; readily apparent obscuration of anatomic architecture; obliteration of skin folds; readily apparent deviation from normal anatomic contour; limiting instrumental ADLs	>30% interlimb discrepancy in volume; gross deviation from normal anatomic contour; limiting self-care ADLs	—	—
Definition: A disorder characterized by swelling caused by excessive fluid accumulation in the upper or lower extremities					
Edema trunk	Swelling or obscuration of anatomic architecture on close inspection	Readily apparent obscuration of anatomic architecture; obliteration of skin folds; readily apparent deviation from normal anatomic contour; limiting instrumental ADLs	Gross deviation from normal anatomic contour; limiting self-care ADLs	—	—
Definition: A disorder characterized by swelling resulting from excessive fluid accumulation in the trunk area					
Facial pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the face					

Continued

General Disorders and Administration Site Conditions—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Fatigue	Fatigue relieved by rest	Fatigue not relieved by rest; limiting instrumental ADLs	Fatigue not relieved by rest, limiting self-care ADLs	—	—
Definition: A disorder characterized by a state of generalized weakness with a pronounced inability to summon sufficient energy to accomplish daily activities					
Fever	38.0°–39.0°C (100.4°–102.2°F)	>39.0°–40.0°C (102.3°–104.0°F)	>40.0°C (>104.0°F) for ≤24 h	>40.0°C (>104.0°F) for >24 h	Death
Definition: A disorder characterized by elevation of the body's temperature above the upper limit of normal					
Flulike symptoms	Mild flulike symptoms present	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by a group of symptoms similar to those observed in patients with the flu. It includes fever, chills, body aches, malaise, loss of appetite, and dry cough.					
Gait disturbance	Mild change in gait (eg, wide based, limping, or hobbling)	Moderate change in gait (eg, wide based, limping, or hobbling); assistive device indicated; limiting instrumental ADLs	Disabling; limiting self-care ADLs	—	—
Definition: A disorder characterized by walking difficulties					
Hypothermia	—	35°–>32°C; 95°–>89.6°F	32°–>28°C; 89.6°–>82.4°F	≤28°C; 82.4°F; life-threatening consequences (eg, coma, hypotension, pulmonary edema, acidemia, ventricular fibrillation)	Death
Definition: A disorder characterized by an abnormally low body temperature. Treatment is required when the body temperature is 35°C (95°F) or below.					
Infusion-related reaction	Mild transient reaction; infusion interruption not indicated; intervention not indicated	Therapy or infusion interruption indicated but responds promptly to symptomatic treatment (eg, antihistamines, NSAIDs, narcotics, IV fluids); prophylactic medications indicated for ≤24 h	Prolonged (eg, not rapidly responsive to symptomatic medication or brief interruption of infusion); recurrence of symptoms following initial improvement; hospitalization indicated for clinical sequelae	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by adverse reaction to the infusion of pharmacologic or biologic substances					
Infusion site extravasation	—	Erythema with associated symptoms (eg, edema, pain, induration, phlebitis)	Ulceration or necrosis; severe tissue damage; operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by leakage of a pharmacologic or a biologic substance from the infusion site into the surrounding tissue. Signs and symptoms include induration, erythema, swelling, burning sensation, and marked discomfort at the infusion site.					
Injection site reaction	Tenderness with or without associated symptoms (eg, warmth, erythema, itching)	Pain; lipodystrophy; edema; phlebitis	Ulceration or necrosis; severe tissue damage; operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an intense adverse reaction (usually immunologic) developing at the site of an injection					
Irritability	Mild; easily consolable	Moderate; limiting instrumental ADLs; increased attention indicated	Severe abnormal or excessive response; limiting self-care ADLs; inconsolable	—	—
Definition: A disorder characterized by an abnormal responsiveness to stimuli or physiologic arousal; may be in response to pain, fright, a drug, an emotional situation, or a medical condition					
Localized edema	Localized to dependent areas; no disability or functional impairment	Moderate localized edema and intervention indicated; limiting instrumental ADLs	Severe localized edema and intervention indicated; limiting self-care ADLs	—	—
Definition: A disorder characterized by swelling caused by excessive fluid accumulation at a specific anatomic site					

General Disorders and Administration Site Conditions—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Malaise	Uneasiness or lack of well-being	Uneasiness or lack of well-being; limiting instrumental ADLs	—	—	—
Definition: A disorder characterized by a feeling of general discomfort or uneasiness, an out-of-sorts feeling					
Multiorgan failure	—	—	Shock with azotemia and acid–base disturbances; significant coagulation abnormalities	Life-threatening consequences (eg, vasopressor dependent and oliguric or anuric or ischemic colitis or lactic acidosis)	Death
Definition: A disorder characterized by progressive deterioration of the lungs, liver, kidney, and clotting mechanisms					
Neck edema	Asymptomatic localized neck edema	Moderate neck edema; slight obliteration of anatomic landmarks; limiting instrumental ADLs	Generalized neck edema (eg, difficulty in turning neck); limiting self-care ADLs	—	—
Definition: A disorder characterized by swelling caused by an accumulation of excessive fluid in the neck					
Noncardiac chest pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by discomfort in the chest unrelated to a heart disorder					
Pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by the sensation of marked discomfort, distress, or agony					
Sudden death NOS	—	—	—	—	Death
Definition: An unexpected cessation of life that cannot be attributed to a CTCAE term associated with grade 5					
General disorders and administration site conditions—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *IV,* intravenous; *NOS,* not otherwise specified; *NSAID,* nonsteroidal antiinflammatory drug.

Hepatobiliary Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Bile duct stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; IV fluids indicated <24 h	Severely altered GI function; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a narrowing of the lumen of the bile duct					
Biliary fistula	—	Symptomatic and intervention not indicated	Severely altered GI function; TPN indicated; endoscopic intervention indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the bile ducts and another organ or anatomic site					

Continued

Hepatobiliary Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Cholecystitis	—	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by inflammation involving the gallbladder. It may be associated with the presence of gallstones.					
Gallbladder fistula	Asymptomatic clinical or diagnostic observations only; intervention not indicated	Symptomatic and intervention not indicated	Symptomatic or severely altered GI function; TPN indicated; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the gallbladder and another organ or anatomic site					
Gallbladder necrosis	—	—	—	Life-threatening consequences; urgent radiologic or operative intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the gallbladder					
Gallbladder obstruction	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function; IV fluids indicated <24 h	Symptomatic and severely altered GI function; tube feeding, TPN, or hospitalization indicated; non-emergent operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by blockage of the normal flow of the contents of the gallbladder					
Gallbladder pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the gallbladder region					
Gallbladder perforation	—	—	—	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a rupture in the gallbladder wall					
Hepatic failure	—	—	Asterixis; mild encephalopathy; limiting self-care ADLs	Moderate to severe encephalopathy; coma; life-threatening consequences	Death
Definition: A disorder characterized by the inability of the liver to metabolize chemicals in the body. Laboratory test results reveal abnormal plasma levels of ammonia, bilirubin, lactic dehydrogenase, and alkaline phosphatase.					
Hepatic hemorrhage	Mild; intervention not indicated	Symptomatic; medical intervention indicated	Transfusion indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the liver					
Hepatic necrosis	—	—	—	Life-threatening consequences; urgent radiologic or operative intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the hepatic parenchyma					
Hepatic pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the liver region					
Perforation of bile duct	—	—	Radiologic, endoscopic or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a rupture in the wall of the extrahepatic or intrahepatic bile duct					

Hepatobiliary Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Portal hypertension	—	Decreased portal vein flow	Reversal or retrograde portal vein flow; associated with varices or ascites	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an increase in blood pressure in the portal venous system					
Portal vein thrombosis	—	Intervention not indicated	Medical intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by the formation of a thrombus (blood clot) in the portal vein					
Hepatobiliary disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *GI,* gastrointestinal; *IV,* intravenous; *TPN,* total parenteral nutrition.

Immune System Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Allergic reaction	Transient flushing or rash, drug fever <38°C (<100.4°F); intervention not indicated	Intervention or infusion interruption indicated; responds promptly to symptomatic treatment (eg, antihistamines, NSAIDs, narcotics); prophylactic medications indicated for ≤24 h	Prolonged (eg, not rapidly responsive to symptomatic medication or brief interruption of infusion); recurrence of symptoms after initial improvement; hospitalization indicated for clinical sequelae (eg, renal impairment, pulmonary infiltrates)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an adverse local or general response from exposure to an allergen					
Anaphylaxis	—	—	Symptomatic bronchospasm, with or without urticaria; parenteral intervention indicated; allergy-related edema or angioedema; hypotension	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an acute inflammatory reaction resulting from the release of histamine and histamine-like substances from mast cells, causing a hypersensitivity immune response. Clinically, it presents with breathing difficulty, dizziness, hypotension, cyanosis, and loss of consciousness and may lead to death.					
Autoimmune disorder	Asymptomatic; serologic or other evidence of autoimmune reaction, with normal organ function; intervention not indicated	Evidence of autoimmune reaction involving a nonessential organ or function (eg, hypothyroidism)	Autoimmune reactions involving major organ (eg, colitis, anemia, myocarditis, kidney)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder resulting from loss of function or tissue destruction of an organ or multiple organs, arising from humoral or cellular immune responses of the individual to his own tissue constituents					

Continued

Immune System Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Cytokine release syndrome	Mild reaction; infusion interruption not indicated; intervention not indicated	Therapy or infusion interruption indicated but responds promptly to symptomatic treatment (eg, antihistamines, NSAIDs, narcotics, IV fluids); prophylactic medications indicated for ≤24 h	Prolonged (eg, not rapidly responsive to symptomatic medication or brief interruption of infusion); recurrence of symptoms following initial improvement; hospitalization indicated for clinical sequelae (eg, renal impairment, pulmonary infiltrates)	Life-threatening consequences; pressor or ventilatory support indicated	Death
Definition: A disorder characterized by nausea, headache, tachycardia, hypotension, rash, and shortness of breath; it is caused by the release of cytokines from the cells					
Serum sickness	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate arthralgia; fever, rash, urticaria, antihistamines indicated	Severe arthralgia or arthritis; extensive rash; steroids or IV fluids indicated	Life-threatening consequences; pressor or ventilatory support indicated	Death
Definition: A disorder characterized by a delayed-type hypersensitivity reaction to foreign proteins derived from an animal serum. It occurs approximately 6 to 21 days after the administration of the foreign antigen. Symptoms include fever, arthralgias, myalgias, skin eruptions, lymphadenopathy, marked chest discomfort, and dyspnea.					
Immune system disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *NSAID,* nonsteroidal antiinflammatory drug.

Infections and Infestations

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Abdominal infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the abdominal cavity					
Anorectal infection	Localized; local intervention indicated	Oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the anal area and the rectum					
Appendicitis	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by acute inflammation to the vermiform appendix caused by a pathogenic agent					

Infections and Infestations—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Appendicitis perforated	—	Symptomatic; medical intervention indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by acute inflammation to the vermiform appendix caused by a pathogenic agent with gangrenous changes resulting in the rupture of the appendiceal wall. The appendiceal wall rupture causes the release of inflammatory and bacterial contents from the appendiceal lumen into the abdominal cavity.					
Arteritis infective	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving an artery					
Biliary tract infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the biliary tract					
Bladder infection	—	Oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the bladder					
Bone infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the bones					
Breast infection	—	Local infection with moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	Severe infection; axillary adenitis; IV antibacterial, antifungal, or antiviral intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the breast					
Bronchial infection	—	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the bronchi					
Catheter-related infection	—	Localized; local intervention indicated; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process that arises secondary to catheter use					
Cecal infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the cecum					

Continued

Infections and Infestations—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Cervicitis infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the uterine cervix					
Conjunctivitis infective	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the conjunctiva. Clinical manifestations include pink or red color in the eyes.					
Corneal infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the cornea					
Cranial nerve infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving a cranial nerve					
Device-related infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the use of a medical device					
Duodenal infection	—	Moderate symptoms; medical intervention indicated (eg, oral antibiotics)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the duodenum					
Encephalitis infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; severe changes in mental status; self-limited seizure activity; focal neurologic abnormalities	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the brain tissue					
Encephalomyelitis infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the brain and spinal cord tissues					
Endocarditis infective	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the endocardial layer of the heart					

Infections and Infestations—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Endophthalmitis	—	Local intervention indicated	Systemic intervention or hospitalization indicated	Blindness (20/200 or worse)	—
Enterocolitis infectious	—	Passage of >3 unformed stools per 24 h or duration of illness >48 h; moderate abdominal pain	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated; profuse watery diarrhea with signs of hypovolemia; bloody diarrhea; fever; severe abdominal pain; hospitalization indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the small and large intestines					
Esophageal infection	—	Local intervention indicated (eg, oral antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the esophagus					
Eye infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated; enucleation	Death
Definition: A disorder characterized by an infectious process involving the eye					
Gallbladder infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the gallbladder					
Gum infection	Local therapy indicated (swish and swallow)	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the gums					
Hepatic infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the liver					
Hepatitis, viral	Asymptomatic; treatment not indicated	—	Symptomatic liver dysfunction; fibrosis by biopsy; compensated cirrhosis; reactivation of chronic hepatitis	Decompensated liver function (eg, ascites, coagulopathy, encephalopathy, coma)	Death
Definition: A disorder characterized by a viral pathologic process involving the liver parenchyma

Infections and Infestations—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Infective myositis	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the skeletal muscles					
Joint infection	—	Localized; local intervention indicated; oral intervention indicated (eg, antibiotic, antifungal, antiviral); needle aspiration indicated (single or multiple)	Arthroscopic intervention indicated (eg, drainage) or arthrotomy (eg, open surgical drainage)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving a joint					
Kidney infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the kidney					
Laryngitis	—	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an inflammatory process involving the larynx					
Lip infection	Localized, local intervention indicated	Oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	—	—
Definition: A disorder characterized by an infectious process involving the lips					
Lung infection	—	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the lungs					
Lymph gland infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the lymph nodes					
Mediastinal infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the mediastinum					

Infections and Infestations—cont'd

Adverse Event	Grade 1	2	3	4	5
Meningitis	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated; focal neurologic deficit	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by acute inflammation of the meninges of the brain, spinal cord, or both					
Mucosal infection	Localized, local intervention indicated	Oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving a mucosal surface					
Nail infection	Localized, local intervention indicated	Oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	—	—
Definition: A disorder characterized by an infectious process involving the nail					
Otitis externa	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the outer ear and ear canal. Contributory factors include excessive water exposure (swimmer's ear infection) and cuts in the ear canal. Symptoms include fullness, itching, swelling, and marked discomfort in the ear and ear drainage.					
Otitis media	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the middle ear					
Ovarian infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the ovary					
Pancreas infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the pancreas					
Papulopustular rash	Papules or pustules covering <10% BSA, which may or may not be associated with symptoms of pruritus or tenderness	Papules or pustules covering 10%–30% BSA, which may or may not be associated with symptoms of pruritus or tenderness; associated with psychosocial impact; limiting instrumental ADLs	Papules or pustules covering >30% BSA, which may or may not be associated with symptoms of pruritus or tenderness; limiting self-care ADLs; associated with local superinfection with oral antibiotics indicated	Papules and/or pustules covering any % BSA, which may or may not be associated with symptoms of pruritus or tenderness and are associated with extensive superinfection with IV antibiotics indicated; life-threatening consequences	Death
Definition: A disorder characterized by an eruption consisting of papules (a small, raised pimple) and pustules (a small pus filled blister), typically appearing in face, scalp, and upper chest and back. Unlike acne, this rash does not present with whiteheads or blackheads and can be symptomatic, with itchy or tender lesions.

Infections and Infestations—cont'd

Adverse Event	Grade 1	2	3	4	5
Paronychia	Nail fold edema or erythema; disruption of the cuticle	Localized intervention indicated; oral intervention indicated (eg, antibiotic, antifungal, antiviral); nail fold edema or erythema with pain; associated with discharge or nail plate separation; limiting instrumental ADLs	Surgical intervention or IV antibiotics indicated; limiting self-care ADLs	—	—
Definition: A disorder characterized by an infectious process involving the soft tissues around the nail					
Pelvic infection	—	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the pelvic cavity					
Penile infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the penis					
Periorbital infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the orbit of the eye					
Peripheral nerve infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the peripheral nerves					
Peritoneal infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the peritoneum					
Pharyngitis	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation of the throat					
Phlebitis infective	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the vein. Clinical manifestations include erythema, marked discomfort, swelling, and induration along the course of the infected vein.					

Infections and Infestations—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Pleural infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the pleura					
Prostate infection	—	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the prostate gland					
Rash pustular	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	—	—
Definition: A disorder characterized by a circumscribed and elevated skin lesion filled with pus					
Rhinitis infective	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	—	—	—
Definition: A disorder characterized by an infectious process involving the nasal mucosal					
Salivary gland infection	—	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the salivary gland					
Scrotal infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the scrotum					
Sepsis	—	—	—	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by the presence of pathogenic microorganisms in the blood stream that cause a rapidly progressing systemic reaction that may lead to shock					
Sinusitis	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the mucous membranes of the paranasal sinuses					
Skin infection	Localized, local intervention indicated	Oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the skin					

Continued

Infections and Infestations—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Small intestine infection	—	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the small intestine					
Soft tissue infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving soft tissues					
Splenic infection	—	—	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the spleen					
Stoma site infection	Localized, local intervention indicated	Oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving a stoma (surgically created opening on the surface of the body)					
Tooth infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving a tooth					
Tracheitis	—	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the trachea					
Upper respiratory infection	—	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the upper respiratory tract (nose, paranasal sinuses, pharynx, larynx, or trachea)					
Urethral infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the urethra					
Urinary tract infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the urinary tract, most commonly the bladder and the urethra					

Infections and Infestations—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Uterine infection	—	Moderate symptoms; oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the endometrium. It may extend to the myometrium and parametrial tissues					
Vaginal infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the vagina.					
Vulval infection	Localized, local intervention indicated	Oral intervention indicated (eg, antibiotic, antifungal, antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the vulva					
Wound infection	—	Localized; local intervention indicated (eg, topical antibiotic, antifungal, or antiviral)	IV antibiotic, antifungal, or antiviral intervention indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an infectious process involving the wound					
Infections and infestations—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *BSA,* body surface area; *IV,* intravenous.

Injury, Poisoning, and Procedural Complications

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Ankle fracture	Mild; nonsurgical intervention indicated	Limiting instrumental ADLs; operative intervention indicated	Limiting self-care ADLs; elective surgery indicated	—	—
Definition: A finding of damage to the ankle joint characterized by a break in the continuity of the ankle bone. Symptoms include marked discomfort, swelling, and difficulty moving the affected leg and foot.					
Aortic injury	—	—	Severe symptoms; limiting self-care ADLs; disabling; repair or revision indicated	Life-threatening consequences; evidence of end-organ damage; urgent operative intervention indicated	Death
Definition: A finding of damage to the aorta					

Continued

Injury, Poisoning, and Procedural Complications—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Arterial injury	Asymptomatic diagnostic finding; intervention not indicated	Symptomatic (eg, claudication); repair or revision not indicated	Severe symptoms; limiting self-care ADLs; disabling; repair or revision indicated	Life-threatening consequences; evidence of end-organ damage; urgent operative intervention indicated	Death
Definition: A finding of damage to an artery					
Biliary anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage of bile caused by breakdown of a biliary anastomosis (surgical connection of two separate anatomic structures)					
Bladder anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage of urine resulting from breakdown of a bladder anastomosis (surgical connection of two separate anatomic structures)					
Bruising	Localized or in a dependent area	Generalized	—	—	—
Definition: A finding of injury of the soft tissues or bone characterized by leakage of blood into surrounding tissues					
Burn	Minimal symptoms; intervention not indicated	Medical intervention; minimal debridement indicated	Moderate to major debridement or reconstruction indicated	Life-threatening consequences	Death
Definition: A finding of impaired integrity to the anatomic site of an adverse thermal reaction. Burns can be caused by exposure to chemicals, direct heat, electricity, flames, and radiation. The extent of damage depends on the length and intensity of exposure and time until provision of treatment.					
Dermatitis radiation	Faint erythema or dry desquamation	Moderate to brisk erythema; patchy moist desquamation, mostly confined to skin folds and creases; moderate edema	Moist desquamation in areas other than skin folds and creases; bleeding induced by minor trauma or abrasion	Life-threatening consequences; skin necrosis or ulceration of full thickness dermis; spontaneous bleeding from involved site; skin graft indicated	Death
Definition: A finding of cutaneous inflammatory reaction occurring as a result of exposure to biologically effective levels of ionizing radiation					
Esophageal anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of an esophageal anastomosis (surgical connection of two separate anatomic structures)					
Fall	Minor with no resultant injuries; intervention not indicated	Symptomatic; noninvasive intervention indicated	Hospitalization indicated	—	—
Definition: A finding of sudden movement downward, usually resulting in injury					
Fallopian tube anastomotic leak	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a fallopian tube anastomosis (surgical connection of two separate anatomic structures)					
Fallopian tube perforation	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic and intervention not indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated (eg, organ resection)	Death
Definition: A finding of rupture of the fallopian tube wall					

Injury, Poisoning, and Procedural Complications—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Fracture	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic but non-displaced; immobilization indicated	Severe symptoms; displaced or open wound with bone exposure; disabling; operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of traumatic injury to the bone in which the continuity of the bone is broken					
Gastric anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a gastric anastomosis (surgical connection of two separate anatomic structures)					
GI anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a GI anastomosis (surgical connection of two separate anatomic structures)					
GI stoma necrosis	—	Superficial necrosis; intervention not indicated	Severe symptoms; hospitalization or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of a necrotic process occurring in the GI tract stoma					
Hip fracture	—	Hairline fracture; mild pain; limiting instrumental ADLs; nonsurgical intervention indicated	Severe pain; hospitalization or intervention indicated for pain control (eg, traction); operative intervention indicated	Life-threatening consequences; symptoms associated with neurovascular compromise	—
Definition: A finding of traumatic injury to the hip in which the continuity of the femoral head, femoral neck, intertrochanteric, or subtrochanteric region is broken					
Injury to carotid artery	—	—	Severe symptoms; limiting self-care ADLs (eg, transient cerebral ischemia); repair or revision indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the carotid artery					
Injury to inferior vena cava	—	—	—	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the inferior vena cava					
Injury to jugular vein	—	—	Symptomatic limiting self-care ADLs; disabling; repair or revision indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the jugular vein					
Injury to superior vena cava	Asymptomatic diagnostic finding; intervention not indicated	Symptomatic; repair or revision not indicated	Severe symptoms; limiting self-care ADLs; disabling; repair or revision indicated	Life-threatening consequences; evidence of end-organ damage; urgent operative intervention indicated	Death
Definition: A finding of damage to the superior vena cava					
Intestinal stoma leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage of contents from an intestinal stoma (surgically created opening on the surface of the body)					

Continued

Injury, Poisoning, and Procedural Complications—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Intestinal stoma obstruction	—	Self-limited; intervention not indicated	Severe symptoms; IV fluids, tube feeding, or TPN indicated ≥24 h; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of blockage of the normal flow of the contents of an intestinal stoma					
Intestinal stoma site bleeding	Minimal bleeding identified on clinical examination; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of blood leakage from an intestinal stoma					
Intraoperative arterial injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to an artery during a surgical procedure					
Intraoperative breast injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the breast parenchyma during a surgical procedure					
Intraoperative cardiac injury	—	—	Primary repair of injured organ or structure indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the heart during a surgical procedure					
Intraoperative ear injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection of injured organ or structure indicated; disabling (eg, impaired hearing; impaired balance)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the ear during a surgical procedure					
Intraoperative endocrine injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the endocrine gland during a surgical procedure					
Intraoperative gastrointestinal injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the GI system during a surgical procedure					
Intraoperative head and neck injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the head and neck during a surgical procedure					
Intraoperative hemorrhage	—	—	Postoperative radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of uncontrolled bleeding during a surgical procedure					
Intraoperative hepatobiliary injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the hepatic parenchyma or biliary tract during a surgical procedure					

Injury, Poisoning, and Procedural Complications—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Intraoperative musculoskeletal injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the musculoskeletal system during a surgical procedure					
Intraoperative neurologic injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the nervous system during a surgical procedure					
Intraoperative ocular injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the eye during a surgical procedure					
Intraoperative renal injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the kidney during a surgical procedure					
Intraoperative reproductive tract injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the reproductive organs during a surgical procedure					
Intraoperative respiratory injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the respiratory system during a surgical procedure					
Intraoperative skin injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the skin during a surgical procedure					
Intraoperative splenic injury	—	Primary repair of injured organ or structure indicated	Resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the spleen during a surgical procedure					
Intraoperative urinary injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to the urinary system during a surgical procedure					
Intraoperative venous injury	Primary repair of injured organ or structure indicated	Partial resection of injured organ or structure indicated	Complete resection or reconstruction of injured organ or structure indicated; disabling	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of damage to a vein during a surgical procedure					
Kidney anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage of urine resulting from breakdown of a kidney anastomosis (surgical connection of two separate anatomic structures)					

Continued

Injury, Poisoning, and Procedural Complications—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Large intestinal anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of an anastomosis (surgical connection of two separate anatomic structures) in the large intestine					
Pancreatic anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a pancreatic anastomosis (surgical connection of two separate anatomic structures)					
Pharyngeal anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a pharyngeal anastomosis (surgical connection of two separate anatomic structures)					
Postoperative hemorrhage	Minimal bleeding identified on clinical examination; intervention not indicated	Moderate bleeding; radiologic, endoscopic, or operative intervention indicated	Transfusion indicated of ≥2 units (10 mL/kg for pediatrics) pRBCs beyond protocol specification; urgent radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of bleeding occurring after a surgical procedure					
Postoperative thoracic procedure complication	—	Extubated within 24–72 h postoperatively	Extubated >72 h postoperatively, but before tracheostomy indicated	Life-threatening airway compromise; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A finding of a previously undocumented problem that occurs after a thoracic procedure					
Prolapse of intestinal stoma	Asymptomatic; reducible	Recurrent after manual reduction; local irritation or stool leakage; difficulty to fit appliance; limiting instrumental ADLs	Severe symptoms; elective operative intervention indicated; limiting self-care ADLs	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of protrusion of the intestinal stoma (surgically created opening on the surface of the body) above the abdominal surface					
Prolapse of urostomy	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Local care or maintenance; minor revision indicated	Dysfunctional stoma; elective operative intervention or major stomal revision indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of displacement of the urostomy					
Radiation recall reaction (dermatologic)	Faint erythema or dry desquamation	Moderate to brisk erythema; patchy moist desquamation, mostly confined to skin folds and creases; moderate edema	Moist desquamation in areas other than skin folds and creases; bleeding induced by minor trauma or abrasion	Life-threatening consequences; skin necrosis or ulceration of full thickness dermis; spontaneous bleeding from involved site; skin graft indicated	Death
Definition: A finding of acute skin inflammatory reaction caused by drugs, especially chemotherapeutic agents, for weeks or months after radiotherapy. The inflammatory reaction is confined to the previously irradiated skin, and the symptoms disappear after the removal of the pharmaceutical agent.					
Rectal anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a rectal anastomosis (surgical connection of two separate anatomic structures)					

Injury, Poisoning, and Procedural Complications—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Seroma	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; simple aspiration indicated	Symptomatic, elective radiologic or operative intervention indicated	—	—
Definition: A finding of tumor-like collection of serum in the tissues					
Small intestinal anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of an anastomosis (surgical connection of two separate anatomic structures) in the small bowel					
Spermatic cord anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a spermatic cord anastomosis (surgical connection of two separate anatomic structures)					
Spinal fracture	Mild back pain; nonprescription analgesics indicated	Moderate back pain; prescription analgesics indicated; limiting instrumental ADLs	Severe back pain; hospitalization or intervention indicated for pain control (eg, vertebroplasty); limiting self-care ADLs; disability	Life-threatening consequences; symptoms associated with neurovascular compromise	Death
Definition: A finding of traumatic injury to the spine in which the continuity of a vertebral bone is broken					
Stenosis of GI stoma	—	Symptomatic; IV fluids indicated <24 h; manual dilation at bedside	Severely altered GI function; tube feeding, TPN, or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of narrowing of the GI stoma (surgically created opening on the surface of the body)					
Stomal ulcer	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; elective operative intervention indicated	—	—
Definition: A disorder characterized by a circumscribed, inflammatory, and necrotic erosive lesion on the jejunal mucosal surface close to the anastomosis site after a gastroenterostomy procedure					
Tracheal hemorrhage	Minimal bleeding identified on clinical or diagnostic examination; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of bleeding from the trachea					
Tracheal obstruction	Partial asymptomatic obstruction on examination (eg, visual, radiologic, or endoscopic)	Symptomatic (eg, noisy airway breathing), no respiratory distress; medical intervention indicated (eg, steroids); limiting instrumental ADLs	Stridor; radiologic or endoscopic intervention indicated (eg, stent, laser); limiting self-care ADLs	Life-threatening airway compromise; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A finding of blockage of the lumen of the trachea.					
Tracheostomy site bleeding	Minimal bleeding identified on clinical examination; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of blood leakage from the tracheostomy site

Adverse Event	**1**	**2**	**3**	**4**	**5**
Ureteric anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a ureteral anastomosis (surgical connection of two separate anatomic structures)					
Urethral anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a urethral anastomosis (surgical connection of two separate anatomic structures)					
Urostomy leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage of contents from a urostomy					
Urostomy obstruction	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; dilation or endoscopic repair or stent placement indicated	Altered organ function (eg, sepsis or hydronephrosis, or renal dysfunction); elective operative intervention indicated	Life-threatening consequences; organ failure; urgent operative intervention indicated	Death
Definition: A finding of blockage of the urostomy					
Urostomy site bleeding	Minimal bleeding identified on clinical examination; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A finding of bleeding from the urostomy site					
Urostomy stenosis	—	Symptomatic but no hydronephrosis, no sepsis or no renal dysfunction; dilation or endoscopic repair or stent placement indicated	Symptomatic (eg, hydronephrosis, or renal dysfunction); elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of narrowing of the opening of a urostomy					
Uterine anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage caused by breakdown of a uterine anastomosis (surgical connection of two separate anatomic structures)					
Uterine perforation	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic and intervention not indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a rupture in the uterine wall					
Vaginal anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a vaginal anastomosis (surgical connection of two separate anatomic structures)					
Vas deferens anastomotic leak	Asymptomatic diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A finding of leakage resulting from breakdown of a vas deferens anastomosis (surgical connection of two separate anatomic structures)					

Injury, Poisoning, and Procedural Complications—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Vascular access complication	—	Device dislodgement, blockage, leak, or malposition; device replacement indicated	Deep vein or cardiac thrombosis; intervention indicated (eg, anticoagulation, lysis, filter, invasive procedure)	Embolic event including pulmonary embolism or life-threatening thrombus	Death
Definition: A finding of a previously undocumented problem related to the vascular access site					
Venous injury	Asymptomatic diagnostic finding; intervention not indicated	Symptomatic (eg, claudication); repair or revision not indicated	Severe symptoms; limiting self-care ADLs; repair or revision indicated; disabling	Life-threatening consequences; evidence of end-organ damage; urgent operative intervention indicated	Death
Definition: A finding of damage to a vein					
Wound complication	Incisional separation of ≤25% of wound, no deeper than superficial fascia	Incisional separation >25% of wound; local care indicated	Hernia without evidence of strangulation; fascial disruption or dehiscence; primary wound closure or revision by operative intervention indicated	Hernia with evidence of strangulation; major reconstruction flap, grafting, resection, or amputation indicated	Death
Definition: A finding of development of a new problem at the site of an existing wound					
Wound dehiscence	Incisional separation of ≤25% of wound, no deeper than superficial fascia	Incisional separation >25% of wound with local care; asymptomatic hernia or symptomatic hernia without evidence of strangulation	Fascial disruption or dehiscence without evisceration; primary wound closure or revision by operative intervention indicated	Life-threatening consequences; symptomatic hernia with evidence of strangulation; fascial disruption with evisceration; major reconstruction flap, grafting, resection, or amputation indicated	Death
Definition: A finding of separation of the approximated margins of a surgical wound					
Wrist fracture	Mild; nonsurgical intervention indicated	Limiting instrumental ADLs; operative intervention indicated	Limiting self-care ADLs; elective surgery indicated	—	—
Definition: A finding of traumatic injury to the wrist joint in which the continuity of a wrist bone is broken					
Injury, poisoning and procedural complications—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *GI,* gastrointestinal; *pRBC,* packed red blood cell; *TPN,* total parenteral nutrition.

Investigations

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Activated partial thromboplastin time prolonged	>ULN–1.5 × ULN	>1.5–2.5 × ULN	>2.5 × ULN; hemorrhage	—	—
Definition: An abnormal laboratory test result in which the partial thromboplastin time is found to be greater than the control value. As a possible indicator of coagulopathy, a prolonged partial thromboplastin time may occur in a variety of diseases and disorders, both primary and related to treatment.					

Continued

Investigations—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Alanine aminotransferase increased	>ULN–3.0 × ULN	>3.0–5.0 × ULN	>5.0–20.0 × ULN	>20.0 × ULN	—
Definition: A finding based on laboratory test results that indicate an increase in the level of alanine aminotransferase (ALT or SGPT) in the blood specimen					
Alkaline phosphatase increased	>ULN–2.5 × ULN	>2.5–5.0 × ULN	>5.0–20.0 × ULN	>20.0 × ULN	—
Definition: A finding based on laboratory test results that indicate an increase in the level of alkaline phosphatase in a blood specimen					
Aspartate aminotransferase increased	>ULN–3.0 × ULN	>3.0–5.0 × ULN	>5.0–20.0 × ULN	>20.0 × ULN	—
Definition: A finding based on laboratory test results that indicate an increase in the level of aspartate aminotransferase (AST or SGOT) in a blood specimen					
Blood antidiuretic hormone abnormal	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Hospitalization indicated	—	—
Definition: A finding based on laboratory test results that indicate abnormal levels of antidiuretic hormone in the blood specimen					
Blood bilirubin increased	>ULN–1.5 × ULN	>1.5–3.0 × ULN	>3.0–10.0 × ULN	>10.0 × ULN	—
Definition: A finding based on laboratory test results that indicate an abnormally high level of bilirubin in the blood. Excess bilirubin is associated with jaundice.					
Blood corticotrophin decreased	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Hospitalization indicated	—	—
Definition: A finding based on laboratory test results that indicate a decrease in levels of corticotrophin in a blood specimen					
Blood gonadotrophin abnormal	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A finding based on laboratory test results that indicate abnormal levels of gonadotrophin hormone in a blood specimen					
Blood prolactin abnormal	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	—	—	—
Definition: A finding based on laboratory test results that indicate abnormal levels of prolactin hormone in a blood specimen					
Carbon monoxide diffusing capacity decreased	3–5 units below LLN; for follow-up, a decrease of 3–5 units (mL/min/mm Hg) below the baseline value	6–8 units below LLN; for follow-up, an asymptomatic decrease of >5–8 units (mL/min/mm Hg) below the baseline value	Asymptomatic decrease of >8 units drop; >5 units drop along with the presence of pulmonary symptoms (eg, >grade 2 hypoxia or ≥grade 2 dyspnea)	—	—
Definition: A finding based on lung function test results that indicate a decrease in the lung capacity to absorb carbon monoxide					
Cardiac troponin I increased	Levels above the ULN and below the level of myocardial infarction as defined by the manufacturer	—	Levels consistent with myocardial infarction as defined by the manufacturer	—	—
Definition: A laboratory test result that indicates increased levels of cardiac troponin I in a biological specimen					
Cardiac troponin T increased	Levels above the ULN and below the level of myocardial infarction as defined by the manufacturer	—	Levels consistent with myocardial infarction as defined by the manufacturer	—	—
Definition: A laboratory test result that indicates increased levels of cardiac troponin T in a biological specimen					
CD4 lymphocytes decreased	<LLN-500/mm^3; <LLN-0.5 × 10^9/L	<500–200/mm^3; <0.5–0.2 × 10^9/L	<200–50/mm^3; <0.2 × 0.05–10^9/L	<50/mm^3; <0.05 × 10^9/L	—
Definition: A finding based on laboratory test results that indicate a decrease in levels of CD4 lymphocytes in a blood specimen					

Investigations—cont'd

Adverse Event	Grade 1	2	3	4	5
Cholesterol high	>ULN–300 mg/dL; >ULN–7.75 mmol/L	>300–400 mg/dL; >7.75–10.34 mmol/L	>400–500 mg/dL; >10.34–12.92 mmol/L	>500 mg/dL; >12.92 mmol/L	—
Definition: A finding based on laboratory test results that indicate higher-than-normal levels of cholesterol in a blood specimen					
CPK increased	>ULN–2.5 × ULN	>2.5 × ULN–5 × ULN	>5 × ULN–10 × ULN	>10 × ULN	—
Definition: A finding based on laboratory test results that indicate an increase in levels of creatine phosphokinase in a blood specimen					
Creatinine increased	>1–1.5 × baseline; >ULN–1.5 × ULN	>1.5–3.0 × baseline; >1.5–3.0 × ULN	>3.0 baseline; >3.0–6.0 × ULN	>6.0 × ULN	—
Definition: A finding based on laboratory test results that indicate increased levels of creatinine in a biological specimen					
Ejection fraction decreased	—	Resting ejection fraction 50%–40%; 10%–19% drop from baseline	Resting ejection fraction 39%–20%; >20% drop from baseline	Resting ejection fraction <20%	—
Definition: The percentage computed when the amount of blood ejected during a ventricular contraction of the heart is compared with the amount that was present before the contraction					
ECG QT corrected interval prolonged	QTc 450–480 ms	QTc 481–500 ms	QTc ≥ 501 ms on at least two separate ECGs	QTc ≥ 501 or >60 ms change from baseline and torsades de pointes or polymorphic ventricular tachycardia or signs or symptoms of serious arrhythmia	—
Definition: A finding of a cardiac dysrhythmia characterized by an abnormally long corrected QT interval					
Fibrinogen decreased	<1.0–0.75 × LLN or <25% decrease from baseline	<0.75–0.5 × LLN or 25%–<50% decrease from baseline	<0.5–0.25 × LLN or 50%–<75% decrease from baseline	<0.25 × LLN or 75% decrease from baseline or absolute value <50 mg/dL	—
Definition: A finding based on laboratory test results that indicate a decrease in levels of fibrinogen in a blood specimen					
FEV decreased	FEV_1% (percentages of observed FEV_1 and FVC related to their respective predicted values) 99%–70% predicted	FEV_1 60%–69%	50%–59%	≤49%	—
Definition: A finding based on test results that indicate a relative decrease in the fraction of the forced vital capacity that is exhaled in a specific number of seconds					
Gamma-glutamyl transferase increased	>ULN–2.5 × ULN	>2.5–5.0 × ULN	>5.0–20.0 × ULN	>20.0 × ULN	—
Definition: A finding based on laboratory test results that indicate higher-than-normal levels of the enzyme gamma-glutamyltransferase in the blood specimen. Gamma-glutamyltransferase catalyzes the transfer of a gamma glutamyl group from a gamma-glutamyl peptide to another peptide, amino acids, or water.					
Growth hormone abnormal	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated; limiting instrumental ADLs	—	—	—
Definition: A finding based on laboratory test results that indicate abnormal levels of growth hormone in a biologic specimen					
Haptoglobin decreased	<LLN	—	—	—	—
Definition: A finding based on laboratory test results that indicate a decrease in levels of haptoglobin in a blood specimen					
Hemoglobin increased	Increase in >0–2 g/dL above ULN or above baseline if baseline is above ULN	Increase in >2–4 g/dL above ULN or above baseline if baseline is above ULN	Increase in >4 g/dL above ULN or above baseline if baseline is above ULN	—	—
Definition: A finding based on laboratory test results that indicate increased levels of hemoglobin in a biological specimen					
INR increased	>1–1.5 × ULN; >1–1.5 times above baseline if on anticoagulation	>1.5–2.5 × ULN; >1.5–2.5 times above baseline if on anticoagulation	>2.5 × ULN; >2.5 times above baseline if on anticoagulation	—	—
Definition: A finding based on laboratory test results that indicate an increase in the ratio of the patient's prothrombin time to a control sample in the blood					
Lipase increased	>ULN–1.5 × ULN	>1.5–2.0 × ULN	>2.0–5.0 × ULN	>5.0 × ULN	—
Definition: A finding based on laboratory test results that indicate an increase in the level of lipase in a biological specimen

Investigations—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Lymphocyte count decreased	<LLN-800/mm^3; <LLN-0.8 × 10^9/L	<800–500/mm^3; <0.8–0.5 ×10^9/L	<500–200/mm^3; <0.5–0.2 × 10^9/L	<200/mm^3; <0.2 × 10^9/L	—
Definition: A finding based on laboratory test results that indicate a decrease in number of lymphocytes in a blood specimen					
Lymphocyte count increased	—	>4000/mm^3–20,000/mm^3	>20,000/mm^3	—	—
Definition: A finding based on laboratory test results that indicate an abnormal increase in the number of lymphocytes in the blood, effusions or bone marrow					
Neutrophil count decreased	<LLN-1500/mm^3; <LLN-1.5 × 10^9/L	<1500–1000/mm^3; <1.5–1.0 × 10^9/L	<1000–500/mm^3; <1.0–0.5 × 10^9/L	<500/mm^3; <0.5 × 10^9/L	—
Definition: A finding based on laboratory test results that indicate a decrease in number of neutrophils in a blood specimen					
Pancreatic enzymes decreased	<LLN and asymptomatic	Increase in stool frequency, bulk, or odor; steatorrhea	Sequelae of absorption deficiency	—	—
Definition: A finding based on laboratory test results that indicate a decrease in levels of pancreatic enzymes in a biological specimen					
Platelet count decreased	<LLN-75,000/mm^3; <LLN-75.0 × 10^9/L	<75,000–50,000/mm^3; <75.0–50.0 × 10^9/L	<50,000–25,000/mm^3; <50.0–25.0 × 10^9/L	<25,000/mm^3; <25.0 × 10^9/L	—
Definition: A finding based on laboratory test results that indicate a decrease in number of platelets in a blood specimen					
Serum amylase increased	>ULN–1.5 × ULN	>1.5–2.0 × ULN	>2.0–5.0 × ULN	>5.0 × ULN	—
Definition: A finding based on laboratory test results that indicate an increase in the levels of amylase in a serum specimen					
Urine output decreased	—	—	Oliguria (<80 mL in 8 h)	Anuria (<240 mL in 24 h)	—
Definition: A finding based on test results that indicate urine production is less relative to previous output					
Vital capacity abnormal	90%–75% of predicted value	<75%–50% of predicted value; limiting instrumental ADLs	<50% of predicted value; limiting self-care ADLs	—	—
Definition: A finding based on pulmonary function test results that indicate an abnormal vital capacity (amount of exhaled after a maximum inhalation) when compared with the predicted value					
Weight gain	5%–<10% from baseline	10%–<20% from baseline	≥20% from baseline	—	—
Definition: A finding characterized by an increase in overall body weight; for pediatrics, greater than the baseline growth curve					
Weight loss	5%–<10% from baseline; intervention not indicated	10%–<20% from baseline; nutritional support indicated	≥20% from baseline; tube feeding or TPN indicated	—	—
Definition: A finding characterized by a decrease in overall body weight; for pediatrics, less than the baseline growth curve					
White blood cell decreased	<LLN-3000/mm^3; <LLN-3.0 × 10^9/L	<3000–2000/mm^3; <3.0–2.0 × 10^9/L	<2000–1000/mm^3; <2.0–1.0 × 10^9/L	<1000/mm^3; <1.0 × 10^9/L	—
Definition: A finding based on laboratory test results that indicate a decrease in number of white blood cells in a blood specimen					
Investigations—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *CPK,* creatine phosphokinase; *ECG,* electrocardiogram; *FEV,* forced expiratory volume; *FVC,* forced vital capacity; *INR,* international normalized ratio; *LLN,* lower limit of normal; *ULN,* upper limit of normal.

Metabolism and Nutrition Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Acidosis	pH < normal, but ≥7.3	—	pH <7.3	Life-threatening consequences	Death
Definition: A disorder characterized by abnormally high acidity (high hydrogen-ion concentration) of the blood and other body tissues					
Alcohol intolerance	—	Present	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an increase in sensitivity to the adverse effects of alcohol, which can include nasal congestion, skin flushes, heart dysrhythmias, nausea, vomiting, indigestion, and headaches					

Metabolism and Nutrition Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Alkalosis	pH > normal, but ≤7.5	—	pH >7.5	Life-threatening consequences	Death
Definition: A disorder characterized by abnormally high alkalinity (low hydrogen ion concentration) of the blood and other body tissues					
Anorexia	Loss of appetite without alteration in eating habits	Oral intake altered without significant weight loss or malnutrition; oral nutritional supplements indicated	Associated with significant weight loss or malnutrition (eg, inadequate oral caloric and/or fluid intake); tube feeding or TPN indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a loss of appetite					
Dehydration	Increased oral fluids indicated; dry mucous membranes; diminished skin turgor	IV fluids indicated <24 h	IV fluids or hospitalization indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by excessive loss of water from the body. It is usually caused by severe diarrhea, vomiting, or diaphoresis.					
Glucose intolerance	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; dietary modification or oral agent indicated	Severe symptoms; insulin indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an inability to properly metabolize glucose					
Hypercalcemia	Corrected serum calcium of >ULN–11.5 mg/dL; >ULN–2.9 mmol/L; ionized calcium >ULN–1.5 mmol/L	Corrected serum calcium of >11.5–12.5 mg/dL; >2.9–3.1 mmol/L; ionized calcium >1.5–1.6 mmol/L; symptomatic	Corrected serum calcium of >12.5–13.5 mg/dL; >3.1–3.4 mmol/L; ionized calcium >1.6–1.8 mmol/L; hospitalization indicated	Corrected serum calcium of >13.5 mg/dL; >3.4 mmol/L; ionized calcium >1.8 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate an elevation in the concentration of calcium (corrected for albumin) in blood					
Hyperglycemia	Fasting glucose value >ULN–160 mg/dL; Fasting glucose value >ULN–8.9 mmol/L	Fasting glucose value >160–250 mg/dL; Fasting glucose value >8.9–13.9 mmol/L	>250–500 mg/dL; >13.9–27.8 mmol/L; hospitalization indicated	>500 mg/dL; >27.8 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate an elevation in the concentration of blood sugar. It is usually an indication of diabetes mellitus or glucose intolerance.					
Hyperkalemia	>ULN–5.5 mmol/L	>5.5–6.0 mmol/L	>6.0–7.0 mmol/L; hospitalization indicated	>7.0 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate an elevation in the concentration of potassium in the blood; associated with kidney failure or sometimes with the use of diuretic drugs					
Hypermagnesemia	>ULN–3.0 mg/dL; >ULN–1.23 mmol/L	—	>3.0–8.0 mg/dL; >1.23–3.30 mmol/L	>8.0 mg/dL; >3.30 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate an elevation in the concentration of magnesium in the blood					
Hypernatremia	>ULN–150 mmol/L	>150–155 mmol/L	>155–160 mmol/L; hospitalization indicated	>160 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate an elevation in the concentration of sodium in the blood					
Hypertriglyceridemia	150–300 mg/dL; 1.71–3.42 mmol/L	>300–500 mg/dL; >3.42–5.7 mmol/L	>500–1000 mg/dL; >5.7–11.4 mmol/L	>1000 mg/dL; >11.4 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate an elevation in the concentration of triglyceride concentration in the blood					
Hyperuricemia	>ULN–10 mg/dL (0.59 mmol/L) without physiologic consequences	—	>ULN–10 mg/dL (0.59 mmol/L) with physiologic consequences	>10 mg/dL; >0.59 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate an elevation in the concentration of uric acid					

Continued

Metabolism and Nutrition Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Hypoalbuminemia	<LLN–3 g/dL; <LLN–30 g/L	<3–2 g/dL; <30–20 g/L	<2 g/dL; <20 g/L	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by laboratory test results that indicate a low concentration of albumin in the blood					
Hypocalcemia	Corrected serum calcium of <LLN–8.0 mg/dL; <LLN–2.0 mmol/L; Ionized calcium <LLN–1.0 mmol/L	Corrected serum calcium of <8.0–7.0 mg/dL; <2.0–1.75 mmol/L; Ionized calcium <1.0–0.9 mmol/L; symptomatic	Corrected serum calcium of <7.0–6.0 mg/dL; <1.75–1.5 mmol/L; Ionized calcium <0.9–0.8 mmol/L; hospitalization indicated	Corrected serum calcium of <6.0 mg/dL; <1.5 mmol/L; Ionized calcium <0.8 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate a low concentration of calcium (corrected for albumin) in the blood					
Hypoglycemia	<LLN–55 mg/dL; <LLN–3.0 mmol/L	<55–40 mg/dL; <3.0–2.2 mmol/L	<40–30 mg/dL; <2.2–1.7 mmol/L	<30 mg/dL; <1.7 mmol/L; life-threatening consequences; seizures	Death
Definition: A disorder characterized by laboratory test results that indicate a low concentration of glucose in the blood					
Hypokalemia	<LLN–3.0 mmol/L	<LLN–3.0 mmol/L; symptomatic; intervention indicated	<3.0–2.5 mmol/L; hospitalization indicated	<2.5 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate a low concentration of potassium in the blood					
Hypomagnesemia	<LLN–1.2 mg/dL; <LLN–0.5 mmol/L	<1.2–0.9 mg/dL; <0.5–0.4 mmol/L	<0.9–0.7 mg/dL; <0.4–0.3 mmol/L	<0.7 mg/dL; <0.3 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate a low concentration of magnesium in the blood					
Hyponatremia	<LLN–130 mmol/L	—	<130–120 mmol/L	<120 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate a low concentration of sodium in the blood					
Hypophosphatemia	<LLN–2.5 mg/dL; <LLN–0.8 mmol/L	<2.5–2.0 mg/dL; <0.8–0.6 mmol/L	<2.0–1.0 mg/dL; <0.6–0.3 mmol/L	<1.0 mg/dL; <0.3 mmol/L; life-threatening consequences	Death
Definition: A disorder characterized by laboratory test results that indicate a low concentration of phosphates in the blood					
Iron overload	—	Moderate symptoms; intervention not indicated	Severe symptoms; intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by accumulation of iron in the tissues					
Obesity	—	BMI 25–29.9 kg/m^2	BMI 30–39.9 kg/m^2	BMI ≥40 kg/m^2	—
Definition: A disorder characterized by having a high amount of body fat					
Tumor lysis syndrome	—	—	Present	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by metabolic abnormalities that result from a spontaneous or therapy-related cytolysis of tumor cells					
Metabolism and nutrition disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *BMI,* body mass index; *IV,* intravenous; *LLN,* lower limit of normal; *TPN,* total parenteral nutrition; *ULN,* upper limits of normal.

Musculoskeletal and Connective Tissue Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Abdominal soft tissue necrosis	—	Local wound care; medical intervention indicated (eg, dressings or topical medications)	Operative debridement or other invasive intervention indicated (eg, tissue reconstruction, flap, or grafting)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the soft tissues of the abdominal wall					
Arthralgia	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in a joint					
Arthritis	Mild pain with inflammation, erythema, or joint swelling	Moderate pain associated with signs of inflammation, erythema, or joint swelling; limiting instrumental ADLs	Severe pain associated with signs of inflammation, erythema, or joint swelling; irreversible joint damage; disabling; limiting self-care ADLs	—	—
Definition: A disorder characterized by inflammation involving a joint					
Avascular necrosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by necrotic changes in the bone tissue caused by interruption of blood supply most often affecting the epiphysis of the long bones, the necrotic changes result in the collapse, and the destruction of the bone structure					
Back pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the back region					
Bone pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the bones					
Buttock pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the buttocks					
Chest wall pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the chest wall region					
Exostosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; elective operative intervention indicated	—	—
Definition: A disorder characterized by nonneoplastic overgrowth of bone					
Fibrosis deep connective tissue	Mild induration, able to move skin parallel to plane (sliding) and perpendicular to skin (pinching up)	Moderate induration, able to slide skin, unable to pinch skin; limiting instrumental ADLs	Severe induration; unable to slide or pinch skin; limiting joint or orifice movement (eg, mouth, anus); limiting self-care ADLs	Generalized; associated with signs or symptoms of impaired breathing or feeding	Death
Definition: A disorder characterized by fibrotic degeneration of the deep connective tissues					
Flank pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation on the lateral side of the body in the region below the ribs and above the hip					
Generalized muscle weakness	Symptomatic; weakness perceived by patient but not evident on physical examination	Symptomatic; weakness evident on physical examination; weakness limiting instrumental ADLs	Weakness limiting self-care ADLs; disabling	—	—
Definition: A disorder characterized by a reduction in the strength of muscles in multiple anatomic sites					

Continued

Musculoskeletal and Connective Tissue Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Growth suppression	Reduction in growth velocity by 10%–29% ideally measured over the period of a year	Reduction in growth velocity by 30%–49% ideally measured over the period of a year or 0%–49% reduction in growth from the baseline growth curve	Reduction in growth velocity of ≥50% ideally measured over the period of 1 year	—	—
Definition: A disorder characterized by of stature that is smaller than normal as expected for age					
Head soft tissue necrosis	—	Local wound care; medical intervention indicated (eg, dressings or topical medications)	Operative debridement or other invasive intervention indicated (eg, tissue reconstruction, flap, or grafting)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the soft tissues of the head					
Joint effusion	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; elective operative intervention indicated; disabling	—	—
Definition: A disorder characterized by excessive fluid in a joint, usually as a result of joint inflammation					
Joint range of motion decreased	≤25% loss of ROM; decreased ROM limiting athletic activity	>25%–50% decrease in ROM; limiting instrumental ADLs	>50% decrease in ROM; limiting self-care ADLs; disabling	—	—
Definition: A disorder characterized by a decrease in joint flexibility of any joint					
Joint ROM decreased: cervical spine	Mild restriction of rotation or flexion between 60 and 70 degrees	Rotation <60 degrees to right or left; <60 degrees of flexion	Ankylosed or fused over multiple segments with no C-spine rotation	—	—
Definition: A disorder characterized by a decrease in flexibility of a cervical spine joint					
Joint ROM decreased: lumbar spine	Stiffness; difficulty bending to the floor to pick up a very light object but able to do athletic activity	Pain with ROM in lumbar spine; requires a reaching aid to pick up a very light object from the floor	<50% lumbar spine flexion; associated with symptoms of ankylosis or fused over multiple segments with no L-spine flexion (eg, unable to reach to floor to pick up a very light object)	—	—
Definition: A disorder characterized by a decrease in flexibility of a lumbar spine joint					
Kyphosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate accentuation; limiting instrumental ADLs	Severe accentuation; operative intervention indicated; limiting self-care ADLs	—	—
Definition: A disorder characterized by an abnormal increase in the curvature of the thoracic portion of the spine					
Lordosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate accentuation; limiting instrumental ADLs	Severe accentuation; operative intervention indicated; limiting self-care ADLs	—	—
Definition: A disorder characterized by an abnormal increase in the curvature of the lumbar portion of the spine					
Muscle weakness: left sided	Symptomatic; perceived by patient but not evident on physical examination	Symptomatic; evident on physical examination; limiting instrumental ADLs	Limiting self-care ADLs; disabling	—	—
Definition: A disorder characterized by a reduction in the strength of the muscles on the left side of the body					
Muscle weakness: lower limb	Symptomatic; perceived by patient but not evident on physical examination	Symptomatic; evident on physical examination; limiting instrumental ADLs	Limiting self-care ADLs; disabling	—	—
Definition: A disorder characterized by a reduction in the strength of the lower limb muscles					

Musculoskeletal and Connective Tissue Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Muscle weakness: right sided	Symptomatic; perceived by patient but not evident on physical examination	Symptomatic; evident on physical examination; limiting instrumental ADLs	Limiting self-care ADLs; disabling	—	—
Definition: A disorder characterized by a reduction in the strength of the muscles on the right side of the body					
Muscle weakness: trunk	Symptomatic; perceived by patient but not evident on physical examination	Symptomatic; evident on physical examination; limiting instrumental ADLs	Limiting self-care ADLs; disabling	—	—
Definition: A disorder characterized by a reduction in the strength of the trunk muscles					
Muscle weakness: upper limb	Symptomatic; perceived by patient but not evident on physical examination	Symptomatic; evident on physical examination; limiting instrumental ADLs	Limiting self-care ADLs; disabling	—	—
Definition: A disorder characterized by a reduction in the strength of the upper limb muscles					
Musculoskeletal deformity	Cosmetically and functionally insignificant hypoplasia	Deformity, hypoplasia, or asymmetry able to be remediated by prosthesis (eg, shoe insert) or covered by clothing	Significant deformity, hypoplasia, or asymmetry, unable to be remediated by prosthesis or covered by clothing; disabling	—	—
Definition: A disorder characterized by of a malformation of the musculoskeletal system					
Myalgia	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation originating from a muscle or group of muscles					
Myositis	Mild pain	Moderate pain associated with weakness; pain limiting instrumental ADLs	Pain associated with severe weakness; limiting self-care ADLs	—	—
Definition: A disorder characterized by inflammation involving the skeletal muscles					
Neck pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the neck area					
Neck soft tissue necrosis	—	Local wound care; medical intervention indicated (eg, dressings or topical medications)	Operative debridement or other invasive intervention indicated (eg, tissue reconstruction, flap, or grafting)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the soft tissues of the neck					
Osteonecrosis of jaw	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated (eg, topical agents); limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the bone of the mandible					
Osteoporosis	Radiologic evidence of osteoporosis or BMD t-score –1 to –2.5 (osteopenia); no loss of height or intervention indicated	BMD t-score <–2.5; loss of height <2 cm; antiosteoporotic therapy indicated; limiting instrumental ADLs	Loss of height ≥2 cm; hospitalization indicated; limiting self-care ADLs	—	—
Definition: A disorder characterized by reduced bone mass, with a decrease in cortical thickness and in the number and size of the trabeculae of cancellous bone (but normal chemical composition), resulting in increased fracture incidence					
Pain in extremity	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the upper or lower extremities					
Pelvic soft tissue necrosis	—	Local wound care; medical intervention indicated (eg, dressings or topical medications)	Operative debridement or other invasive intervention indicated (eg, tissue reconstruction, flap or grafting)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the soft tissues of the pelvis					

Continued

Musculoskeletal and Connective Tissue Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Scoliosis	<20 degrees; clinically undetectable	>20–45 degrees; visible by forward flexion; limiting instrumental ADLs	>45 degrees; scapular prominence in forward flexion; operative intervention indicated; limiting self-care ADLs; disabling	—	—
Definition: A disorder characterized by a malformed, lateral curvature of the spine					
Soft tissue necrosis: lower limb	—	Local wound care; medical intervention indicated (eg, dressings or topical medications)	Operative debridement or other invasive intervention indicated (eg, tissue reconstruction, flap, or grafting)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the soft tissues of the lower extremity					
Soft tissue necrosis: upper limb	—	Local wound care; medical intervention indicated (eg, dressings or topical medications)	Operative debridement or other invasive intervention indicated (eg, tissue reconstruction, flap, or grafting)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the soft tissues of the upper extremity					
Superficial soft tissue fibrosis	Mild induration, able to move skin parallel to plane (sliding) and perpendicular to skin (pinching up)	Moderate induration, able to slide skin, unable to pinch skin; limiting instrumental ADLs	Severe induration; unable to slide or pinch skin; limiting joint or orifice movement (eg, mouth, anus); limiting self-care ADLs	Generalized; associated with signs or symptoms of impaired breathing or feeding	Death
Definition: A disorder characterized by fibrotic degeneration of the superficial soft tissues					
Trismus	Decreased ROM (range of motion) without impaired eating	Decreased ROM requiring small bites, soft foods or purees	Decreased ROM with inability to adequately aliment or hydrate orally	—	—
Definition: A disorder characterized by lack of ability to open the mouth fully as a result of a decrease in the range of motion of the muscles of mastication					
Unequal limb length	Mild length discrepancy <2 cm	Moderate length discrepancy 2–5 cm; shoe lift indicated; limiting instrumental ADLs	Severe length discrepancy >5 cm; limiting self-care ADLs; disabling; operative intervention indicated	—	—
Definition: A disorder characterized by of a discrepancy between the lengths of the lower or upper extremities					
Musculoskeletal and connective tissue disorder—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *BMD,* bone mineral density; *ROM,* range of motion.

Neoplasms: Benign, Malignant, and Unspecified (Including Cysts and Polyps)

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Leukemia secondary to oncology chemotherapy	—	—	—	Present	Death
Definition: A disorder characterized by leukemia arising as a result of the mutagenic effect of chemotherapy agents					
Myelodysplastic syndrome	—	—	—	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by insufficiently healthy hematopoietic cell production by the bone marrow					
Treatment-related secondary malignancy	—	—	Non–life-threatening secondary malignancy	Acute life-threatening secondary malignancy; blast crisis in leukemia	Death
Definition: A disorder characterized by development of a malignancy most probably as a result of treatment for a previously existing malignancy					
Tumor pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort from a neoplasm that may be pressing on a nerve, blocking blood vessels, inflamed, or fractured from metastasis					
Neoplasms, benign, malignant, and unspecified (including cysts and polyps)—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living.

Nervous System Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Abducens nerve disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by involvement of the abducens nerve (6th cranial nerve)					
Accessory nerve disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by involvement of the accessory nerve (11th cranial nerve)					
Acoustic nerve disorder: not otherwise specified	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by involvement of the acoustic nerve (8th cranial nerve)					
Akathisia	Mild restlessness or increased motor activity	Moderate restlessness or increased motor activity; limiting instrumental ADLs	Severe restlessness or increased motor activity; limiting self-care ADLs	—	—
Definition: A disorder characterized by an uncomfortable feeling of inner restlessness and inability to stay still; this is a side effect of some psychotropic drugs					
Amnesia	Mild; transient memory loss	Moderate; short-term memory loss; limiting instrumental ADLs	Severe; long-term memory loss; limiting self-care ADLs	—	—
Definition: A disorder characterized by systematic and extensive loss of memory					

Continued

Nervous System Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Aphonia	—	—	Voicelessness; unable to speak	—	—
Definition: A disorder characterized by the inability to speak. It may result from injuries to the vocal cords or may be functional (psychogenic).					
Arachnoiditis	Mild symptoms	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation of the arachnoid membrane and adjacent subarachnoid space					
Ataxia	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; mechanical assistance indicated	—	—
Definition: A disorder characterized by lack of coordination of muscle movements resulting in the impairment or inability to perform voluntary activities					
Brachial plexopathy	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by regional paresthesia of the brachial plexus, marked discomfort and muscle weakness, and limited movement in the arm or hand					
Central nervous system necrosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; corticosteroids indicated	Severe symptoms; medical intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the brain, spinal cord, or both					
Cerebrospinal fluid leakage	Postcraniotomy: asymptomatic; postlumbar puncture: transient headache; postural care indicated	Postcraniotomy: moderate symptoms; medical intervention indicated; postlumbar puncture: persistent moderate symptoms; blood patch indicated	Severe symptoms; medical intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by loss of cerebrospinal fluid into the surrounding tissues					
Cognitive disturbance	Mild cognitive disability; not interfering with work, school, or life performance; specialized educational services or devices not indicated	Moderate cognitive disability; interfering with work, school, or life performance but capable of independent living; specialized resources on part time basis indicated	Severe cognitive disability; significant impairment of work, school, or life performance	—	—
Definition: A disorder characterized by a conspicuous change in cognitive function					
Concentration impairment	Mild inattention or decreased level of concentration	Moderate impairment in attention or decreased level of concentration; limiting instrumental ADLs	Severe impairment in attention or decreased level of concentration; limiting self-care ADLs	—	—
Definition: A disorder characterized by a deterioration in the ability to concentrate					
Depressed level of consciousness	Decreased level of alertness	Sedation; slow response to stimuli; limiting instrumental ADLs	Difficult to arouse	Life-threatening consequences	Death
Definition: A disorder characterized by a decrease in ability to perceive and respond					
Dizziness	Mild unsteadiness or sensation of movement	Moderate unsteadiness or sensation of movement; limiting instrumental ADLs	Severe unsteadiness or sensation of movement; limiting self-care ADLs	—	—
Definition: A disorder characterized by a disturbing sensation of lightheadedness, unsteadiness, giddiness, spinning, or rocking					
Dysarthria	Mild slurred speech	Moderate impairment of articulation or slurred speech	Severe impairment of articulation or slurred speech	—	—
Definition: A disorder characterized by slow and slurred speech resulting from an inability to coordinate the muscles used in speech					

Nervous System Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Dysesthesia	Mild sensory alteration	Moderate sensory alteration; limiting instrumental ADLs	Severe sensory alteration; limiting self-care ADLs	—	—
Definition: A disorder characterized by distortion of sensory perception, resulting in an abnormal and unpleasant sensation					
Dysgeusia	Altered taste but no change in diet	Altered taste with change in diet (eg, oral supplements); noxious or unpleasant taste; loss of taste	—	—	—
Definition: A disorder characterized by abnormal sensual experience with the taste of foodstuffs; it can be related to a decrease in the sense of smell					
Dysphasia	Awareness of receptive or expressive characteristics; not impairing ability to communicate	Moderate receptive or expressive characteristics; impairing ability to communicate spontaneously	Severe receptive or expressive characteristics; impairing ability to read, write, or communicate intelligibly	—	—
Definition: A disorder characterized by impairment of verbal communication skills, often resulting from brain damage					
Edema, cerebral	—	—	—	Life-threatening consequences; urgent intervention indicated	—
Definition: A disorder characterized by swelling resulting from an excessive accumulation of fluid in the brain					
Encephalopathy	Mild symptoms	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a pathologic process involving the brain					
Extrapyramidal disorder	Mild involuntary movements	Moderate involuntary movements; limiting instrumental ADLs	Severe involuntary movements or torticollis; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by abnormal, repetitive, involuntary muscle movements, frenzied speech, and extreme restlessness					
Facial muscle weakness	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by a reduction in the strength of the facial muscles					
Facial nerve disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by involvement of the facial nerve (seventh cranial nerve)					
Glossopharyngeal nerve disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by involvement of the glossopharyngeal nerve (ninth cranial nerve)					
Headache	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in various parts of the head, not confined to the area of distribution of any nerve					
Hydrocephalus	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; intervention not indicated	Severe symptoms or neurologic deficit; intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal increase of cerebrospinal fluid in the ventricles of the brain					
Hypersomnia	Mild increased need for sleep	Moderate increased need for sleep	Severe increased need for sleep	—	—
Definition: A disorder characterized by characterized by excessive sleepiness during the daytime					

Continued

Nervous System Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Hypoglossal nerve disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by involvement of the hypoglossal nerve (12th cranial nerve)					
Intracranial hemorrhage	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; medical intervention indicated	Ventriculostomy, ICP monitoring, intraventricular thrombolysis, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the cranium					
Ischemia, cerebrovascular	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms	—	—	—
Definition: A disorder characterized by a decrease or absence of blood supply to the brain caused by obstruction (thrombosis or embolism) of an artery resulting in neurologic damage.					
Fourth nerve disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by involvement of the trochlear nerve (fourth cranial nerve)					
Lethargy	Mild symptoms; reduced alertness and awareness	Moderate symptoms; limiting instrumental ADLs	—	—	—
Definition: A disorder characterized by a decrease in consciousness characterized by mental and physical inertness					
Leukoencephalopathy	Asymptomatic; small focal T2/FLAIR hyperintensities; involving periventricular white matter or <1/3 of susceptible areas of cerebrum ± mild increase SAS or mild ventriculomegaly	Moderate symptoms; focal T2/FLAIR hyperintensities, involving periventricular white matter extending into centrum semiovale or involving 1/3 to 2/3 of susceptible areas of cerebrum ± moderate increase in SAS or moderate ventriculomegaly	Severe symptoms; extensive T2/FLAIR hyperintensities, involving periventricular white matter involving 2/3 or more of susceptible areas of cerebrum ± moderate to severe increase in SAS or moderate to severe ventriculomegaly	Life-threatening consequences; extensive T2/FLAIR hyperintensities, involving periventricular white matter involving most of susceptible areas of cerebrum ± moderate to severe increase in SAS or moderate to severe ventriculomegaly	Death
Definition: A disorder characterized by diffuse reactive astrocytosis with multiple areas of necrotic foci without inflammation					
Memory impairment	Mild memory impairment	Moderate memory impairment; limiting instrumental ADLs	Severe memory impairment; limiting self-care ADLs	—	—
Definition: A disorder characterized by a deterioration in memory function					
Meningismus	Mild symptoms	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by neck stiffness, headache, and photophobia resulting from irritation of the cerebral meninges					
Movements: involuntary	Mild symptoms	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by uncontrolled and purposeless movements					
Myelitis	Asymptomatic; mild signs (eg, Babinski reflex or Lhermitte sign)	Moderate weakness or sensory loss; limiting instrumental ADLs	Severe weakness or sensory loss; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation involving the spinal cord. Symptoms include weakness, paresthesia, sensory loss, marked discomfort and incontinence.					

Nervous System Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Neuralgia	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by intense painful sensation along a nerve or group of nerves					
Nystagmus	—	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by involuntary movements of the eyeballs					
Oculomotor nerve disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by involvement of the oculomotor nerve (third cranial nerve)					
Olfactory nerve disorder	—	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by involvement of the olfactory nerve (first cranial nerve)					
Paresthesia	Mild symptoms	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by functional disturbances of sensory neurons resulting in abnormal cutaneous sensations of tingling, numbness, pressure, cold, and warmth that are experienced in the absence of a stimulus					
Peripheral motor neuropathy	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; assistive device indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation or degeneration of the peripheral motor nerves					
Peripheral sensory neuropathy	Asymptomatic; loss of deep tendon reflexes or paresthesia	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation or degeneration of the peripheral sensory nerves					
Phantom pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort related to a limb or an organ that is removed from or is not physically part of the body					
Presyncope	—	Present (eg, near fainting)	—	—	—
Definition: A disorder characterized by an episode of lightheadedness and dizziness that may precede an episode of syncope					
Pyramidal tract syndrome	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by dysfunction of the corticospinal (pyramidal) tracts of the spinal cord. Symptoms include an increase in the muscle tone in the lower extremities, hyperreflexia, positive Babinski sign, and a decrease in fine motor coordination					
Radiculitis	Mild symptoms	Moderate symptoms; limiting instrumental ADLs; medical intervention indicated	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation involving a nerve root. Patients experience marked discomfort radiating along a nerve path because of spinal pressure on the connecting nerve root.					
Recurrent laryngeal nerve palsy	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms	Severe symptoms; medical intervention indicated (eg, thyroplasty, vocal cord injection)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by paralysis of the recurrent laryngeal nerve					
Reversible posterior leukoencephalopathy syndrome	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; abnormal imaging studies; limiting instrumental ADLs	Severe symptoms; very abnormal imaging studies; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by headaches, mental status changes, visual disturbances, and seizures associated with imaging findings of posterior leukoencephalopathy. It has been observed in association with hypertensive encephalopathy, eclampsia, and immunosuppressive and cytotoxic drug treatment. It is an acute or subacute reversible condition.					

Continued

Nervous System Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Seizure	Brief partial seizure; no loss of consciousness	Brief generalized seizure	Multiple seizures despite medical intervention	Life-threatening; prolonged repetitive seizures	Death
Definition: A disorder characterized by a sudden, involuntary skeletal muscular contraction of cerebral or brainstem origin					
Sinus pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort in the face, between the eyes, or upper teeth originating from the sinuses					
Somnolence	Mild but more than usual drowsiness or sleepiness	Moderate sedation; limiting instrumental ADLs	Obtundation or stupor	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by characterized by excessive sleepiness and drowsiness					
Spasticity	Mild or slight increase in muscle tone	Moderate increase in muscle tone and increase in resistance through ROM	Severe increase in muscle tone and increase in resistance through ROM	Life-threatening; unable to move active or passive ROM	Death
Definition: A disorder characterized by increased involuntary muscle tone that affects the regions interfering with voluntary movement. It results in gait, movement, and speech disturbances.					
Stroke	Asymptomatic or mild neurologic deficit; radiographic findings only	Moderate neurologic deficit	Severe neurologic deficit	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a sudden loss of sensory function caused by an intracranial vascular event					
Syncope	—	—	Fainting; orthostatic collapse	—	—
Definition: A disorder characterized by spontaneous loss of consciousness caused by insufficient blood supply to the brain					
Transient ischemic attacks	Mild neurologic deficit with or without imaging confirmation	Moderate neurologic deficit with or without imaging confirmation	—	—	—
Definition: A disorder characterized by a brief attack (<24 hours) of cerebral dysfunction of vascular origin, with no persistent neurologic deficit					
Tremor	Mild symptoms	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by the uncontrolled shaking movement of the whole body or individual parts					
Trigeminal nerve disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by involvement of the trigeminal nerve (fifth cranial nerve)					
Vagus nerve disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by involvement of the vagus nerve (10th cranial nerve)					
Vasovagal reaction	—	—	Present	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a sudden drop of the blood pressure, bradycardia, and peripheral vasodilation that may lead to loss of consciousness. It results from an increase in the stimulation of the vagus nerve.					
Nervous system disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *FLAIR,* fluid-attenuated inversion recovery; *ICP,* intracranial pressure; *ROM,* range of motion; *SAS,* subarachnoid space.

Pregnancy, Puerperium, and Perinatal Conditions

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Fetal death	—	—	—	—	Fetal loss at any gestational age
Definition: A disorder characterized by death in utero; failure of the product of conception to show evidence of respiration, heartbeat, or definite movement of a voluntary muscle after expulsion from the uterus, without possibility of resuscitation					
Fetal growth restriction	—	<10% percentile of weight for gestational age	<5% percentile of weight for gestational age	<1% percentile of weight for gestational age	—
Definition: A disorder characterized by inhibition of fetal growth resulting in the inability of the fetus to achieve its potential weight					
Premature delivery	Delivery of a liveborn infant at >34–37 weeks of gestation	Delivery of a liveborn infant at >28–34 weeks of gestation	Delivery of a liveborn infant at 24–28 weeks of gestation	Delivery of a liveborn infant at ≤24 weeks of gestation	—
Definition: A disorder characterized by delivery of a viable infant before the normal end of gestation. Typically, viability is achievable between the 20th and 37th week of gestation.					
Unintended pregnancy	—	—	Unintended pregnancy	—	—
Definition: A disorder characterized by an unexpected pregnancy at the time of conception					
Pregnancy, puerperium and perinatal conditions—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate, local or noninvasive intervention indicated; limiting instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living.

Psychiatric Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Agitation	Mild mood alteration	Moderate mood alteration	Severe agitation; hospitalization not indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a state of restlessness associated with unpleasant feelings of irritability and tension					
Anorgasmia	Inability to achieve orgasm not adversely affecting relationship	Inability to achieve orgasm adversely affecting relationship	—	—	—
Definition: A disorder characterized by an inability to achieve orgasm					
Anxiety	Mild symptoms; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; hospitalization not indicated	Life-threatening; hospitalization indicated	Death
Definition: A disorder characterized by apprehension of danger and dread accompanied by restlessness, tension, tachycardia, and dyspnea unattached to a clearly identifiable stimulus					
Confusion	Mild disorientation	Moderate disorientation; limiting instrumental ADLs	Severe disorientation; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a lack of clear and orderly thought and behavior					
Delayed orgasm	Delay in achieving orgasm not adversely affecting relationship	Delay in achieving orgasm adversely affecting relationship	—	—	—
Definition: A disorder characterized by sexual dysfunction characterized by a delay in climax					

Continued

Psychiatric Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Delirium	Mild acute confusional state	Moderate and acute confusional state; limiting instrumental ADLs	Severe and acute confusional state; limiting self-care ADLs; hospitalization indicated	Life-threatening consequences, threats of harm to self or others; hospitalization indicated	Death
Definition: A disorder characterized by the acute and sudden development of confusion, illusions, movement changes, inattentiveness, agitation, and hallucinations. Usually it is a reversible condition.					
Delusions	—	Moderate delusional symptoms	Severe delusional symptoms; hospitalization not indicated	Life-threatening consequences, threats of harm to self or others; hospitalization indicated	Death
Definition: A disorder characterized by false personal beliefs held contrary to reality, despite contradictory evidence and common sense					
Depression	Mild depressive symptoms	Moderate depressive symptoms; limiting instrumental ADLs	Severe depressive symptoms; limiting self-care ADLs; hospitalization not indicated	Life-threatening consequences, threats of harm to self or others; hospitalization indicated	Death
Definition: A disorder characterized by melancholic feelings of grief or unhappiness					
Euphoria	Mild mood elevation	Moderate mood elevation	Severe mood elevation (eg, hypomania)	—	—
Definition: A disorder characterized by an exaggerated feeling of well-being that is disproportionate to events and stimuli					
Hallucinations	Mild hallucinations (eg, perceptual distortions)	Moderate hallucinations	Severe hallucinations; hospitalization not indicated	Life-threatening consequences, threats of harm to self or others; hospitalization indicated	Death
Definition: A disorder characterized by a false sensory perception in the absence of an external stimulus					
Insomnia	Mild difficulty falling asleep, staying asleep, or waking up early	Moderate difficulty falling asleep, staying asleep, or waking up early	Severe difficulty in falling asleep, staying asleep, or waking up early	—	—
Definition: A disorder characterized by difficulty in falling asleep or remaining asleep					
Libido decreased	Decrease in sexual interest not adversely affecting relationship	Decrease in sexual interest adversely affecting relationship	—	—	—
Definition: A disorder characterized by a decrease in sexual desire					
Libido increased	Mild increase in sexual interest not adversely affecting relationship	Moderate increase in sexual interest adversely affecting relationship	Severe increase in sexual interest leading to dangerous behavior	—	—
Definition: A disorder characterized by an increase in sexual desire					
Mania	Mild manic symptoms (eg, elevated mood, rapid thoughts, rapid speech, decreased need for sleep)	Moderate manic symptoms (eg, relationship and work difficulties; poor hygiene)	Severe manic symptoms (eg, hypomania; major sexual or financial indiscretions); hospitalization not indicated	Life-threatening consequences, threats of harm to self or others; hospitalization indicated	Death
Definition: A disorder characterized by excitement of psychotic proportions manifested by mental and physical hyperactivity, disorganization of behavior and elevation of mood					
Personality change	Mild personality change	Moderate personality change	Severe personality change; hospitalization not indicated	Life-threatening consequences, threats of harm to self or others; hospitalization indicated	Death
Definition: A disorder characterized by a conspicuous change in a person's behavior and thinking					

Psychiatric Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Psychosis	Mild psychotic symptoms	Moderate psychotic symptoms (eg, disorganized speech; impaired reality testing)	Severe psychotic symptoms (eg, paranoid; extreme disorganization); hospitalization not indicated	Life-threatening consequences, threats of harm to self or others; hospitalization indicated	Death
Definition: A disorder characterized by personality change, impaired functioning, and loss of touch with reality. It may be a manifestation of schizophrenia, bipolar disorder, or brain tumor.					
Restlessness	Mild symptoms; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by an inability to rest, relax, or be still					
Suicidal ideation	Increased thoughts of death but no wish to kill oneself	Suicidal ideation with no specific plan or intent	Specific plan to commit suicide without serious intent to die, which may not require hospitalization	Specific plan to commit suicide with serious intent to die, which requires hospitalization	—
Definition: A disorder characterized by thoughts of taking one's own life					
Suicide attempt	—	—	Suicide attempt or gesture without intent to die, which may not require hospitalization	Suicide attempt with intent to die, which requires hospitalization	Death
Definition: A disorder characterized by self-inflicted harm in an attempt to end one's own life					
Psychiatric disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; disabling; limiting self-care ADLs	Life-threatening consequences; hospitalization or urgent intervention indicated	Death

ADL, Activity of daily living.

Renal and Urinary Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Acute kidney injury	Creatinine level increase of >0.3 mg/dL; creatinine 1.5–2.0 × baseline	Creatinine 2–3 × baseline	Creatinine >3 × baseline or >4.0 mg/dL; hospitalization indicated	Life-threatening consequences; dialysis indicated	Death
Definition: A disorder characterized by the acute loss of renal function; traditionally classified as prerenal (low blood flow into kidney), renal (kidney damage), and postrenal causes (ureteral or bladder outflow obstruction)					
Bladder perforation	—	Extraperitoneal perforation, indwelling catheter indicated	Intraperitoneal perforation; elective radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; organ failure; urgent operative intervention indicated	Death
Definition: A disorder characterized by a rupture in the bladder wall					
Bladder spasm	Intervention not indicated	Antispasmodics indicated	Hospitalization indicated	—	—
Definition: A disorder characterized by a sudden and involuntary contraction of the bladder wall					
Chronic kidney disease	eGFR or CrCl <LLN-60 mL/min/1.73 m^2 or proteinuria 2+ present; urine protein/creatinine >0.5	eGFR or CrCl 59–30 mL/min/1.73 m^2	eGFR or CrCl 29–15 mL/min/1.73 m^2	eGFR or CrCl <15 mL/min/1.73 m^2; dialysis or renal transplant indicated	Death
Definition: A disorder characterized by gradual and usually permanent loss of kidney function resulting in renal failure					

Continued

Renal and Urinary Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Cystitis, noninfective	Microscopic hematuria; minimal increase in frequency, urgency, dysuria, or nocturia; new onset of incontinence	Moderate hematuria; moderate increase in frequency, urgency, dysuria, nocturia, or incontinence; urinary catheter placement or bladder irrigation indicated; limiting instrumental ADLs	Gross hematuria; transfusion, IV medications, or hospitalization indicated; elective endoscopic, radiologic, or operative intervention indicated	Life-threatening consequences; urgent radiologic or operative intervention indicated	Death
Definition: A disorder characterized by inflammation of the bladder that is not caused by an infection of the urinary tract					
Hematuria	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; urinary catheter or bladder irrigation indicated; limiting instrumental ADLs	Gross hematuria; transfusion, IV medications, or hospitalization indicated; elective endoscopic, radiologic, or operative intervention indicated; limiting self-care ADLs	Life-threatening consequences; urgent radiologic or operative intervention indicated	Death
Definition: A disorder characterized by laboratory test results that indicate blood in the urine					
Hemoglobinuria	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	—	—	—	—
Definition: A disorder characterized by laboratory test results that indicate the presence of free hemoglobin in the urine					
Proteinuria	1+ proteinuria; urinary protein <1.0 g/24 h	Adults: 2+ proteinuria; urinary protein 1.0–3.4 g/24 h Pediatric: urine protein:creatinine ratio 0.5–1.9	Adults: urinary protein ≥3.5 g/24 h; Pediatric: urine protein:creatinine ratio >1.9	—	—
Definition: A disorder characterized by laboratory test results that indicate the presence of excessive protein in the urine. It is predominantly albumin but also globulin.					
Renal calculi	Asymptomatic or mild symptoms; occasional use of nonprescription analgesics indicated	Symptomatic; oral antiemetics indicated; around the clock nonprescription analgesics or any oral narcotic analgesics indicated	Hospitalization indicated; IV intervention (eg, analgesics, antiemetics); elective endoscopic or radiologic intervention indicated	Life-threatening consequences; urgent radiologic, endoscopic, or operative intervention indicated	Death
Definition: A disorder characterized by the formation of crystals in the pelvis of the kidney					
Renal colic	Mild pain not interfering with activity; nonprescription medication indicated	Moderate pain; limiting instrumental ADLs; prescription medication indicated	Hospitalization indicated; limiting self-care ADLs	—	—
Definition: A disorder characterized by paroxysmal and severe flank marked discomfort radiating to the inguinal area. Often, the cause is the passage of kidney stones.					
Renal hemorrhage	Mild symptoms; intervention not indicated	Analgesics and hematocrit monitoring indicated	Transfusion, radiation, or hospitalization indicated; elective radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent radiologic or operative intervention indicated	Death
Definition: A disorder characterized by bleeding from the kidney					

Renal and Urinary Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Urinary fistula	—	Noninvasive intervention indicated; urinary or suprapubic catheter placement indicated	Limiting self-care ADLs; elective radiologic, endoscopic, or operative intervention indicated; permanent urinary diversion indicated	Life-threatening consequences; urgent radiologic or operative intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between any part of the urinary system and another organ or anatomic site					
Urinary frequency	Present	Limiting instrumental ADLs; medical management indicated	—	—	—
Definition: A disorder characterized by urination at short intervals					
Urinary incontinence	Occasional (eg, with coughing, sneezing), pads not indicated	Spontaneous; pads indicated; limiting instrumental ADLs	Intervention indicated (eg, clamp, collagen injections); operative intervention indicated; limiting self-care ADLs	—	—
Definition: A disorder characterized by inability to control the flow of urine from the bladder.					
Urinary retention	Urinary, suprapubic, or intermittent catheter placement not indicated; able to void with some residual urine	Placement of urinary, suprapubic, or intermittent catheter placement indicated; medication indicated	Elective operative or radiologic intervention indicated; substantial loss of affected kidney function or mass	Life-threatening consequences; organ failure; urgent operative intervention indicated	Death
Definition: A disorder characterized by accumulation of urine within the bladder because of the inability to urinate					
Urinary tract obstruction	Asymptomatic; clinical or diagnostic observations only	Symptomatic but no hydronephrosis, sepsis, or renal dysfunction; urethral dilation, urinary or suprapubic catheter indicated	Symptomatic and altered organ function (eg, hydronephrosis or renal dysfunction); elective radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by blockage of the normal flow of contents of the urinary tract					
Urinary tract pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the urinary tract					
Urinary urgency	Present	Limiting instrumental ADLs; medical management indicated	—	—	—
Definition: A disorder characterized by a sudden compelling urge to urinate					
Urine discoloration	Present	—	—	—	—
Definition: A disorder characterized by a change in the color of the urine					
Renal and urinary disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate, local, or noninvasive intervention indicated; limiting instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *CCr,* creatinine clearance; *eGFR,* estimated glomerular filtration rate; *IV,* intravenous; *LLN,* lower limit of normal.

Reproductive System and Breast Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Azoospermia	—	—	Absence of sperm in ejaculate	—	—
Definition: A disorder characterized by laboratory test results that indicate complete absence of spermatozoa in the semen					
Breast atrophy	Minimal asymmetry; minimal atrophy	Moderate asymmetry; moderate atrophy	Asymmetry >1/3 of breast volume; severe atrophy	—	—
Definition: A disorder characterized by underdevelopment of the breast					
Breast pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the breast region					
Dysmenorrhea	Mild symptoms; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by abnormally painful abdominal cramps during menses					
Dyspareunia	Mild discomfort or pain associated with vaginal penetration; discomfort relieved with use of vaginal lubricants or estrogen	Moderate discomfort or pain associated with vaginal penetration; discomfort or pain partially relieved with use of vaginal lubricants or estrogen	Severe discomfort or pain associated with vaginal penetration; discomfort or pain unrelieved by vaginal lubricants or estrogen	—	—
Definition: A disorder characterized by painful or difficult coitus					
Ejaculation disorder	Diminished ejaculation	Anejaculation or retrograde ejaculation	—	—	—
Definition: A disorder characterized by problems related to ejaculation. This category includes premature, delayed, retrograde, and painful ejaculation.					
Erectile dysfunction	Decrease in erectile function (frequency or rigidity of erections) but intervention not indicated (eg, medication or use of mechanical device, penile pump)	Decrease in erectile function (frequency or rigidity of erections), erectile intervention indicated (eg, medication or mechanical devices such as penile pump)	Decrease in erectile function (frequency or rigidity of erections) but erectile intervention not helpful (eg, medication or mechanical devices such as penile pump); placement of a permanent penile prosthesis indicated (not previously present)	—	—
Definition: A disorder characterized by the persistent or recurrent inability to achieve or to maintain an erection during sexual activity					
Fallopian tube obstruction	Diagnostic observations only; intervention not indicated	Mild symptoms; elective intervention indicated	Severe symptoms; elective operative intervention indicated	—	—
Definition: A disorder characterized by blockage of the normal flow of the contents in the fallopian tube					
Fallopian tube stenosis	Asymptomatic clinical or diagnostic observations only; intervention not indicated	Symptomatic and intervention not indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated (eg, organ resection)	Death
Definition: A disorder characterized by a narrowing of the fallopian tube lumen					
Female genital tract fistula	Asymptomatic clinical or diagnostic observations only; intervention not indicated	Symptomatic and intervention not indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between a female reproductive system organ and another organ or anatomic site					
Feminization acquired	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	—	—	—
Definition: A disorder characterized by the development of secondary female sex characteristics in males resulting from extrinsic factors					

Reproductive System and Breast Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Genital edema	Mild swelling or obscuration of anatomic architecture on close inspection	Readily apparent obscuration of anatomic architecture; obliteration of skin folds; readily apparent deviation from normal anatomic contour	Lymphorrhea; gross deviation from normal anatomic contour; limiting self-care ADLs	—	—
Definition: A disorder characterized by swelling resulting from an excessive accumulation of fluid in the genitals					
Gynecomastia	Asymptomatic breast enlargement	Symptomatic (eg, pain or psychosocial impact)	Severe symptoms; elective operative intervention indicated	—	—
Definition: A disorder characterized by excessive development of the breasts in males					
Hematosalpinx	Minimal bleeding identified on imaging study or laparoscopy; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by the presence of blood in a fallopian tube					
Irregular menstruation	Intermittent menses with skipped menses for no more than 1–3 months	Intermittent menses with skipped menses for more than 4 months	Persistent amenorrhea for more than 6 months	—	—
Definition: A disorder characterized by irregular cycle or duration of menses					
Lactation disorder	Mild changes in lactation, not significantly affecting production or expression of breast milk	Changes in lactation, significantly affecting production or expression of breast milk	—	—	—
Definition: A disorder characterized by disturbances of milk secretion. It is not necessarily related to pregnancy that is observed in female patients and can be observed in male patients.					
Menorrhagia	Mild; iron supplements indicated	Moderate symptoms; medical intervention indicated (eg, hormones)	Severe; transfusion indicated; surgical intervention indicated (eg, hysterectomy)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by abnormally heavy vaginal bleeding during menses					
Nipple deformity	Asymptomatic; asymmetry with slight retraction or thickening of the nipple–areolar complex	Symptomatic; asymmetry of nipple areolar complex with moderate retraction or thickening of the nipple–areolar complex	—	—	—
Definition: A disorder characterized by a malformation of the nipple					
Oligospermia	Sperm concentration >48 million/mL or motility >68%	Sperm concentration 13–48 million/mL or motility 32%–68%	Sperm concentration <13 million/mL or motility <32%	—	—
Definition: A disorder characterized by a decrease in the number of spermatozoa in the semen					
Ovarian hemorrhage	Minimal bleeding identified on imaging study or laparoscopy; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by bleeding from the ovary					
Ovarian rupture	Asymptomatic clinical or diagnostic observations only; intervention not indicated	Symptomatic and intervention not indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by tearing or disruption of the ovarian tissue					
Ovulation pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in one side of the abdomen between menstrual cycles, around the time of the discharge of the ovum from the ovarian follicle					

Continued

Reproductive System and Breast Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Pelvic floor muscle weakness	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic, not interfering with bladder, bowel, or vaginal function; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a reduction in the strength of the muscles of the pelvic floor					
Pelvic pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the pelvis					
Penile pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the penis					
Perineal pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the area between the genital organs and the anus					
Premature menopause	—	—	Present	—	—
Definition: A disorder characterized by ovarian failure before 40 years of age. Symptoms include hot flashes, night sweats, mood swings, and a decrease in sex drive.					
Prostatic hemorrhage	Minimal bleeding identified on imaging study; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by bleeding from the prostate gland					
Prostatic obstruction	Diagnostic observations only; intervention not indicated	Mild symptoms; elective intervention indicated	Severe symptoms; elective operative intervention indicated	—	—
Definition: A disorder characterized by compression of the urethra secondary to enlargement of the prostate gland. This results in voiding difficulties (straining to void, slow urine stream, and incomplete emptying of the bladder).					
Prostatic pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the prostate gland					
Scrotal pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the scrotal area					
Spermatic cord hemorrhage	Minimal bleeding identified on imaging study; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by bleeding from the spermatic cord					
Spermatic cord obstruction	Diagnostic observations only; intervention not indicated	Mild symptoms; elective intervention indicated	Severe symptoms; elective operative intervention indicated	—	—
Definition: A disorder characterized by blockage of the normal flow of the contents of the spermatic cord					
Testicular disorder	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic but not interfering with urination or sexual activities; intervention not indicated; limiting instrumental ADLs	Severe symptoms; interfering with urination or sexual function; limiting self-care ADLs; intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by involvement of the testis					
Testicular hemorrhage	Minimal bleeding identified on imaging study; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by bleeding from the testis					

Reproductive System and Breast Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Testicular pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the testis					
Uterine fistula	Asymptomatic clinical or diagnostic observations only; intervention not indicated	Symptomatic and intervention not indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the uterus and another organ or anatomic site					
Uterine hemorrhage	Minimal bleeding identified on imaging study; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by bleeding from the uterus					
Uterine obstruction	Diagnostic observations only; intervention not indicated	Mild symptoms; elective intervention indicated	Severe symptoms; elective operative intervention indicated	—	—
Definition: A disorder characterized by blockage of the uterine outlet					
Uterine pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the uterus					
Vaginal discharge	Mild vaginal discharge (greater than baseline for patient)	Moderate to heavy vaginal discharge; use of perineal pad or tampon indicated	—	—	—
Definition: A disorder characterized by vaginal secretions. Mucus produced by the cervical glands is discharged from the vagina naturally, especially during the childbearing years.					
Vaginal dryness	Mild vaginal dryness not interfering with sexual function	Moderate vaginal dryness interfering with sexual function or causing frequent discomfort	Severe vaginal dryness resulting in dyspareunia or severe discomfort	—	—
Definition: A disorder characterized by an uncomfortable feeling of itching and burning in the vagina					
Vaginal fistula	Asymptomatic clinical or diagnostic observations only; intervention not indicated	Symptomatic and intervention not indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the vagina and another organ or anatomic site					
Vaginal hemorrhage	Minimal bleeding identified on clinical examination or imaging study; intervention not indicated	Moderate bleeding; medical intervention indicated	Severe bleeding; transfusion indicated; radiologic or endoscopic intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by bleeding from the vagina					
Vaginal inflammation	Mild discomfort or pain, edema, or redness	Moderate discomfort or pain, edema, or redness; limiting instrumental ADLs	Severe discomfort or pain, edema, or redness; limiting self-care ADLs; small areas of mucosal ulceration	Widespread areas of mucosal ulceration; life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation involving the vagina. Symptoms may include redness, edema, marked discomfort, and an increase in vaginal discharge.					
Vaginal obstruction	Diagnostic observations only; intervention not indicated	Mild symptoms; elective intervention indicated	Severe symptoms; elective operative intervention indicated	—	—
Definition: A disorder characterized by blockage of the vaginal canal					
Vaginal pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by a sensation of marked discomfort in the vagina					

Continued

Reproductive System and Breast Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Vaginal perforation	Asymptomatic clinical or diagnostic observations only; intervention not indicated	Symptomatic and intervention not indicated	Severe symptoms; elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a rupture in the vaginal wall					
Vaginal stricture	Asymptomatic; mild vaginal shortening or narrowing	Vaginal narrowing or shortening not interfering with physical examination	Vaginal narrowing or shortening interfering with the use of tampons, sexual activity, or physical examination	—	Death
Definition: A disorder characterized by a narrowing of the vaginal canal					
Vaginismus	Mild discomfort or pain associated with vaginal spasm or tightening; no impact on sexual function or physical examination	Moderate discomfort or pain associated with vaginal spasm or tightening; disruption in sexual function and physical examination	Severe discomfort or pain associated with vaginal spasm or tightening; unable to tolerate vaginal penetration or physical examination	—	—
Definition: A disorder characterized by involuntary spasms of the pelvic floor muscles, resulting in pathologic tightness of the vaginal wall during penetration such as during sexual intercourse					
Reproductive system and breast disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living.

Respiratory, Thoracic, and Mediastinal Disorders

Adverse Event	Grade 1	2	3	4	5
Acute respiratory distress syndrome	—	—	Present with radiologic findings; intubation not indicated	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by progressive and life-threatening pulmonary distress in the absence of an underlying pulmonary condition, usually following major trauma or surgery					
Allergic rhinitis	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	—	—	—
Definition: A disorder characterized by an inflammation of the nasal mucous membranes caused by an IgE-mediated response to external allergens. The inflammation may also involve the mucous membranes of the sinuses, eyes, middle ear, and pharynx. Symptoms include sneezing, nasal congestion, rhinorrhea, and itching.					
Apnea	—	—	Present; medical intervention indicated	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by cessation of breathing					

Respiratory, Thoracic, and Mediastinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Aspiration	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Altered eating habits; coughing or choking episodes after eating or swallowing; medical intervention indicated (eg, suction or oxygen)	Dyspnea and pneumonia symptoms (eg, aspiration pneumonia); hospitalization indicated; unable to aliment orally	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by inhalation of solids or liquids into the lungs					
Atelectasis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic (eg, dyspnea, cough); medical intervention indicated (eg, chest physiotherapy, suctioning); bronchoscopic suctioning	Oxygen indicated; hospitalization or elective operative intervention indicated (eg, stent, laser)	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by the collapse of part or the entire lung					
Bronchial fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; tube thoracostomy or medical management indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; endoscopic or operative intervention indicated (eg, stent or primary closure)	Life-threatening consequences; urgent operative intervention with thoracoplasty, chronic open drainage or multiple thoracotomies indicated	Death
Definition: A disorder characterized by an abnormal communication between the bronchus and another organ or anatomic site					
Bronchial obstruction	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic (eg, mild wheezing); endoscopic evaluation indicated; radiographic evidence of atelectasis or lobar collapse; medical management indicated (eg, steroids, bronchodilators)	Shortness of breath with stridor; endoscopic intervention indicated (eg, laser, stent placement)	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by blockage of a bronchus passage, most often by bronchial secretions and exudates					
Bronchial stricture	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic (eg, rhonchi or wheezing) but without respiratory distress; medical intervention indicated (eg, steroids, bronchodilators)	Shortness of breath with stridor; endoscopic intervention indicated (eg, laser, stent placement)	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by a narrowing of the bronchial tube					
Bronchopleural fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; tube thoracostomy or medical intervention indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; endoscopic or operative intervention indicated (eg, stent or primary closure)	Life-threatening consequences; urgent operative intervention with thoracoplasty, chronic open drainage or multiple thoracotomies indicated	Death
Definition: A disorder characterized by an abnormal communication between a bronchus and the pleural cavity					
Bronchopulmonary hemorrhage	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	Transfusion, radiologic, endoscopic, or operative intervention indicated (eg, hemostasis of bleeding site)	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the bronchial wall or lung parenchyma					

Continued

Respiratory, Thoracic, and Mediastinal Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Bronchospasm	Mild symptoms; intervention not indicated	Symptomatic; medical intervention indicated; limiting instrumental ADLs	Limiting self-care ADLs; oxygen saturation decreased	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by a sudden contraction of the smooth muscles of the bronchial wall					
Chylothorax	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; thoracentesis or tube drainage indicated	Severe symptoms; elective operative intervention indicated	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by milky pleural effusion (abnormal collection of fluid) resulting from accumulation of lymph fluid in the pleural cavity					
Cough	Mild symptoms; nonprescription intervention indicated	Moderate symptoms, medical intervention indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by sudden, often repetitive, spasmodic contraction of the thoracic cavity, resulting in violent release of air from the lungs and usually accompanied by a distinctive sound					
Dyspnea	Shortness of breath with moderate exertion	Shortness of breath with minimal exertion; limiting instrumental ADLs	Shortness of breath at rest; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an uncomfortable sensation of difficulty breathing					
Epistaxis	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated (eg, nasal packing, cauterization; topical vasoconstrictors)	Transfusion, radiologic, endoscopic, or operative intervention indicated (eg, hemostasis of bleeding site)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the nose					
Hiccups	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated; limiting instrumental ADLs	Severe symptoms; interfering with sleep; limiting self-care ADLs	—	—
Definition: A disorder characterized by repeated gulp sounds that result from an involuntary opening and closing of the glottis. This is attributed to a spasm of the diaphragm.					
Hoarseness	Mild or intermittent voice change; fully understandable; self-resolving	Moderate or persistent voice changes; may require occasional repetition but understandable on telephone; medical evaluation indicated	Severe voice changes including predominantly whispered speech	—	—
Definition: A disorder characterized by harsh and raspy voice arising from or spreading to the larynx					
Hypoxia	—	Decreased oxygen saturation with exercise (eg, pulse oximeter <88%); intermittent supplemental oxygen	Decreased oxygen saturation at rest (eg, pulse oximeter <88% or PaO_2 ≤55 mm Hg)	Life-threatening airway compromise; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A disorder characterized by a decrease in the level of oxygen in the body					
Laryngeal edema	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated (eg, dexamethasone, epinephrine, antihistamines)	Stridor; respiratory distress; hospitalization indicated	Life-threatening airway compromise; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A disorder characterized by swelling resulting from an excessive accumulation of fluid in the larynx					

Respiratory, Thoracic, and Mediastinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Laryngeal fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; tube thoracostomy or medical management indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; endoscopic or operative intervention indicated (eg, stent or primary closure)	Life-threatening consequences; urgent operative intervention indicated (eg, thoracoplasty, chronic open drainage or multiple thoracotomies)	Death
Definition: A disorder characterized by an abnormal communication between the larynx and another organ or anatomic site					
Laryngeal hemorrhage	Mild cough or trace hemoptysis; laryngoscopic findings	Moderate symptoms; medical intervention indicated	Transfusion, radiologic, endoscopic, or operative intervention indicated (eg, hemostasis of bleeding site)	Life-threatening airway compromise; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A disorder characterized by bleeding from the larynx					
Laryngeal inflammation	Mild sore throat; raspy voice	Moderate sore throat; analgesics indicated	Severe throat pain; endoscopic intervention indicated	—	—
Definition: A disorder characterized by an inflammation involving the larynx					
Laryngeal mucositis	Endoscopic findings only; mild discomfort with normal intake	Moderate discomfort; altered oral intake	Severe pain; severely altered eating or swallowing; medical intervention indicated	Life-threatening airway compromise; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A disorder characterized by an inflammation involving the mucous membrane of the larynx					
Laryngeal obstruction	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic (eg, noisy airway breathing), but causing no respiratory distress; medical management indicated (eg, steroids); limiting instrumental ADLs	Limiting self-care ADLs; stridor; endoscopic intervention indicated (eg, stent, laser)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by blockage of the laryngeal airway					
Laryngeal stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic (eg, noisy airway breathing), but causing no respiratory distress; medical management indicated (eg, steroids)	Limiting self-care ADLs; stridor; endoscopic intervention indicated (eg, stent, laser)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a narrowing of the laryngeal airway					
Laryngopharyngeal dysesthesia	Mild symptoms; no anxiety; intervention not indicated	Moderate symptoms; mild anxiety, but no dyspnea; short duration of observation and or anxiolytic indicated; limiting instrumental ADLs	Severe symptoms; dyspnea and swallowing difficulty; limiting self-care ADLs	Life-threatening consequences	Death
Definition: A disorder characterized by an uncomfortable persistent sensation in the area of the laryngopharynx					
Laryngospasm	—	Transient episode; intervention not indicated	Recurrent episodes; noninvasive intervention indicated (eg, breathing technique, pressure point massage)	Persistent or severe episodes associated with syncope; urgent intervention indicated (eg, fiberoptic laryngoscopy, intubation, Botox injection)	Death
Definition: A disorder characterized by paroxysmal spasmodic muscular contraction of the vocal cords					

Continued

Respiratory, Thoracic, and Mediastinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Mediastinal hemorrhage	Radiologic evidence only; minimal symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated (eg, hemostasis of bleeding site)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the mediastinum					
Nasal congestion	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	Associated with bloody nasal discharge or epistaxis	—	—
Definition: A disorder characterized by obstruction of the nasal passage resulting from mucosal edema					
Pharyngeal fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; tube thoracostomy or medical intervention indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; endoscopic or operative intervention indicated (eg, stent or primary closure)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the pharynx and another organ or anatomic site					
Pharyngeal hemorrhage	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	Transfusion, radiologic, endoscopic, or operative intervention indicated (eg, hemostasis of bleeding site)	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the pharynx					
Pharyngeal mucositis	Endoscopic findings only; minimal symptoms with normal oral intake; mild pain but analgesics not indicated	Moderate pain and analgesics indicated; altered oral intake; limiting instrumental ADLs	Severe pain; unable to adequately aliment or hydrate orally; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an inflammation involving the mucous membrane of the pharynx					
Pharyngeal necrosis	—	—	Inability to aliment adequately by GI tract; tube feeding or TPN indicated; radiologic, endoscopic, or operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by a necrotic process occurring in the pharynx					
Pharyngeal stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic (eg, noisy airway breathing), but causing no respiratory distress; medical management indicated (eg, steroids); limiting instrumental ADLs	Limiting self-care ADLs; stridor; endoscopic intervention indicated (eg, stent, laser)	Life-threatening airway compromise; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A disorder characterized by a narrowing of the pharyngeal airway					
Pharyngolaryngeal pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the pharyngolaryngeal region					
Pleural effusion	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; intervention indicated (eg, diuretics or limited therapeutic thoracentesis)	Symptomatic with respiratory distress and hypoxia; surgical intervention, including chest tube or pleurodesis indicated	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by an increase in amounts of fluid within the pleural cavity. Symptoms include shortness of breath, cough, and marked chest discomfort.					

Respiratory, Thoracic, and Mediastinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Pleural hemorrhage	Asymptomatic; mild hemorrhage confirmed by thoracentesis	Symptomatic or associated with pneumothorax; chest tube drainage indicated	>1000 mL of blood evacuated; persistent bleeding (150–200 mL/h for 2–4 h); persistent transfusion indicated; elective operative intervention indicated	Life-threatening respiratory or hemodynamic compromise; intubation or urgent intervention indicated	Death
Definition: A disorder characterized by bleeding from the pleural cavity					
Pleuritic pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the pleura					
Pneumonitis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; oxygen indicated	Life-threatening respiratory compromise; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A disorder characterized by inflammation focally or diffusely affecting the lung parenchyma					
Pneumothorax	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; intervention indicated (eg, tube placement without sclerosis)	Sclerosis and/or operative intervention indicated; hospitalization indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by abnormal presence of air in the pleural cavity resulting in the collapse of the lung					
Postnasal drip	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	—	—	—
Definition: A disorder characterized by excessive mucous secretion in the back of the nasal cavity or throat, causing sore throat, coughing, or both					
Productive cough	Occasional or minimal production of sputum with cough	Moderate sputum production; limiting instrumental ADLs	Persistent or copious production of sputum; limiting self-care ADLs	—	—
Definition: A disorder characterized by expectorated secretions upon coughing					
Pulmonary edema	Radiologic findings only; minimal dyspnea on exertion	Moderate dyspnea on exertion; medical intervention indicated; limiting instrumental ADLs	Severe dyspnea or dyspnea at rest; oxygen indicated; limiting self-care ADLs	Life-threatening respiratory compromise; urgent intervention or intubation with ventilatory support indicated	Death
Definition: A disorder characterized by accumulation of fluid in the lung tissues that causes a disturbance of the gas exchange that may lead to respiratory failure					
Pulmonary fibrosis	Mild hypoxemia; radiologic pulmonary fibrosis <25% of lung volume	Moderate hypoxemia; evidence of pulmonary hypertension; radiographic pulmonary fibrosis 25%–50%	Severe hypoxemia; evidence of right-sided heart failure; radiographic pulmonary fibrosis >50%–75%	Life-threatening consequences (eg, hemodynamic or pulmonary complications); intubation with ventilatory support indicated; radiographic pulmonary fibrosis >75% with severe honeycombing	Death
Definition: A disorder characterized by the replacement of the lung tissue by connective tissue, leading to progressive dyspnea, respiratory failure, or right heart failure					
Pulmonary fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; tube thoracostomy or medical management indicated; limiting instrumental ADLs	Limiting self-care ADLs; endoscopic stenting or operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by an abnormal communication between the lung and another organ or anatomic site					

Continued

Respiratory, Thoracic, and Mediastinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Pulmonary hypertension	Minimal dyspnea; findings on physical examination or other evaluation	Moderate dyspnea, cough; requiring evaluation by cardiac catheterization and medical intervention	Severe symptoms, associated with hypoxemia, right heart failure; oxygen indicated	Life-threatening airway consequences; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A disorder characterized by an increase in pressure within the pulmonary circulation caused by a lung or heart disorder					
Respiratory failure	—	—	—	Life-threatening consequences; urgent intervention, intubation, or ventilatory support indicated	Death
Definition: A disorder characterized by impaired gas exchange by the respiratory system resulting in hypoxemia and a decrease in oxygenation of the tissues that may be associated with an increase in arterial levels of carbon dioxide					
Retinoic acid syndrome	Fluid retention; <3 kg of weight gain; intervention with fluid restriction or diuretics indicated	Moderate signs or symptoms; steroids indicated	Severe symptoms; hospitalization indicated	Life-threatening consequences; ventilatory support indicated	Death
Definition: A disorder characterized by weight gain, dyspnea, pleural and pericardial effusions, leukocytosis, or renal failure originally described in patients treated with all-trans retinoic acid					
Sinus disorder	Asymptomatic mucosal crusting; blood-tinged secretions	Symptomatic stenosis or edema or narrowing interfering with airflow; limiting instrumental ADLs	Stenosis with significant nasal obstruction; limiting self-care ADLs	Necrosis of soft tissue or bone; urgent operative intervention indicated	Death
Definition: A disorder characterized by involvement of the paranasal sinuses					
Sleep apnea	Snoring and nocturnal sleep arousal without apneic periods	Moderate apnea and oxygen desaturation; excessive daytime sleepiness; medical evaluation indicated; limiting instrumental ADLs	Oxygen desaturation; associated with hypertension; medical intervention indicated; limiting self-care ADLs	Cardiovascular or neuropsychiatric symptoms; urgent operative intervention indicated	Death
Definition: A disorder characterized by cessation of breathing for short periods during sleep					
Sneezing	Mild symptoms; intervention not indicated	Moderate symptoms; medical intervention indicated	—	—	—
Definition: A disorder characterized by the involuntary expulsion of air from the nose					
Sore throat	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs; limiting ability to swallow	—	—
Definition: A disorder characterized by of marked discomfort in the throat					
Stridor	—	—	Respiratory distress limiting self-care ADLs; medical intervention indicated	Life-threatening airway compromise; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A disorder characterized by a high-pitched breathing sound resulting from laryngeal or upper airway obstruction					
Tracheal fistula	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; tube thoracostomy or medical intervention indicated; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs; endoscopic or operative intervention indicated (eg, stent or primary closure)	Life-threatening consequences; urgent operative intervention indicated (eg, thoracoplasty, chronic open drainage or multiple thoracotomies)	Death
Definition: A disorder characterized by an abnormal communication between the trachea and another organ or anatomic site					

Respiratory, Thoracic, and Mediastinal Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Tracheal mucositis	Endoscopic findings only; minimal hemoptysis, pain, or respiratory symptoms	Moderate symptoms; medical intervention indicated; limiting instrumental ADLs	Severe pain; hemorrhage or respiratory symptoms; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an inflammation involving the mucous membrane of the trachea					
Tracheal stenosis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic (eg, noisy airway breathing), but causing no respiratory distress; medical management indicated (eg, steroids)	Stridor or respiratory distress limiting self-care ADLs; endoscopic intervention indicated (eg, stent, laser)	Life-threatening airway compromise; urgent intervention indicated (eg, tracheotomy or intubation)	Death
Definition: A disorder characterized by a narrowing of the trachea					
Voice alteration	Mild or intermittent change from normal voice	Moderate or persistent change from normal voice; still understandable	Severe voice changes including predominantly whispered speech; may require frequent repetition or face-to-face contact for understandability; may require assistive technology	—	—
Definition: A disorder characterized by a change in the sound or speed of the voice					
Wheezing	Detectable airway noise with minimal symptoms	Moderate symptoms; medical intervention indicated; limiting instrumental ADLs	Severe respiratory symptoms limiting self-care ADLs; oxygen therapy or hospitalization indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a high-pitched, whistling sound during breathing. It results from the narrowing or obstruction of the respiratory airways.					
Respiratory, thoracic and mediastinal disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *GI,* gastrointestinal; *TPN,* total parenteral nutrition.

Skin and Subcutaneous Tissue Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Alopecia	Hair loss of <50% of normal for that individual that is not obvious from a distance but only on close inspection; a different hair style may be required to cover the hair loss, but it does not require a wig or hairpiece to camouflage	Hair loss of ≥50% normal for that individual that is readily apparent to others; a wig or hair piece is necessary if the patient desires to completely camouflage the hair loss; associated with psychosocial impact	—	—	—
Definition: A disorder characterized by a decrease in density of hair compared with normal for a given individual at a given age and body location					

Continued

Skin and Subcutaneous Tissue Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Body odor	Mild odor; physician intervention not indicated; self-care interventions	Pronounced odor; psychosocial impact; patient seeks medical intervention	—	—	—
Definition: A disorder characterized by an abnormal body smell resulting from the growth of bacteria on the body					
Bullous dermatitis	Asymptomatic; blisters covering <10% BSA	Blisters covering 10%–30% BSA; painful blisters; limiting instrumental ADLs	Blisters covering >30% BSA; limiting self-care ADLs	Blisters covering >30% BSA; associated with fluid or electrolyte abnormalities; ICU care or burn unit indicated	Death
Definition: A disorder characterized by inflammation of the skin characterized by the presence of bullae that are filled with fluid					
Dry skin	Covering <10% BSA and no associated erythema or pruritus	Covering 10%–30% BSA and associated with erythema or pruritus; limiting instrumental ADLs	Covering >30% BSA and associated with pruritus; limiting self-care ADLs	—	—
Definition: A disorder characterized by flaky and dull skin; the pores are generally fine, but the texture is a papery thin texture					
Erythema multiforme	Target lesions covering <10% BSA and not associated with skin tenderness	Target lesions covering 10%–30% BSA and associated with skin tenderness	Target lesions covering >30% BSA and associated with oral or genital erosions	Target lesions covering >30% BSA; associated with fluid or electrolyte abnormalities; ICU care or burn unit indicated	Death
Definition: A disorder characterized by target lesions (a pink-red ring around a pale center)					
Erythroderma	—	Erythema covering >90% BSA without associated symptoms; limiting instrumental ADLs	Erythema covering >90% BSA with associated symptoms (eg, pruritus or tenderness); limiting self-care ADLs	Erythema covering >90% BSA with associated fluid or electrolyte abnormalities; ICU care or burn unit indicated	Death
Definition: A disorder characterized by generalized inflammatory erythema and exfoliation. The inflammatory process involves >90% of the BSA.					
Fat atrophy	Covering <10% BSA and asymptomatic	Covering 10%–30% BSA and associated with erythema or tenderness; limiting instrumental ADLs	Covering >30% BSA; associated with erythema or tenderness; limiting self-care ADLs	—	—
Definition: A disorder characterized by shrinking of adipose tissue					
Hirsutism	In women, increase in length, thickness, or density of hair in a male distribution that the patient is able to camouflage by periodic shaving, bleaching, or removal of hair	In women, increase in length, thickness, or density of hair in a male distribution that requires daily shaving or consistent destructive means of hair removal to camouflage; associated with psychosocial impact	—	—	—
Definition: A disorder characterized by the presence of excess hair growth in women in anatomic sites where growth is considered to be a secondary male characteristic and under androgen control (beard, mustache, chest, abdomen)					
Hyperhidrosis	Limited to one site (palms, soles, or axillae); self-care interventions	Involving >1 site; patient seeks medical intervention; associated with psychosocial impact	Generalized involving sites other than palms, soles, or axillae; associated with electrolyte or hemodynamic imbalance	—	—
Definition: A disorder characterized by excessive perspiration					

Skin and Subcutaneous Tissue Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Hypertrichosis	Increase in length, thickness, or density of hair that the patient is either able to camouflage by periodic shaving or removal of hairs or is not concerned enough about the overgrowth to use any form of hair removal	Increase in length, thickness, or density of hair at least on the usual exposed areas of the body (face [not limited to the beard and mustache area] ± arms) that requires frequent shaving or use of destructive means of hair removal to camouflage; associated with psychosocial impact	—	—	—
Definition: A disorder characterized by hair density or length beyond the accepted limits of normal in a particular body region, for a particular age or race					
Hypohidrosis	—	Symptomatic; limiting instrumental ADLs	Increase in body temperature; limiting self-care ADLs	Heat stroke	Death
Definition: A disorder characterized by reduced sweating					
Lipohypertrophy	Asymptomatic and covering <10% BSA	Covering 10%–30% BSA and associated tenderness; limiting instrumental ADLs	Covering >30% BSA and associated tenderness and narcotics or NSAIDs indicated; lipohypertrophy; limiting self-care ADLs	—	—
Definition: A disorder characterized by hypertrophy of the subcutaneous adipose tissue at the site of multiple subcutaneous injections of insulin					
Nail discoloration	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	—	—	—	—
Definition: A disorder characterized by a change in the color of the nail plate					
Nail loss	Asymptomatic separation of the nail bed from the nail plate or nail loss	Symptomatic separation of the nail bed from the nail plate or nail loss; limiting instrumental ADLs	—	—	—
Definition: A disorder characterized by loss of all or a portion of the nail					
Nail ridging	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	—	—	—	—
Definition: A disorder characterized by vertical or horizontal ridges on the nails					
Pain of skin	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the skin					
Palmar-plantar erythrodysesthesia syndrome	Minimal skin changes or dermatitis (eg, erythema, edema, or hyperkeratosis) without pain	Skin changes (eg, peeling, blisters, bleeding, edema, or hyperkeratosis) with pain; limiting instrumental ADLs	Severe skin changes (eg, peeling, blisters, bleeding, edema, or hyperkeratosis) with pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by redness, marked discomfort, swelling, and tingling in the palms of the hands or the soles of the feet					
Periorbital edema	Soft or nonpitting	Indurated or pitting edema; topical intervention indicated	Edema associated with visual disturbance; increased intraocular pressure, glaucoma, or retinal hemorrhage; optic neuritis; diuretics indicated; operative intervention indicated	—	—
Definition: A disorder characterized by swelling resulting from an excessive accumulation of fluid around the orbits of the face					

Continued

Skin and Subcutaneous Tissue Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Photosensitivity	Painless erythema and erythema covering <10% BSA	Tender erythema covering 10%–30% BSA	Erythema covering >30% BSA and erythema with blistering; photosensitivity; oral corticosteroid therapy indicated; pain control indicated (eg, narcotics or NSAIDs)	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an increase in sensitivity of the skin to light					
Pruritus	Mild or localized; topical intervention indicated	Intense or widespread; intermittent; skin changes from scratching (eg, edema, papulation, excoriations, lichenification, oozing or crusts); oral intervention indicated; limiting instrumental ADLs	Intense or widespread; constant; limiting self-care ADLs or sleep; oral corticosteroid or immunosuppressive therapy indicated	—	—
Definition: A disorder characterized by an intense itching sensation					
Purpura	Combined area of lesions covering <10% BSA	Combined area of lesions covering 10%–30% BSA; bleeding with trauma	Combined area of lesions covering >30% BSA; spontaneous bleeding	—	—
Definition: A disorder characterized by hemorrhagic areas of the skin and mucous membrane. Newer lesions appear reddish in color. Older lesions are usually a darker purple color and eventually become a brownish-yellow color.					
Rash, acneiform	Papules or pustules covering <10% BSA, which may or may not be associated with symptoms of pruritus or tenderness	Papules or pustules covering 10%–30% BSA, which may or may not be associated with symptoms of pruritus or tenderness; associated with psychosocial impact; limiting instrumental ADLs	Papules or pustules covering >30% BSA, which may or may not be associated with symptoms of pruritus or tenderness; limiting self-care ADLs; associated with local superinfection with oral antibiotics indicated	Papules or pustules covering any % BSA, which may or may not be associated with symptoms of pruritus or tenderness and are associated with extensive superinfection with IV antibiotics indicated; life-threatening consequences	Death
Definition: A disorder characterized by an eruption of papules and pustules, typically appearing on the face, scalp, upper chest, and back					
Rash, maculopapular	Macules or papules covering <10% BSA with or without symptoms (eg, pruritus, burning, tightness)	Macules or papules covering 10%–30% BSA with or without symptoms (eg, pruritus, burning, tightness); limiting instrumental ADLs	Macules or papules covering >30% BSA with or without associated symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by the presence of macules (flat) and papules (elevated). Also known as morbilliform rash, it is one of the most common cutaneous adverse events, frequently affecting the upper trunk, spreading centripetally, and associated with pruritus.					
Scalp pain	Mild pain	Moderate pain; limiting instrumental ADLs	Severe pain; limiting self-care ADLs	—	—
Definition: A disorder characterized by marked discomfort sensation in the skin covering the top and the back of the head					
Skin atrophy	Covering <10% BSA; associated with telangiectasias or changes in skin color	Covering 10%–30% BSA; associated with striae or adnexal structure loss	Covering >30% BSA; associated with ulceration	—	—
Definition: A disorder characterized by the degeneration and thinning of the epidermis and dermis					
Skin hyperpigmentation	Hyperpigmentation covering <10% BSA; no psychosocial impact	Hyperpigmentation covering >10% BSA; associated psychosocial impact	—	—	—
Definition: A disorder characterized by darkening of the skin due to excessive melanin deposition					

Skin and Subcutaneous Tissue Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Skin hypopigmentation	Hypopigmentation or depigmentation covering <10% BSA; no psychosocial impact	Hypopigmentation or depigmentation covering >10% BSA; associated psychosocial impact	—	—	—
Definition: A disorder characterized by loss of skin pigment					
Skin induration	Mild induration, able to move skin parallel to plane (sliding) and perpendicular to skin (pinching up)	Moderate induration, able to slide skin, unable to pinch skin; limiting instrumental ADLs	Severe induration, unable to slide or pinch skin; limiting joint movement or orifice (eg, mouth, anus); limiting self-care ADLs	Generalized; associated with signs or symptoms of impaired breathing or feeding	Death
Definition: A disorder characterized by an area of hardness in the skin					
Skin ulceration	Combined area of ulcers <1 cm; nonblanchable erythema of intact skin with associated warmth or edema	Combined area of ulcers 1–2 cm; partial thickness skin loss involving skin or subcutaneous fat	Combined area of ulcers >2 cm; full-thickness skin loss involving damage to or necrosis of subcutaneous tissue that may extend down to fascia	Any size ulcer with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures with or without full thickness skin loss	Death
Definition: A disorder characterized by circumscribed, inflammatory, and necrotic erosive lesions on the skin					
Stevens-Johnson syndrome	—	—	Skin sloughing covering <10% BSA with associated signs (eg, erythema, purpura, epidermal detachment and mucous membrane detachment)	Skin sloughing covering 10%–30% BSA with associated signs (eg, erythema, purpura, epidermal detachment and mucous membrane detachment)	Death
Definition: A disorder characterized by <10% total body skin area separation of dermis. The syndrome is thought to be a hypersensitivity complex affecting the skin and the mucous membranes.					
Telangiectasia	Telangiectasias covering <10% BSA	Telangiectasias covering >10% BSA; associated with psychosocial impact	—	—	—
Definition: A disorder characterized by local dilatation of small vessels resulting in red discoloration of the skin or mucous membranes					
Toxic epidermal necrolysis	—	—	—	Skin sloughing covering ≥30% BSA with associated symptoms (eg, erythema, purpura, or epidermal detachment)	Death
Definition: A disorder characterized by >30% total body skin area separation of dermis. The syndrome is thought to be a hypersensitivity complex affecting the skin and the mucous membranes.					
Urticaria	Urticarial lesions covering <10% BSA; topical intervention indicated	Urticarial lesions covering 10%–30% BSA; oral intervention indicated	Urticarial lesions covering >30% BSA; IV intervention indicated	—	—
Definition: A disorder characterized by an itchy skin eruption characterized by wheals with pale interiors and well-defined red margins					
Skin and subcutaneous tissue disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living; *BSA,* body surface area; *ICU,* intensive care unit; *IV,* intravenous; *NSAID,* nonsteroidal antiinflammatory drug.

Social Circumstances

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Menopause	Menopause occurring at 46–53 years of age	Menopause occurring at 40–45 years of age	Menopause occurring before 40 years of age	—	—
Definition: A disorder characterized by the permanent cessation of menses, usually defined as 12 consecutive months of amenorrhea in a woman older than 45 years of age					
Social circumstances—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living.

Surgical and Medical Procedures

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Surgical and medical procedures—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

ADL, Activity of daily living.

Vascular Disorders

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Capillary leak syndrome	—	Symptomatic; medical intervention indicated	Severe symptoms; intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by leakage of intravascular fluids into the extravascular space. This syndrome is observed in patients who demonstrate a state of generalized leaky capillaries following shock syndromes, low-flow states, ischemia-reperfusion injuries, toxemias, medications, or poisoning. It can lead to generalized edema and multiple organ failure.					
Flushing	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Moderate symptoms; medical intervention indicated; limiting instrumental ADLs	Symptomatic, associated with hypotension or tachycardia; limiting self-care ADLs	—	—
Definition: A disorder characterized by episodic reddening of the face					
Hematoma	Mild symptoms; intervention not indicated	Minimally invasive evacuation or aspiration indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by a localized collection of blood, usually clotted, in an organ, space, or tissue, resulting from a break in the wall of a blood vessel					

Vascular Disorders—cont'd

	Grade				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Hot flashes	Mild symptoms; intervention not indicated	Moderate symptoms; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by an uncomfortable and temporary sensation of intense body warmth and flushing, sometimes accompanied by sweating upon cooling					
Hypertension	Prehypertension (systolic BP 120–139 mm Hg or diastolic BP 80–89 mm Hg)	Stage 1 hypertension (systolic BP 140–159 mm Hg or diastolic BP 90–99 mm Hg); medical intervention indicated; recurrent or persistent (≥24 h); symptomatic increase by >20 mm Hg (diastolic) or to >140/90 mm Hg if previously WNL; monotherapy indicated Pediatric: recurrent or persistent ≥24 h) BP >ULN; monotherapy indicated	Stage 2 hypertension (systolic BP ≥160 mm Hg or diastolic BP ≥100 mm Hg); medical intervention indicated; more than one drug or more intensive therapy than previously used indicated Pediatric: same as adult	Life-threatening consequences (eg, malignant hypertension, transient or permanent neurologic deficit, hypertensive crisis); urgent intervention indicated Pediatric: same as adult	Death
Definition: A disorder characterized by a pathologic increase in BP; a repeated elevation in the BP >140/90 mm Hg					
Hypotension	Asymptomatic; intervention not indicated	Non-urgent medical intervention indicated	Medical intervention or hospitalization indicated	Life-threatening and urgent intervention indicated	Death
Definition: A disorder characterized by BP that is below the normal expected for an individual in a given environment					
Lymph leakage	—	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by the loss of lymph fluid into the surrounding tissue or body cavity					
Lymphedema	Trace thickening or faint discoloration	Marked discoloration; leathery skin texture; papillary formation; limiting instrumental ADLs	Severe symptoms; limiting self-care ADLs	—	—
Definition: A disorder characterized by excessive fluid collection in tissues that causes swelling					
Lymphocele	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; medical intervention indicated	Severe symptoms; radiologic, endoscopic, or elective operative intervention indicated	—	—
Definition: A disorder characterized by a cystic lesion containing lymph					
Peripheral ischemia	—	Brief (<24 h) episode of ischemia managed nonsurgically and without permanent deficit	Recurring or prolonged (≥24 h) and/or invasive intervention indicated	Life-threatening consequences; evidence of end-organ damage; urgent operative intervention indicated	Death
Definition: A disorder characterized by impaired circulation to an extremity					
Phlebitis	—	Present	—	—	—
Definition: A disorder characterized by inflammation of the wall of a vein					
Superficial thrombophlebitis	—	Present	—	—	—
Definition: A disorder characterized by a blood clot and inflammation involving a superficial vein of the extremities					

Continued

Vascular Disorders—cont'd

Adverse Event	Grade 1	2	3	4	5
Superior vena cava syndrome	Asymptomatic; incidental finding of SVC thrombosis	Symptomatic; medical intervention indicated (eg, anticoagulation, radiation, or chemotherapy)	Severe symptoms; multimodality intervention indicated (eg, anticoagulation, chemotherapy, radiation, stenting)	Life-threatening consequences; urgent multimodality intervention indicated (eg, lysis, thrombectomy, surgery)	Death
Definition: A disorder characterized by obstruction of the blood flow in the SVC. Signs and symptoms include swelling and cyanosis of the face, neck, and upper arms; cough; orthopnea; and headache.					
Thromboembolic event	Venous thrombosis (eg, superficial thrombosis)	Venous thrombosis (eg, uncomplicated deep vein thrombosis), medical intervention indicated	Thrombosis (eg, uncomplicated pulmonary embolism [venous], nonembolic cardiac mural [arterial] thrombus), medical intervention indicated	Life-threatening (eg, pulmonary embolism, cerebrovascular event, arterial insufficiency); hemodynamic or neurologic instability; urgent intervention indicated	Death
Definition: A disorder characterized by occlusion of a vessel by a thrombus that has migrated from a distal site via the bloodstream					
Vasculitis	Asymptomatic; intervention not indicated	Moderate symptoms, medical intervention indicated	Severe symptoms, medical intervention indicated (eg, steroids)	Life-threatening; evidence of peripheral or visceral ischemia; urgent intervention indicated	Death
Definition: A disorder characterized by inflammation involving the wall of a vessel					
Visceral arterial ischemia	—	Brief (<24 h) episode of ischemia managed medically and without permanent deficit	Prolonged (≥24 h) or recurring symptoms and/or invasive intervention indicated	Life-threatening consequences; evidence of end-organ damage; urgent operative intervention indicated	Death
Definition: A disorder characterized by a decrease in blood supply caused by narrowing or blockage of a visceral (mesenteric) artery					
Vascular disorders—other, specify	Asymptomatic or mild symptoms; clinical or diagnostic observations only; intervention not indicated	Moderate; minimal, local, or noninvasive intervention indicated; limiting age-appropriate instrumental ADLs	Severe or medically significant but not immediately life threatening; hospitalization or prolongation of existing hospitalization indicated; disabling; limiting self-care ADLs	Life-threatening consequences; urgent intervention indicated	Death

Blood Component Therapy

Despite the recent increase in the use of hematopoietic growth factors, transfusion therapy plays an important role in caring for oncology patients, particularly now that more effective treatment regimens have led to longer survival. In many instances, a patient with cancer behaves like a patient with a chronic disease requiring frequent blood components caused by disorders secondary to the disease, treatment, or both. Whole blood is separated into cellular and noncellular components, including red blood cells (RBCs), platelets, and plasma.

1. Blood component: A portion of blood is separated by physical and mechanical means, such as differential centrifugation (Fig. C.1). Cell separation technology, capable of collecting platelets, plasma, granulocytes, peripheral blood stem cells, and RBCs, has an increasingly important role in transfusion medicine. Anticoagulants and other additives used in blood collection containers allow storage of liquid red cells for up to 42 days.
   a. Packed red blood cells (PRBCs): These cells are prepared from whole blood by centrifugation and subsequent removal of plasma.
      (1) Hematocrit: 60% to 80%
      (2) Indications
         (a) Replacement of hemoglobin-containing cells in an anemic patient with heart failure, renal failure, burns, or bone marrow failure
         (b) Debilitated patients
         (c) Elderly patients
         (d) Patients with liver disease
      (3) Recommend to use PRBCs for losses of blood less than 1000 to 1500 mL/70 kg; with greater losses, other blood components should be used
      (4) Therapeutic effect: In a 70-kg adult, each unit should increase the hematocrit by 3% to 4%.
   b. Frozen RBCs: Long-term preservation of frozen RBCs without damage can be accomplished by the addition of glycerol; before transfusion, the RBCs should be thawed and washed to remove glycerol
      (1) Advantages
         (a) Blood of rare types can be stored for long periods.
         (b) 2,3-Diphosphoglycerol and adenosine triphosphate levels remain the same as they were on the day that the blood was frozen.
         (c) Free of plasma protein, platelets, white blood cells, and fibrin
         (d) Has been claimed to reduce the incidence of hepatitis acquired from a blood transfusion
      (2) Disadvantages
         (a) Expensive
         (b) Outdated in 24 hours after thaw
         (c) Takes time to thaw and deglycerolize
   c. Buffy coat: poor erythrocytes; would reduce the incidence of febrile transfusion reaction
      (1) Indications
         (a) Patients with repeated febrile nonhemolytic transfusion reaction caused by leukocyte antibody
         (b) Hematopoietic growth factors applied to oncologies from transfusion therapy is designed to limit the exposure of patients to allogenic blood with its innate risks. The synthesis of erythropoietin (EPO) by recombinant technology was a very important advance in decreasing RBC transfusions. EPO has also been used to increase the yield of autologous donations and to stimulate erythropoiesis after surgery.
   d. Platelet concentrates
      (1) One unit of platelet concentrate contains 5.5×10^{10} platelets suspended in 30 to 50 mL of plasma
      (2) Shelf-life: 72 hours at room temperature
      (3) Thrombocytopenia does not usually produce serious bleeding unless the platelet count is below 20,000, except if there is a platelet function defect, a coagulation defect, or local cause of hemorrhage (e.g., trauma, surgery)
   e. Fresh-frozen plasma (FFP)
      (1) Contains albumin, globulin, active coagulation factors, complement, and electrolytes
      (2) Should be type specific
      (3) Shelf life: 12 months at −20° to −30°C; should be used within 2 hours after thawing
      (4) Indications
         (a) Deficiency in coagulation factors
         (b) Situation with plasma loss
         (c) Rapid reversal of oral anticoagulant therapy
   f. Cryoprecipitate: Cold insoluble precipitate remains when FFP is allowed to thaw at 4°C; it contains factor VIII with fibrinogen and factor XIII
      (1) Indications
         (a) von Willebrand disease
         (b) Replacement of fibrinogen, factor XIII

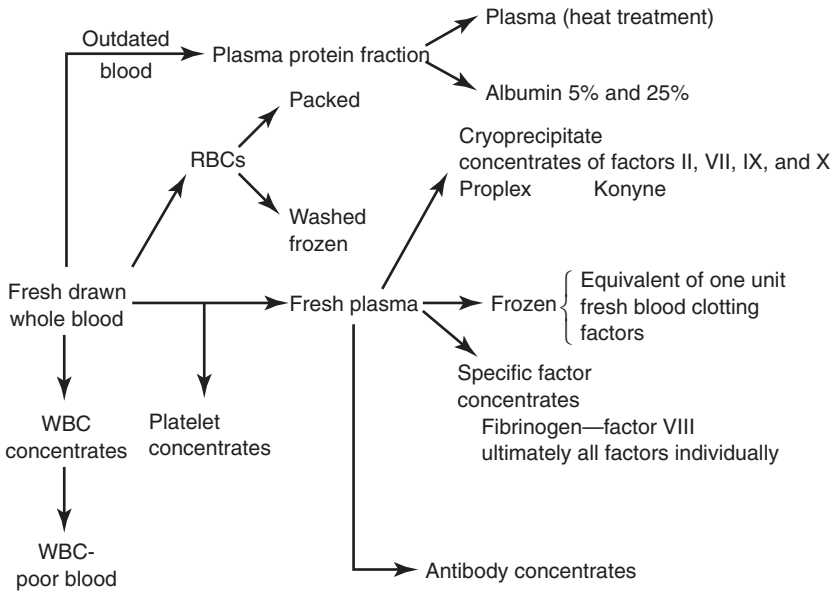

FIGURE C.1 Separation of a unit of whole blood into its various components. *RBC,* Red blood cell; *WBC,* white blood cell.

2. Plasma fraction: derivatives of plasma are obtained by a chemical process such as alcohol precipitation
   a. Coagulation factor concentrates
      (1) Factor VIII concentrates
      (2) Factor IX concentrates
      (3) Prothrombin complex (factor II, VII, IX, X concentrates)
      (4) Fibrinogen concentrates
   b. Immunoglobulin concentrates
   c. Albumin: filtered and pasteurized by heating for 10 hours at 60°C to eliminate the risks of viral hepatitis
      (1) 5% albumin: isosmotic, sodium 145 mEq/L; for rapid expansion of vascular volume
      (2) 25% albumin: sodium 145 mEq/L; given intravenously; one volume of 25% albumin will draw about four volumes of additional fluid from the extravascular space into the circulation; used for treatment of hypoalbuminemia
   d. Plasma protein factor: 5% solution of selected human plasma protein in buffered saline solution; heat treated to eliminate the risk of hepatitis; indicated for rapid expansion of vascular volume
3. Stroma-free hemoglobin solution
   a. Advantages
      (1) No need for blood typing
      (2) Longer storage capacity
      (3) Maintains better microcirculation
      (4) Potentially improved oxygenation of ischemic myocardium
      (5) No antigenicity
4. Autologous blood: The collection and reinfusion of the patient's own blood by preoperative autologous blood donation or intraoperative blood salvage. For autologous blood donation, the blood should be taken at least 2 weeks before the surgical procedure, and the patient must maintain a hemoglobin level of 11 g/dL or more. If large amounts of blood are required, frozen cells are another option. Many patients can donate as often as once a week. Intraoperative blood salvage requires the sterile collection and reinfusion of shed blood that is free of infecting agents such as malignant cells. The RBCs are collected in sterile plastic bags, washed, and concentrated before being reinfused into the patient.
5. Complications: infection, transfusion reactions, and alloimmunization are the major complications associated with the transfusion of blood components (Table C.1).

TABLE C.1 Risk of Infection

Agent Risk	Unit
Hepatitis B	1:50,000
Hepatitis C	1:100,000
Human immunodeficiency virus	1:150,000–1:1,000,000
Human T cell lymphotropic virus	1:50,000

From ACOG, Technical Bulletin 199, Nov. 1994, and Management of Hepatitis C. NIH Consensus Statement Online 1997;15(3):1.

Once in each 6000 units of blood transferred, an acute hemolytic reaction will occur, with a mortality rate of 1 in 17. These reactions are usually due to ABO incompatibility and resultant intracellular hemolysis. Patients develop fever, chills, chest pain, nausea, hypotension, and disseminated intravascular coagulation. Mild reactions to leukocyte and platelet antigens are usually associated with a febrile episode alone. Hemolytic reactions to other blood groups such as Kidd, Duffy, and Kell can be associated with fever, anemia, and hyperbilirubinemia and a positive direct Coombs test result. Some of these milder

transfusions reactions manifest themselves 7 to 10 days after the transfusion.

Hematopoietic growth factors are designed to limit the exposure of oncology patients to blood and blood products. RBC substitutes are currently in development, and some are in phase II and III clinical trials. None are currently approved for clinical use in the United States. They consist of artificially derived products that have oxygen-carrying properties and are structurally similar to hemoglobin. Their development has been hampered by relatively short half-life in the circulation.

The isolation and then synthesis of erythropoietin has been very helpful in limiting RBC transfusions. Granulocyte colony-stimulating factor (G-CSF) has been proven to decrease infection rates in neutropenic patients after chemotherapy. The limitations of platelet transfusions have stimulated the research into agents that can stimulate platelet production, and such products are now available. In addition, thrombopoietic growth factors have the potential to stimulate platelet apheresis donors and increase stem cell harvest yields, thus expanding progenitor cells.

APPENDIX D

Suggested Recommendations for Routine Cancer Screening

CERVICAL CANCER

Cervical cancer screening should begin at age 21 years. Cytologic screening is recommended every 2 years for women ages 21 to 29 years with either conventional or liquid-based cytology. Women ages 30 years and older who have had three consecutive cervical cytology test results that are negative for intraepithelial lesions and malignancy may be screened every 3 years. Women with any of the following risk factors may require more frequent cervical cytology:

1. Women who are immunosuppressed
2. Women who are infected with human immunodeficiency virus (HIV)
3. Women who were exposed to diethylstilbestrol in utero
4. Women who were previously treated for cervical intraepithelial neoplasia (CIN) 2 or 3 or cancer

Co-testing using the combination of cytology plus HPV DNA testing is appropriate screening for women older than 30 years. Co-testing in women younger than 30 years is not recommended.

In women who have had a total hysterectomy for benign indications with no history of high-grade CIN, routine cytology testing should be discontinued.

It is reasonable to discontinue cervical cancer screening between 65 and 70 years of age in women who have had three or more negative cytology test results in a row and no abnormal test results in the past 10 years.

Women who have been immunized against HPV-16 and HPV-18 should be screened by the same regimen as nonimmunized women.

BREAST CANCER

Mammography should be performed every year for women 40 years of age and older.

Evidence from several studies indicates that there is a decrease in mortality for all women when appropriate screening by mammography is instituted and performed by qualified personnel. The efficacy of mammography is not in doubt. The question that remains is the optimal screening frequency, and the answer may be provided by data now being compiled. Safety is no longer a concern, but it is recognized that mammography is the most costly of all screening modalities. Dedicated equipment is essential, and considerable skill and experience are required to interpret the films. It is important, therefore, to determine the most prudent utilization of resources. Until the optimal screening frequency is determined, it appears reasonable to follow recommendations of the American College of Obstetricians and Gynecologists, American Cancer Society, and National Cancer Institute.

ENDOMETRIAL CANCER

Total population screening for endometrial cancer and its precursors is neither cost effective nor warranted. High-risk patients may require endometrial sampling.

The cost effectiveness of screening asymptomatic women for endometrial cancer and its precursors is very low; therefore, the practice is unwarranted. On the other hand, perimenopausal and postmenopausal women with a history or evidence of abnormal vaginal hemorrhage are at high risk for endometrial cancer, and their symptoms should be investigated by endometrial biopsy or curettage. Dilatation and curettage are recommended when endometrial hyperplasia or questionable endometrial carcinoma is present and when there is insufficient tissue for diagnosis by endometrial biopsy.

If estrogen and progestin therapy is instituted, endometrial biopsy is not required before treatment is begun unless there are reasons (e.g., abnormal bleeding) to place the patient at high risk for endometrial neoplasia. If unexpected breakthrough bleeding occurs during therapy, endometrial biopsy is recommended to rule out the development of abnormal endometrial histology. Endometrial biopsy by aspiration curettage performed in the office is diagnostically reliable and cost effective in symptomatic patients. The timing of further biopsies, if needed, is a clinical decision that should be based on previous histologic results and the patient's history.

OVARIAN CANCER

No available techniques are currently suitable for routine screening. Many different techniques, including peritoneal fluid profiles, investigation of tumor-associated antigens, and ultrasonography, have been or are being investigated as possible screening tools for ovarian cancer. To date, none of these techniques has proved to be practical or effective.

COLORECTAL CANCER

Beginning at 50 years of age, one of three screening options should be selected: (1) yearly fecal occult blood testing plus flexible sigmoidoscopy every 5 years, (2) colonoscopy every 10 years, or (3) double-contrast barium enema (DCBE) every 5 to 10 years. A digital rectal examination should be performed at the time of each screening sigmoidoscopy, colonoscopy, or DCBE.

Available data do not substantiate the cost-effectiveness of various screening recommendations. Because colorectal cancer is a significant risk to women, the task force suggests that the recommendations of the American Cancer Society (American College of Obstetricians and Gynecology [ACOG]) and the National Cancer Institute be used as a guide.

LUNG CANCER

No available techniques are currently suitable for routine screening. The only effective way to reduce mortality from lung cancer is to promote a "stop smoking" message to the public. Although some support is evolving for annual radiographic screening for those at risk (i.e., women 50 years and older who smoke more than one pack of cigarettes daily), neither the American Cancer Society nor the National Cancer Institute has adopted this guideline. This information is based on the ACOG Committee Opinion, No. 247, December 2000.

APPENDIX E

Nutritional Therapy

In patients with cancer, malnutrition may appear simultaneously with the disease. Patients with cancer often exhibit anorexia because of decreased nutritional intake with resultant weight loss. There may be an increased nutritional requirement because of the increased demands of the patient and the tumor. Resting metabolic rates can vary greatly, but in as many as 60% of patients, the rate may be elevated. The stage of malnutrition in patients with cancer can lead to cachexia with weakness and tissue wasting. The extent of malnutrition in the patient may be greater than can be explained by decreased nutritional intake. Metabolic abnormalities include an abnormal response to glucose tolerance testing, increased gluconeogenesis (which can result in decreased muscle protein synthesis), and abnormalities in protein and fat metabolism. A patient with a malignancy may need additional nutritional support while undergoing intensive treatment, which can include surgery and chemotherapy. **Parenteral nutrition seems to improve a patient's tolerance of the treatment and improves her nutritional state; however, parenteral nutrition has not been shown to improve survival.**

The malnutrition seen in cancer patients is commonly referred to as *cancer cachexia.* Nutritional depletion is seen as a protein-calorie malnutrition with a loss of body cell mass. The importance of protein-calorie nutrition is its association with increases in postoperative complications, deficiencies in immune function, and poorer tolerance of therapy.

Dietary nutrients required for good health include water, protein, fat, carbohydrates, vitamins, and minerals. Energy is required for normal body function, growth, and repair. Protein is necessary for growth and development to maintain body structures and function. It is the source of the essential amino acids and nitrogen needed for the synthesis of nonessential amino acids. Dietary protein replaces the essential amino acids and nitrogen that are lost through protein turnover and normal body functions. During illness, protein requirements increase. **Nitrogen balance is essential for good health and requires intake of protein and energy.** At higher energy intakes, less protein is needed to achieve nitrogen balance. Nitrogen is lost continuously in the body through normal body functions. Fat is the food substance with the highest concentration of calories.

The visual protein compartment is best measured by assessment of the plasma albumin, transferrin, and total lymphocyte count. Albumin is the major determinant of plasma colloidal osmotic pressure because its large size does not permit it to pass the capillary membrane. The appearance of edema is often a sign of low serum albumin. Serum levels lower than 3.0 g/dL are reflective of nutritional deficiency. Transferrin is a protein of hepatic origin and transports iron. The level is reflective of the patient's ability to make serum protein. Transferrin levels are more sensitive than albumin levels because of its shorter half-life (8 days compared with 20 days), and it is preferable to evaluate the efficacy of nutritional therapy. The response of a patient's total lymphocyte count to nutritional therapy may also be a favorable prognostic sign during the first 7 to 14 days of therapy (Table E.1).

Linoleic acid is the only essential fatty acid required in the diet; it is necessary for the synthesis of arachidonic acid, which is a major precursor of prostaglandin. Linoleic acid comes mainly from polyunsaturated vegetable oils. **A deficiency of essential fatty acids results in poor wound healing, hair loss, and dermatitis.** Fatty acids and cholesterol make up most of the fat in our diets. Carbohydrates include sugar, starch, and fibers. **When carbohydrates are not included in the diet, ketosis begins to occur, and there is excessive breakdown of protein as amino acids are used for gluconeogenesis.** Water-soluble and fat-soluble vitamins cannot be synthesized in adequate amounts by the body. **Fat-soluble vitamins are required for absorption, transport, metabolism, and storage.** They are not excreted in the urine like the water-soluble vitamins, and an excess accumulation can lead to well-known toxic conditions. Major minerals, as well as trace elements, are important in human nutrition.

Lack of appetite with reduction in food intake is a key factor in cancer cachexia. The role of the neurotransmitter serotonin appears to be central to appetite. Inhibition of serotonin increases appetite and food intake in animals. Cancer patients also report a loss of taste and smell with a resulting loss of appeal of most foods. Weight loss may also be greatly influenced when the location of the tumor affects the ability to take nutrition (eg, a mass causing a partial bowel obstruction). Cytokines produced by the patient in response to a growing neoplasm may result in nutritional derangements. Cytokines can regulate appetite and metabolic rate, so they can be very important factors. Dudrick and coworkers suggest that patients who have a 10-lb weight loss or a 10% decrease in body weight 2 months before assessment, serum albumin of less than 3.4 g/dL, alergy to four of five standard skin test antigens, and a low total lymphocyte count and who cannot or will not eat enough are candidates for nutritional assessment. Nutritional history, with a 24-hour dietary recall, can be used to assess nutritional intake. Anthropometric measurements are useful when assessing the

TABLE E.1 Indications for Total Parenteral Nutrition*

Severely malnourished patients undergoing surgery
Patients with postoperative complications that require nutritional support
Therapy-induced complications that require nutritional support

*Routine use of total parenteral nutrition (TPN) in patients with cancer is not indicated.

patient's nutritional status. **Relative body weight is probably the most useful of these measurements because rapid weight loss is usually an indication of protein-calorie undernutrition.** The triceps skinfold test assesses fat stores, and midarm circumference tends to assess protein status. **Edema, which is often seen with protein-calorie deficiency, can mask true weight loss and muscle wasting. Serum albumin is probably the single most important test for determining protein calorie undernutrition. Albumin is the main plasma protein needed to maintain plasma osmotic pressure as well as other functions.** In a patient with low albumin, morbidity and mortality are increased. Albumin can be influenced by conditions other than malnutrition and may be affected by hydration status. **Transferrin binds and transports iron in the plasma and is a good indicator of protein nutritional status.** The extent of malnutrition depends on the type and site of the cancer. Cancers such as ovarian cancer, with its potential effect on the gastrointestinal (GI) tract, appear to contribute to malnutrition to a greater degree than does cervical cancer. As expected, malnutrition becomes worse as the cancer progresses. The mechanism of cancer-related malnutrition is unknown. There are probably multiple contributing factors. **Decreased food intake because of anorexia, early satiety, nausea, and vomiting can all play a role. Poor absorption of nutrients can also be a contributing factor. Food aversion, particularly in patients undergoing chemotherapy or irradiation, is well known.** Change of taste and smell can contribute to decreased intake. Generalized weakness may also contribute to decreased food intake. Decrease in total lymphocyte count (<1200 cells/mL) is also suggestive of malnutrition. Creatinine height index (CHI) may be helpful because urinary creatinine excretion is proportional to total body muscle mass. As muscles become depleted, creatinine excretion falls. A CHI of 80% or more usually indicates a normal lean body mass. A CHI between 60% and 80% indicates moderate depletion; a CHI of less than 60% indicates severe depletion.

ENTERNAL NUTRITION

Numerous clinical trials have been published using aggressive enteral nutritional support as a supplement during cancer therapy in patients who would not eat well. The trials are not consistent in demonstrating benefit of enteral nutrition. However, it is a well-accepted concept that enteral therapy is the preferred route for feeding cancer patients when the GI tract is not obstructed. Methods of enteral nutrition vary from frequent snack between meals to the insertion of a comfortable nasogastric feeding tube on a continuous drip of nutritional supplements. Others have used gastrostomy or jejunostomy feeding tubes.

The role of total parenteral nutrition (TPN) in patients with cancer has yet to be determined. TPN can correct nutritional deficits that commonly occur in patients with cancer. TPN can also improve nitrogen balance and decrease catabolism. Glucose turnover and clearance rates are increased, gluconeogenesis is suppressed, and free fatty acid oxidation is increased. TPN can increase body weight and reverse serum markers of malnutrition; however, as an adjuvant to cancer therapy, the results have not been encouraging. TPN has not added to lean body mass or eliminated the GI or hematologic toxicity associated with chemotherapy. **In patients treated with chemotherapy, response rates and survival have not been increased with TPN.** Although irradiation can contribute to poor nutrition (eg, diarrhea, enteritis, and malabsorption), particularly to the GI tract when gynecologic cancers are treated, **TPN has not produced a significant improvement regarding treatment response, tolerance to treatment, local control, survival, or decreased complications of therapy. Nutritional support for patients with cancer requiring surgery is also ill defined.** Malnourished patients undergoing surgery have a higher postoperative morbidity and mortality compared with well-nourished patients. Whether TPN can affect morbidity and mortality in patients with cancer is undetermined, and the concern that TPN may stimulate tumor growth is unfounded. **Although routine use of TPN in patients with cancer is not warranted, it may be indicated in severely malnourished patients undergoing surgery or for those with postoperative complications.**

Nutritional supports are of two main types: enteric and parenteral. For a patient with a functional GI tract, enteric nutrition may be considered through the use of a nasoenteric tube. A gastrostomy or jejunostomy tube may also be used. Obviously, GI dysfunction is a contraindication to this method. Nevertheless, this method appears to be cost effective; it probably maintains the GI mucosa integrity, provides a normal sequence of intestinal and hepatic metabolism before systemic distribution, appears to preserve normal hormonal patterns, and avoids the risk of sepsis. Enteric solutions differ in composition, calorie content, and multiple other factors. These solutions are usually complete because they contain a full supplement of nutrient requirements or incomplete when they are designated to contain a specific macronutrient such as fat, protein, or carbohydrate. **Most solutions contain 1000 calories and 37 to 45 g/L of protein.** Elemental diets consist mainly of amino acids and simple sugars. They are extremely hypertonic and may induce diarrhea, which may be corrected with a formula of lower osmolarity. Electrolyte imbalance and glucose intolerance can also occur.

Many patients with cancer who require nutritional supplementation will need TPN. In some cases, TPN can be administered through a peripheral vein, particularly if TPN is to be given for only a short amount of time. Although adequate protein can usually be infused peripherally, high-caloric

supplementation is usually given centrally. Fat solutions, which can account for a high caloric intake, can be given peripherally. **Major complications of peripheral TPN are thrombophlebitis and infiltration. In most cases, TPN is given through a central vein—either the subclavian vein or a major neck vessel.** The catheter can be inserted in the superior vena cava, which allows rapid infusion of hypertonic solutions without difficulty. **Infusion of parenteral solution should be started slowly to prevent hyperglycemia. If glucose intolerance develops, a small amount of insulin is used to control blood sugars.** Meticulous care must be taken of the central catheter because this site can be a major source of infection. Frequent changing of intravenous tubing and filters and the catheter is required routinely. TPN is usually managed as a team endeavor with the attending physician, nutritionist, nurse, pharmacist, and dietitian. Daily requirements must be standardized regarding calories, proteins, fat, minerals, vitamins, and trace elements. These should be varied as the situation demands. **Metabolic complications may include hyperglycemia or hypoglycemia, hyperosmolarity, azotemia, hyperchloremic metabolic acidosis, mineral electrolyte disorder, liver enzyme elevations, and anemia.** In many hospitals, standard hyperalimentation solutions with appropriate nutrients have been formulated, and adjustments are made for specific needs. Intense metabolic monitoring is required in these patients, and established hospital protocols are now available in many institutions.

Today, both enteric and parenteral nutritional support can be implemented successfully on an outpatient basis. Indications are not uniformly agreed on for this method of nutrition. In patients with cancer, nutritional support may be indicated to help satisfy nutritional needs while toxicity of treatment is abating. Most authorities do not believe that home nutritional support is needed for terminally ill cancer patients.

A typical nutritional guideline for adult patients is shown in Table E.2 (see the Expert Consult website). Many institutions have nutritional protocols in place. Although there may be

TABLE E.2 Nutritional Guidelines for Adult Patients

I. Daily protein needs

Maintenance	0.8–1 g/kg
Mild to moderate stress	1–1.5 g/kg
Moderate to severe stress	1.5–2 g/kg
Very high stress or burns	>2 g/kg

II. Daily caloric needs

(Consider initiating HAL with 50%–75% of estimated patient needs on day 1.)

- Maintenance, mild stress: 20–25 kcal/kg (15–20 NPC/kg)
- Mild to moderate stress (routine surgery, minor infection): 25–30 kcal/kg (20–25 NPC/kg)
- Moderate to severe stress (major surgery, sepsis, tumor treatment): 30–35 kcal/kg (25–30 NPC/kg)

III. Body weight calculations

- TBW = patient's weight (kg)
- IBW (male) = 50 kg + (2.3 × no. of inches >5 ft)
- IBW (female) = 45 kg + (2.3 × no. of inches >5 ft)
- ABW for an obese patient = IBW + 0.3 × (TBW − IBW)

IV. Suggested laboratory tests

- Baseline and weekly: Chem 10, Chem 13
- Daily: Chem 10 × 3 days or until stabilized prealbumin as clinically indicated

V. Formula

A. Standard formula

	Central	Peripheral ($D^{10}A_{3,6}$)
Amino acids (g)	55 mg/L	30 g/L
Dextrose (kcal)	555 kcal/L	280 kcal/L
Lipids (kcal)	400 kcal/L	350 kcal/L
NPC	955 NPC/L	630 NPC/L
Total kcal	1175 kcal/L	750 kcal/L
Desired total volume/day	_____ mL*	_____ mL*

B. Modified central formula

1. Protein:
   Daily protein needs × Body weight calculations = _____ g protein/day
2. NPC:
   Daily caloric needs × Body weight calculations = _____ NPC/day
3. Percentages of NPC:
   Usually 50%–70% of daily NPC as CHO + usually 30%–50% of daily NPC as fat = 100%
4. Infusion rate (see HAL bag for exact infusion rate)
   ☐ Maximally concentrated† or ☐ infusion rate _____ mg/h

Continued

TABLE E.2 Nutritional Guidelines for Adult Patients—cont'd

VI. Electrolytes	□ Standard	□ Modified	Acetate/Chloride
Sodium	80 mEq/L	_____ mEq/L	_____balance
Potassium	40 mEq/L	_____ mEq/L	_____ maximum acetate
Calcium	5 mEq/L	_____ mEq/L	_____ maximum chloride
Magnesium	8 mEq/L	_____ mEq/L	_____ : _____ chloride : acetate

VII. Vitamins and trace elements

(MV1-12 and standard trace elements will automatically be added unless otherwise specified)

_____ vitamin K 1 mg/day _____ no vitamin K

A. Content of MV1-12

Vitamin A	3300 IU	Vitamin B_5	15 mg
Vitamin D	200 IU	Vitamin B_6	4 mg
Vitamin E	10 mg	Vitamin B_{12}	5 mcg
Vitamin B_1	3 mg	Vitamin C	100 mg
Vitamin B_2	3.6 mg	Biotin	60 mcg
Vitamin B_3	40 mg	Folic acid	0.4 mg

B. Content of standard trace elements

Chromium chloride	12 mcg
Copper sulfate	1.2 mg
Manganese sulfate	0.3 mg
Zinc sulfate	3 mg

VIII. Other additives

_____ Humulin regular insulin _____ units/day

_____ H_2 antagonist _____ m/day

_____ Other (specify)

IX. Hyperalimentation access

_____ Central _____ Peripheral

X. Special instructions

*See HAL bag for exact infusion rate.

†Calculation of volume of maximally concentrated HAL:

[1]AA: _____ protein/day × 10 mL/g AA = _____ mL 10% AA solution.

[2]Dextrose: _____ NPC/day × _____% as CHO = _____ kcal CHO ÷ 3.4 kcal/g CHO = _____ g CHO × 1.43 mL/g = _____ mL D70.

[3]Lipid: _____ NPC/day × _____% as fat = _____ kcal fat ÷ 2 kcal/mL = _____ mL 20% lipids.

[4]Maximally concentrated volume = _____ (from 1 above) mL 10% AA + _____ (from 2 above) mL D70 + _____ (from 3 above) mL 20% lipids = _____ mL/day.

[5]Approximate infusion rate = _____ (from 4 above) mL/day ÷ 24 hr/day = _____ mL/hr. (Actual infusion rate may be altered by volume of additives; see HAL bag for exact infusion rate.)

AA, Amino acid; *ABW,* adjusted body weight; *CHO,* carbohydrate; *HAL,* hyperalimentation; *IBW,* ideal body weight; *MV,* multivitamins; *TBW,* total body weight.

Courtesy of the Nutritional and Pharmacy Divisions of the Medical University of South Carolina.

variations on the theme, these guidelines have become relatively standardized.

Additional therapies can also be considered along with nutritional support to alleviate cancer cachexia. Synthetic progestins (megestrol acetate and medroxyprogesterone acetate) in high doses decrease the production of cytokines and serotonin and thus improve appetite and a sense of well-being. Responses often are seen within 15 to 30 days of therapy, and side effects are minimal. Some authors have reported more thromboembolic events with megestrol acetate but not in placebo-controlled studies.

  in pregnancy, 353–418
  vulvar, 411–412
Capecitabine, 459*t*–462*t*
Carboplatin, 459*t*–462*t*
Carcinoembryonic antigen, 397*t*
Carcinogenesis, radiation-induced, 390
Carcinoid tumor, 304
Carcinoma
  endometrial
    distribution by stage, 133*t*
    histologic patterns in, 130*f*
    staging system for, 133*t*
    subtypes, 129*t*
  infiltrating lobular, 338–339
  inflammatory, 339
  invasive duct, 338
  serous tubal intraepithelial, 316
  of the vulva, survival rates for, 207*t*
Carcinoma in situ
  of vagina, 28*f*
  of vulva
    histologic section of, 32*f*
    pseudopigmented lesions of, 32*f*
Carcinosarcoma, 150–152, 150*f*–151*f*
  adjuvant therapy for, 152–153
  of cervix, 86–87, 86*f*
  radiation therapy for, 152
Cardiac toxicity, in chemotherapy, 467–468
Cardinal ligament, 60*f*
Cardiotoxicity, in targeted therapy, 490
Cardiovascular disease, estrogen replacement therapy and, 115–117, 115*t*
Cavitational ultrasonic surgical aspirator (CUSA), for vulvar intraepithelial neoplasia, 35–36
CC1-779 (temsirolimus), 480–481
Cediranib, 477, 477*f*
Celecoxib, 543*t*
Cell cycle, 594*f*
  control, 450–453, 451*f*–452*f*
Cervical adenocarcinoma, oral contraceptive use and, 3
Cervical canal, 38–39
Cervical cancer, 611
  advanced, surgical staging for, 568–569
  anatomy of, 38–39
  angiogenesis inhibitors for, 103
  bevacizumab for, 476, 476*f*
  carcinosarcoma, 86–87, 86*f*
  cervical conization, for adenocarcinoma in situ, and microinvasive carcinoma, 72–73, 73*t*
  chemotherapy for, 98–103, 98*t*–100*t*, 100*f*–102*f*, 103*t*
  description of, 1
Cervical cancer *(Continued)*
  early-stage, 53*t*, 55–75, 58*f*–59*f*
    fertility-sparing surgery for, 568, 568*t*
    postoperative adjuvant therapy, indications for, 65–67, 65*t*
    radical abdominal hysterectomy, with lymphadenectomy, 40*f*, 58–65, 60*f*–63*f*, 60*t*, 64*t*, 65*f*
    radical hysterectomy for, 566–568, 567*t*
  epidemiologic studies of, 39–41, 39*t*, 40*f*
  episiotomy site recurrence and, 364–365, 364*t*
  family history in, role of, 4–5
  fertility-preserving surgery, for early-stage tumors, 58*f*–59*f*, 72
  glandular tumors of, 49–50
  glassy cell carcinoma, 86–87
  goal of, prevention measures during pregnancy, 19
  gross appearance of, 46–47, 47*f*
  human papillomavirus infections and, 1
  human papillomavirus-targeted tumor-infiltrating T cells, 104
  immunotherapy for, 104
  invasive, 38–104
    clinical profile of, 41*t*, 44–49, 44*f*–45*f*, 46*t*
    pregnancy and, 361, 362*f*
  laparoscopic radical hysterectomy, with lymphadenectomy, 70–71, 70*t*, 71*f*
  lateral ovarian transposition for, 75
  lymphoma, 86–87, 87*f*
  management and prognosis of, 92
  melanoma, 86–87
  microinvasive carcinoma of, 41–44, 41*t*
  minimally invasive surgery for, 566–569
    fertility-sparing surgery, 568, 568*t*
    radical hysterectomy, 566–568, 567*t*
    surgical staging, 568–569
  morbidity and mortality in, 94–96, 96*f*–97*f*
  neoadjuvant chemotherapy, and novel treatment approaches, 83–84, 84*t*
  nerve-sparing radical hysterectomy, 67–69, 68*f*–69*f*, 68*t*
  neuroendocrine and uncommon tumors in, 85–86, 85*f*
  patient selection, 93–94, 95*f*, 95*t*
  pelvic exenteration for, 92–93, 92*f*–94*f*
  planned delay of therapy in, 365–366, 365*t*
  pregnancy and, 355–367
  quality of life in, 532*t*, 533–534
  radiation and chemotherapy for, 81–83, 81*t*–82*t*, 82*f*, 97–98
  radical hysterectomy for, 92–97
  robotic-assisted laparoscopic radical hysterectomy, with lymphadenectomy, 71–72, 71*f*, 72*t*
  routes of spread, 47–49, 47*t*, 48*f*–49*f*, 49*t*
  screening guidelines of, comparison of, 8*t*
  sentinel lymph node identification, 69–70, 69*f*, 70*t*
  sexual function after therapy for, 67
  signs and symptoms of, 96*t*
  smoking and, 3
  staging of, 50–55
    International Federation of Gynecology and Obstetrics, 50–52, 51*f*–53*f*
    positron emission tomography, 52–54, 54*f*, 54*t*
    surgical, 54–55, 55*f*–57*f*
  suboptimal treatment situations, 84–85
  survival results in, 95*t*, 96–97
  symptoms of, 46
Cervical cancer *(Continued)*
  therapeutic human papillomavirus vaccine, 104
  therapy for, 103–104
  treatment of, 75–85
    extended-field irradiation therapy for, 79–81, 79*f*, 80*t*
    intensity-modulated whole pelvic radiotherapy for, 76–77
    interstitial therapy for, 79, 79*f*
    radiotherapy for, 75–81, 76*t*
    radium and cesium therapy for, 77–79, 77*f*–78*f*
  vaginal radical trachelectomy, with laparoscopic lymphadenectomy, 73–75, 73*t*–74*t*, 74*f*–75*f*, 82*f*
Cervical conization, for adenocarcinoma in situ, and microinvasive carcinoma, 72–73, 73*t*
Cervical disease, treatment of, 17–18, 18*f*, 18*t*
Cervical dysplasia, in pregnancy, diagnosis of, 355–356
Cervical fascia, 60*f*
Cervical intraepithelial neoplasia (CIN)
  Bethesda 2001 classification, 6, 6*t*
  of exocervix, cone biopsy for, 18, 18*f*
  high-grade, 1–2
  incidence of, 9*f*
  with multiple mitotic figures, 2*f*
  in pregnancy
    management of, 359–360, 359*f*
    natural history of, 357–358
  smoking and, 3
  transition time of, 3*t*
Cervical laser ablation, for cervical disease, 17–18
Cervical myomas, 235*f*
Cervix, 38–39, 69*f*
  carcinoma of, 88–104, 88*t*, 89*f*–90*f*
  clear cell adenocarcinoma of, 227*t*
  glandular tumors of, 49–50
  glassy cell carcinoma of, 86
  malignant melanoma of, 87, 87*f*
  neuroendocrine and uncommon tumors of, 85–86, 85*f*
  preinvasive disease of, 1–19
    epidemiology of, 4–5
    future directions of, 19
    management of abnormal screening test results in, 12–15
    natural history of, 1–4
    Papanicolaou cytology testing for, 6
    screening of, 6–9, 6*t*, 8*t*, 9*f*–10*f*
Cervix uteri, 606
Cesarean-radical hysterectomy, with pelvic lymphadenectomies, 362–363, 362*f*
Cetuximab, 485
Chemoradiation therapy, for cancer of the vulva, 201
Chemotherapy
  for acute leukemia in pregnancy, 399
  basic principles of, 449–469
    cell cycle control in, 450–453, 451*f*–453*f*, 455*f*
    historical overview of, 450
  clinical response to, 450, 450*t*
  criteria for, 450
  cycle-specific agents in, 452–453, 454*t*
  cytotoxic, 471–472
  drugs in, categories of, 458–464
    agents derived from plants in, 463
    alkylating agents in, 458–463
    antiangiogenesis in, 459*t*–462*t*
    antimetabolites in, 459*t*–462*t*, 463

Chemotherapy *(Continued)*
antitumor antibiotics in, 459*t*–462*t*, 463
aromatase inhibitors in, 459*t*–462*t*
camptothecin analogs in, 459*t*–462*t*
hormonal agents in, 459*t*–462*t*, 463
immunotherapy in, 463–464
PARP inhibitors in, 459*t*–462*t*
targeted therapies in, 463–464
dynamics of, 453–454, 455*f*
endodermal sinus tumor treated with, 299–300
endometrial cancer treated with, 145
for epithelial ovarian cancer during pregnancy, 374–375
evaluation of new agents in, 468–469
germ cell tumors treated with, 294–296, 295*t*
for gestational trophoblastic neoplasia, 178*t*, 182*t*, 184, 188
gonadal function effect, 297
high-dose, for breast cancer, 348
for metastatic breast cancer, 380
nausea and vomiting in, 466, 466*t*–467*t*
neoadjuvant, 348–349
and adjuvant, for pregnancy-associated breast cancer, 379–380
for nonepithelial ovarian cancer during pregnancy, 373
for ovarian cancer, 275
pharmacologic principles of, 454–458
calculation of dosage in, 456–458, 457*f*–458*f*, 457*t*–458*t*
drug interactions in, 455–456
drug resistance in, 456, 456*t*
during pregnancy, 391–397
anthracycline, 393
antitumor antibiotics, 393
breastfeeding, 395
long-term neonatal follow-up, 395
maternal risks of, 394
occupational exposure, 394
