Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

We dedicate this book in memory of our friend, colleague, and co-editor, Dr. Scott McMeekin, who recently lost his own battle with cancer at 51 years of age. Readers of this book are undoubtedly familiar with his name because he authored more than 100 publications in the field of gynecologic oncology, and his expertise in uterine cancer placed him at the forefront of defining the standard of care for the management of this disease. His dedication to helping women with gynecologic cancers was only surpassed by his dedication to his wife Cathy; their children Charlotte, Jackson, and Remy; and his loving parents, Donald and Charlene. Although we will benefit from his scientific contributions for years to come, we will all miss his presence.

PREFACE

The first eight editions of *Clinical Gynecologic Oncology* were stimulated by a recognized need for a readable text on gynecologic cancer and related subjects addressed primarily to the community physician, resident, and other students involved with these patients. The practical aspects of the clinical presentation and management of these problems were heavily emphasized in these editions, and we have continued that style in this text. As in every other textbook, the authors interjected their own biases on many topics, especially in areas where more than one approach to management has been used. On the other hand, most major topics are treated in depth and supplemented with ample references to current literature so that the text can provide a comprehensive resource for study by the resident, fellow, or student of gynecologic oncology and serve as a source for review material.

We continued the practice of placing an outline on the first page of each chapter as a guide to the content for that section. We added "bullet" points to the chapters of this edition to emphasize important areas. Readers will notice that we have included topics not discussed in the former editions and expanded areas previously introduced. Some of these areas include new guidelines for managing dying patients; current management and reporting guidelines for cervical and vulvar cancer; current management and reporting guidelines for breast cancer; expanded discussion on the basic principles of genetic alterations in cancer; techniques for laparoscopic surgery in treatment of gynecologic cancers; and new information on breast, cervical, and colon cancer screenings and detection. The seventh edition contained, for the first time, color photographs of key gross and microscopic specimens for readers' review; we have continued that in this edition. In addition, Drs. Di Saia and Creasman have handed the reigns over to the three associate editors. We have included several new authors. Much more information is included to make the text as practical as possible for the practicing gynecologist. In addition, key points are highlighted for easy review.

Fortunately, many of the gynecologic malignancies have a high "cure" rate. This relatively impressive success rate with gynecologic cancers can be attributed in great part to the development of diagnostic techniques that can identify precancerous conditions, the ability to apply highly effective therapeutic modalities that are more restrictive elsewhere in the body, a better understanding of the disease spread patterns, and the development of more sophisticated and effective treatment in cancers that previously had very poor prognoses. As a result, today a patient with a gynecologic cancer may look toward more successful treatment and longer survival than at any other time. This optimism should be realistically transferred to the patient and her family. Patient denial must be tolerated until the patient decides that a frank conversation is desired. When the prognosis is discussed, some element of hope should always be introduced within the limits of reality and possibility.

The physician must be prepared to treat the malignancy in light of today's knowledge and to deal with the patient and her family in a compassionate and honest manner. Patients with gynecologic cancer need to feel that their physicians are confident and goal oriented. Although, unfortunately, gynecologic cancers will cause the demise of some individuals, it is hoped that the information collected in this book will help to increase the survival rate of these patients by bringing current practical knowledge to the attention of the primary care and specialized physician.

Our ideas are only intellectual instruments which we use to break into phenomena; we must change them when they have served their purpose, as we change a blunt lancet that we have used long enough.

—Claude Bernard (1813-1878)

Some patients, though conscious that their condition is perilous, recover their health simply through their contentment with the goodness of their physician.

—Hippocrates (440-370 bc)

ACKNOWLEDGMENTS

We wish to acknowledge the advice given and contributions made by several colleagues, including Michael A. Bidus, Wendy R. Brewster, Dana Chase, Christina S. Chu, Daniel L. Clarke-Pearson, Robert L. Coleman, Larry J. Copeland, Eric Eisenhauer, Jeffrey Fowler, Mary L. Gemignani, Emily M. Ko, Robert S. Mannel, Cara Mathews, D. Scott McMeekin, David Miller, Bradley J. Monk, David G. Mutch, G. Scott Rose, Stephen C. Rubin, Ritu Salani , Jeanne Schilder, Brian M. Slomovitz, John T. Soper, Frederick B. Stehman, Krishnansu S. Tewari, Joan Walker, Lari B. Wenzel, Siu-Fun Wong, Catheryn Yashar, and Rosemary E. Zuna. We give special thanks to Lucy DiGiuseppe and, especially, Lisa Kozik for their diligent administrative support in preparing the manuscript and to David F. Baker, Carol Beckerman, Richard Crippen, Susan Stokskopf, and David Wyer for their excellent and creative contributions to many of the illustrations created for this book.

We are grateful to the sincere and diligent efforts of Kate Dimock, Rebecca Gruliow, Teresa McBryan, Ashley Miner, and Beula Christopher from Elsevier in bringing this book to fruition. Through their deliberate illumination and clearing of our path, this material has traversed the far distance from mere concept to a compelling reference book.

Drs. Mannel, McMeekin, and Mutch would like to acknowledge and thank Drs. DiSaia and Creasman for their continuous and tireless mentorship throughout our careers. They have served as role models in our professional and personal lives.

OUTLINE

Natural History
Epidemiology
Human Papillomavirus Vaccination
Screening
Core Principles for Managing Abnormal Screening Test Results
Managing Abnormal Cervical Cancer Screening Test Results
Managing Abnormal Results in Young Women
Unsatisfactory Cytology
Pap-Negative, Human Papillomavirus–Positive Women
Atypical Squamous Cells of Undetermined Significance Cytology
Atypical Squamous Cells, Cannot Exclude HSIL
Low-Grade Squamous Intraepithelial Lesion
High-Grade Squamous Intraepithelial Lesion
Atypical Glandular Cells
Endometrial Cells in Older Women
Postcolposcopy Management
Managing Women With No Lesion or CIN1 at Colposcopy
Managing Women With CIN2 or CIN3
Treatment of Cervical Disease
Managing Abnormal Results During Pregnancy
Future Directions

KEY POINTS

1. Human papillomavirus (HPV) persistent expression is required for progression to cancer.
2. HPV vaccination has the potential to eradicate cervical cancer.
3. Cervical cancer screening now relies heavily on HPV testing.
4. mRNA expression is as sensitive but more specific than DNA testing.
5. Screening guidelines have changed dramatically with the use of contesting and increased intervals between screenings.

Cervical cancer was once the most common cancer in women. It is among the most preventable cancers, and it has become rare among women who engage in cervical cancer prevention programs. Nevertheless, with some 100,000 preinvasive lesions diagnosed in the United States annually, it remains a substantial threat. After tremendous gains following introduction of cytology screening half a century ago, cervical cancer rates continue to fall by about 1% annually. Careful compliance with evidence-based guidelines remains critical to sustaining progress. Effective programs reflect organized public health efforts encompassing patient and clinician education, vaccination against causative types of human papillomavirus (HPV), cytology and HPV screening, colposcopy triage for abnormal screening test results, and destruction of the at-risk cervical transformation zone for women with cancer precursors.

NATURAL HISTORY

Essentially all cervical cancers arise from persistent genital HPV infections (Fig. 1.1)**.** The International Agency for Research on Cancer has designated as carcinogenic 12 HPV types: HPV-16, -18, -31, -33, -35, -39, -45, -51, -52, -56, -58, and -59. As described by Halec and associates, another eight types have been designated as possibly or probably carcinogenic: HPV–26, -53, -66, -67, -68, -70, -73, and -82. Almost 200 HPV types have been identified. A new genotype is based on DNA sequencing. A new type must share less than 90% DNA homology in the L1, E6, and E7 compared with known HPV types.

HPV-16 is the most oncogenic, accounting for more than 50% of cervical cancers. HPV-18 is found in 10% of cervical cancers and plays a particularly important role in adenocarcinogenesis. Types 31, 33, and 45 each account for around 5% of cancers. The other types are less oncogenic but have been reported in large typing studies of cervical cancers. HPV-18 and related HPV-45 are linked to cancers found at a younger age.

HPV infection leads to cancer through multiple pathways, but interaction of the HPV E6 and E7 gene products with p53 and pRb are critical: By inactivating or activating degradation of their targets, E6 and E7 eliminate genetic surveillance and allow unchecked cell cycling, leading to accumulation of mutations and eventual invasive cancer. HPV-16 E6 and E7 bind their targets with greater affinity than other HPV types; this may

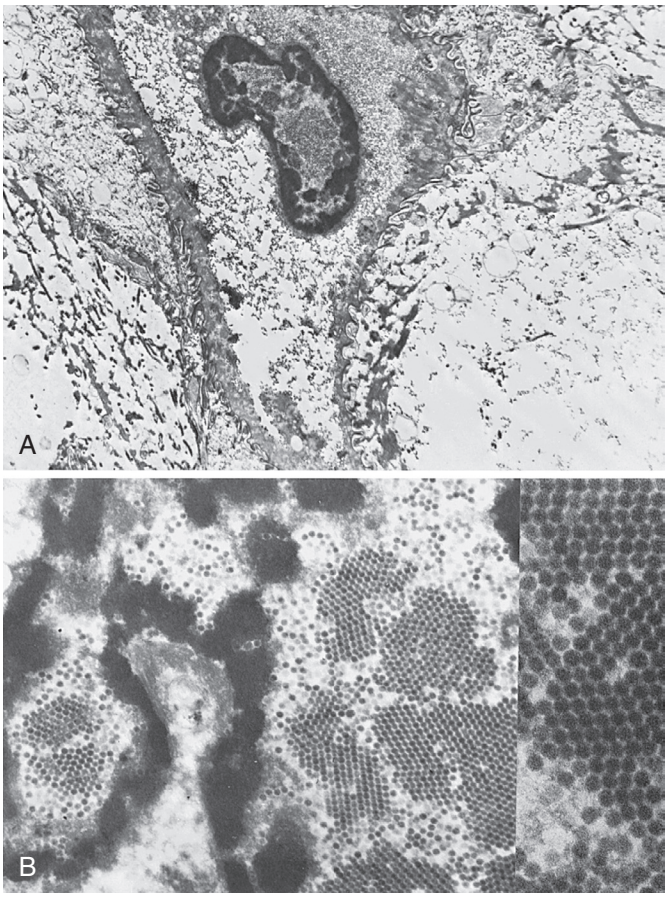

FIGURE 1.1 A, Koilocytotic cells with intranuclear virions (×6900). B, Human papillomavirus particles. Note the intranuclear crystalline array ("honeycomb") arrangement of virions (×20,500). See the *insert* (×80,000). (Courtesy of Alex Ferenczy, MD, Montreal, Canada.)

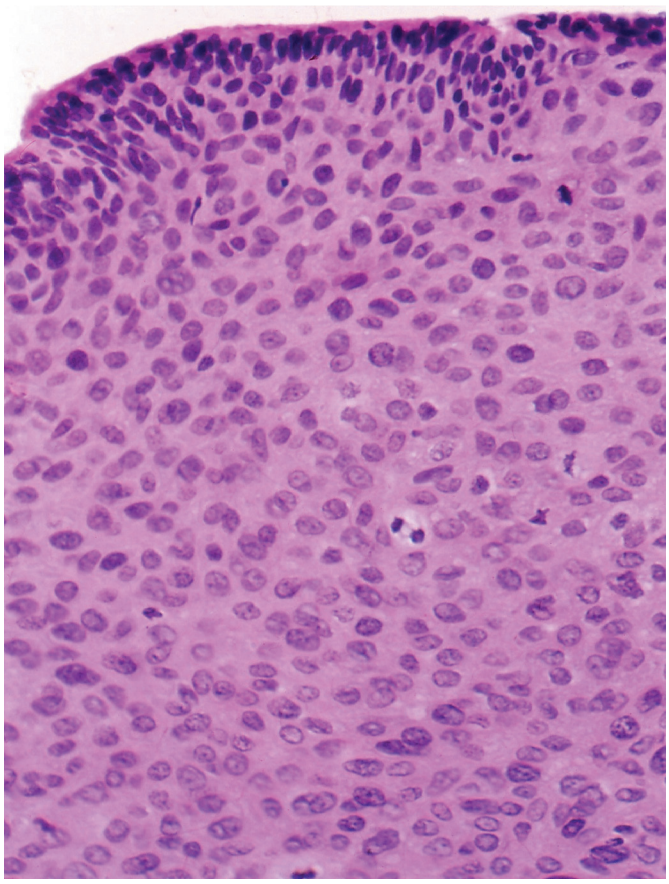

FIGURE 1.2 A cervical intraepithelial neoplasia lesion with multiple mitotic figures.

partly explain its greater oncogenicity. Persistent infections lead to cancer in steps: Initial infection into basal epithelial cells leads to establishment of a ring chromosome from which carcinogenic proteins are elaborated while virion production occurs in maturing epithelium. Disruption of the ring, often at the HPV E2 regulatory region, allows integration of E6 and E7 sequence into the host genome. The accumulation of mutations leads to nuclear changes visible cytologically as a high-grade squamous intraepithelial lesion (HSIL) and histologically as high-grade cervical intraepithelial neoplasia (CIN) (Fig. 1.2) is apparent histologically. Selection for invasiveness and metastasis through additional mutation and through gene methylation results in evolution to cancer. Multitype infections do not appear to increase cancer risk, and when multitype infections include HPV-16, most lesions are caused by HPV-16. Extant HPV infections do not appear to predispose to or protect from infection by unrelated types.

Vertical transmission of HPV from mother to infant has been documented in the Finnish HPV Family Study but does not appear to result in cervical infection, with genital HPV in only 1.5% of infants after 2 years; fathers' HPV infections did not increase infant HPV risk. Although lifetime abstinence protects against genital HPV infection, nonpenetrative sexual behaviors may transmit the virus, and male exposures modulate female risk. For example, spouses of men who engaged in sex with prostitutes were at higher risk for cervical cancer than those of men who did not, and cervical cancer risk is higher among women whose husbands had more sexual partners. Women who report recent sex only with women are also at risk, though their risk may be marginally lower than that of heterosexual women. Condom use is not fully protective against HPV infection because condoms fail to cover wide areas of genital skin, though it speeds clearance of HPV infections. Male circumcision also reduces but does not eliminate HPV and cancer risks. For these reasons, all women with prior sexual experience, including those who have not been sexually active for years, remain at risk for cervical cancer and merit screening until they have multiple negative test results.

Despite the high frequency of HPV infection, most women infected with carcinogenic HPV, including those with HPV-16, do not develop cervical cancer. Instead, most infections are cleared immunologically. HPV is an intraepithelial virus, and clearance appears to require recognition of infection by cell-mediated immune cells. Roughly half of new infections are cleared within 6 months, with half of the remainder cleared by the end of the first year after infection. Clearance is associated with greater density of CD8+ cells and lower density of

T-regulatory cells in underlying stroma. Cervical treatment speeds clearance and reduces risk for posttreatment acquisition of new HPV infections. The type distribution of HPV infection after hysterectomy shows that HPV-16 and HPV-18 have a greater predilection for cervical rather than vaginal epithelium, with HPV types of lesser oncogenicity dominating in the posthysterectomy vagina.

HPV persistence is required for progression of infection to cancer, and women who clear their infections are at low risk. New infections in older women typically do not progress to preinvasive disease or cancer, and women who clear carcinogenic HPV infections have low risk for reappearance with subsequent high-grade CIN. These findings have important implications for termination of screening. Nevertheless, aging appears to result in immune senescence, with many HPV infections in older women attributable to reactivation of previously acquired by latent infections. Oral contraceptive use reduces clearance.

Although determinants of HPV persistence and progression of HPV infection to invasive cancer are poorly understood, several risk factors are known. HPV infection of a cervix undergoing active metaplasia increases risk, as reflected by the epidemiologic observations that early onset of first intercourse is associated with cancer. Smoking is linked to both CIN and cervical cancer. Benzopyrenes have been identified in cervical mucus, and the interaction of tobacco carcinogens with carcinogenic HPV increases risk substantially. Smoking also reduces immune-mediated HPV clearance. Cervical adenocarcinoma and adenocarcinoma in situ (AIS) have been linked to oral contraceptive use. Deficiencies in nutrients such as folate have been linked to cervical oncogenesis but are uncommon among US women. Variants of common HPV types that segregate by ethnicity and polymorphisms in genes related to HPV immune recognition or HPV protein products also modulate HPV persistence and carcinogenic progression. Perhaps most important, lack of screening is a high risk factor for progression of HPV infection to precancer and cancer: Whereas appropriately screened women with multiple risk factors are at relatively low risk, women with few risk factors who are not screened are at higher risk.

Immune factors play a clear role in the clearance or persistence of HPV-related cervical lesions, but the nature of immune defects is poorly understood. Fukuda and associates showed that lesions that persist have fewer Langerhans cells and helper T cells than lesions that are cleared, and tobacco smoking also lowers Langerhans and helper T-cell numbers. In contrast, Molling and associates showed that, although natural killer cells are decreased, regulatory T-cell numbers are increased in women with persistent HPV-16. Immunosuppression related to coinfection with the human immunodeficiency virus (HIV-1) illustrates the importance of immunity in the typical control of HPV. Women with HIV have much higher rates of HPV infection, including multitype infections. HPV clearance rates are lower, although most women do clear their HPV infections if observed long enough, especially if immune reserve as measured by CD4 lymphocyte count remains above 200/cmm. Although most HPV infections in HIV-seropositive women are cleared to such low levels of viral expression that they become nondetectable even with sensitive assays, reactivation appears to occur. This is apparent in cohort studies as the reappearance of previously cleared infections in women who deny sexual activity, often because of illness. Risks in other immunosuppressed states appear to be similar.

HPV infection predicts risk for subsequent high-grade CIN, even among cytologically normal women. In most cases, persistent HPV infections result first in cytologically detectable abnormalities and then in colposcopically visible lesions that grow laterally before developing into invasive cancers. The 10-year risk of high-grade CIN after a single detected HPV infection exceeds 10%.

As developed by Richart through observational studies of the cervix using cytology and colpomicroscopy, a diagnosis of CIN was based on progressively severe nuclear aneuploidy, abnormal mitotic figures, and loss of epithelial maturation. Initially considered a progressive lesion, CIN was thought to begin as a small lesion with atypia near the basement membrane of the cervical transformation zone, gradually increasing in size and becoming less differentiated with an increasing proportion of the epithelium taken up by atypical cells until a full-thickness carcinoma in situ developed and then became invasive. Given this concept of progression from low-grade to high-grade disease to cancer, lesions of all grades were treated. When progression does occur, however, it appears to require years. The median age of sexual debut in the United States is around 17 years of age, and HPV acquisition commonly follows, but the peak age of cervical cancer diagnosis lags by some 3 decades. This long transition time allows for even moderately sensitive screening tests to identify persistent lesions for treatment before invasive cancer develops (Table 1.1).

Gradually, the regressive nature of most low- and midgrade lesions became apparent. Low-grade lesions, including warts and CIN1, are histologic expressions of HPV infection. Greenberg and associates found that of 163 women with CIN1 after low-grade cytology followed for a median of 36 months, 49% regressed, 43% persisted, and only 8% progressed to CIN3. In the Atypical Squamous Cells of Undetermined Significance/Low Grade Squamous Intraepithelial Lesion Triage Study (ALTS), a large randomized trial of management options for women with borderline cytology results conducted under the auspices of the US National Cancer Institute (NCI), 2-year risk for CIN3 were 10% among women with CIN1. **As reported by Castle and coworkers, after controlling for HPV genotype, with HPV-16–associated CIN1 progressing to CIN3 in 19% of cases, biopsy-proven CIN1 was not a risk factor for progression. These risk estimates may be substantially higher for women with prior high-grade cytology.**

TABLE 1.1 Transition Time of Cervical Intraepithelial Neoplasia

Stages	Mean Years
Normal to mild to moderate dysplasia	1.62
Normal to moderate to severe dysplasia	2.2
Normal to carcinoma in situ	4.51

Higher grades of dysplasia appear to represent clonal lesions arising from single-type HPV infections. Although women may harbor multiple HPV types in the genital tract, most multitype infections are associated with multifocal lesions. Moscicki and her team showed that 63% of adolescents and young women with CIN2 resolved lesions without treatment within 2 years; subsequent clearance was minimal, rising only to 68% after an additional year. McAllum and colleagues showed a similar 62% regression after only 8 months of observation for women with CIN2 younger than 25 years of age. No patients in either study progressed to cancer during observation. In both studies, identified CIN2 likely represented recent HPV infections. Regression rates are lower in older women, at least in part because lesions detected later may have been persistent for years, and lesions that have evolved mechanisms to evade host immune-mediated clearance are likely to continue to persist. Castle and coworkers compared CIN2 rates in the immediate colposcopy and cytology surveillance arms of the ALTS. They found that over 2 years, some 40% of CIN2 regressed. Trimble and colleagues showed that HPV-16–associated lesions are less likely to resolve. Their finding of associations with human leukocyte antigen (HLA) alleles and regression support a role for HLA-restricted HPV-specific immune responses in determining clearance.

Untreated, CIN3 poses considerable risk of progression to invasive cancer. This was best shown in a study of New Zealand women with CIN3 who were diagnosed between 1955 and 1976 and were observed. Among 143 women reported by McCredie and coworkers, managed only by punch or wedge biopsy, 31 progressed to cancer of the cervix or vagina after 30 years. Risk rose to 59% in 92 women with persistent disease after 2 years of observation. These findings show both that treatment of CIN3 is mandatory regardless of age or other factors but also that not all CIN3 lesions will inevitably progress to cancer.

Treated CIN3 continues to pose a risk of progression to cancer. Women in the New Zealand study whose treatment appeared adequate by current standards faced only 0.7% cancer risk after 30 years. Studies from Scandinavian countries with integrated health systems can link databases on procedures and subsequent cancers and provide accurate long-term results with minimal loss to follow-up. Strander and associates showed that risk for cervical cancer rose significantly in previously treated women after age 50 years, with standardized incidence ratios compared with untreated women ranging from 3 to 5. Vaginal cancer risks were elevated across all ages, although the absolute risk of vaginal cancer was low. Kalliala and colleagues in Finland confirmed this long-term increased risk and also found an increased risk for nongenital smoking-related cancers. Jakobsson and coworkers found that in addition to cervical cancer, women treated for CIN faced higher mortality rates from circulatory system, alcohol-related, and traumatic death, consistent with the demographic and behavioral factors linked to CIN.

EPIDEMIOLOGY

More than 80% of sexually active individuals acquire genital HPV infections. Some 20 million Americans and 630 million persons worldwide are infected with HPV. In the United States, about 6.2 million people will acquire a new infection annually. Prevalence rates are highest among women in their late teens and early 20s, declining with age. Risk factors for HPV acquisition include smoking, oral contraceptive use, and new male partners.

Among high-risk HPV types, HPV-53 is most common, detected in 5.8% of US women ages 14 to 59 years screened in the National Health and Nutrition Examination Survey (NHANES) in 2003 to 2006. This was followed by HPV-16 (4.7%), HPV-51 (4.1%), HPV-52 (3.6%), and HPV-66 (3.4%). HP-V18 was present in only 1.8% of screened women. In NHANES, demographic risk factors for prevalent HPV infection included younger age, peaking at ages 20 to 24 years; non-Hispanic black ethnicity; unmarried; never educated beyond high school; and living below the poverty line. Behavioral risk factors included reporting ever having sex, first intercourse before age 16 years, greater numbers of lifetime partners, and number of partners in the past year. HPV type distributions vary across continents.

HPV infection determines subsequent risk for precancer. Among women enrolled in a Portland health maintenance organization who had HPV-16, the 10-year risk for CIN3, AIS, or cancer was more than 15% after HPV-16 infection, almost 15% after HPV-18, less than 3% after other oncogenic HPV infections, and less than 1% after a negative HPV test result.

In the United States more than 400,000 cases of CIN are identified annually, at a cost of approximately $570 million. Of these, Flagg and colleagues estimate about 100,000 are true precancers. The annual incidence of high-grade CIN is some 6 to 10 times higher than cervical cancer incidence. Preinvasive lesions begin to appear some 2 years after infection. Cancer risk is quite low soon after infection: Despite a high prevalence of HPV detection among sexually active teens, cervical cancer incidence is only about 1 in 1,000,000 before 20 years of age. Among women who develop high-grade CIN, only 30% to 50% will develop cancer over years of observation.

Although demographic and behavioral risk factors cannot be used to target evaluation or therapy, clear risks for CIN and cervical cancer have been identified. The international Collaboration of Epidemiological Studies of Cervical Cancer reviewed evidence for various risk factors for cervical cancer and carcinoma in situ, although their studies were not linked to HPV data. They found that oral contraceptive use raised the risk for cervical disease by 1.9-fold for every 5 years of use. First intercourse before 15 years of age was associated with twice the risk of cervical cancer found in women with first intercourse after 23 years of age, and having more than five lifetime sexual partners carried more than double the cervical cancer risk of lifetime monogamy. Lesser but still significant increases in risk were associated with number of pregnancies and earlier age at first term pregnancy. Both squamous cancers and adenocarcinomas share epidemiologic risk factors, except that smoking is linked only to the former.

The role of family history in determining cervical cancer risk. Dissociating genetic components of familial risk from cultural ones is difficult, as sexual attitudes and behaviors, reproductive patterns, and smoking are often linked to family.

Zelmanowicz and associates assessed the role of family history in cohorts of women prospectively studied in Costa Rica and the United States. A family history of cervical cancer in a first-degree relative tripled the risk for CIN3 or squamous cervical cancer. The effect persisted after controlling for HPV exposure. No effect of family history on adenocarcinoma risk was seen. Although several genome-wide association studies (GWASs) have identified a range of genetic variants in candidate pathways that might contribute to cervical oncogenesis, Chen and colleagues in a large Chinese GWAS found that only HLA and major histocompatibility class I polypeptide-related sequence A genes were identified as candidate risk genes across several populations.

Lower socioeconomic status (SES) and minority ethnicity are also linked to CIN and cervical cancer risk in the United States, although distinguishing cultural contributions to cervical cancer risk, such as a sense of fatalism, distrust of the medical care system providing screening services, and lack of health education about the benefits of screening, are difficult to distinguish from biologic risks related to ethnicity and SES, such as genetic predisposition, toxin exposure, and micronutrient deficiencies.

HUMAN PAPILLOMAVIRUS VACCINATION

Because HPV is the cause of essentially all cervical cancer, HPV vaccination has the potential to eliminate cervical cancer. However, the US experience with HPV vaccination has shown that several barriers will limit achievement of this goal.

Intramuscular delivery of synthetic HPV L1 capsid antigens results in humor immunity; current vaccines are created in protein synthesis using cell culture systems; because no actual live or killed virions are used, HPV vaccines cannot cause HPV-related cancer. Despite early concerns that humoral immunity would be insufficient to prevent infection, vaccine efficacy appears to approach 100%. However, currently available vaccines are prophylactic: They must be delivered before HPV exposure and do not appear to reduce risk in untreated women with established target-type HPV infections. This is reflected in the epidemiology of vaccine effectiveness, which declines with age, number of prior sexual partners, and prior abnormal cytology. These findings mean that, although vaccination is effective for type-specific HPV naïve women through 45 years of age, population effectiveness is too low to justify widespread use of vaccines beyond the upper age limit in vaccine trials, which extended to 26 years of age. Within trials, effectiveness declined with age, and the American Cancer Society has reiterated its guidance that HPV vaccination extend only through 18 years of age.

Three HPV vaccines are available. US clinicians have favored the quadrivalent HPV vaccine, which protects against HPV-16 and -18, which together account for almost 70% of all cervical cancers, as well as HPV-6 and -11, which are the most common causes of genital warts. The benefit of cervical cancer prevention, which might take decades to become manifest, is augmented by its ability to prevent genital warts, a concern for many young women. The bivalent HPV vaccine protects against only HPV-16 and -18 and is less commonly used in the United States. It may have superior antigenicity and may have some cross-protection against HPV types related to HPV-16 and -18. Most recently, a nonavalent vaccine has been introduced, which is effective against the same types as the quadrivalent vaccine and also includes coverage against HPV types 31, 33, 45, 52, and 58; enhanced coverage should prevent 90% of all cervical cancers.

Because HPV vaccines are prophylactic, population-based vaccination should begin before first sexual intercourse. Because some 5% of US 13-year-old girls are sexually active, the target age for HPV vaccination is the ages of 11 to 12 years. However, vaccination can be initiated at 9 years of age in populations in which sexual debut may occur earlier. Three injections over 6 months are recommended for all vaccines, although schedules vary. Some data suggest that two injections or even one may be sufficient, at least for adolescents, but shortened vaccination schedules have not been approved by the US Food and Drug Administration (FDA). Because teen sexual activity is unpredictable, delaying vaccination until girls are more mature risks missing the vaccination window for many. Nevertheless, many sexually active young women show no evidence of infection by target HPV types, and "catch-up" vaccination should be considered. Testing of cervicovaginal secretions and serum antibody testing are both insensitive for detecting prior HPV vaccination and are not recommended before a decision about HPV vaccination.

Several countries have instituted organized vaccination programs, either mandatory or using a school-based opt-in mechanism with high uptake. Countries that used quadrivalent vaccine have documented a dramatic decrease in genital warts among teens but not older women, and abnormal cytology rates have also fallen in the youngest women.

In the United States, vaccination rates are suboptimal, with barely one-third of girls in target populations having received all three injections. Regrettably, despite the potential for vaccination to eliminate the disparately high risk of cervical cancer among women of minority ethnicity and lower SES, uptake has been lowest in these groups, potentially widening cancer disparities in future years. Nevertheless, decreases in HPV-16 and -18 in the pool of sexually active young women have been documented, suggesting that less than ideal vaccination rates may nevertheless eventually yield population effectiveness.

Vaccine risks appear tolerable. Common side effects include fever, rash, injection site pain, nausea, headache, and dizziness. Anaphylactic and vagal reactions may be fatal, so vaccination should only be administered in sites with ability to manage anaphylaxis and fainting. Despite initial concerns, HPV vaccination status does not enter into young women's decisions to initiate sex. Vaccination is contraindicated for pregnant women, although no congenital anomalies or adverse pregnancy outcomes have been linked to HPV vaccination; the vaccine series may begin after delivery. Interruption of vaccination does not appear to require reinitiation of the three-shot series.

The duration of vaccine effectiveness is unclear, but antibody levels remain elevated for several years after vaccination. Booster doses are not recommended at this time. However,

revaccination with nonavalent vaccine may provide additional benefit and should be considered for women younger than 26 years of age who previously completed bivalent or quadrivalent vaccines, especially those who have not initiated sexual activity and so are at low risk for having acquired HPV.

A history of HPV vaccination does not alter screening recommendations for US women. This is because many women of screening age were not vaccinated before initiating intercourse, so vaccine effectiveness is unclear. There is no central US vaccine registry, and identifying vaccinated women by self-report may be inaccurate. No HPV vaccine covers all carcinogenic HPV types, so women vaccinated before first intercourse remain at risk for infection and cancer due to nonvaccine types. However, for women known to have been vaccinated against HPV-16 and -18 before first intercourse, and so at much lower risk for disease, deferring screening initiation until age 25 years and screening with HPV testing alone at 5-year intervals is rational.

SCREENING

The goal of any cancer prevention program is the reduction of morbidity and mortality through intervention before symptom onset. The current mechanism to achieve this goal is the identification and destruction of high-grade CIN lesions that are presumed precancers. Many novices and some experienced clinicians mistake the mechanism for the goal. However, identification of apparent precancers in women with comorbidities that will be fatal in the medium term, before progression to symptomatic cancer, is not helpful. High-grade CIN in young women may resolve spontaneously and in some cases may be observed to avoid the sequelae of treatment. On the other hand, some women without identified high-grade CIN face cancer risks similar to those of women with high-grade CIN and merit destructive cervical therapy.

Classically, screening has relied on Papanicolaou cytology testing followed by colposcopic assessment of women with Pap abnormalities, directed biopsy of the worst colposcopic lesion, and treatment of biopsy proven high-grade lesions. Papanicolaou testing is relatively insensitive: A single Pap test may be negative in almost half of women with high-grade CIN. However, progression from HPV infection to cancer usually requires several years, allowing for multiple rounds of screening, with greater sensitivity than single tests.

Cytology is the interpretation of all the mutations, methylations, and other genetic modifications that alter the nuclear and cytoplasmic appearance of cells. As such, it is infinitely graded. To be clinically useful, these changes must be aggregated into categories that reflect a common natural history. Papanicolaou developed a five-class grading system, from normal to invasive cancer, with atypia, dysplasia, and carcinoma in situ between. Modified systems were developed, and alternatives were proposed. To unify terminology, the NCI convened a consensus meeting that developed the 1988 terminology known as the Bethesda System for cervicovaginal cytologic diagnosis. With the most recent update in 2001, this classification system identifies cytology as satisfactory or unsatisfactory, includes nonneoplastic changes, and divides epithelial cell abnormalities into squamous and glandular changes of varying degrees of severity (Table 1.2). Distinguishing squamous from glandular abnormalities is critical because glandular abnormalities carry much higher risk for high-grade CIN, including squamous dysplasias, as well as endometrial cancer and cervical adenocarcinoma and AIS. Squamous changes related to HPV are termed "squamous intraepithelial lesions (SILs)" because some lesser changes do not reflect dysplasia or neoplasia, only cytomorphologic changes of HPV infection. Indeterminate lesions are termed "atypical squamous cells (ASC)," and these are subdivided into ASC "of undetermined significance (ASC-US)," which carries a low risk of associated high-grade CIN, or "cannot exclude high-grade SIL (ASC-H)," which is a more ominous finding that requires immediate colposcopy (see later discussion). An online atlas allows pathologists to standardize findings and interpretations against national norms (http://nih.techriver.net). The 2001 update provided the basis for subsequent consensus conferences that provided risk-based management guidelines.

TABLE 1.2 Bethesda 2001 Classification

1. Negative for intraepithelial lesion or malignancy
   - a. Organisms may be identified
   - b. Other nonneoplastic findings may be noted
     - (1) Inflammation
     - (2) Radiation changes
     - (3) Atrophy
   - c. Glandular cells status after hysterectomy
   - d. Atrophy
2. Epithelial cell abnormalities
   - a. Squamous cells
     - (1) Atypical squamous cells (ASC)
     - (2) Of undetermined significance (ASC-US)
     - (3) Cannot exclude high-grade squamous intraepithelial lesion (ASC-H)
     - (4) Low-grade squamous intraepithelial lesions (LSIL)
     - (5) Human papillomavirus (HPV), cervical intraepithelial neoplasia (CIN) 1
     - (6) HSIL (CIN2, CIN3)
     - (7) Squamous cell carcinoma
   - b. Glandular cell
     - (1) Atypical glandular cells (AGC)—specify origin
     - (2) Atypical glandular cells favor neoplastic—specify origin
     - (3) Endocervical adenocarcinoma in situ (AIS)
     - (4) Adenocarcinoma

Traditional Pap smears were collected by smearing samples across a glass slide and applying fixative followed by staining with a Papanicolaou stain. Today most cytology tests in the United States are conducted using liquid-based assays. In these tests, cells are collected and suspended in preservative solution and then transferred to a slide. Liquid-based cytology results in an even dispersion of cells, and techniques are available that allow for elimination of red and white blood cells, but the "tumor diathesis" of pus and necrosis that allowed identification of cancer is lost, as are the "microbiopsies" that allowed

interpretation of epithelial fragments. Liquid-based cytology was marketed as more sensitive than conventional Pap smears. However, a meta-analysis by Arbyn and colleagues showed that, although liquid-based cytology yields more abnormalities, including high-grade SILs, it is not superior to conventional smears in cancer prevention. It remains preferred in the United States because it allows for molecular triage of equivocal results using HPV and other assays. Interpretation is still done visually, although some centers use automated imaging and pattern recognition software to eliminate the least abnormal slides. Cytotechnologists perform initial assessment, with slides containing abnormal findings and a proportion of normal slides read by cytopathologists.

The effectiveness of screening has not been demonstrated in randomized trials, but population studies have shown unequivocal benefits. Papanicolaou and Traut propounded the concept of screening in 1941. An NCI study by Erickson and associates assessed cytology screening by vaginal aspiration for 108,000 women in Shelby County, Tennessee. They showed a high yield of unsuspected high-grade CIN and early cancer at the first screen, with a substantial reduction in invasive lesions in the second screen. Gustafsson and associates reviewed data from 17 cancer registries and showed marked effects, especially in Scandinavian countries. Eddy assessed the impact of screening on cervical cancer incidence and death. Without screening, a 20-year-old average-risk woman faces a 2.5% risk of cancer and a 1.2% risk of cancer death. Triennial screening between ages 20 and 75 years reduces risk to less than 0.4% and 0.1%. Annual screening improves effectiveness but by less than 5% of these low rates, with substantial increase in cost.

Initially, screening was opportunistic: Women had screening when they presented for care, usually at annual visits. Opportunistic screening remains the norm in the United States, although screening intervals have lengthened; some electronic medical records prompt clinicians when screening is due; and some health care organizations have developed standards, rewards, and reminders. Several countries with centralized medical care systems have developed organized screening, with coordinated identification, invitation, and management of women due for screening. Serraino and colleagues showed that the move from opportunistic to organized screening in Italy resulted in a decline in cervical cancer incidence and a downstaging of incident cervical cancers after an increase in precursor detection. Quinn and coworkers found that institution a national call/recall system with incentive payments to general practitioners in Britain instituted in 1988 increased screening coverage to 85% of the target population, increased detection of high-grade CIN, and reduced mortality in women younger than age 55 years.

Cytology-based screening has several weaknesses. Most fundamentally, the process of screening, triage, and treatment is cumbersome, and noncompliance at any point renders it ineffective. Cytology results are reported in ways that can be confusing, and efficient, effective management may require integration of current results with prior abnormalities. Multiple studies have shown that most women who develop cervical cancer in developed countries, especially those presenting at advanced stages, are inadequately screened. Sung and associates studied incident cancers in a US prepaid health plan. They reported that 53% were nonadherent to screening, 28% had false-negative Pap tests, 4% had inadequate follow-up after an abnormal Pap test result, and the rest either developed cancer despite appropriate investigations or were unclassified. Kinney and associates in the same US health maintenance organization found that 60% of cervical cancer patients were inadequately screened. Deeper exploration of the records of long-standing plan members with inadequate screening showed that 70% had missed opportunities for screening in primary care clinics.

In addition, cytology-based screening performs poorly in younger women. Sasieni and colleagues from Britain showed that cervical screening in women ages 20 to 24 years had little impact on actual cancer risk until those women reached 30 years of age, but screening older women results in an immediate benefit. Because younger women have low rates of cervical cancer incidence and death but high rates of HPV infection, abnormal cytology, and CIN destined to regress, the benefits of early initiation of screening may be difficult to balance against potential harms. Cytology preferentially detects squamous cell carcinomas, and the impact of cytology screening on adenocarcinoma incidence has been muted.

The harms of excessive screening are more difficult to quantify. These include stigmatization, unfounded fear of cancer, and interventions without cancer prevention benefit. Sharp and associates showed that depression, distress, and anxiety occurred in 15% to 30% of women in the months after reporting of marginal cytology abnormalities. The costs, pain, and inconvenience of testing, triage, and treatment of abnormalities destined to regress with no impact on cancer morbidity or mortality must outweigh nonexistent benefits, though prospectively identifying these lesions in individuals is problematic.

Essentially all cervical cancer is caused by HPV. Castle and colleagues have shown that women who test HPV negative remain at low risk for precancer and cancer for more than a decade. Incorporation of HPV testing into screening has allowed for longer screening intervals. The development of HPV assays has allowed the development of protocols for HPV testing as a primary screening test in combination screening with cytology (co-testing) and as a triage test for women with borderline cytology results. Only high-risk HPV types have a role in screening; because low-risk types essentially play no role in screening and identification of HPV infection in the absence of visible genital warts causes stigmatization without impacting care, testing for low-risk types is contraindicated. HPV genotyping assays for types 16 and 18 identifies women at higher risk. The disadvantage of HPV testing is poor specificity, with up to 30% of young women testing positive in some studies. Because all commercially available HPV tests have a detection threshold designed to balance sensitivity and specificity, a negative test result does not absolutely exclude HPV infection, and prior cytologic or histologic abnormalities may mandate close follow-up or even treatment despite absence of detectable HPV. The performance characteristics of HPV assays that have not been FDA approved are unknown, and these tests should not be used in the absence of peer-reviewed literature describing

their sensitivity and specificity against histologically defined precancer in large screening populations. HPV tests also should not be collected in media whose effects of test performance have not been evaluated by the FDA.

Although only one HPV assay was approved in the United States for primary screening at the time of writing, four assays were approved for risk stratification for women with ASC-US cytology and for screening in conjunction with Pap testing. Comparative trials are few. Cuzick et al. studied six HPV assays, some of which are available only in Europe. They found that an mRNA test had similar sensitivity but greater specificity than DNA tests.

Beyond these weaknesses, screening has potential harms. Identification of HPV infection, abnormal cytology, and cervical cancer precursors is not without consequences, including anxiety, relationship disruption after diagnosis of a sexually transmitted infection, the inconvenience and cost of accelerated follow-up visits, and the pain of repeated examinations. Treatment of precursor lesions also carries risks, including bleeding, infection, and injury to adjacent organs. Some studies have suggested that destructive cervical treatments increase the risk for preterm delivery and pregnancy loss. US studies have failed to replicate these results in women after cervical loop electrosurgical excision procedure (LEEP). Women with cervical dysplasias are at higher risk for pregnancy loss that those who do not, perhaps because of common risk factors, including smoking, nutritional deficiencies, and lower SES, and these confounding factors may account for differences. However, there may be a threshold effect for treatment, and women with deep or repeated excisional procedures may be at higher risk for pregnancy loss. Shorter screening intervals with increasingly sensitive tests will reduce cancer risk, but benefits decline toward an irreducible asymptote, but harms and costs climb.

After the utility of screening is accepted, societies, women at risk, and clinicians must decide when to initiate screening, which screening tests to use, how often to screen, and when toward the end of life the identification of asymptomatic disease ceases to be beneficial. With all choices, sensitivity and specificity must be balanced. Earlier screening starts with more sensitive tests at shorter intervals until later in life will decrease cancer incidence and mortality, but costs and harms from diagnosing lesions that would never have progressed to cancer will increase. In developed societies, guidelines for screening have been developed by experts assessing evidence for benefit and harm and deciding how these can best be balanced. **In the United States, the most cited guidelines were released in 2012 guidelines by the US Preventive Services Task Force (USPSTF) and a consensus conference sponsored the American Cancer Society (ACS), the American Society for Colposcopy and Cervical Pathology (ASCCP), and the American Society for Clinical Pathology (ASCP)** (Table 1.3)**.** The two guidelines were developed from a common evidence assessment and reached similar conclusions. In both sets, screening is recommended to begin at 21 years of age, continuing at 3-year intervals until 65 years of age, when screening should stop if the patient is adequately screened and has no history or prior high-grade CIN. Screening also should stop at the time of total hysterectomy for indications other than high-grade CIN or cervical cancer. The ACS/ASCCP/ASCP guidelines contain a preference for screening using combination cytology and HPV testing beginning at 30 years of age; the USPSTF considered co-testing between 30 and 65 years of age to be acceptable but did not find evidence sufficiently compelling to prefer it. Table 1.3 compares the two guidelines.

TABLE 1.3 Comparison of Current US Cervical Cancer Screening Guidelines

	USPSTF	ACS/ASCCP/ASCP
When to start?	Age 21 years	Age 21 years
How often?	Pap tests every 3 years Co-tests every 5 years at ages 30–64	Pap tests every 3 years at ages 21–29 years Co-tests every 5 years at ages 30–64 years preferred Pap tests every 3 years remain an option
When to stop?	Age 65 years if adequate prior screens	Age 65 years if the patient has had three negative Pap tests or two negative co-tests After hysterectomy for benign disease

ACS, American Cancer Society; *ASCCP,* American Society for Colposcopy and Cervical Pathology; *ASCP,* American Society for Clinical Pathology; *USPSTF,* US Preventive Services Task Force.

The rationale for initiating screening at 21 years of age is founded on the low risk of cervical cancer in teens: with only one to two cases per 1,000,000 women, few cancers will be missed by a later screening start. HPV infections are common in sexually active young women, and the specificity of screening in that population is suboptimal. Although CIN2 and CIN3 are more common, most HPV infections, abnormal cytology test results, CIN1 and CIN2 in young women will regress with time. Harms from screening appear to outweigh benefits. As girls who were vaccinated before their first intercourse reach the age of screening initiation, population risk for cancer and precancer will decline. Future US screening guidelines may recommend initiation at 25 years of age. Although some societies and clinicians retain 18 years of age for screening initiation, many societies with organized programs defer screening until age 25 years, and some delay screening until 30 years of age.

Consensus conferences and professional societies in the United States have established 3-year cytology screening as providing optimal balance between benefits and harms. Because HPV testing is more sensitive than cytology, adding an HPV test to cytology should provide greater reassurance against missed disease and so lead to longer screening intervals. Dillner and colleagues have shown that a 5-year Pap/HPV co-testing interval provides superior negative predictive value against precancer than 3-year cytology testing, with a risk that is similar to 1-year cytology testing intervals (Fig. 1.3). Intervals should be based on documented cytology results; Boyce and others have shown that women's ability to recall prior screening is flawed. Centers

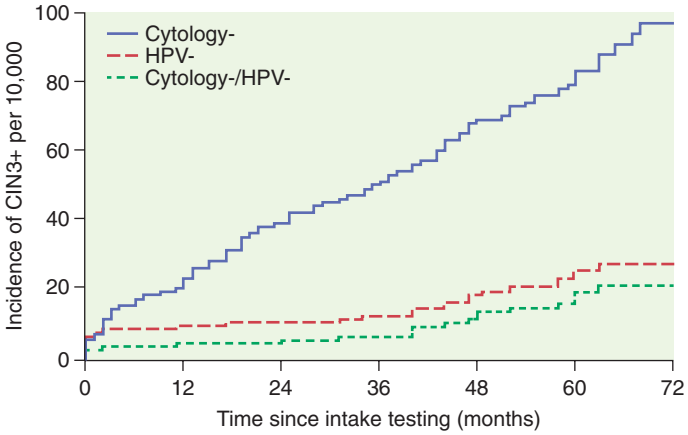

FIGURE 1.3 Incidence of cervical intraepithelial neoplasia (CIN) 3 or worse across time after negative screening test results. Five-year risk after a negative human papillomavirus (HPV) test of cytology/HPV co-test approximates risk 1 year after negative cytology. (From Dillner J, Rebolj M, Birembaut P, et al.; Joint European Cohort Study. Long term predictive values of cytology and human papillomavirus testing in cervical cancer screening: joint European cohort study. *BMJ* 2008;337:a1754.)

for Disease Control and Prevention (CDC) researchers have shown that despite guidelines, US clinicians continue to screen women at short intervals.

The risk for cervical cancer in adequately screened women after 65 years of age becomes negligible. Prior HPV infection that has been cleared without development of high-grade CIN does not appear to increase risk substantially. New HPV infections may be acquired after 65 years of age despite prior negative screening, but in the absence of active metaplasia, these are unlikely to progress to cancer for years and so are unlikely to result in morbidity or mortality, but evaluation and treatment of atrophic postmenopausal women is technically difficult and painful. Vaginal cancer risks are low after hysterectomy for benign disease; too low to justify screening. Women with high-grade CIN remain at risk for cervical and vaginal cancer despite treatment, including hysterectomy, and evaluation until comorbidity suggests a short residual lifespan remains indicated.

Women at low risk for disease during their remaining lifespans should not be screened. This is most apparent for women with illnesses that will be fatal in the medium term: The discomfort and risks of screening and treatment of identified precursors are not justified when the woman is unlikely to survive long enough to develop symptomatic cervical cancer. Similarly, cervical and vaginal cancer risk in the absence of a cervix is functionally zero. After hysterectomy for CIN, screening appears justified based on risk for coexistent vaginal intraepithelial neoplasia and vaginal cancer, and post-treatment surveillance for recurrent cervical cancer treated with hysterectomy is recommended. Women who reach 65 years of age after multiple negative cytology results, including three in the previous decade and two in the previous 5 years, are at low risk for cervical cancer, as are women with two negative HPV–cytology co-test results, including one in the previous 5 years. These women can stop undergoing screening. Women without adequate prior screening should continue undergoing screening until they meet these criteria. Although older women can acquire new HPV infections, they are not undergoing active metaplasia, and transition time to cancer appears to be decades long, as in younger women, so few are likely to survive to develop cancer. For this reason, acquisition of new sexual partners by women who have otherwise met criteria for stopping should not be a consideration for continuing screening.

In 2014, the Food and Drug Administration approved HPV testing as a primary screening test for cervical cancer. Approval was granted only for the cobas HPV test (Roche). At a consensus meeting sponsored by the Society of Gynecologic Oncologists and ASCCP, Huh and fellow consensus meeting delegates developed guidelines to inform clinicians and women at risk on strategies to incorporate primary screening into practice. When used according to an algorithm (Fig. 1.4) that appears to optimize disease detection while minimizing colposcopy, HPV testing is more sensitive that Pap testing when initiated at 25 years of age. Screening intervals for primary HPV testing are controversial. Huh and coauthors recommended that screening be no more often than every 3 years, language that reflected disagreement about 3-year versus 5-year testing intervals. The pivotal trial for the cobas HPV test did not extend beyond 3 years, so performance data are unknown. However, other HPV tests with similar sensitivity and specificity have been tested, and a 5-year interval seems to provide sensitivity superior to 3-year cytology screening while allowing more time for transient lesions to regress.

Few predictors of high-grade CIN have been identified that would allow clinicians to focus more intensive screening efforts on high-risk groups. Boardman and colleagues found that smokers faced a higher risk of CIN2 or worse than nonsmokers, but the odds ratio of 1.6 did not provide sufficient discrimination to allow observation of nonsmokers. Fundamentally, cytology and HPV testing are powerful tools for identifying risk, and the low positive predictive value of borderline cytology grades can be refined by triage using HPV testing or genotyping. Women with abnormal cytology or high-risk HPV infections merit further assessment regardless of demographic or behavioral risks.

CORE PRINCIPLES FOR MANAGING ABNORMAL SCREENING TEST RESULTS

In 2007, Castle and colleagues at the US NCI proposed that management of abnormal cervical cancer screening tests should be based on the associated risk for significant disease. Cancer mortality would be the ideal risk outcome for comparison across tests, but it is too uncommon in screened populations and its frequency is determined by downstream interventions after most tests. Katki and associates proposed instead that risk after various test results and combinations should be benchmarked to CIN3 or worse (CIN3+, including CIN3, AIS, and cancer). Because some lesions are present but inapparent initially because women fail to present for assessment or lesions are clinically too small for detection, the optimal benchmark endorsed by a 2012 consensus conference is 5-year risk for

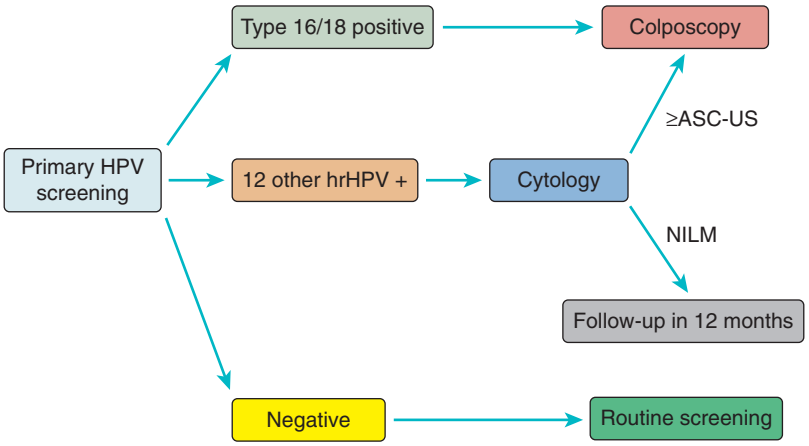

FIGURE 1.4 Strategies for incorporating primary human papillomavirus screening into practice. *ASC-US,* Atypical squamous cells undetermined significance; *hrHPV,* high risk human papillomavirus; *NILM,* negative for intraepithelial lesion or malignancy.

CIN3+. Using this benchmark, clinicians can use similar management strategies for women with similar levels of risk, without regard to how risk was determined. Conventionally, risk was defined by cytology and colposcopy findings. More recently, HPV testing allowed recalibration of risk, especially for women with borderline findings such as ASC-US. HPV genotyping for types 16 and 18 further defines risk categories. On the horizon are other molecular tests whose results will modify risk stratification and management, such as spectroscopic analysis and molecular testing for $p16^{ink4a}$, the Ki-67 proliferation marker, and others.

Determining optimal management for each test or combination can be confusing. In an ideal world, comparative trials would define which triage tests were optimal. Unfortunately, few comparative trials have been undertaken. National health budgets across the developed world are increasingly constrained. Industry lacks incentive to fund trials that might find their products inferior. With the proliferation of screening tests, management options become increasingly complex because algorithms must incorporate all options clinicians might select. In fact, current management guidelines have been criticized as too complex for even experts to master. Fortunately, computerized decision tools have eliminated the need for clinicians to memorize cervical cancer prevention strategies. Electronic medical record platforms can be programmed to generate reminders when women come due for screening. Online algorithm sets are available. Smartphone apps allow entry of patient information and lead clinicians to relevant algorithms. Clinicians still must understand the limits of algorithm-based management, especially the impact of prior abnormalities on subsequent emergence of disease.

To address these concerns, Katki and colleagues analyzed data from more than 1 million women screened by the Kaiser Permanente of Northern California health care system to define 5-year CIN3+ risk after various tests and test combinations. At the base of management options is the 5-year follow-up for women who test negative in Pap/HPV co-testing; these women have a 5-year CIN3+ risk of less than 0.01%. Women screened with cytology alone are followed at 3-year intervals when their test results are negative, with a 5-year CIN3+ risk of less than 0.1%. One-year retesting is standard for women with a positive test result for HPV but negative cytology, with a risk less than 5%. The consensus threshold for colposcopy in the United States is a low-grade SIL result, with 5-year CIN3+ risk of just above 5%; lesser results are triaged by serial testing or triage tests. The threshold for treatment is CIN2, although not all women with CIN2 require treatment, and few studies have assessed use of other test results except high-grade SIL cytology as a treatment indication.

Traditionally, colposcopy was used as the triage modality to identify women with high-grade CIN for treatment. Colposcopy is the magnified stereoscopic visualization of the cervix under intense illumination. Magnification ranges from 3× to 30×. A green filter over the light source accentuates vascular patterns and lesion margins. Although colposcopy without staining has been advocated to maximize visualization of cancer, most colposcopic assessments are augmented by the application of vital stains such as 3% to 5% acetic acid and Lugol's iodine solution.

In colposcopy, the cervical transformation zone is assessed. The transformation zone is that area of the cervix and vagina initially covered by columnar epithelium that has undergone metaplasia to squamous epithelium. A range of terms are used to describe colposcopic findings (Table 1.4 **and** Figs. 1.5 **to** 1.8)**. The procedure for colposcopy is inspection of the cervix without stains and then cleansing of the cervix with an application of 3% to 5% acetic acid for at least 90 seconds. This removes mucus and debris and accentuates vascular and epithelial patterns. Most cervical lesions stain white with acetic acid (acetowhitening).**

Because earlier lesions have been targeted via the inclusion of low-grade SIL, HPV+ ASC-US, persistent HPV infection, and HPV-16/-18 infection as thresholds for colposcopy, colposcopy is being done for women with smaller and less apparent lesions. The accuracy of colposcopy has been questioned, and now multiple colposcopic biopsies are recommended. HPV vaccination

promises to reduce cervical cancer risk in coming decades but more immediately will reduce the prevalence of high-grade lesions. This in turn will reduce the specificity of screening tests and lower the sensitivity of colposcopy. Opportunities for further changes to screening and management strategies will follow, especially longer screening intervals, more HPV-based assessment, more intermediate triage tests before colposcopy, and a move toward immediate treatment without colposcopy for women at highest risk.

Immunocompromised women are screened under management guidelines defined by the CDC. Women with HIV are screened according to the guidelines for the prevention and treatment of opportunistic infections in HIV-infected adolescents and adults from the CDC. Under these guidelines, women should be screened with cytology alone twice within a year of

FIGURE 1.6 White epithelium at the cervical os (a colposcopic view).

sexual activity, if previously HIV infected, or within 1 year of HIV diagnosis, regardless of age, followed by lifetime annual cytology. These guidelines were in review at the time of publication and may change.

Diethylstilbestrol- (DES-) exposed women continue Pap testing annually for life; evidence on HPV–cytology co-testing for DES-exposed women is insufficient to recommend for or against it.

MANAGING ABNORMAL CERVICAL CANCER SCREENING TEST RESULTS

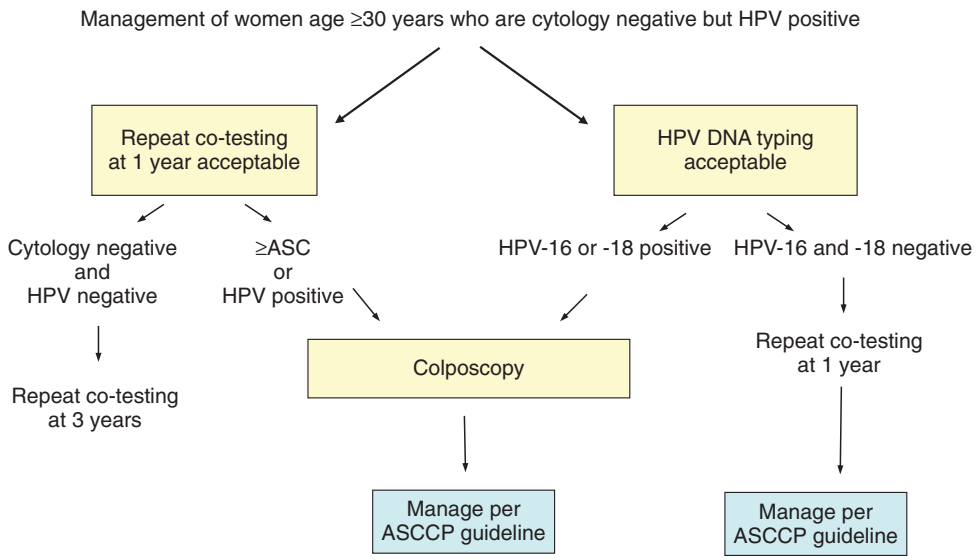
Since 2001, the ASCCP has led three consensus development conferences to define standard guidelines for management of US women with abnormal cervical cancer screening test results and CIN or AIS. Conferences were cosponsored by numerous professional societies, with collaboration from the American Cancer Society, federal agencies, and other stakeholder groups. The most recent conference, in 2012, used risk estimates developed by Katki and colleagues to define management.

Clinicians should keep in mind that guidelines are for women with abnormal screening tests; for women with symptoms such as abnormal bleeding or pain or abnormal examination findings such as contact bleeding, cervical friability, or cervical enlargement, biopsy may be indicated regardless of cytology or HPV results. In addition, guidelines do not cover all potential permutations of screening test, colposcopy, and biopsy results, especially accumulated abnormalities across years. Prior abnormal results raise risk for CIN3+ associated with subsequent abnormalities: Management does not "reset" after each test. For example, risk is higher after two cytology reports read as ASC-US than after only one, and ASC-US cytology after prior treatment for CIN3 is more ominous than a first ASC-US report; in both of these cases, colposcopy is indicated.

Managing Abnormal Results in Young Women

Cervical cancer risk is low among women 21 to 24 years of age, but high-risk HPV infections can be found in more than 20%. Most CIN1 and many CIN2 lesions in this age group will regress without intervention. CIN3 is unlikely to progress to cancer in the short run if missed. Treatment of intermediate-risk lesions may impact future pregnancies. For these reasons, women in this age group are managed less aggressively than older women. For women in this age group, most abnormal cytology results reflect HPV infection; HPV testing should not be ordered, and if obtained, results should not modify management.

In addition, because of concern about impact on subsequent pregnancies, women with biopsies read as CIN2, CIN2,3, or HSIL can be observed, provided colposcopy is satisfactory. There is no specific age range for observational management of these lesions, and a decision to treat or follow these lesions depends on a discussion between the woman and her clinician, balancing the potential risk to future pregnancies against the risk of progression to cancer during observation; both risks appear to be low.



Unsatisfactory Cytology

When cytology is unsatisfactory for evaluation, it must be repeated. The only exception is when the test was not indicated, as in an adolescent younger than 21 years of age, after hysterectomy for a benign condition, or in women older than 65 years of age with adequate prior screening. Some studies have suggested that rates of abnormality might be increased immediately after sampling, but a large US trial failed to validate this, suggesting that immediate resampling is acceptable. For women with atrophy, a short course of vaginal estrogen may improve sample cellularity. Women with obscuring inflammation should be assessed for specific infections and treated for any that might be identified; empiric vaginal antibiotic therapy does not appear beneficial. Samples that are unsatisfactory because of obscuring blood raise concern for cancer. When repeated samples are unsatisfactory, colposcopy should be considered.

Pap-Negative, Human Papillomavirus–Positive Women (Fig. 1.9)

Identification of a carcinogenic HPV type carries substantial risk for CIN3+, but the 5-year risk does not reach the 5% threshold for colposcopy. A positive HPV result is most often encountered in HPV–cytology co-testing for women ages 30 to 65 years.

Women with a positive HPV test but negative concurrent cytology may be managed in one of two ways. They can be reassessed with repeat HPV–cytology co-testing in 1 year, allowing

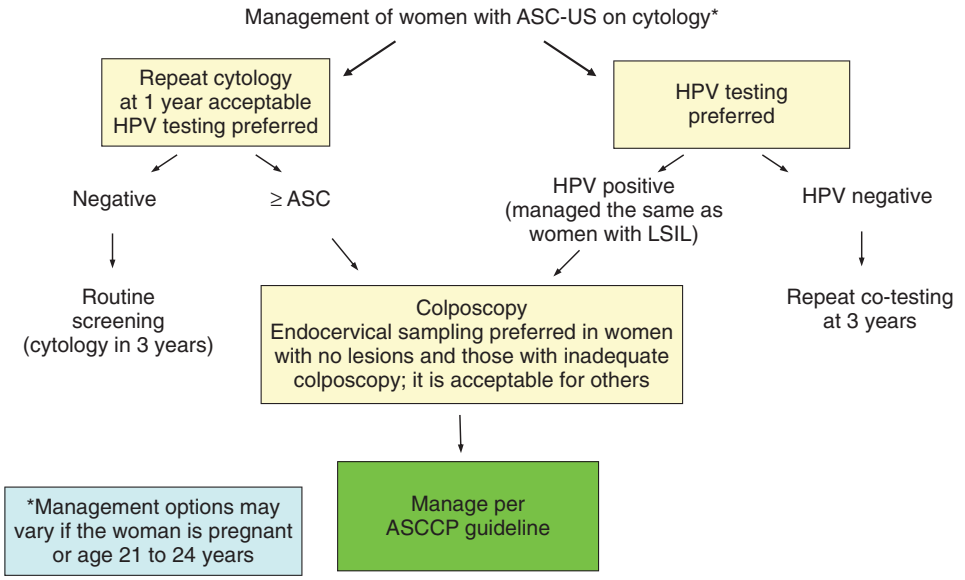
time for HPV regression; if either test result is abnormal, then colposcopy is indicated. Disadvantages to this approach include losing the advantage of HPV testing for early detection of cytology-negative cancers and the inability to assess whether persistent HPV positivity results from persistence of the same HPV type or clearance of the original type followed by reinfection with a second type, with low risk for CIN3+ unless the new infection becomes persistent. Alternatively, women can be triaged immediately using a genotyping test for HPV-16 or -18; women positive for either type should have colposcopy, but those with negative results should have co-testing repeated in 1 year, with colposcopy only if either test result is abnormal.

Atypical Squamous Cells of Undetermined Significance (Fig. 1.10)

Risk of CIN3+ among women with ASC-US cytology is insufficient to justify immediate colposcopy, at about 3%. ASC-US results are common. Triage using HPV testing on the liquid-based cytology sample appears to be cost effective and minimizes delay and loss to follow-up. If HPV testing is positive for high-risk types, then colposcopy is indicated. A negative HPV result in the context of ASC-US indicates a low risk of CIN3+, though the risk is higher than among women with negative co-testing; 3-year co-testing is recommended.

HPV genotyping distinguishes between higher risk women with HPV-16/-18 and lower risk women negative for HPV-16/-18, but for all HPV-positive women, 5-year CIN3+ risk approximates or exceeds the threshold for colposcopy. Because management is not changed by results, HPV genotyping is not recommended for triage of ASC-US cytology.

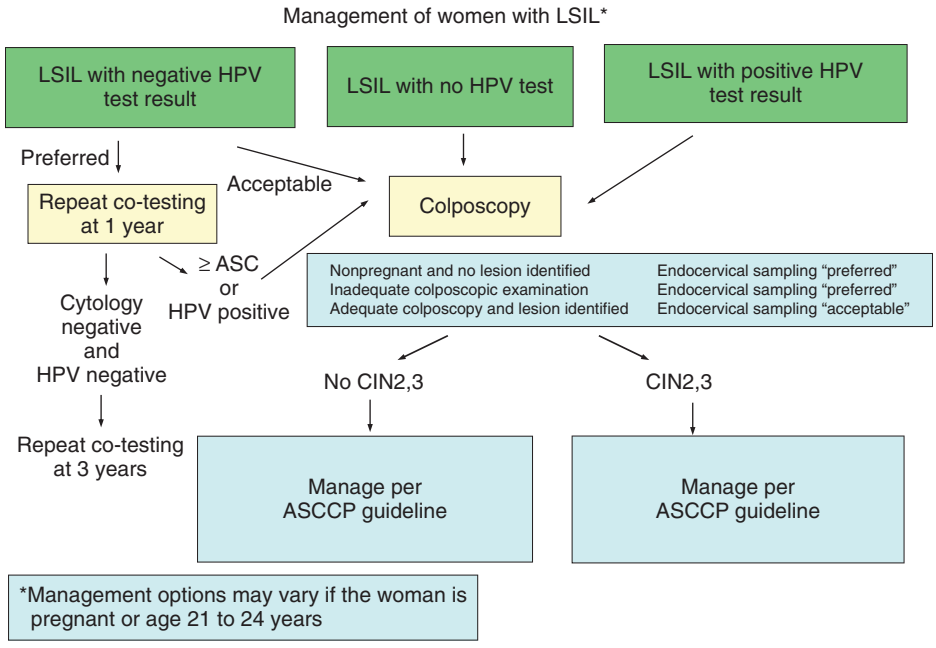
Where HPV testing is not available and follow-up is reliable, ASC-US cytology results can be triaged using a repeat Pap test in 1 year with colposcopy if persistently abnormal and return to routine 3-year Pap testing if negative.



For women 21 to 24 years of age, ASC-US cytology results should be followed with annual rather than triennial Pap testing. Colposcopy is not indicated unless ASC-US or low-grade squamous intraepithelial lesion (LSIL) cytology results persist for 2 years or unless cytology returns ASC-H, HSIL, or AGC.

Low-Grade Squamous Intraepithelial Lesion (Fig. 1.11)

Low-grade squamous intraepithelial lesion is the paradigmatic threshold for colposcopy in the United States. With few exceptions (pregnancy, age 21–24 years, HPV-negative result), women with LSIL cytology should be managed with colposcopy. When HPV co-testing is available women with HPV-LSIL should have repeat co-testing in 1 year, with colposcopy if HPV positive or with persistent abnormal cytology. LSIL triage may be considered in postmenopausal women, given their lower background risk for HPV.



Atypical Squamous Cells, Cannot Exclude HSIL

Women with a cytology report of "atypical squamous cells, cannot exclude high-grade squamous intraepithelial lesion" have a 5-year risk of CIN3+ similar to that of women with HSIL cytology, although their immediate risk of CIN3+ is lower. All women with ASC-H should undergo colposcopy, regardless of HPV result. In contrast to young women with ASC-US, women

21 to 24 years of age need colposcopy after ASC-H cytology, as do pregnant women.

High-Grade Squamous Intraepithelial Lesion

CIN2+ is found in some 60% of women with HSIL cytology, and some 2% will have cancer at colposcopy. This substantial risk justifies aggressive management. In many settings, especially for women in clinics with high rates of loss to follow-up and for women who have completed childbearing, immediate loop excision is an efficient approach to management. Immediate excision is unacceptable for women up to 24 years of age because of their low near-term risk for cancer and the likelihood that CIN2 and CIN2,3, but not CIN3, will regress. HPV results modulate risk, but even women with HPV-HSIL face a 30% 5-year risk for CIN3+. For this reason, colposcopy is required regardless of HPV result, and triage of HSIL cytology using HPV testing is unacceptable. Observation with repeat cytology is similarly unacceptable.

Atypical Glandular Cells

Despite its name, AGC cytology is more often associated with squamous than glandular lesions. The risk of CIN3, AIS, or cancer (CIN3+) after a Pap test read as AGC is almost 10%, and risk for cancer is 3%. Squamous and glandular lesions can coexist, and identification of CIN does not rule out adenocarcinoma. Many associated cancers are of endometrial origin and would be HPV negative; endometrial lesions are more common in older women and in women with such risk factors as obesity, unexplained bleeding, and anovulation. Thorough evaluation is needed regardless of HPV test results.

Women with AGC cytology need colposcopy with endocervical sampling and biopsies of any acetowhite cervical lesion. Endometrial sampling is needed if the patient is older than 35 years of age or if endometrial cancer risk factors are present. For women with AGC subcategorized as "atypical endometrial cells," evaluation can be truncated: Initial endometrial biopsy and endocervical curettage are needed, with colposcopy only if no endometrial pathology is found. In contrast to ASC-US, triage of AGC results with HPV testing or serial cytology testing is inappropriate. Management of AGC in women 21 to 24 years of age is identical to that of older women. Pregnant women with AGC cytology results need colposcopy, but endocervical curettage and endometrial sampling are contraindicated.

Endometrial Cells in Older Women

Among postmenopausal women, a finding of benign endometrial cells on cytology is associated with a 5% risk of clinically important pathology, including cancer. However, endometrial cells appear to have no association with disease in premenopausal women, and no further evaluation is needed for them. For postmenopausal women with endometrial cells on cytology, endometrial assessment is indicated using either endometrial sampling or imaging of endometrial thickness.

POSTCOLPOSCOPY MANAGEMENT

Managing Women With No Lesion or CIN1 at Colposcopy (Fig. 1.12)

A colposcopic biopsy result of no lesion or CIN1 does not exclude the presence of a higher grade lesion in an unsampled area of the cervix. Risk for subsequent CIN3+ depends on patient age and the prior abnormality. Risk is lower for women with what ASCCP terms "lesser abnormalities" than for women with ASC-H, HSIL, or AGC. Lesser abnormalities include negative cytology with either HPV-16 or repeated HPV positivity, ASC-US, or LSIL.

For women with lesser abnormalities and no lesion or only CIN1 on colposcopy, observation with serial co-testing is indicated. If a first co-test result is negative, repeat testing is indicated 3 years later. If all test results are negative, then routine screening is appropriate. If any test result is abnormal, repeat colposcopy is required. This can become burdensome. Treatment of CIN1 is acceptable once disease has persisted for 2 years, although continuing observation is also acceptable if fertility is a concern. Treatment of persistent HPV-positive tests or persistent ASC-US/LSIL cytology in the absence of a cervical lesion is not indicated because many of these women will have vaginal lesions. This includes topical therapies such as trichloroacetic acid. Hysterectomy is never indicated for CIN1 or abnormal cytology.

For women 21 to 24 years of age with no lesion or CIN1 after ASC-US or LSIL, observation with repeat cytology annually is indicated. Repeat colposcopy is only needed if cytology progresses to ASC-H, HSIL, or AGC, or if cytology remains borderline abnormal for 2 years. After a negative result, routine screening at 3 years is indicated. HPV testing and co-testing are not indicated in this age groups. For pregnant women with no lesion or CIN1 after lesser abnormalities during pregnancy, colposcopy should be deferred until postpartum.

When colposcopy reveals no lesion or CIN1 after ASC-H or HSIL cytology, risk for CIN3+ is much higher, and more aggressive management is indicated. ASCCP guidelines lump together ASC-H and HSIL, but diagnostic excision is more often indicated after HSIL; observation with annual co-testing is more appropriate after ASC-H, although either management strategies can be used after either result, according to clinical risk profiling. Observation is limited to women with satisfactory colposcopy and negative endocervical sampling; CIN1 in endocervical curettings is managed like CIN1 on cervical biopsy. If observation is elected, repeat colposcopy and biopsies are indicated after a positive HPV test or any grade of abnormal cytology. Women with persistent HSIL despite negative colposcopy should have a diagnostic excision procedure.

For women 21 to 24 years of age with no lesion or CIN1 after ASC-H or HSIL, diagnostic excision is indicated if colposcopy is unsatisfactory. When colposcopy is satisfactory in visualizing the entire squamocolumnar junction, either treatment or observation is indicated. Observation entails colposcopy and cytology every 6 months until two test result are negative, when routine screening can resume. If HSIL cytology persists,

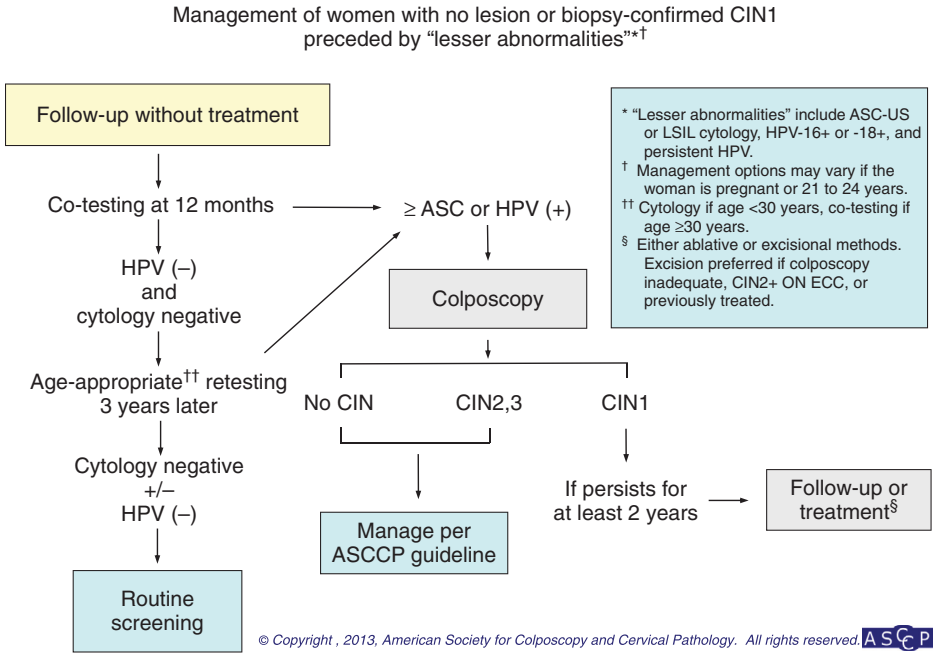

FIGURE 1.12 Management of women with no lesion or biopsy-confirmed grade 1 cervical intraepithelial neoplasia (CIN1) preceded by "lesser abnormalities." *ASCCP,* American Society for Colposcopy and Cervical Pathology; *ASC-US,* atypical squamous cells undetermined significance; *CIN,* cervical intraepithelial neoplasia; *ECC,* endocervical curettage; *HPV,* human papillomavirus; *LSIL,* low-grade squamous intraepithelial lesion. (From Massad SL, Einstein MH, Huh WK, et al. 2012 Updated consensus guidelines for the management of abnormal cervical cancer screening tests and cancer precursors. *J Low Genit Tract Dis* 2013;17(5 suppl 1):S1-S27, © 2013 American Society for Colposcopy and Cervical Pathology.)

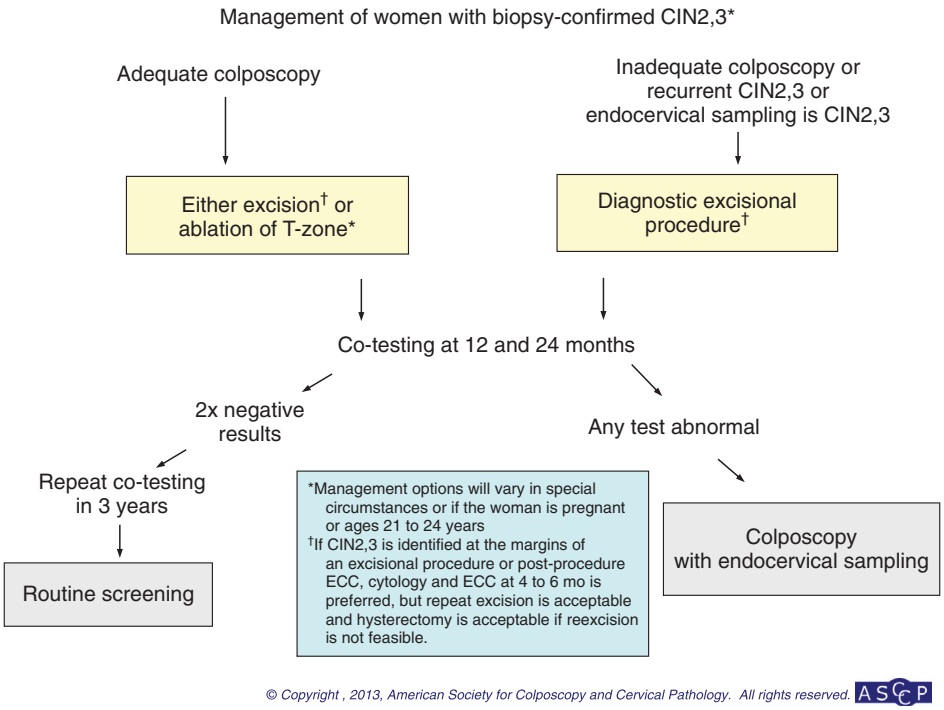
treatment is indicated. For pregnant women with no lesion or only CIN1 after ASC-H or HSIL, colposcopy should be repeated post partum: The short-term cancer risk is low, and no other intervention is needed during pregnancy



When no lesion or CIN1 is found after AGC cytology, annual co-testing is indicated, with colposcopy for any abnormality; after two negative co-test results, risk declines, and 3-year co-testing intervals are appropriate. Colposcopy is needed if any result is abnormal. Hysterectomy is unacceptable as primary therapy for any grade of CIN, although after prior excision, hysterectomy may be indicated if lesions recur or persist and repeat diagnostic excision is not feasible.

Managing Women With CIN2 or CIN3 (Fig. 1.13)

A colposcopic biopsy of CIN2 is the threshold for treatment. CIN2 is an intermediate lesion: Many represent transient but exuberant HPV infection, and half or more resolve without therapy. Some progress to CIN3 and cancer. Because compliance with follow-up cannot be assured, treatment is recommended. Testing biopsy specimens for the presence of block staining for $p16^{ink4a}$ can identify CIN2 lesions at risk for progression and can be used as a test for triage. All lesions read as CIN3 should be treated regardless of the patient's age or desire for future childbearing, because there is no margin for progression, and some will harbor undiagnosed cancer; ongoing pregnancy is the main exception to this standard. Biopsies read as high grade or CIN2,3 can be managed expectantly or with immediate treatment, depending on patient risk and preferences.

Observation is an acceptable option for women who after counseling consider risk to future pregnancies from treatment to outweigh cancer risk from observation. There is no specific age threshold: A 21-year-old woman who has had a tubal ligation should be treated, but a 43-year-old woman undergoing infertility treatment after a diagnosis of incompetent cervix might prefer to be observed. Observation is only acceptable when the entire lesion and squamocolumnar junction is observed colposcopically. Observation consists of colposcopy and cytology at 6-month intervals until the lesion resolves, as evidenced by regression of colposcopic abnormalities and normalization of cytology. After that occurs, women should be followed with a co-test 1 year later and then 3 additional years later before returning to routine screening; if either the Pap test or HPV test result is abnormal in follow-up, then colposcopy and biopsies should be repeated.

Women with a diagnosis of AIS on colposcopic biopsy should be managed with diagnostic excision to exclude associated invasive cancer. The excision should be done to produce a single specimen; traditionally, this has involved knife conization, but needle, straight wire, or loop conization is acceptable if thermal artifact is minimized. If the margins of the excision specimen are involved or uninterpretable, then reexcision or hysterectomy is required. Women with negative margins at diagnostic excision face a 10% risk of persistent AIS and a lesser

FIGURE 1.13 Management of women with biopsy-confirmed grade 2 and 3 cervical intraepithelial neoplasia (CIN2,3). (From Massad SL, Einstein MH, Huh WK, et al. 2012 Updated consensus guidelines for the management of abnormal cervical cancer screening tests and cancer precursors. *J Low Genit Tract Dis* 2013;17(5 suppl 1):S1-S27, © 2013 American Society for Colposcopy and Cervical Pathology.)

risk of invasive cancer, as shown by Costa and colleagues. This risk justifies hysterectomy when childbearing is complete. However, the risk is considered acceptable for women who wish to preserve fertility, although careful monitoring is recommended using colposcopy and co-testing 6 months after the diagnostic excision procedure, with co-testing in follow-up at 1- to 3-year intervals.

TREATMENT OF CERVICAL DISEASE

Although Trimble and colleagues have shown that a therapeutic vaccine can achieve almost 50% efficacy in the elimination of CIN2/3, 90% cure rates for CIN2+ still require destructive therapies. In the United States, ablational therapies include cryotherapy and laser ablation. Excision can be accomplished with an electrosurgical wire loop or needle or with a scalpel.

Cervical ablation results in the elimination of lesional tissue without rendering a specimen for pathologic analysis. For this reason, many gynecologists consider outpatient loop excision a preferred approach. However, randomized trials showed similar failure rates for excision and ablation. This suggests that as long as invasive cancer is microinvasive, with little risk for metastasis, the method of destruction is irrelevant. Nevertheless, using ablational therapies for cervical disease requires careful attention to well-defined exclusion criteria. Ablation cannot be undertaken unless the entire squamocolumnar junction, including all lesional tissue, is visible colposcopically. Ablation of such an unsatisfactory transformation zone risks missing invasive cancer within the endocervix that then progresses undetected. A corollary to this is that ablation should not be attempted when disease extends into the endocervix above the depth that can be ablated. Thus, although manipulation may allow visualization of the squamocolumnar junction deep in the endocervical canal, ablation would remain inappropriate. Other criteria that must be met before proceeding with ablation include concordance of high-grade cytology with colposcopy and histology findings; an endocervical curettage specimen showing no dysplasia or only CIN1; and suspicion of invasive cancer by cytology, colposcopy, or biopsy.

Cryotherapy is performed using nitrous oxide, a delivery gun, and various sizes of metal probes designed to cover the transformation zone of the cervix. Figge and Creasman described use of a freeze–thaw–freeze technique with good success rates, but regardless of the use of double- or single-freeze approaches, identifying the development of at least a 5-mm "ice ball" or zone of freezing lateral to the cryotherapy probe is essential to achieving deep thermal destruction. One standard approach is outlined in Table 1.5. Advantages of cryotherapy include relatively low cost and low risk for injury. Disadvantages include a copious discharge from cervical tissues suffering from sublethal thermal injury and lack of a surgical specimen.

Cervical laser ablation involves the use of carbon dioxide laser energy to destroy abnormal cervical tissue. When optimally used, the laser energy is delivered at a power density of 750 to 1250 W/cm^2. This results in flash boiling of impacted cells, and

TABLE 1.5 Cryosurgery Technique

1. N_2O or CO_2
2. K-Y Jelly on probe
3. Double-freeze

   b. Thaw
   c. 4- to 5-mm ice ball

energy is dissipated from the operating field through the smoke plume without causing deeper tissue injury. Lower power density may create the illusion of greater control of tissue destruction, but it requires longer beam application, with greater hidden, delayed coagulation injury to underlying stroma. As with all therapies, laser should be used to ablate the entire at-risk transformation zone. CIN can involve the metaplastic epithelium of cervical glands, which extend some 5 mm into the cervical stroma; for this reason, ablation should be carried to a depth of about 7 mm and should encompass all lesional tissue. If the lesion extends onto the vagina, ablation is carried only to 1 to 2 mm in depth. As described by Stanhope and associates, laser therapy can result in persistent CIN risk of less than 90%. Advantages include precision in application, allowing extension of therapy to lesions that involve the vagina, and rapid recovery from injury. Disadvantages include the need for an expensive laser generator that requires frequent maintenance. Unskilled use of laser energy can result in immediate and delayed injury.

Most US gynecologists treat cervical precancers by excision with electrosurgical loops, termed LEEP or large loop excision of the transformation zone (LLETZ). The entire transformation zone is excised using loops with diameters of 1.5 to 2.5 cm. Excision should extend to the deepest glands, or 7 to 8 mm. For women with disease extending into the endocervical canal and those with inadequate colposcopy, either using deeper loops or a second endocervical pass, colloquially termed a "top-hat" excision for the appearance of the stacked specimen that results; this endocervical excision must encompass the lateral extent of endocervical glands, so 6 to 8 mm from the endocervical surface. For most women, LEEP can be done in an office setting under local anesthesia. Epinephrine is injected with the local anesthetic to minimize blood loss. The injection should be subepithelial rather than stromal, and a paracervical block does not provide the same hemostatic benefit of intracervical injection. Although an operating suite it not required, office LEEP should be done in a setting that includes equipment for suturing and response to anaphylactic reactions. Colposcopic visualization allows optimal tailoring of the excision. Hemostasis is achieved with a combination of fulguration using ball electrodes and application of Monsel's paste. Delayed bleeding should occur in fewer than 5% of cases but is a known complication of the procedure. Obese women and those with anatomic variations or anxiety that prevents optimal cervical visualization in the office may require general anesthesia. Advantages to LEEP include the availability of a surgical specimen with minimal thermal artifact at margins and the ability to adapt excision to the extent of lesions and metaplasia. Disadvantages include risk of surgical injury and hemorrhage and the need for careful operator technique.

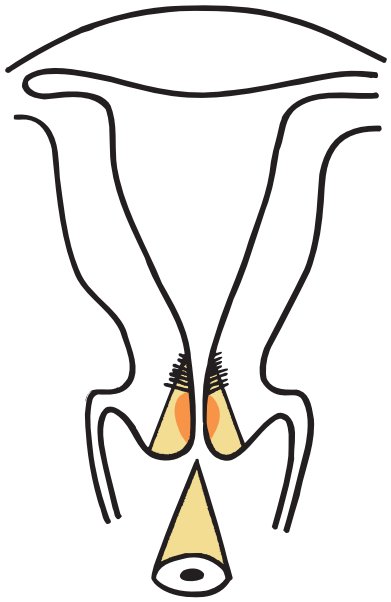

FIGURE 1.14 Cone biopsy for endocervical disease. Limits of the lesion were not seen colposcopically.

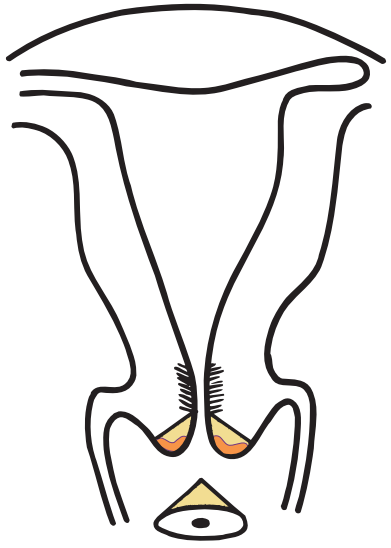

FIGURE 1.15 Cone biopsy for cervical intraepithelial neoplasia of the exocervix. Limits of the lesion were identified colposcopically

Some lesions require intact diagnostic specimens to exclude invasive cancer and assess margins. These include in situ adenocarcinomas and microinvasive cancers. Traditionally, these lesions have been treated with knife conization (Figs. 1.14 and 1.15), which results in an optimal diagnostic specimen while treating in situ and microinvasive lesions for women who wish to retain fertility. As LEEP has become pervasive in training programs, knife conization skills may be disappearing. Needle or straight wire electrosurgical conization has been developed as an alternative, allowing similar adaptation of excision while minimizing blood loss and tissue injury.

MANAGING ABNORMAL RESULTS DURING PREGNANCY

The goal of cervical cancer prevention measures during pregnancy is to identify cervical cancer so malignant lesions can be monitored closely for progression or treated. The risk is remote for cancer developing during pregnancy in women who have CIN, including CIN3. ASC-US and LSIL cytology results do not require colposcopy until postpartum, even if associated with HPV infection, although colposcopy is acceptable. Wetta and colleagues found no cancers and few high-grade lesions among 625 pregnant women with these borderline cytology results. For women with ASC-H, HSIL, or AGC cytology results, colposcopy is indicated. Because of the vascularity of the pregnant cervix, often only one biopsy can be obtained; mini-Tischler forceps should be used and immediate direct pressure applied to the biopsy site. Clinicians without experience with colposcopy during pregnancy should consider referral to a center with expertise because pregnancy will cause colposcopic abnormalities. Biopsy should be done for lesions that appear high grade because limiting biopsy to malignant-appearing lesions results in missed cancers. Women with CIN2+ may be followed with postpartum colposcopy and repeat biopsy or with serial colposcopy during pregnancy, with repeat biopsy only if the colposcopic impression worsens. Conization is indicated only when cancer is suspected by examination, cytology is read as showing malignant cells, or colposcopy or biopsy shows possible invasion. When performed, complete excision of the transformation zone is not needed because the goal is to determine if a deeply invasive cancer is present, not to definitively treat the cervix. Limited excision using an electrosurgical loop with blended current in a controlled operating room setting that allows for cervical suturing may be considered.

FUTURE DIRECTIONS

In developed countries with effective HPV vaccination programs, HPV-16 and HPV-18 are being eliminated from the circulating pool of HPV types. This will have profound implications for cervical cancer prevention. In fact, the introduction of nonavalent vaccination promises to reduce cervical cancer incidence to a rate too low to justify screening. The transition to such a welcome development over the coming decades will create opportunities and controversies as the scientific community adapts to the disappearance of what was once the most common cancer killer of women. Whether this promising future is attained in the United States, with its opportunistic approach to vaccination, remains to be measured.

As HPV-16 prevalence falls among at-risk women as vaccinated girls age, the prevalence of CIN3+ will decline. This will result in a lower incidence of abnormal Pap test results and more abnormalities that occur will reflect transient HPV infections or benign cytologic changes: As disease prevalence falls, the positive predictive value of an abnormality should decline. This should drive a shift away from cytology as a primary screening test. Primary HPV testing should replace cytology. Although cytology may be retained as a triage test for women with HPV types other than 16 or 18, as described by Huh and colleagues, other tests may prove superior, either because of greater predictive accuracy or because they can be automated.

Risk-based guidelines will need to become flexible as risk becomes dynamic. Vaccinated women are likely to face much lower risk than unvaccinated women, and epidemiologic studies suggest that vaccination will result in age-specific declines in HPV-16/-18 and CIN3+ prevalence as sexual segregation by age results in herd immunity for younger women. As vaccinated age cohorts mature, the optimal age for initiation of screening will rise. As more CIN2+ identified by colposcopy reflects infection by HPV types other than HPV-16/-18, with lower oncogenic potential, observation for immune-mediated regression may become preferred over treatment. Integrating this change into practice will be difficult because by the time age-based changes in risk are observed, published, reviewed, and integrated into new guidelines, women will have grown older yet retained immunity. This welcome challenge will structure coming debates on cervical cancer for decades to come.

Preinvasive Disease of the Vagina and Vulva and Related Disorders

Cara A. Mathews, MD, Joan L. Walker, MD

OUTLINE

Embryology
Examination and Treatment of Females Exposed to Diethylstilbestrol
Nonneoplastic Epithelial Disorders of the Vulva
- Lichen Simplex Chronicus
- Lichen Sclerosus
- Lichen Planus
- Diagnosis and Treatment

Intraepithelial Neoplasia of the Vagina
- Clinical Profile
- Diagnosis
- Management

Vulvar Intraepithelial Neoplasia
- Clinical Profile
- Diagnosis
- Pigmented Lesions
- Management

KEY POINTS

1. Lichen sclerosis is associated with vulvar cancer.
2. Treatment of vaginal intraepithelial neoplasia III is laser vaporization.
3. Wide local excision is the treatment of choice for vulvar intraepithelial neoplasia III.
4. Imiquimod treatment is a potentially noninvasive treatment of vulvar dysplasia.

EMBRYOLOGY

At approximately 12 to 14 weeks of gestation, the simple columnar epithelium that lines the vaginal portion of the uterovaginal canal begins to undergo transformation into stratified Müllerian epithelium. This transformation proceeds cranially until it reaches the columnar epithelium of the future endocervical canal. The vagina, which is lined initially by simple columnar epithelium of Müllerian origin, acquires stratified Müllerian epithelium. The vaginal plate advances in a caudocranial direction, obliterating the existing vaginal lumen. By caudal cavitation of the vaginal plate, a new lumen is formed, and the stratified Müllerian epithelium is replaced by a stratified squamous epithelium, probably from a urogenital sinus origin. Local proliferation of the vaginal plate in the region of the cervicovaginal junction produces the circumferential enlargement of the vagina known as the vaginal fornices, which surround the vaginal part of the cervix.

The administration of diethylstilbestrol (DES) through the 18th week of gestation can apparently result in the disruption of the transformation of columnar epithelium of Müllerian origin to the stratified squamous successor (Fig. 2.1). This retention of Müllerian epithelium gives rise to adenosis. Adenosis may exist in many forms: glandular cells in place of the normal squamous lining of the vagina, glandular cells hidden beneath an intact squamous lining, or mixed squamous metaplasia when new squamous cells attempt to replace glandular cells.

Vaginal adenosis has been observed in patients without a history of DES exposure but rarely to a clinically significant degree. Adenosis is more common in patients whose mothers began DES treatment early in pregnancy and is not observed if DES administration began after 18 weeks of gestation. At least 20% of women exposed to DES show an anatomic deformity of the upper vagina and cervix; transverse vaginal and cervical ridges, cervical collars, vaginal hoods, and cockscomb cervices have all been described. The transverse ridges and anatomic deformities found in one-fifth of women exposed to DES make it difficult to ascertain the boundaries of the vagina and cervix. The cervical eversion causes the cervix grossly to have a red appearance. This coloration is caused by the numerous normal-appearing blood vessels in the submucosa. With a colposcope and application of 3% acetic acid solution, numerous papillae ("grapes") of columnar epithelium are observed, similar to those seen in the native columnar epithelium of the endocervix. The hood (Fig. 2.2) is a fold of mucous membrane surrounding the portio of the cervix; it often disappears if the portio is pulled down with a tenaculum or is displaced by the speculum. The cockscomb is an atypical peaked appearance of the anterior lip of the cervix, and vaginal ridges are protruding circumferential bands in the upper vagina that may hide the cervix. A pseudopolyp formation (see Fig. 2.2) has been described that occurs

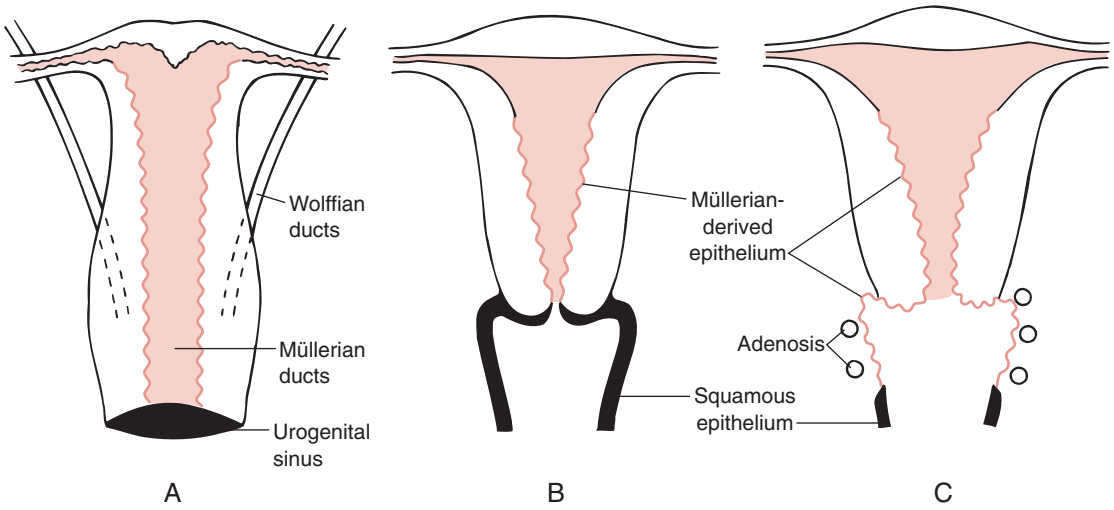

FIGURE 2.1 A–C, Schematic representations of the embryologic development of the vagina in unexposed (A) and diethylstilbestrol-exposed (B and C) women. (From Stillman RJ. In utero exposure to diethylstilbestrol: adverse effects on the reproductive tract and reproductive performance in male and female offspring. *Am J Obstet Gynecol* 1982;142(7):905.)

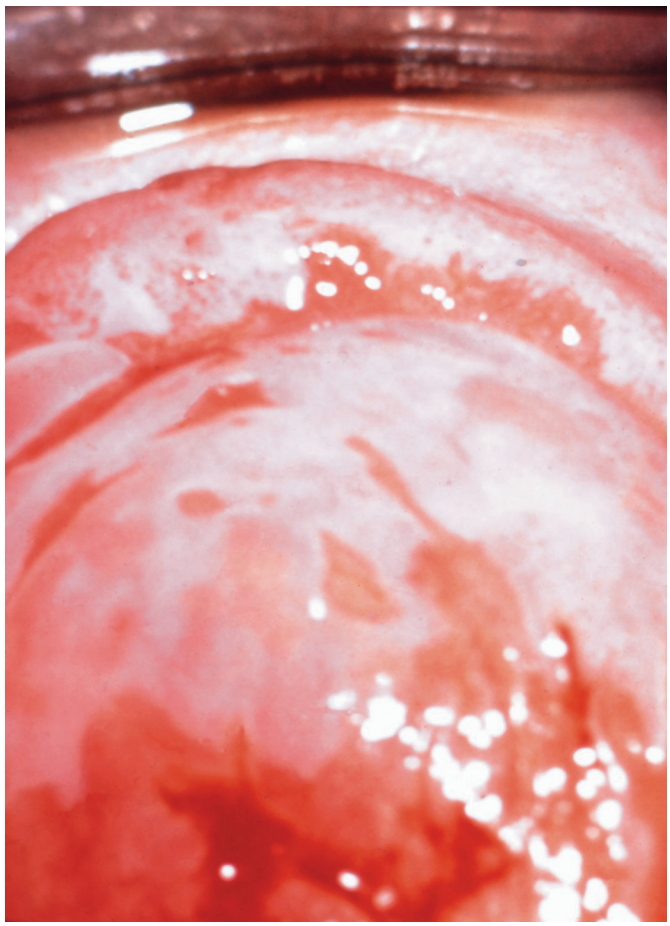

FIGURE 2.2 Hood surrounding the small diethylstilbestrol-exposed cervix, which is completely covered by columnar epithelium (pseudopolyp).

when the portio of the cervix is small and protrudes through a wide cervical hood.

The occurrence of vaginal adenosis among young women without in utero DES exposure implies that an event in embryonic development is responsible. The development of the Müllerian system depends on and follows formation of the Wolffian, or mesonephric, system. The emergence of the Müllerian system as the dominant structure appears unaffected by intrauterine exposure to DES when studied in animal systems. However, it is apparent that steroidal and nonsteroidal estrogens, when administered during the proper stage of vaginal embryogenesis in mice, can permanently prevent the transformation of Müllerian epithelium into the adult type of vaginal epithelium, thus creating a situation like adenosis. The colposcopic and histologic features of vaginal adenosis strongly support the concept of persistent, untransformed Müllerian columnar epithelia in the vagina as the explanation of adenosis.

EXAMINATION AND TREATMENT OF FEMALES EXPOSED TO DIETHYLSTILBESTROL

Essentially no DES has been prescribed to pregnant women since 1971, when the US Food and Drug Administration issued an alert regarding the risk of vaginal clear cell adenocarcinoma for females exposed in utero. The youngest women with in utero exposure were born in 1972, and many previously important clinical topics have become less relevant in everyday practice. The associated congenital anomalies and teenage cancers, for example, are no longer being diagnosed. However, an understanding of the disease process remains essential in order to care for this cohort of women as they age. Additionally, the evolution and understanding of DES is of great historical importance with many implications and lessons for today's practice.

Approximately 60% of women with in utero DES exposure have vaginal adenosis, cervical-like epithelium in the vagina, which appears red and granular. This is a benign condition that does not require treatment unless symptomatic, and it will generally resolve on its own over time. The premenopausal risk of clear cell adenocarcinoma is approximately 40 times higher among women with in utero DES exposure compared with those without the exposure. In unexposed women, clear cell adenocarcinoma occurs almost exclusively in menopause; in women with in utero exposure, most cases are diagnosed during the late teens and 20s. The oldest reported patient with DES-associated clear cell adenocarcinoma was diagnosed at 51 years. Overall, the incidence of clear cell adenocarcinoma is low in women with in utero exposure (≈1.5 cases/1000 women), but the risk is significantly higher than among unexposed women. The etiology of clear cell adenocarcinoma is unclear, and evolution of adenosis to cancer has never been directly proven, only suspected. Because of an increased risk of clear cell adenocarcinoma of the cervix and vagina and an increased risk of cervical intraepithelial neoplasia (CIN), annual examinations with Pap cytology testing are recommended for the entire lifetime of women with in utero DES exposure. No increased association has been observed between DES and squamous cell cervical cancer.

All DES-exposed females should have an annual gynecologic examination with cytology screening (Table 2.1). Cytology should include separate sampling of the cervix and upper vagina. If suspicious lesions are present, colposcopy and directed biopsies should be performed regardless of the cytology results. If delineations of the vagina, cervix, and endocervix are difficult, Lugol's solution may be helpful in detecting abnormal areas. Colposcopic examination of these patients is hindered by the abnormal patterns seen with squamous metaplasia (Fig. 2.3), which can be confused with neoplastic lesions. Histologic confirmation is essential before any treatment is undertaken. Marked mosaic (Fig. 2.4) and punctation patterns that normally herald intraepithelial neoplasia are commonly seen in the vagina of DES-exposed women as a result of widespread metaplasia. The purpose of regular examination is to permit

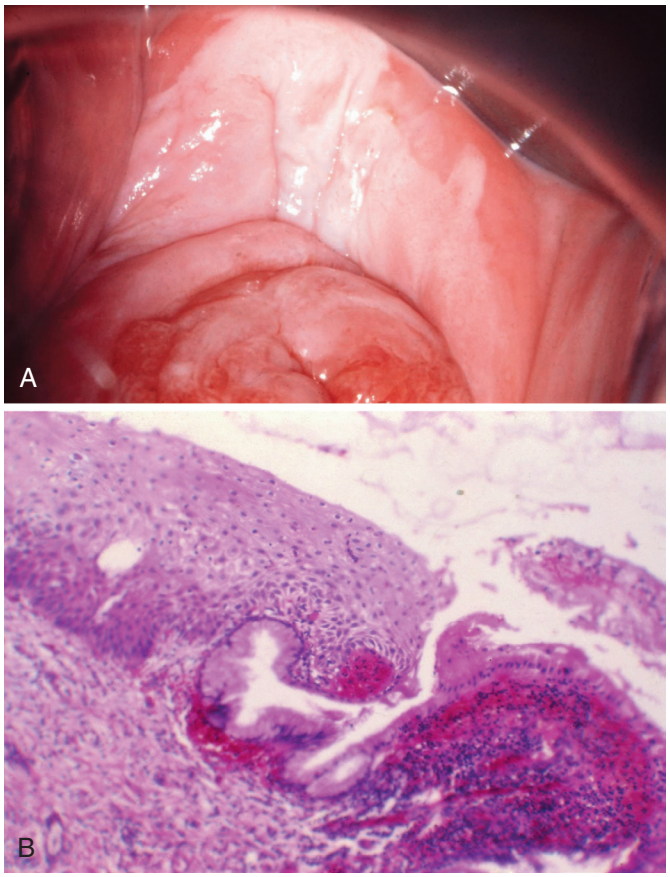

FIGURE 2.3 **A,** Area of white epithelium of squamous metaplasia. **B,** Histologic section of the area in *A* showing metaplasia to the left partially covering the adenosis (columnar epithelium) to the right.

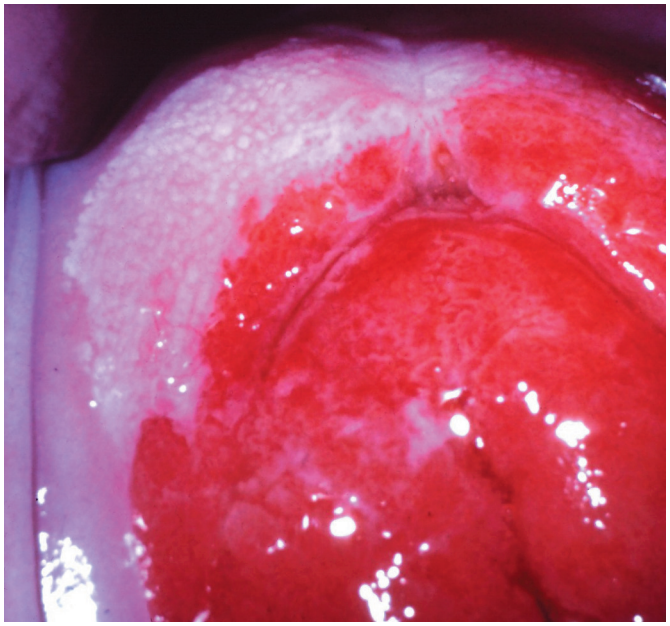

FIGURE 2.4 Heavy mosaic pattern (histologically proven metaplasia) in a hood surrounding the cervix of an offspring exposed to diethylstilbestrol.

TABLE 2.1 Examination of the Female Offspring Exposed to Diethylstilbestrol

1. Inspect the introitus and hymen to assess the patency of the vagina.
2. Palpate the vaginal membrane with the index finger (especially noting non–Lugol-staining areas), noting areas of induration or exophytic lesions, which should be considered for biopsy.
3. Perform a speculum examination with the largest speculum that can be comfortably inserted (virginal-type speculums are often necessary). Adenosis usually appears red and granular (strawberry surface).
4. Obtain cytologic specimens from the cervical os and the walls of the upper third of the vagina.
5. Perform a colposcopic examination or Lugol staining on the initial visit.
6. Do a biopsy of indurated or exophytic areas and colposcopically abnormal areas with a dysplastic Papanicolaou smear.
7. Perform a bimanual rectovaginal examination.

detection of adenocarcinoma and squamous neoplasia during the earliest stages of development. Although many therapies have been attempted, no recommended treatment plan for vaginal adenosis exists. In most cases, the area of adenosis is physiologically transformed into squamous epithelium during varying periods of observation, and no therapy is necessary.

NONNEOPLASTIC EPITHELIAL DISORDERS OF THE VULVA

Nonneoplastic epithelial disorders of the vulvar skin and mucosa are frequently seen in clinical practice. Diagnosis is difficult without a biopsy to provide a histologic result, and multiple changes in terminology over the past 25 years add confusion to clinical management. The most recent classification guidelines were published in 2007 by the International Society for the Study of Vulvovaginal Disease (ISSVD) (Table 2.2). The lichenoid pattern subset includes two chronic diseases, lichen sclerosus and lichen planus, which are relevant to this review because of the association of those two diseases with vulvar cancer. Lichen simplex chronicus is not included in the lichenoid subset; it is classified in the acanthotic pattern subset. This is appropriate from an oncology viewpoint because lichen simplex chronicus is not associated with invasive cancer. With similar presenting symptoms and a hyperkeratotic appearance, however, lichen simplex chronicus can be difficult to discriminate from lichen sclerosus and lichen planus on examination (Table 2.3).

TABLE 2.2 2006 World Congress International Society for the Study of Vulvovaginal Disease (Classification of Vulvar Dermatoses)

Pathologic Subset	Clinical Correlate
Spongiotic pattern	Atopic dermatitis
	Allergic contact dermatitis
	Irritant contact dermatitis
Acanthotic pattern	Psoriasis
	Lichen simplex chronicus
	Primary (idiopathic)
	Secondary (superimposed on other vulvar disease)
Lichenoid pattern	Lichen sclerosus
	Lichen planus
Dermal homogenization/sclerosis pattern	Lichen sclerosus
Vesiculobullous pattern	Pemphigoid, cicatricial type
	Linear IgA disease
Acantholytic pattern	Hailey-Hailey disease
	Darier disease
	Papular genitocrural acantholysis
Granulomatous pattern	Crohn's disease
	Melkersson-Rosenthal syndrome
Vasculopathic pattern	Aphthous ulcers
	Behçet disease
	Plasma cell vulvitis

Lichen Simplex Chronicus

Lichen simplex chronicus presents in girls and women of all ages, but it is more common in the reproductive and postmenopausal years. Lichen simplex chronicus is a chronic eczematous condition, and most women with this condition also have a history of atopic dermatitis. Pruritus is the most common symptom, and over time, scratching leads to epithelial thickening and hyperkeratosis. The status of the skin usually relates to the amount of scratching. Exacerbating agents may include heat, moisture, sanitary or incontinence pads, and topical agents. Lichen simplex chronicus may be seen in conjunction with other processes such as *Candida* infections or lichen sclerosus; these primary diseases must be treated in order to treat the pruritus leading to scratching and hyperkeratosis.

The locations most often involved on the vulva include the labia majora, interlabial folds, outer aspects of the labia minor, and clitoris. Changes can also extend to the lateral surfaces of the labia majora or beyond. Areas of lichen simplex chronicus are often localized, elevated, and well-delineated, but they may be extensive and poorly defined. The appearance of lesions may vary greatly even in the same patient. The vulva often appears dusky red when the degree of hyperkeratosis is slight and may appear thickened and leathery when hyperkeratosis persists. At other times, well-defined white patches may be seen, or a combination of red and white areas may be observed in different locations. Thickening, fissures, and excoriations require careful evaluation because carcinoma may be exhibited by these same features. For this reason, biopsy is essential in ascertaining the correct diagnosis.

Biopsy reveals a variable increase in the thickness of the horny layer (hyperkeratosis) and irregular thickening of the

TABLE 2.3 Other Dermatoses

Disorder	Lesion	Genital	Other Locations
Seborrheic dermatitis	Erythema with mild scale oval plaques	Mild scaling; also "inverse type"	Central face, neck, scalp, chest, back
Psoriasis	Annular scaly plaques that bleed easily	Red plaques with gray-white scale	Scalp, elbows, knees, sacrum
Tinea	Annular plaques with central clearing	Common	Skinfolds or single "ringworm" lesion
Lichen simplex chronicus	Lichenified plaques, some dermatitic	Scrotum or labia majora	Nape of the neck, ankle, forearm, antecubital and popliteal fossae
Lichen planus	Flat-topped lilac papules and plaques	White network, erosive vaginitis	Volar wrists, shins, buccal mucosa

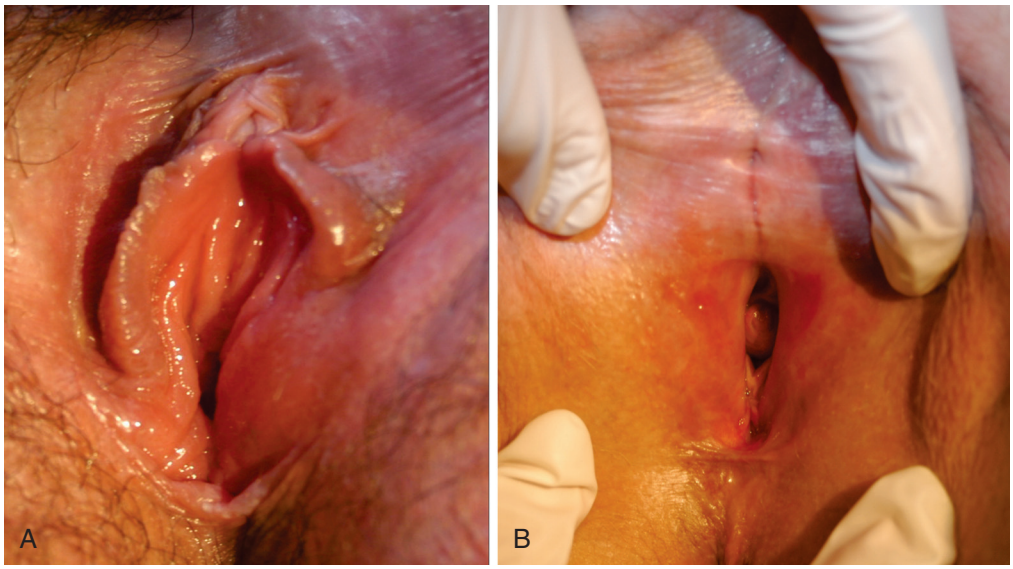

FIGURE 2.5 Progression from early (**A**) to late (**B**) lichen sclerosus, with characteristic loss of labial architecture. (Courtesy Dr. Lori Boardman, MD, ScM, University of Central Florida College of Medicine.)

malpighian layer (acanthosis). This latter process produces a thickened epithelium and lengthening and distortion of the rete pegs. Parakeratosis may also be present. The granular layer of the epithelium is usually prominent. An inflammatory reaction is often present within the dermis with varying numbers of lymphocytes and plasma cells.

Lichen Sclerosus

Lichen sclerosus represents a specific disease found in genital and nongenital sites. The vulva is the most common lesion site in women. The age distribution of the disease is bimodal with peaks during the premenarchal and postmenopausal years, but the highest incidence is among postmenopausal women. Although the overall incidence and prevalence are unknown, Leibovitz and colleagues reported the prevalence among elderly women in a nursing home setting as 1 in 30. The mean age in this population was 82 years, 88% were wheelchair users, and 86% were incontinent (Figs. 2.5 and 2.6).

Over time, pruritus occurs with essentially all lesions, leading to scratching, which can develop into ecchymosis and ulceration. Symptoms evolve to include burning, tearing, and dyspareunia. Studies have suggested that the epithelium in lichen sclerosus is metabolically active and nonatrophic. A chronic inflammatory, lymphocyte-mediated dermatosis is present. The etiology of the disease is poorly understood, but autoimmune mechanisms appear to be involved.

The microscopic features of lichen sclerosus include hyperkeratosis, epithelial thickening with flattening of the rete pegs, cytoplasmic vacuolization of the basal layer of cells, and follicular plugging. Beneath the epidermis is a zone of homogenized, pink-staining, collagenous-appearing tissue that is relatively acellular. Edema is occasionally seen in this area. Elastic fibers are absent. Immediately below this zone lies a band of inflammatory cells that is consistent with lymphocytes and some plasma cells. Lichen sclerosus is often associated with foci of both hyperplastic epithelium and thin epithelium. Lichen simplex chronicus has been found in 27% to 35% of women with lichen sclerosus after microscopic study of vulvar specimens, likely secondary to pruritus and scratching.

FIGURE 2.6 Lichen sclerosus with stenosis of the introitus, fissuring in the posterior fourchette, and perianal involvement producing the "keyhole appearance." (Courtesy of Dr. Lori Boardman, MD, ScM, University of Central Florida College of Medicine.)

In a well-developed classic lesion, the skin of the vulva is crinkled ("cigarette paper") and thinned, or appears parchment-like. The process often extends around the anal region in a figure-of-8 or keyhole configuration, and 30% of women have perianal lesions. At other times, the changes are localized, especially in the periclitoral area or the perineum. Clitoral involvement is usually associated with edema of the foreskin, which may obscure the glans clitoris. Phimosis of the clitoris is often seen late in the course of the disease. As the disease progresses, there is loss of architecture of the normal external genitalia. The labia minora may completely disappear as a result of atrophy. Synechiae often develop between the edges of the skin in these locations, causing pain and limited physical activity. Fissures also develop in the natural folds of the skin and especially in the posterior fourchette. The introitus may become so strictured or stenosed that intercourse is impossible. The vaginal mucosa is generally spared in this disease, which is helpful in discriminating between lichen sclerosus and lichen planus. In a study by Dalziel, 44 women with lichen sclerosus were evaluated for sexual dysfunction. Apareunia was experienced by 19 of the women at some point. Dyspareunia and decreased frequency of intercourse were noted by 80%, and orgasm was altered and relationships were affected in half. Local steroids improved sexual function in two-thirds of these patients.

Lichen sclerosus is a risk factor for invasive vulvar cancer, likely as a result of chronic inflammation and sclerosis. In untreated populations, approximately 5% of patients with lichen sclerosus also have intraepithelial neoplasia. Wallace followed 290 women with lichen sclerosus for an average of 12.5 years and found that 4% (n = 12) developed vulvar cancer. Carlson et al. reported that 4.5% of patients with lichen sclerosus developed vulvar cancer over a mean of 10 years. In treated populations, however, the risk may be lower. Cooper and associates treated 233 women in a vulvar teaching clinic over a 10-year period; 89% of the cohort received superpotent steroid treatment. Invasive vulvar cancer developed in 3% (n = 7), and vaginal intraepithelial neoplasia (VAIN) developed in 2% (n = 4). Jones and colleagues reported one case of cancer from a vulvar clinic treating 213 girls and women older than age 8 years. Renaud-Vilmer et al. reported results from an urban dermatology clinic caring for 83 girls and women with no prior treatment of vulvar lichen sclerosus. Invasive cancer was present at the time of presentation in 7% (n = 6) and developed in 2% (n = 2); in those who developed cancer, one did not return for follow-up, and one did not use the prescribed treatment. In a cohort followed prospectively with repeat vulvar examinations at the University of Florence by Carli and associates, two cases of invasive cancer and one case of vulvar intraepithelial neoplasia (VIN) developed among 211 women with treated lichen sclerosus. All three cases occurred after more than 3 years of follow-up in the cohort.

The absolute incidence of vulvar cancer is low in women with lichen sclerosus, but 50% to 70% of squamous cell vulvar cancers occur in a background of lichen sclerosus. Currently, there is no diagnostic tool to differentiate between lichen sclerosus that will remain benign versus lichen sclerosus that will evolve into squamous cell carcinoma (SCC). Two biomarkers, p53 and monoclonal antibody MIB1, have shown promise in retrospective tissues studies, but further testing is necessary. The standard of care for cancer screening in this population remains serial examination with directed biopsies for new, evolving, or suspicious lesions, teaching self-examination with a mirror, and having self-reporting to a physician when lesions change visibly and to palpation.

Lichen Planus

Lichen planus is a distinct dermatologic disease that may affect the oral mucosa, esophageal mucosa, skin, scalp, nails, and eyes in addition to the vulva. Approximately 1% of the population likely develops lichen planus; 25% to 50% of women with lichen planus are believed to have vulvar symptoms. Both vulvovaginal-gingival syndrome and penile-gingival syndrome have been described. The disease appears to be a cell-mediated immune disorder causing chronic inflammation. Similar to lichen sclerosus, symptoms are most common in postmenopausal women in their 50s and 60s; usually include pruritus; and can evolve as the disease progresses to include burning, pain, and dyspareunia. Labial agglutination and loss of architecture of the labia and clitoris may occur. The vaginal mucosa is frequently involved, as opposed to lichen sclerosus, which rarely involves the vagina (Fig. 2.7).

The relationship between lichen planus and vulvar cancer is not as well-established as the association between lichen sclerosus and cancer. Small studies have suggested an increased risk of vulvar cancer, and subjects with oral lichen planus may also

FIGURE 2.7 Erosive lichen planus. (Courtesy of Dr. Lori Boardman, MD, ScM, University of Central Florida College of Medicine.)

have an increased risk of oral cancer. In the early 1990s, case reports by Franck and Young, Lewis and Harrington, and Dwyer and colleagues reported incidences of vulvar SCC in subjects with lichen planus and within erosive lichen planus lesions. In a review of 113 patients with erosive vulvar lichen planus followed by Kennedy and colleagues over an 8-year period, one woman developed vulvar cancer. Of interest, two women in this cohort with oral lichen planus were subsequently diagnosed with oral or esophageal cancer, and two additional women were diagnosed with cervical adenocarcinoma in situ and rectal adenocarcinoma. Similar findings were reported by Cooper and associates. Of 114 women with erosive vulvar lichen planus, seven developed VIN, one developed oral SCC, two developed anogenital SCCs of the labium minora and perianal area.

Diagnosis and Treatment

Biopsies are critical to appropriate management; before any treatment is given on a long-term basis, biopsies should be performed from representative areas to ensure the correct diagnosis. (The exception for biopsy is the pediatric population, which will not be discussed here.) Biopsies should be focused at sites of fissuring, ulceration, induration, and thick plaques. Patient education regarding hygienic measures for keeping the vulva clean and dry is important; any soaps, perfumes, deodorizers, or other contact irritants should be avoided. A thorough history should be taken to evaluate possible causes of vulvar pruritus. After lesions with malignant potential have been ruled out, local measures for control of symptoms, primarily pruritus, can be instituted (Table 2.4). Additionally, infectious vaginitis should be ruled out with a saline wet preparation, potassium hydroxide (KOH) wet preparation, and yeast culture to evaluate for atypical yeast that may be missed on plain microscopy.

Lichen Simplex Chronicus

Therapy for lichen simplex chronicus is treatment of the underlying cause of irritation and pruritus. All offending environmental agents should be avoided, including wipes, lubricants, sanitary and incontinence pads, detergents, perfumes, and soaps. A thorough history is often necessary to identify possible sources of irritation. Any underlying vaginitis also requires treatment. For isolated lichen simplex chronicus, a topical steroid ointment such as triamcinolone 0.1% or hydrocortisone 2.5% can be applied daily (after bathing to help seal in moisture) until symptoms are improved, generally in 3 to 4 weeks. If symptoms are particularly severe or a course of low-dose steroids is insufficient, a trial of higher dose steroid ointment is acceptable. Pruritus is often most severe at night, and short-term use of a pharmacologic sleep aid may be necessary. Lichen simplex chronicus should resolve with removal of the offending agent and treatment; if symptoms persist or recur, repeat biopsies and the diagnosis should be reconsidered.

TABLE 2.4 Vulvar Nonneoplastic Epithelial Disorders

Disorder	Treatment
Lichen sclerosus	Topical high-potency steroid ointment
Lichen planus	Topical high-potency steroid ointment
Lichen simplex chronicus	Topical corticosteroid after evaluation and removal of offending environmental agents and treatment of concurrent vaginitis, lichen sclerosus, or lichen planus

Lichen Sclerosus

Lichen sclerosus is a chronic condition with no curative treatment; the goal is symptom control. The standard treatment for lichen sclerosus is a topical corticosteroid. Typical regimens begin with a superpotent steroid ointment (ie, clobetasol propionate ointment 0.05%) used nightly until resolution of symptoms (usually 8–12 weeks). Because of the chronicity of lichen sclerosus, maintenance therapy is necessary after initial treatment; application one to three times per week is usually sufficient. Many women stop treatment when their symptoms improve and then present again months later with recurrent symptoms. Therapy can be reinitiated at treatment levels for 6 to 12 weeks, and emphasis given to maintenance therapy. Theoretically, long-term use of topical steroids may result in striae and thinning of the dermis, but this is infrequently observed in patients with lichen sclerosus. Topical testosterone is no longer the treatment of choice for lichen sclerosus.

A prospective randomized study by Bracco and associates evaluated 79 patients with lichen sclerosus using four different treatment regimens: a 3-month course of testosterone (2%), progesterone (2%), clobetasol propionate (0.05%), and a cream base preparation. Patients experienced greater relief of symptoms with clobetasol (75%) than with testosterone (20%) or other preparations (10%). Clobetasol therapy was the only treatment in which the gross and histologic evaluation of patients improved after treatment. Recurrences after stopping the steroid occurred, but symptoms were relieved when therapy was resumed. Clobetasol was also more effective than testosterone in the randomized trial performed by Bornstein and colleagues, with a significant improvement in long-term relief experience by clobetasol users. Lorenz and colleagues reported 77% had complete remission of symptoms with clobetasol therapy but again noted that maintenance therapy was needed after baseline treatment. In the cohort followed by Cooper and associates discussed previously, 65% were symptom free, 31% had a partial response, and 5% has a poor response after steroid use. Improvement was also seen on physical examination; 23% had total resolution, 69% had partial resolution (improvement in purpura, hyperkeratosis, fissures, and erosions but no change in color and texture), 6% had minor resolution, and 2% had no improvement. Renaud-Vilmer and colleagues noted a different response rate by age group in women treated with 0.05% clobetasol propionate ointment. Complete remission, defined as complete resolution of symptoms, normalization of physical examination, and histologic regression of lichen sclerosus, was observed in 72% of women younger than age 50 years, 23% of women between 50 and 70 years, and 0% in women older than 70 years. Relapse was 84% at 4 years but was not associated with subject age.

Occasionally, vulvar pruritus is so persistent that it cannot be relieved by topical measures. Topical treatment may also fail

if significant hyperkeratosis is present. In such cases, intradermal and lesional injection of steroids has been reported to be effective. If lesions persist and symptoms do not improve after a course of superpotent topical steroids, biopsies should be repeated to confirm the initial diagnosis. It is again critical to rule out cancer and VIN to ensure appropriate treatment. Other regimens have been reported for lichen sclerosus recalcitrant to corticosteroids. Specifically, tacrolimus and photodynamic therapy may have some efficacy, but further trials are necessary.

Lichen Planus

Lichen planus is similarly treated with complete evaluation, patient education, and topical steroids. Additionally, the physical examination should exclude the presence of lichen planus on the skin, scalp, nail beds, and oral mucosa. If systemic disease is present, consultation with a dermatologist is useful. Treatment of vulvar lesions should begin with an ultrapotent steroid ointment (ie, clobetasol propionate ointment 0.05%) applied nightly for 6 to 8 weeks. If symptoms improve, the frequency of application can be reduced to two to three times weekly for 4 to 8 additional weeks. Cooper and associates reported that in a cohort of 114 women followed and treated for lichen planus, 71% of those treated with ultrapotent topical corticosteroids experienced relief of symptoms with treatment. On examination, 50% experienced healing of erosions, but no patients had resolution of scarring. When lichen planus symptoms are in a prolonged remission, the lowest effective dose is used for maintenance therapy, which may involve less frequent administration and a lower potency steroid. Similar to lichen sclerosus, symptoms will return if maintenance therapy is not used.

Lichen planus does appear more resistant to therapy than lichen sclerosus. In a small series of women with vulvar lichen planus that was nonresponsive to other treatments, Byrd and colleagues at the Mayo Clinic reported that 15 of 16 subjects experienced symptomatic relief after a course of topical tacrolimus. The mean response time was 4 weeks, and six subjects experienced mild irritation, burning, or tingling that resolved with persistent use. Tacrolimus therapy was less successful in the subjects followed by Cooper and associates, who were nonresponsive to topical steroid treatment. Of seven patients treated, two had complete symptomatic relief, three had some relief, and two had no improvement in symptoms.

INTRAEPITHELIAL NEOPLASIA OF THE VAGINA

Clinical Profile

The incidence of VAIN is not well described. The first report was by Graham and Meigs in 1952. They reported three patients with carcinoma of the vagina, two intraepithelial and one invasive, that were discovered 6, 7, and 10 years, respectively, after total hysterectomy for CIS (carcinoma in situ) of the cervix. Carcinoma in situ is a historical diagnosis, equivalent to the modern diagnosis of HSIL or CIN2/3. The most recent analysis of the incidence of VAIN in the United States, published in 1977, reported 0.2 to 0.3 cases per 100,000 women. Data published by Joura and colleagues from a large vaccine trial give a more recent estimate: The incidence of high-grade VAIN in the placebo group—women from 24 countries between 16 and 26 years of age who were followed for a mean of 36 months—was 21 cases in 9087 subjects. There may be multiple reasons for the higher incidence observed in the vaccine trial such as a true rise in incidence since 1977 similar to the increase seen for VIN, a higher rate of diagnosis because the women were being followed with serial examinations, or a different population from a more heterogeneous international setting. VAIN has many of the same risk factors associated with CIN, including smoking, earlier age at first intercourse, increased number of sexual partners, and HPV infection.

CIN of the vagina is much less common than that of the cervix or vulva. For the year 2015, the American Cancer Society estimated that 4080 cases of invasive cancer of the vagina would be diagnosed in the United States. Although the incidence of vaginal cancer has increased over the past several years, it remains rare. Because of the low prevalence of the disease, routine screening for VAIN and vaginal cancer is not recommended. After hysterectomy for benign disease, the incidence of VAIN is extraordinarily low, and guidelines from the American College of Obstetricians and Gynecology (ACOG) and the American Society for Colposcopy and Cervical Pathology (ASCCP) do not support Pap testing in this population. These guidelines were written in part based on evidence from Pearce and colleagues, Noller and Stokes-Lampard and colleagues showing that a huge number of women would undergo unnecessary cytology screening and colposcopy in order to diagnose a rare outcome. The exceptions to this guideline include women who have a history of in utero DES exposure, are immunosuppressed, or have a history of cervical or vulvar dysplasia. Many women have accepted historical guidelines recommending annual Pap testing and may require counseling and patient education to accept these new guidelines. Rare, unfortunate cases of VAIN or invasive cancer will occasionally be diagnosed in women who have undergone hysterectomy for benign disease, but these exceptional cases cannot drive screening guidelines. Additionally, because VAIN and vaginal cancer are strongly associated with HPV infection, the HPV vaccination should drive a decrease in the number of these cases in the future.

Patients with VAIN tend to have either an antecedent or coexistent neoplasia in the lower genital tract. This is the usual situation in at least half to two-thirds of all patients with VAIN. In patients who have been treated for disease in the cervix or vulva, VAIN can appear many years later, necessitating long-term follow-up. First van der Linde, then Gusberg and Marshall, and later Parker indicated that 2%, 1.9%, and 0.9% of patients, respectively, had vaginal recurrences after hysterectomy for a similar lesion in the cervix. More recently, Schockaert and associates were able to follow 94 women who had hysterectomies and concurrently carried a diagnosis of CIN II, CIN III, or FIGO stage Ia1 cervical cancer. In a median interval of 35 months, 7.4% ($n = 7$) developed VAIN II+ (vaginal intraepithelial neoplasia II or greater), including two vaginal cancers. Ferguson and Maclure reported positive cytologic findings in 151 (20.3%) of 633 previously treated patients. This large group included invasive and in situ cancers of the cervix, which were

treated by irradiation or hysterectomy. The long-term recurrence rate for CIS of the vagina is uncertain, but it is sufficient to merit continued careful follow-up.

Vaginal intraepithelial neoplasia and invasive cancer are both associated with HPV. HPV positivity rates reported in the literature range from 82% to 94% for VAIN and 60% to 75% for vaginal cancer, and HPV-16 and -18 account for the majority of HPV positivity. In early reports, vaccination appears to be effective at preventing HPV-16– and HPV-18–associated vaginal lesions in women who receive the vaccination before HPV exposure. HPV mapping has shown identical DNA integration loci between primary lesions of cervical dysplasia and later dysplastic lesions of the vagina and vulva, indicating that later disease may result from monoclonal lesions from the primary cervical dysplasia. Vaginal dysplasia appears to mimic cervical dysplasia with a high prevalence of HPV infection, as opposed to vulvar dysplasia, which displays inconsistent associations.

Isolated lesions can usually be recognized colposcopically (Fig. 2.8). The most frequent finding is acetowhite epithelium; mosaicism and punctuation can also be present, and some authors have described a "pink blush" appearance or a slightly granular texture. The diagnosis is confirmed by biopsy. The extent of the lesion can be evaluated with the colposcope or with Lugol's solution. Almost all lesions are asymptomatic, although a patient will occasionally have discharge or postcoital staining. An abnormal Pap smear result usually initiates the diagnostic survey. In almost all series, the upper third of the vagina is most frequently involved (as is the case with the invasive variety), and the posterior wall of the vagina appears more susceptible.

FIGURE 2.8 Carcinoma in situ of the vagina (colposcopic view).

Diagnosis

Patients with an abnormal Pap test result who do not have a cervix or patients with an abnormal Pap test result and no cervical abnormality visualized should undergo a careful examination of the vaginal epithelium. Colposcopic examination of the vagina can be difficult to perform. The largest possible speculum should be used and repositioned frequently to allow inspection of all surfaces. Colposcopic findings are similar to those described for the cervix. Each of the four walls should be examined from the apex to the introitus as separate and sequential steps. Small biopsy specimens are taken with a Tischler or Kevorkian–Younge alligator-jaw forceps. Sometimes a sterilized skin-hook for traction at the biopsy site may be helpful. Most patients can tolerate these biopsies without local anesthesia, but the anticipated pain from the biopsies versus pain from a local anesthetic injection should be considered. Lugol's solution is often helpful in delineating lesions of the vagina. Normal vaginal epithelium is stained brown, but dysplastic lesions with abnormal glycogen levels remain pale. In postmenopausal patients, local use of estrogen creams for several weeks helps to highlight the abnormal areas for identification by colposcopy.

The majority of VAIN is multifocal; even if a lesion is identified, one must search the entire vagina for coexisting, multiple lesions. Lesions are more common in the upper third of the vagina, but disease-free skip areas may be encountered with additional VAIN in the lower vagina. In hard-to-locate lesions, selective cytologic methods, such as obtaining Pap smears from different locations in the vagina, can often pinpoint the area of abnormality so that attention can be paid specifically to the area of highest suspicion.

Management

Local excision of the involved area has been the mainstay of therapy. In many cases, a single isolated lesion can be removed easily in the office with biopsy forceps. If larger areas are involved, an upper colpectomy may be necessary if the lesion is to be removed by surgery. A dilute pitressin solution or lidocaine with epinephrine can be injected submucosally at the beginning of the procedure and will greatly facilitate the vaginectomy.

As in CIN, outpatient modalities of therapy have been investigated for VAIN. Many patients have been treated historically with 5-fluorouracil (5-FU), but toxicity generally makes this a less desirable option, particularly in women who are sexually active. However, studies by Petrilli and associates and Caglar and colleagues indicate that this modality can be effective. One of the problems with 5-FU is the selection of the best mode of application, dosage, and length of treatment. Several techniques have been suggested with equivalent results. One-quarter applicator of 5% 5-FU cream is inserted high in the vagina each night after the patient is in bed. The patient can be instructed to coat the vulva and introitus with white petroleum because the cream leaks out during sleep. A small tampon or cotton ball at the introitus is also helpful to prevent leakage. Because of irritation

to the vagina and perineum, the cream should be removed by douching with warm water the next morning. This is done every night for 5 to 8 days followed by a 10- to 14-day rest period, and then the application cycle is repeated. This usually allows an adequate treatment time without having the patient experience the tremendous local reaction that can occur with prolonged use. Treatment can be repeated if it is not successful after the first cycle. Weekly insertions of 5-FU cream, approximately 1.5 g (one-third of an applicator), deep into the vagina once per week at bedtime for 10 consecutive weeks has also been shown to be efficacious. Placement of cotton balls at the introitus and application of a petroleum barrier on the perineum and vaginal introitus help prevent 5-FU contamination of the perineum with resultant skin irritation. Douching the next morning, which is advocated by some, is unnecessary with the weekly instillation. Patient compliance is likely higher and toxicity less with the second approach.

Dungar and Wilkinson noted an interesting finding in the vagina after 5-FU therapy, and it has been confirmed by others. After treatment, a red area suggestive of a lack of squamous epithelium may be present. They found that this represented columnar epithelium consistent with a metaplastic process in which squamous epithelium is replaced with columnar epithelium. They called this finding "acquired vaginal adenosis." These changes are usually found in the upper third of the vagina but may extend into the middle third. The columnar epithelium was of a low cuboidal or mucus-secreting endocervical type. In some cases, squamous epithelium was noted overlying the glandular elements. Marked superficial chronic inflammation was also present. This has also been noted in the vagina after laser therapy.

Cryosurgery has largely fallen out of favor in the treatment of VAIN, and laser therapy is preferred as an ablative technique. To give guidance about the depth of vaginal destruction required by the laser, Benedet and associates evaluated 56 patients who ranged from 22 to 84 years of age. Measurement of the epithelium was performed on involved and uninvolved tissue. The involved epithelium had a mean thickness of 0.46 mm (range, 0.1–1.4 mm). Uninvolved tissue was thinner and had a mean thickness of 0.28 mm. No statistical difference was seen in the thickness of the involved epithelium in the premenopausal and postmenopausal patients; however, the uninvolved epithelium was thinner in the postmenopausal patients compared with the premenopausal patients (0.25 vs. 0.37 mm). Based on this study, the authors believed that destruction of 1 to 1.5 mm would only destroy the epithelium without damaging underlying structures.

Over a 6-year period, Townsend and associates treated 36 patients from two large referral hospitals with a CO_2 laser. In 92% of the patients, the lesions were completely removed by the laser without significant side effects. Almost one-fourth of the patients, however, required more than one treatment session. Krebs treated 22 patients with topical 5-FU and 37 patients with laser therapy. The success rate was similar for the two treatments. Pain and bleeding have been the main complications but appear to be minimal. Healing is excellent, and impaired sexual function has not been a problem. The optimal technique of laser therapy for vaginal lesions has yet to be determined; whereas some investigators suggest removing only the identified lesions, others advocate treating the entire vagina to avoid missing other lesions. A thorough diagnostic investigation of the vagina to rule out invasive cancer can be difficult, but it is obviously mandatory. Evidence from vaginectomy series shows that invasive cancer may be present concurrently with VAIN. In the 105 patients with VAIN II or VAIN III treated with vaginectomy by Indermaur and colleagues, 12% ($n = 13$) had invasive cancer on final pathology, and 22% ($n = 23$) had negative findings. Multifocal lesions, particularly posthysterectomy, with deep vaginal angles may be difficult to treat with the laser. Small skin hooks and dental mirrors can be used as adjuncts to successful laser therapy.

More recently, experience with 5% imiquimod cream in the management of VAIN has been reported. In a study by Buck and Guth, 56 women with VAIN (mostly low grade) were treated with 0.25 g of the cream placed in the vagina once weekly for 3 weeks. Of 42 women available for follow-up, 36 (86%) were clear of VAIN on colposcopic evaluation 1 week or later after the last treatment. Five patients' disease required two treatment cycles, and one needed three treatment cycles before clearing of their lesions. Vulvar or vestibular excoriation was reported in only two individuals. No vaginal ulcerations were noted.

Ultrasonic surgical aspiration has been successfully used by Robinson, von Gruenigen and colleagues, and Matsuo and colleagues, but the technique is not widely practiced. Some have advocated surface irradiation using an intravaginal applicator, but adverse effects may be severe and include vaginal stenosis, urinary symptoms, and vaginal ulceration. Additionally, vaginal stenosis can make follow-up extremely difficult. Total vaginectomy, with vaginal reconstruction using a split-thickness skin graft, should be reserved for the patient who has failed more conservative therapy because there appears to be no recurrence benefit from the more invasive procedure.

Treated VAIN often recurs, regardless of the treatment method, and there is no clear standard of treatment. In a retrospective series of 121 women treated for VAIN between 1989 and 2000 by Dodge and colleagues, 33% of subjects experienced recurrence of VAIN, and 2% progressed to invasive cancer; multifocal lesions were more likely to recur. When stratified by treatment type, VAIN recurred in 0% ($n = 0$ of 13) of those treated with partial vaginectomy, 38% ($n = 16$ of 42) of those treated with laser, and 59% ($n = 13$ of 22) of those treated with 5-FU. However, Indermaur and colleagues noted a higher rate of recurrence in their cohort of patients treated with vaginectomy. Of 52 patients available for follow-up who received vaginectomy as treatment for VAIN II or VAIN III, six patients recurred at a mean of 24 months, and one was diagnosed with invasive cancer. Sillman and associates reported on 94 patients with VAIN who were treated by various methods. The remission rate was high, but 5% of the cases progressed to invasive disease despite close follow-up.

Incomplete excision of sufficient vaginal cuff with hysterectomy for CIS of the cervix with involvement of the fornices may explain an early recurrence. The finding of CIS in the vaginal

cuff area in less than 1 year after hysterectomy makes this explanation likely. Therefore, it is important to perform a preoperative evaluation of the upper vagina by Schiller tests or colposcopy at the time of hysterectomy for CIS of the cervix. This allows the surgeon to determine accurately how much of the upper vagina has to be removed. It is also apparent that both CIS and dysplasia may develop in the vagina as primary lesions without an association with a similar process on the cervix or vulva. Still other preinvasive lesions of the vagina may appear after irradiation therapy for invasive carcinoma of the cervix. Data from MD Anderson suggest that these postradiation lesions are premalignant and can progress to invasive cancer if they are not treated. Without therapy, approximately 25% of the patients in this series progressed to the invasive state over varying periods of follow-up. Local therapy must be executed with care because of the previous irradiation.

VULVAR INTRAEPITHELIAL NEOPLASIA

Clinical Profile

Many pathologists still identify intraepithelial lesions of the vulva as VIN I, VIN II, and VIN III, but terminology has recently changed. In 2004, the ISSVD clarified the VIN classification system (Table 2.5), and in 2012, a consensus group was cosponsored by the College of American Pathologists and the American Society for Colposcopy and Cervical Pathology to further clarify terminology (Lower Anogenital Squamous Terminology [LAST]) among HPV-associated lesions of the lower genital tract, including the cervix, vagina, vulva, and anus.

The ISSVD eliminated the previous term "VIN I" because there was no evidence that it was a precancerous lesion. The term "VIN" now refers only to lesions previously classified as VIN II or VIN III. In the current system, there is no discrimination between VIN II and III, and the two previously distinct classifications are consolidated as "VIN." Many pathology laboratories still include the older VIN I, II, and III terminology in parentheses for clarity.

Two distinct subtypes of VIN exist: the usual type and the differentiated type. The two subtypes are different in epidemiology, morphology, and their association with vulvar cancer (Table 2.6). Whereas the differentiated type may also be called simplex VIN, the usual type may be called warty, basaloid, or undifferentiated VIN. In comparison with the usual type, the differentiated type tends to occur in older women, be unifocal and unicentric, be found at the edge of vulvar SCC and in the setting of lichen sclerosus or planus, and be less associated with HPV. Usual type VIN, with warty and basaloid subtypes, is found in younger women, has a strong association with cigarette smoking, is often multifocal, is less frequently found in conjunction with squamous cell cancer, and is usually associated with HPV. Although there is an association between VIN and vulvar cancer, the relationship is less clear than the known progression from CIN to invasive cervical squamous carcinoma.

The LAST Project attempted to unify terminology referring to HPV associated-intraepithelial neoplasia of the lower genital tract. The recommended terminology for all cervical, vaginal, vulvar, and anal lesions is "low-grade" or "high-grade" squamous intraepithelial lesion (SIL) based on a combination of cell morphology and p16 immunostaining. Unfortunately, vulvar intraepithelial lesions are not as strongly associated with HPV as cervical lesions, so these guidelines would only be applicable to usual type VIN as differentiated VIN is normally p16 negative and p53 positive. Additionally, VIN I was eliminated by the ISSVD in 2004, so all currently diagnosed HPV-associated VIN should by definition be HSIL vulvar intraepithelial lesions. As clinical pathology practice continues to catch up to new guidelines, it is important to understand all of the terminology used recently and to talk to the pathologist before making meaningful clinical decisions if there is any doubt about terminology being used.

According to a Surveillance, Epidemiology, and End Results (SEER) data analysis by Judson and colleagues, whereas the incidence of vulvar CIS increased 411% between 1973 and 2000, the rates of invasive vulvar cancer rose only 20%. Several hypotheses regarding the changing incidence of VIN exist: increased physician awareness and evaluation of vulvar disease, increased prevalence of smoking among women, and increased HPV prevalence. Women with a history of preinvasive cervical disease or cervical cancer are at increased risk of preinvasive

   3. Mixed (warty or basaloid) type
B. VIN, differentiated type

*The previous classifications of VIN II and VIN III were consolidated as VIN, and the previous classification of VIN I was eliminated.

TABLE 2.6 Vulvar Intraepithelial Neoplasia Histologic Subtypes and Associations

	Usual (Warty-Basaloid, Undifferentiated)	Differentiated (Simplex)
Age	Premenopausal women (30s–40s)	Postmenopausal women (65 years)
Overall %VIN	≈95	≈5
HPV associated	Yes	No
HPV type	16	N/A
Risk factors	Smoking, immunosuppression	None identified
Distribution	Multifocal	Unifocal, unicentric
Background histology	Lichen sclerosus	
Progression to	Warty, basaloid squamous cell cancer	Keratinizing squamous cell cancer
	Invasive cancer	(Rare)

NA, Not applicable.

vulvar dysplasia. HPV is a risk factor for vulvar disease, but the progression from HPV infection to precancer to invasive cancer is poorly understood. In contrast to cervical cancer, which has a peak age in dysplasia incidence followed by a peak age in invasive cancer (after a lag period), there is no similar time course established in vulvar cancer. In fact, the peak incidence of VIN occurs during the mid-40s followed by a declining incidence, but the incidence of invasive vulvar cancer continues to increase and never stabilizes, reaching approximately 13 in 100,000 women by the age of 80 years.

Case reports definitively document the development of invasive squamous cell cancers in VIN usual type lesions in patients followed prospectively. In a review of more than 3300 patients with VIN III, van Seters identified occult invasive cancer in 3.2% of subjects at the time of excision, and an additional 3.3% developed cancer during follow-up. Chafe and associates noted that 19% of women who were thoroughly evaluated and thought to have VIN actually had invasive cancer on the vulvectomy specimen. Kagie and associates reported on 66 women with invasive vulvar SCC; 39 (62%) had synchronous VIN. In other cases, it appears that invasive lesions may arise de novo rather than from precursor VIN lesions, but this may be from a misdiagnosis of differentiated VIN previously diagnosed as lichen sclerosus. In a population of 405 women followed for VIN II and III in New Zealand between 1962 and 2003, 2% of cases recurred as invasive cancer at a median time of 2.4 years, and 1.8% of cases recurred as invasive cancer in new fields at a median time of 13.5 years. Additionally, 11.6% of biopsy-proven VIN regressed before treatment (mean age, 24.6 years). If observation is considered in young women with small lesions and usual type histology, frequent examinations with directed biopsies are necessary. Barbero and colleagues noted three of 55 patients treated with VIN whose conditions progressed to carcinoma in 14 months to 15 years. These three patients ranged in age from 58 to 74 years. In the New Zealand cohort, there were 10 cancers diagnosed in untreated patients; Jones and McLean have previously reported on five of the cases diagnosed between 1970 and 1974, and an additional five cases were diagnosed between 1983 and 1992. The median interval between VIN and invasive cancer was 3.9 years (range, 1.1–7.3 years).

HPV is strongly associated with VIN usual type, but it is less commonly associated with VIN differentiated type. There is a wide variation in the reported presence of HPV in VIN because of the changing terminology and classification of VIN and the improved sensitivity of recent HPV testing. The usual type comprises the majority of VIN, so a high prevalence of HPV positivity would be expected in studies that do not differentiate between the two histologies. In more recently published literature, HPV is present in 61% to 100% of VIN. HPV-16 appears to be the most common type, accounting for as high as 91% of infection in some series. The prevalence of HPV infection in VIN and vulvar cancer decreases with age, probably reflecting a change in the underlying histology. The efficacy of HPV vaccines in preventing vulvar dysplasia and cancer will be determined not only by the vaccine properties but also by the prevalence of HPV-related vulvar disease in the population. For example, the HPV VVAP (Vulvar, Vaginal, and Penile) study group published an analysis of HPV contribution to VIN and invasive cancers worldwide. In their sample, whereas approximately 89% of VIN was associated with HPV positivity, 25% of invasive cancer was HPV positive, and HPV-16 was the most common type, accounting for 72.5%. Among geographic regions, however, HPV was more likely in cases from North America.

In initial publications from the vaccine studies, there does appear to be efficacy against VIN. Joura and colleagues report on the vaccine efficacy in reducing specifically HPV-16– or HPV-18–related VIN with a mean duration of follow-up of 36 months. Among subjects who remained HPV negative while receiving the vaccination series, the vaccine was 100% efficacious; zero cases were diagnosed in 7811 vaccinated women, and eight cases were diagnosed in 7785 women who received placebo. Among subjects who were HPV negative at the time of the first injection but did not necessarily remain HPV negative for the duration of the vaccination series, the vaccine was 95% efficacious; one case was diagnosed in 8757 vaccinated women, and 20 cases were diagnosed in 8774 women who received placebo. An analysis was also performed on the incidence of VIN, regardless of HPV association, among all subjects, HPV naïve and HPV exposed at the time of vaccination, and the rate of VIN II/III was reduced by half in the vaccinated group, but there did not appear to be any benefit for those who were HPV exposed at the time of vaccination.

One recent study by Kenter and colleagues tested a synthetic long-peptide vaccine as treatment for VIN in women with HPV-16–positive VIN using a series of three or four vaccinations. Among 19 patients examined on 12-month follow-up, nine had a complete clinical response, and this was maintained at 24 months. This suggests a potential treatment role for vaccines in addition to prevention.

Diagnosis

The disease is asymptomatic in more than 50% of cases. In the remainder of cases, the predominant symptom is pruritus. The presence of a distinct mass, bleeding, or discharge strongly suggests invasive cancer. The most productive diagnostic technique is careful inspection of the vulva in bright light during a routine pelvic examination followed by biopsies of suspicious lesions. A handheld lens or colposcope can be very helpful, especially after application of 5% acetic acid to the skin and introitus.

Careful inspection of the vulva during routine gynecologic examinations is essential; this remains the most likely diagnostic technique. The milder forms of VIN first appear clinically as pale areas that vary in density. More severe forms are seen as papules or macules, coalescent or discrete, or single or multiple. Lesions on the cutaneous surface of the vulva usually appear as lichenified or hyperkeratotic plaques or white epithelium (Figs. 2.9 and 2.10). By contrast, lesions of mucous membranes are usually macular and pink or red. Vulvar lesions are hyperpigmented in 10% to 15% of patients (Fig. 2.11). These lesions range from mahogany to dark brown, and they stand out sharply when observed solely with the naked eye.

The entire vulva, perineum, and perianal area must be evaluated for multifocal lesions. It is not uncommon to find

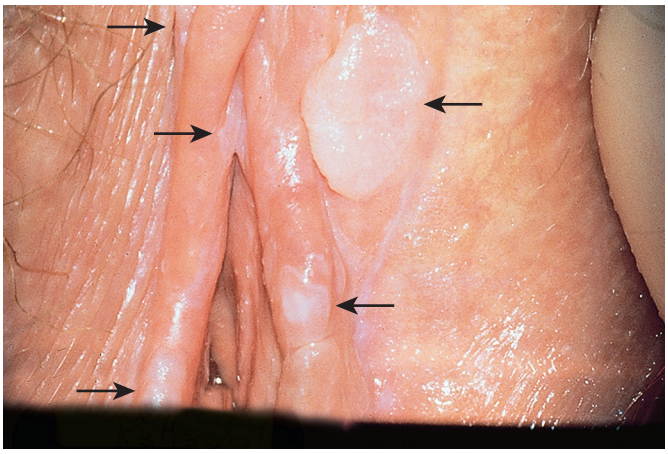

FIGURE 2.9 Multiple white lesions *(arrows)* of the vulva caused by vulvar intraepithelial neoplasia.

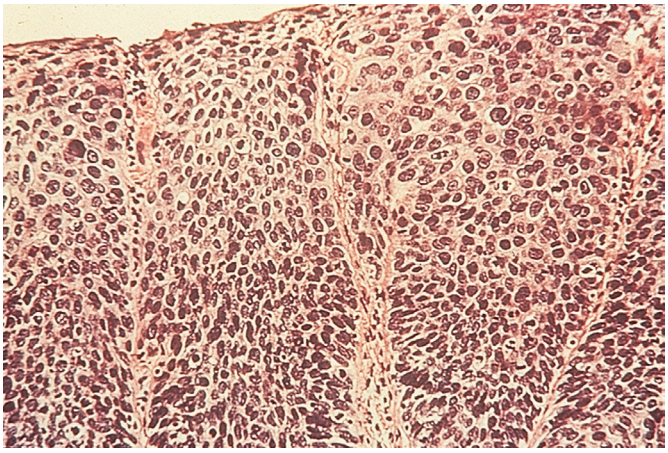

FIGURE 2.10 Histologic section of carcinoma in situ of the vulva.

intraepithelial lesions on hemorrhoid tags or more superiorly in the gluteal cleft. The use of acetic acid is helpful in identifying subtle lesions. In contrast to the mucous membrane of the cervix, the keratinized epithelium of the vulva requires application of acetic acid for 5 minutes or longer before many lesions become apparent. Placement of soaked cotton balls or sponges on the vulva for several minutes before examination is effective. After a lesion has been diagnosed, colposcopic examination of the entire vulva and perianal area should follow to rule out multifocal disease. A handheld magnifying glass can also be used, which allows greater viewing area at one time compared with the colposcope. In general, whereas multifocal lesions are more common in premenopausal patients, postmenopausal patients have a higher rate of unifocal disease.

Some investigators prefer to use toluidine blue to identify vulvar lesions. A 1% aqueous solution of the dye is applied to the external genital area. After drying for 2 to 3 minutes, the region is then washed with 1% to 2% acetic acid solution. Suspicious foci of increased nuclear activity become deeply stained (royal blue); normal skin accepts little or none of the dye. Hyperkeratotic lesions, even though neoplastic, are only lightly stained, but benign excoriations are often brilliant, an observation that accounts for the high false-positive and false-negative rates.

FIGURE 2.11 Pseudopigmented lesions of vulvar carcinoma in situ.

The diagnosis of VIN can be subtle. To avoid delay, the physician must exercise a high degree of suspicion. Vulvar biopsy should be performed on any suspicious lesion. It is best accomplished under local anesthesia (lidocaine or bupivacaine) with a Keyes dermatologic punch (4- to 6-mm size). This instrument allows removal of an adequate tissue sample and orientation for future sectioning. The biopsy site can be made hemostatic with silver nitrate, Monsel's, a stitch, or a piece of absorbable gelatin powder (eg, Gelfoam) cut with the Keyes punch; this is positioned in the skin defect and kept in place with a small dressing for at least 24 hours. Adequate biopsy specimens can also be obtained with a sharp alligator-jaw instrument if one has proper traction on the skin. The problem with ordinary knife "shave" biopsies is that only superficial epithelium can be reached. If this technique is used, one must be careful to get full-thickness skin to adipose tissue for adequate sampling of deeper layers.

Pigmented Lesions

Pigmented lesions of the vulva are usually intraepithelial, with the exception of melanoma. Pigmented lesions account for approximately 10% of all vulvar disease. The most common pigmented lesion is a lentigo, which is a concentration of melanocytes in the basal layer of cells. It can have the clinical

appearance of a freckle, although it is more commonly confused with a nevus. The borders are fuzzy, but it is not a raised lesion. A lentigo is benign, and the diagnosis is usually made by inspection with magnification. If there is any doubt, a biopsy should always be performed.

Intraepithelial neoplasia of the vulva may appear as a pigmented lesion. Friedrich found that CIS of the vulva was more frequent in pigmented lesions than in nevi. Characteristic raised, hyperkeratotic pigmented lesions are suggestive of CIS and should be biopsied.

Bowenoid papulosis is a variant of a pigmented lesion noted by dermatologists for some time. These are small pigmented papules that develop and spread rapidly. According to dermatologists, these papules often regress spontaneously. Histologically, at least on the vulva, these are SCCs in situ. These lesions have been reported to have an aneuploid DNA pattern. Many authorities have not found bowenoid papulosis of the vulva to spontaneously regress. Regardless of the clinical characteristics, if VIN is present histologically, the physician should treat the patient accordingly.

The management of nevi can be conservative. A nevus can often be detected only microscopically. Unfortunately, a simple nevus and an early melanoma cannot be differentiated on clinical evaluation. Excisional biopsy of these raised, smooth, pigmented areas can be done easily in the physician's office. If the nevus changes in color, size, and shape, it should be removed for diagnostic purposes. After a nevus is removed, no further therapy is needed regardless of whether it is a compound, intradermal, or junctional type.

Management

Surgical excision has been the mainstay of therapy for VIN, although laser is a frequently used technique, especially for multifocal lesions, and medical management with immune modulators has gained recent prominence. An important advantage of surgical excision is that complete histologic assessment is performed; lesions with early invasion can thus be found. Most localized lesions are managed effectively by wide local excision with end-to-end approximation of the defect. The vulvar skin and mucous membrane are usually very elastic, and cosmetic results are satisfactory after uncomplicated healing. There are inadequate data to evaluate the best surgical ablative techniques, but studies are ongoing.

Excision

Wide local excision is the most commonly performed treatment of VIN. The goal of VIN surgery is to obtain a 5-mm disease-free margin. Margin status and histology results are available on final pathology results, which is a benefit of the excisional procedure. Modesitt and associates reported that recurrences were three times higher (46% vs. 17%) when margins were positive for residual VIN II and III. In the New Zealand study discussed earlier, 50% of those with positive margins versus 15% of those with negative margins required further treatment. Hillemanns and colleagues showed an overall recurrence rate of 43% in subjects retrospectively analyzed who had been heterogeneously treated with laser, photodynamic therapy, excision, or vulvectomy. No patients recurred in the vulvectomy group ($n = 8$). In the natural history review by van Seters and colleagues, 1921 patients were surgically treated. Recurrence was noted in 19% after vulvectomy, 18% after partial vulvectomy, and 22% after local excision. Recurrences were significantly lower after free surgical margins (17%) than after positive surgical margins (47%). Progression to invasive disease occurred in 58 patients, 52% of the time after vulvectomy, and 48% of the time after local excision. In this retrospective review, the surgical approach was likely selected based on individual patient characteristics so that patients considered at higher risk for invasive cancer may have more frequently received vulvectomy. However, there is no definitive evidence or randomized controlled trial (RCT) to show that vulvectomy is associated with better outcomes and the morbidity associated with the procedure is much greater. Wide local excision is the accepted excisional procedure for VIN.

In the series by Modesitt and colleagues, 17 of 73 subjects were diagnosed with invasive cancer at the time of treatment for VIN III. Similarly, 16 of 78 patients undergoing surgical excision for VIN III had invasive cancer in the report by Husseinzadeh and Recinto. To avoid returning to the operating room for deeper reexcision and lymph node dissection, biopsies must be liberally performed preoperatively. Multiple biopsies may be required. Adequate postoperative follow-up with repeat biopsy for any suspicious lesions is also essential.

Occasionally, a skinning vulvectomy is indicated. With multicentric lesions (Fig. 2.12), the involved skin can be excised and substituted with a split-thickness skin graft taken from the buttocks or inner aspect of the thigh. This skinning vulvectomy and skin graft procedure was introduced by Rutledge and Sinclair in 1968 (Fig. 2.13). Its purpose was to replace the skin at risk in the

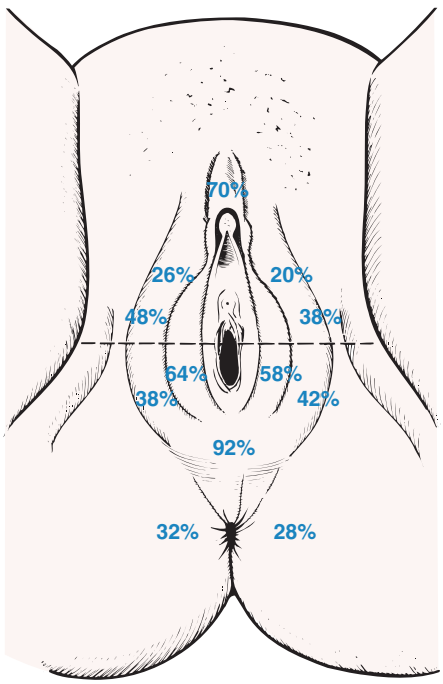

FIGURE 2.12 Plot of lesion locations in 36 patients treated for multifocal carcinoma in situ of the vulva.

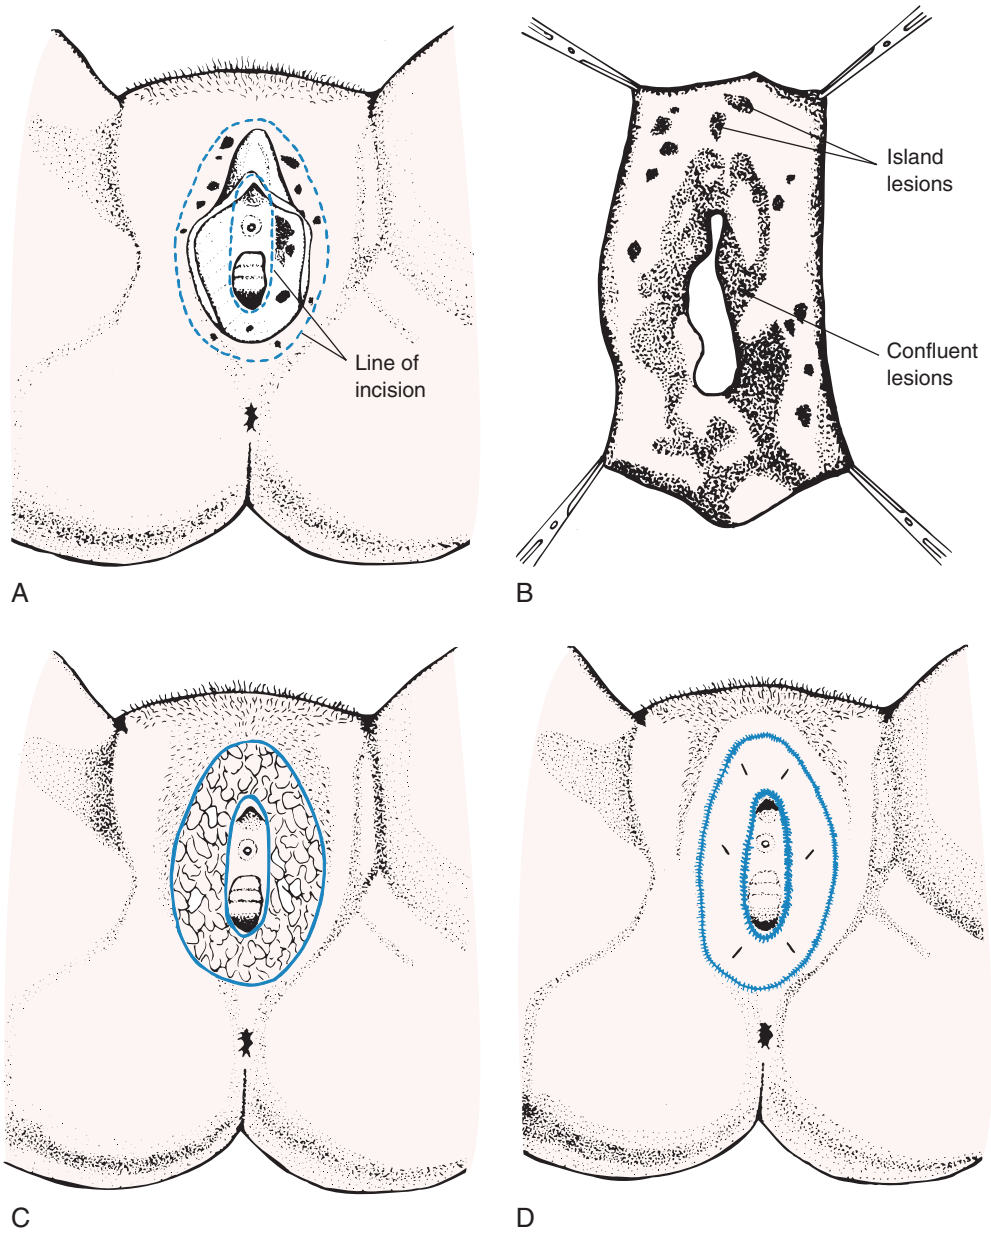

FIGURE 2.13 Skinning vulvectomy and skin graft. **A,** Excise all areas of involvement en bloc. **B,** Lesions may be isolated or confluent. **C,** Preserve all subcutaneous tissue as the graft bed. **D,** Suture the skin graft to the graft bed.

vulvar site with ectopic epidermis from a donor site. In more than 100 patients treated, the authors reported no complaints of dyspareunia or diminished sexual responsiveness. The benefits of the skinning vulvectomy and skin graft procedure are preservation of the subcutaneous tissue of the vulva and a better cosmetic and functional result (Fig. 2.14). In previous editions of this text, Creasman reported a modification of the procedure with preservation of the clitoris, in which any lesions on the glans are scraped off with a scalpel blade, and the epithelium of the glans regenerates without loss of sensation. In older adult patient, simple vulvectomy may be preferred because the skinning vulvectomy and skin graft operation requires prolonged bedrest (6–7 days) to allow the split-thickness graft to adhere to the graft bed. Thus, the potential for morbidity is increased. The patient's wishes concerning cosmetic results and sexual function, however, must be taken into account regardless of the person's age.

Laser

Ablative therapy is an alternative to excision. The disadvantage of ablative therapy is that a necrotic ulcer on the vulva may result, and wound healing may be slow. Complete healing may take up to 3 months. The treated area is often very painful for much of that time. Many consider laser therapy the treatment of choice in the management of VIN, particularly for those who have multifocal disease. Townsend and colleagues treated 33 patients with laser therapy and reported success in 31 (94%), but 14 patients required two or more treatments, and two

FIGURE 2.14 Excellent cosmetic results are present after superficial vulvectomy and skin graft for vulvar intraepithelial neoplasia.

TABLE 2.7 CO_2 Laser Vaporization of the Vulva

Instrument	CO_2 laser, colposcopic, micromanipulator
Power density	600–1000 W/cm^2
Depth of destruction	Nonhairy areas <1 mm
Hairy areas	>3 mm
Lateral margins	"Brush"
Anesthesia	General, local
Analgesia	Significant postlaser pain: narcotics

patients required five laser treatments. The results published by Baggish and Dorsey were similar; 32 of 35 patients were believed to have been cured from their disease, 26 of 35 patients required three or more treatments, and two women had six treatments. In the review article of the 253 patients treated with laser, 23% recurred.

Only a small portion of the vulva can be treated on an outpatient basis. Patients require general anesthesia if large areas of the vulva are treated at one time. Pain, which is severe in some patients, is the main complication with laser therapy. Bleeding and infection have also been reported. The cosmetic results appear to be excellent. It appears that laser therapy can be an acceptable treatment modality, but patients must be carefully evaluated before treatment to rule out invasive carcinoma (Table 2.7). Greater expertise with the laser is required for this therapy than is needed for cervical vaporization. The depth of destruction must be controlled. Too deep a wound can result in long-term ulcers, which may take some time to heal and cause considerable discomfort. Benedet and colleagues evaluated 165 women with VIN. Of the 122 patients with VIN III, the mean thickness of the epithelium was 0.52 mm (range, 0.1–1.9 mm). In patients with hair follicles involved with VIN, the mean depth of involvement was 1.9 mm (range, 1–3.4 mm). Only 19 patients had appendiceal involvement. Age did not seem to affect the thickness of involved epithelium. Multifocal lesions were present in 64% of all patients. The most common sites were the labia minora, posterior fourchette, and perineum. Based on this study, the authors believe that 1-mm destruction of non–hair-bearing epithelium is adequate treatment. If skin appendages are involved, 2.5 to 3 mm is required (Fig. 2.15). When performing excision, the burn level does not need to be carried to the level of the subcutaneous fat. Also, the carbon from the surgical site can be wiped during the procedure to be certain that the shiny white lower dermis is preserved. Reid has defined surgical planes in the vulva as a guide to laser therapy. The first plane is the surface epithelium only, which includes the basement membrane. Opalescent cell debris is noted through the heat char. Healing is rapid, with good cosmetic results. The second plane involves the dermal papillae, with necrosis extending to the deep papillary area. The appearance is a homogeneous yellow color that resembles a chamois cloth. Again, healing is rapid with good cosmesis. The third plane affects the upper and midreticular area, where the pilosebaceous ducts are located. Some hypertrophy may appear in this area during the healing process. The fourth plane affects the deep reticular area, and "sand grains" can be visualized. Healing is slow and usually occurs by granulation from the sides. Skin grafting may be required. Destruction to the third plane is adequate for hair-bearing tissue; plane one to two is the depth needed for non–hair-bearing skin.

After laser therapy, the vulva is covered with Silvadene. Sitz baths, topical lidocaine, and rinsing of the vulva with water after urination and defecation are important. A hair dryer is then used to dry the area. Repeat application of steroids is used after each washing and drying. A local anesthetic can be applied for mild to moderate pain control. Oral pain medication, including narcotics, may be necessary. The most severe pain is usually evident 3 to 4 days after the laser therapy. Laser therapy is particularly effective around the areas where excision can lead to external sphincter weakening.

Cavitational Ultrasonic Surgical Aspirator

A cavitational ultrasonic surgical aspirator (CUSA) is a less frequently used ablative option. In a randomized prospective

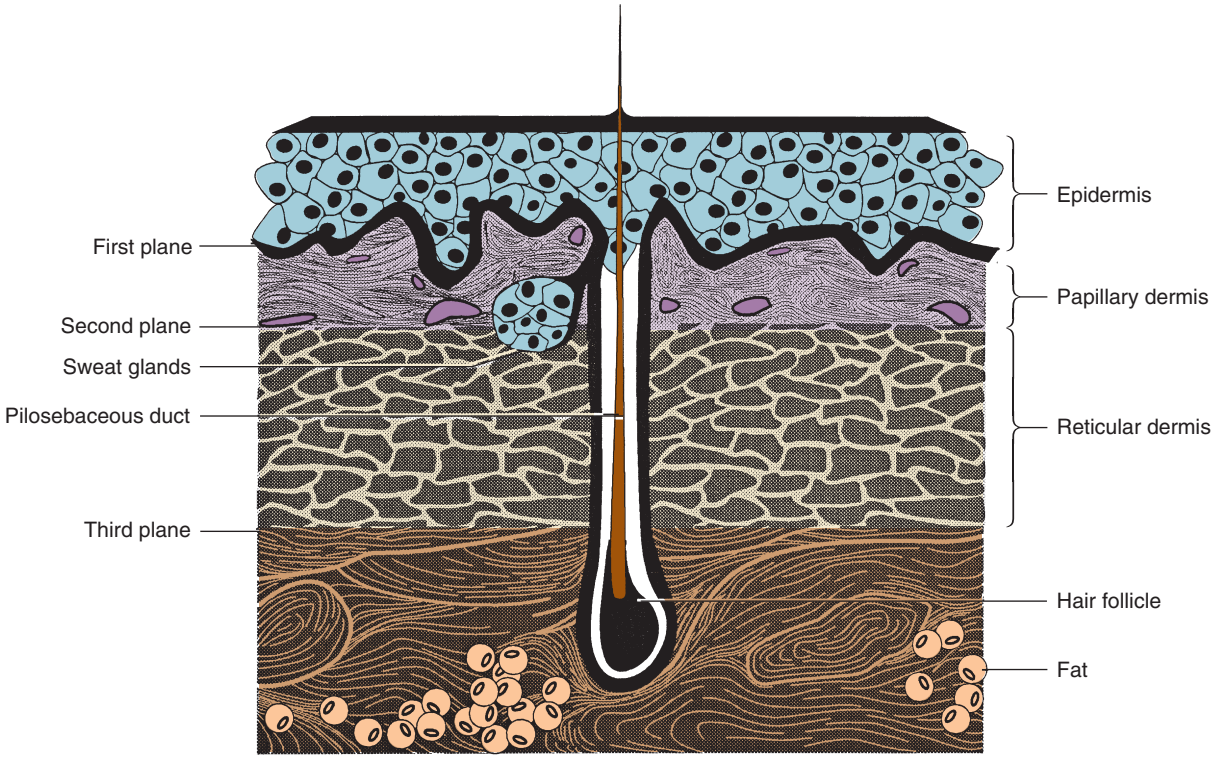

FIGURE 2.15 "Planes" for therapy for vulvar intraepithelial neoplasia using a laser.

trial, von Gruenigen and associates compared outcomes from laser ablation versus CUSA. Recurrence was similar in both arms (25% overall), but subjects treated with CUSA had less postoperative pain and less scarring. Other adverse events, including infection, dysuria, adhesions, and discharge, were similar between both groups.

Imiquimod

Imiquimod 5% cream is an immune response modifier with indirect antiviral and antitumor properties. It activates macrophages and dendritic cells to release interferon-α and other cytokines that provoke an antigen-specific immune response. Imiquimod cream was first shown to be effective and safe in the treatment of HPV-associated genital warts and was subsequently evaluated and has shown great promise in the treatment of VIN. In a phase II trial completed by Le and colleagues, 33 patients with VIN were treated for 16 weeks with 5% imiquimod application; six additional subjects were unable to complete the study. At 20 weeks, 21 of 33 subjects had complete response (complete disappearance of the visible lesion and histologic regression), nine of 33 had a partial response (50% decrease from baseline measurement), and three had stable lesions. In a randomized, double-blinded controlled trial, Mathieson and associates treated 21 subjects with 5% imiquimod and 10 with placebo. There was a complete response in 17 of 21 subjects in the treatment group (complete histologic regression) and in none of the 10 subjects in the placebo group. Because of side effects, the dose was reduced in 14 of 21 women in the treatment group. Van Seters and colleagues report similar results but also include 12-month follow-up from their RCT. In 26 subjects treated with imiquimod, histologic and virologic regression was seen in 15 and 14 subjects, respectively. In the 26 subjects who received placebo, histologic and virologic regression was seen in one and two subjects, respectively. Progression to invasive disease occurred in one subject in the treatment arm (who initially had a weak, partial response with imiquimod) and two subjects in the placebo arm. Treatment was reduced to once-weekly application in five women receiving imiquimod because of severe inflammation. Investigator-reported side effects, including erythema, erosion, vesiculation, and edema, were significantly worse in the treatment group than in the placebo group. At 20 weeks and 12 months, however, self-reported pruritus and pain were significantly better in the treatment group than in the placebo group. In a recent study of women randomized to surgical excision alone versus surgical excision followed by imiquimod, there was no difference in recurrence between groups (45% and 48%, respectively), but recurrence was more common in women with multifocal disease. Cidofovir, an antiviral agent with activity against HPV, has also been reported as treatment for VIN. In an RCT (n = 180) comparing imiquimod and cidofovir, 46% of patients in each treatment group achieved a complete clinical response at the 6-week posttreatment visit. However, grade 3 or higher toxicities were more significant in the imiquimod group (46%) compared with the cidofovir group (37%) with grade 3 vulvar pain reported in 2% of cidofovir users and 1% of imiquimod users.

One of the obvious benefits of medical therapy is avoidance of disfiguring surgery. Randomized trials show promise in its use as a primary therapy for VIN, and it has been relatively well

tolerated, but dose reductions have been necessary in all trials for a considerable number of subjects. The trials previously mentioned varied in application frequency from once per week to three times per week when tolerated. Because some of the main benefits are quality-of-life related, it will be important to evaluate the side effects and complications of imiquimod versus excisional procedures. Even in women who did not receive a complete response, a partial response was observed in many. Reduction in lesion size may be another potential application of the therapy, particularly if disease is present in a multifocal, clitoral, or sphincter distribution. Another important question for future trials is whether immune modulators have any effect on non–HPV-associated VIN; it is possible that the treatment varies depending on the origin and differentiation. Because the ISSVD classification has now changed, future trials should specifically evaluate efficacy in usual type VIN versus differentiated type VIN.

After initial diagnosis and treatment, American College of Obstetrics and Gynecology guidelines recommend repeat visualization of the vulva at 6 months and 12 months and annually thereafter. An increased risk of recurrence has previously been associated with increasing lesion size, positive margins, smoking history, and multifocal disease.

In summary, it is important to remember that these lesions often develop in young women who remain asymptomatic. Women should be taught vulvar self-examination to identify early lesions. Physical examination performed by a physician will likely become inadvertently less frequent as Pap screening guidelines continue to evolve, and self-examination may become more important in the future. Postmenopausal women should be instructed in the importance of annual vulvar examinations, even if Pap screening is not required. The goal of earlier diagnosis and intervention is more successful therapy that is also less radical. Early diagnosis depends on careful vulvar examination under a bright light at regular intervals. Biopsy must be done on any suspicious lesions, and if the histologic report confirms intraepithelial neoplasia, an examination for multicentric foci should follow. The therapy of choice depends on the extent of disease, the location of the lesions, and the personal desires of the patient.

Invasive Cervical Cancer

Krishnansu S. Tewari, MD, Bradley J. Monk, MD

OUTLINE

General Observations
- Anatomy
- Epidemiologic Studies

Microinvasive Carcinoma of the Cervix

Clinical Profile of Invasive Cancer
- Symptoms
- Gross Appearance
- Routes of Spread

Glandular Tumors of the Cervix

Staging
- International Federation of Gynecology and Obstetrics
- Positron Emission Tomography
- Surgical Staging

Treatment of Early-Stage Disease
- Radical Abdominal Hysterectomy With Lymphadenectomy
- Indications for Postoperative Adjuvant Therapy
- Nerve-Sparing Radical Hysterectomy
- Sentinel Lymph Node Identification
- Laparoscopic Radical Hysterectomy With Lymphadenectomy
- Robotic-Assisted Laparoscopic Radical Hysterectomy With Lymphadenectomy
- Fertility-Preserving Surgery for Early-Stage Tumors
- Cervical Conization for Adenocarcinoma in Situ and Microinvasive Carcinoma
- Vaginal Radical Trachelectomy With Laparoscopic Lymphadenectomy
- Lateral Ovarian Transposition

Treatment of Locally Advanced Disease
- Radiotherapy
- Radiation and Chemotherapy
- Neoadjuvant Chemotherapy and Other Novel Treatment Approaches
- Suboptimal Treatment Situations

Neuroendocrine and Other Uncommon Tumors of the Cervix

Glassy Cell Carcinoma, Carcinosarcoma, Lymphoma, and Melanoma

Survival Results and Prognostic Factors for Early-Stage and Locally Advanced Disease

Recurrent and Advanced Carcinoma of the Cervix
- Management and Prognosis
- Surgical Therapy: Radical Hysterectomy
- Radiation
- Chemotherapy
- Targeted Therapies

KEY POINTS

1. Conservative management of early staged cervical cancer in young women should be considered if childbearing is important to that patient.
2. In many developing countries, cervical cancer is the leading cause of cancer death in young women.
3. Adenocarcinoma of the cervix is increasing in frequency.
4. Positron emission tomography is a very sensitive method for detecting the extent of cervical cancer.
5. Adjuvant chemotherapy using cisplatin and concomitant radiation therapy is the standard of care for locally advanced cervical cancer.

GENERAL OBSERVATIONS

Anatomy

The cervix (Latin for "neck") is a narrow, cylindrical segment of the uterus; it enters the vagina through the anterior vaginal wall and lies, in most cases, at a right angle to it. In the average patient, the cervix measures 2 to 4 cm in length and is contiguous with the inferior aspect of the uterine corpus. The point of juncture of the uterus and the cervix is known as the isthmus; this area is marked by slight constriction of the lumen. Anteriorly, the cervix is separated from the bladder by fatty tissue and is connected laterally to the broad ligament and parametrium (through which it obtains its blood supply). The lower intravaginal portion of the cervix, a free segment that projects into the vault of the vagina, is covered with mucous membrane. The cervix opens into the vaginal cavity through the external os. The cervical canal extends from the anatomic external os to the internal os, where it joins the uterine cavity. The histologic internal os is where there is a transition from endocervical to endometrial glands. **The intravaginal portion of the cervix (portio vaginalis, exocervix) is covered with stratified squamous epithelium that is essentially identical to the epithelium of the vagina. The endocervical mucosa is arranged in branching folds (plicae palmatae) and is lined by cylindrical, columnar epithelium.** The stroma of the cervix consists of connective tissue with stratified muscle fibers and elastic tissue. The elastic

tissue is found primarily around the walls of the larger blood vessels.

The stratified squamous epithelium of the portio vaginalis is composed of several layers that are conventionally described as basal, parabasal, intermediate, and superficial. The basal layer consists of a single row of cells and rests on a thin basement membrane. This is the layer in which active mitosis occurs. The parabasal and intermediate layers together constitute the prickle-cell layer, which is analogous to the same layer in the epidermis. The superficial layer varies in thickness, depending on the degree of estrogen stimulation. It consists primarily of flattened cells that show an increasing degree of cytoplasmic acidophilia toward the surface. The thickness and the glycogen content of the epithelium increase after estrogen stimulation and account for the therapeutic effect of estrogens in atrophic vaginitis. The staining of glycogen in the normal epithelium of the portio vaginalis is the basis of the Schiller test.

Epidemiologic Studies

Clinical Profile

In the United States, the mortality from cervical cancer in 1945 was 15 of 100,000 women. This had declined to approximately 4.6 of 100,000 by 1986 and 3.4 of 100,000 by 1991. It is unclear whether the mortality rate from cervical cancer is falling as a result of cervical cytologic screening and intervention at the in situ stage or whether cervical screening has caused an increase in the proportion of early-stage cancer at diagnosis and registration. After therapy for invasive disease, adequate follow-up is the key to early detection of a recurrence (Table 3.1). The yield of examinations such as intravenous pyelography (IVP), computed tomography (CT) scan, and chest radiograph in patients with initial early disease (stages I–IIa) is so low that many have discontinued their routine use.

West studied the age of registration and the age of death of women with cervical cancer in South Wales. He found that the observed age at death was very close to 59 years regardless of stage and age at diagnosis. Although the 5-year survival rate of women with localized (early-stage) cervical cancer was much higher than that of women with nonlocalized (late-stage) cancer, the women with localized cancer tended to be younger than those with advanced cancer. Calculations of expected age at death of the whole population suggest that more than half the advantage in survival rate shown by women with early-stage cancers is a result of the diagnosis of the former in younger women.

Christopherson and colleagues reported that the percentage of patients diagnosed as having stage I disease increased by 78% in the population studied from 1953 to 1965. The increase was most remarkable in younger women. The authors concluded that the major problem in cervical cancer control was the screening of older women. Older women had higher incidence rates; the percentage with stage I disease also decreased with each decade, reaching a low of 15% for those 70 years of age and older. These older women with cervical cancer are rarely screened and contribute heavily to the death rate. The initial advanced stage contributes to the patient population with advanced recurrent cervical cancer. These patients, therefore, deserve very close posttreatment observation in an effort to detect a recurrence in its earliest possible form.

In 2011, there were 12,710 new cases of invasive cervical cancer and 4290 deaths from this disease in the United States. **In fact, for the past decade, the annual incidence and mortality rates due to cervical cancer have been approximately 12,000 and 4,000, respectively.** It is particularly distressing that more than one-third of women diagnosed will die from a disease that is largely preventable by vaccination and screening. There is no other human malignancy for which we have identified the causative agent, have successfully implemented excellent screening programs, and now have efficacious and tolerable prophylactic vaccination available (Fig. 3.2). Oncogenic subtypes of the human papillomavirus (HPV) have been identified as the etiologic cause of cervical neoplasia (Fig. 3.1). The power, consistency, and specificity of the association between subclinical HPV infection and cervical neoplasia raise the strong possibility that this relationship is causal. The biologic plausibility of this is supported by evidence that this sexually transmitted oncogenic virus often produces persistent asymptomatic infection of metaplastic epithelium in the cervical transformation zone.

Epidemiologic surveillance studies performed in the United States during the past 2 decades have documented decreased incidence rates for invasive cervical cancer. Ethnic and racial disparities, however, still exist. In a Surveillance, Epidemiology and End Results (SEER) analysis of 13 US cancer registries containing cases from 1992 to 2003, Hispanic whites had the highest incidence rate of cervical cancer overall (24 per 100,000), squamous cell carcinoma (SCC) (18 per 100,000), and adenocarcinoma (5 per 10,000). Non-Hispanic whites had the lowest rates of cervical cancer overall (11 per 100,000) and SCC (7 per 100,000), and African Americans had the lowest rate of adenocarcinoma (2 per 100,000). In a recent study using data obtained from the Cancer in North America (CINA) deluxe 1995 to 2004 database created by the North American Association of Central Cancer Registries (NAACCR), African American and Hispanic US populations continue to have the highest rates of invasive cervical cancer compared with non-Hispanic whites. Variations

TABLE 3.1 Proposed Schedule for Interval Evaluation of Cervical Cancer after Radiotherapy or Surgery (Asymptomatic Patient*)

Year	Frequency	Examination
1	3 months	Pelvic examination, Pap smear
	6 months	Chest radiography, CBC, BUN, creatinine
	1 year	IVP or CT scan with contrast
2	4 months	Pelvic examination, Pap smear
	1 year	Chest radiography, CBC, BUN, creatinine, IVP or CT scan with contrast
3–5	6 months	Pelvic examination, Pap smear

*Symptomatic patients should have appropriate examination where indicated.

BUN, Blood urea nitrogen; *CBC,* complete blood count; *CT,* computed tomography; *IVP,* intravenous pyelogram; *Pap,* Papanicolaou.

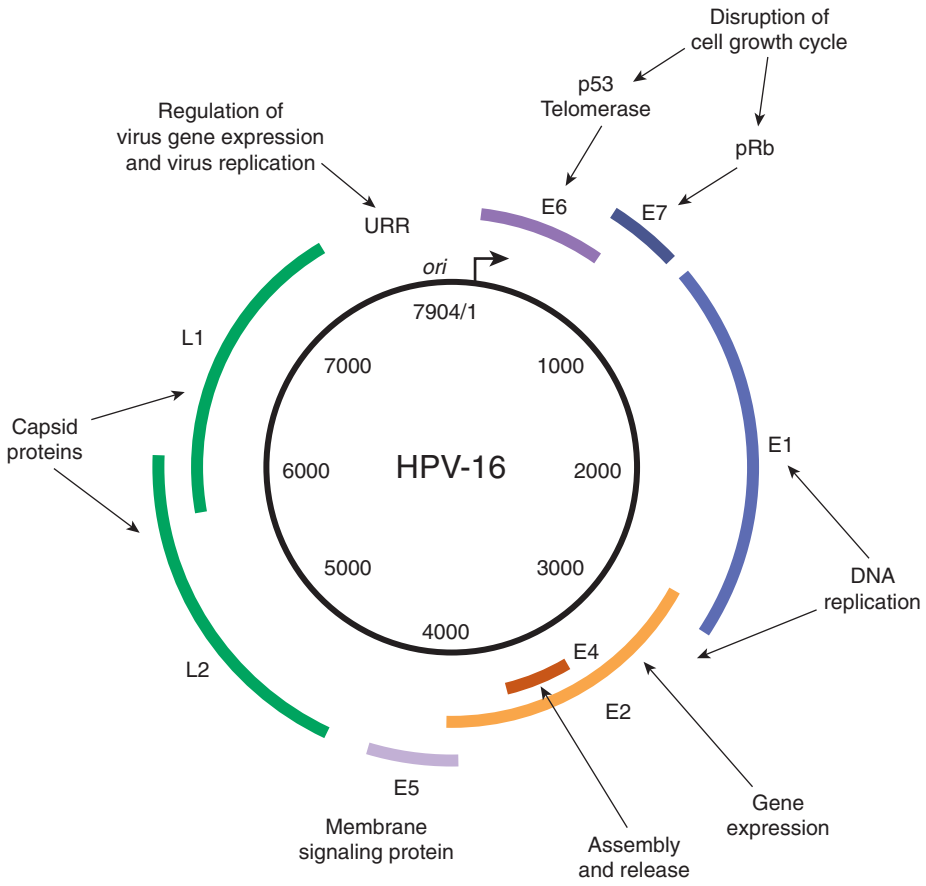

FIGURE 3.1 Human papillomavirus genome. (From microbiologybytes.com.)

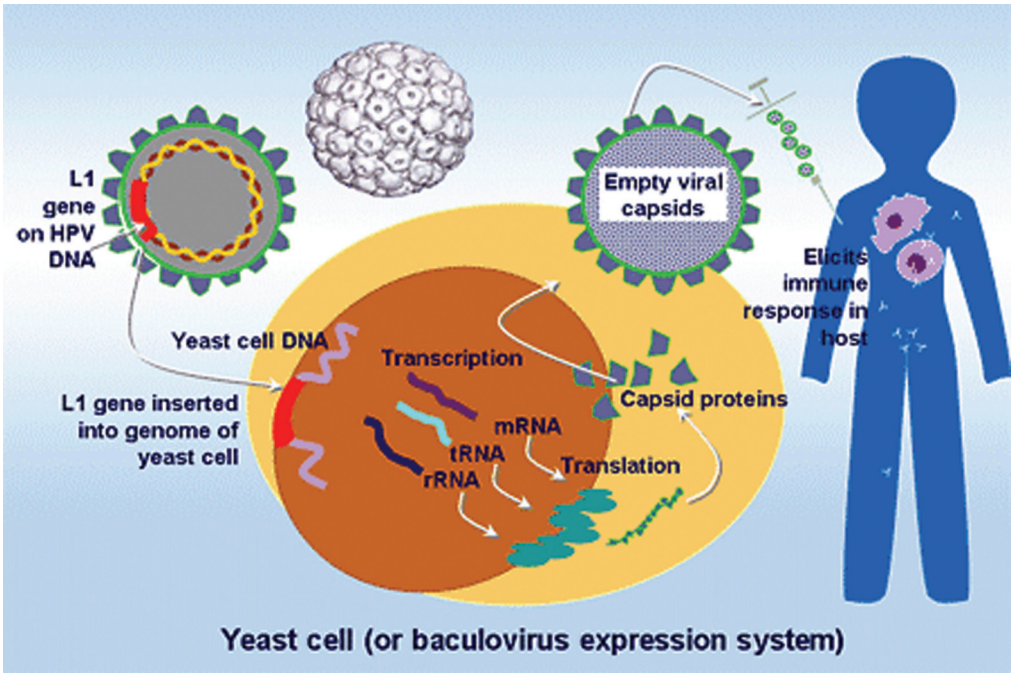

FIGURE 3.2 Human papillomavirus prophylactic vaccine. (From www.cancer.gov.)

in screening utilization and socioeconomic status are thought to account for the majority of the racial/ethnic disparities.

In November 2014, the nine-valent, HPV9 (providing protection against HPV-6, -11, -16, -18, -31, -33, -45, -52, and -58), was approved by the US Food and Drug Administration (FDA) for the same indications as HPV-4 (ie, GARDASIL).

MICROINVASIVE CARCINOMA OF THE CERVIX

The diagnosis and management of microinvasive carcinoma of the cervix remains controversial. The evolution and sometimes revolution concerning the diagnosis and management have occurred since Mestwerdt, in 1947, observed that invasive cervical cancer diagnosed only microscopically could be cured by nonradical surgery. During the past 3 decades, definitions and treatment plans have changed dramatically. It is hoped that most of these changes had occurred as new data became available and that changes were therefore logical. Much of the confusion can be related to the fact that the Federation of International Gynecologists and Obstetricians (FIGO) has changed the criteria for early-stage invasive carcinoma of the cervix since 1960. These changes were made as additional information in regard to this disease process became available. Other influences, however, also contributed to the confusion. Over the years, as many as 20 different definitions have been proposed, and as many as 27 terms have been applied to this entity. The recommended therapy has also changed, going from radical surgery with any invasion to being more conservative with various depths of invasion.

In 1971, FIGO designated stage Ia carcinoma of the cervix as cases of preclinical carcinoma. In 1973, the Society of Gynecologic Oncologists (SGO) accepted the following statement concerning the definition of microinvasive carcinoma of the cervix:

1. Cases of intraepithelial carcinoma with questionable invasion should be regarded as intraepithelial carcinoma; and
2. A microinvasive lesion should be defined as one in which a neoplastic epithelium invaded the stroma in one or more places to the depth of less than 3 mm below the base of the epithelium and in which lymphatic or vascular involvement is not demonstrated.

In 1985, for the first time, FIGO attempted to quantify the histologic definition of stage Ia carcinoma of the cervix. Stage Ia was defined as the earliest form of invasion in which minute foci of invasion are visible only microscopically. Stage Ia2 is a macroscopically measurable microcarcinoma that should not exceed 5 mm in depth and 7 mm in width. Vascular space involvement, either venous or lymphatic, should not alter staging. This definition has been criticized for several reasons. Although the upper limits of invasion for depth and width were stated, upper limits for measurement for stage Ia1 were not defined. It was therefore difficult to quantify patients in the two subgroups. Other areas of criticism were aimed at the fact that the FIGO definition could not be used as a guide for treatment, and the definition covered patients with vascular lymphatic channel involvement. These variations illustrate the problem with a specific definition.

TABLE 3.2 Stage 1a Cancer of the Cervix

Stage	Description
Ia	Cancer invasion identified only microscopically. All gross lesions, even with superficial invasion, are stage Ib cancers. Measured stromal invasion with maximum depth of 5 mm and no wider than 7 mm*
Ial	Measured invasion of stroma up to 3 mm
Ia2	Measured invasion of stroma of 3–5 mm and no wider than 7 mm

*The depth of invasion should not be larger than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates. Vascular space involvement, either venous or lymphatic, should not alter the staging.

In 1994, FIGO, in an attempt to better qualify the definition of microinvasive carcinoma of the cervix, adopted the following definition for microinvasive carcinoma of the cervix (Table 3.2). **Stage Ia1 cancers are those with stromal invasion up to 3 mm in depth and no greater than 7 mm. Stage Ia2 are when invasion is present at 3 to 5 mm in depth and no greater than 7 mm.** Lymphatic vascular space involvement does not exclude a patient from this definition. The recurrence rate of patients in these two substages is probably no more than 1% to 2%. Survival of stage Ia1 approaches 99%, and stage Ia2 survival approaches 97% to 98%. This new definition allows further evaluation of what might be appropriate therapy for the different substages, particularly stage Ia2 cancers.

Vascular space involvement was not excluded from the FIGO definition for several reasons. Pathologists disagree with regard to the reproducibility of this entity. At least in one study, the number of slides prepared from the cervix depended on the incidence of capillary-like space involvement. Shrinkage artifact can lead to an overdiagnosis, and verification has been suggested with special staining to verify true capillary-like space involvement. In one study in which immunoperoxidase staining with Ulex Europaeus agglutinin 1 lectin (UEAI) was used, 10 of 32 cases of vascular space involvement were excluded in which involvement was initially thought to exist. In a combined study of 1004 patients at three reference centers, Burghardt and colleagues observed that the frequency with which angiolymphatic space involvement was detected ranged from 9% in Munich to 23% in Erlangen and finally up to 43% in Graz.

As greater experience is obtained, the tendency has been toward conservative management involving conization of the cervix if fertility preservation is desired or simple hysterectomy for superficial invasion (0–3 mm) and even in some patients with 3–5 mm of invasion. In 1978, Lohe reported on 285 patients with early stromal invasion and 134 patients with microcarcinoma. He defined early stromal invasion as only isolated, variably shaped projections with true signs of infiltration present, whereas microcarcinomas' true confluent carcinomatosis masses were present. Tumor length and depth were 10 mm and 5 mm. He stated that the three-dimensional definition of the size of the tumor is essential to the microscopic diagnosis of early stromal invasion and of microcarcinoma. In

his series, 72% with early stromal invasion and 41% with microcarcinoma were treated with conservative surgery (conization or simple hysterectomy). After long-term follow-up, no patients with early stromal invasion died. Three patients with microcarcinomas have recurred and died. In a larger collected series of 435 patients with microcarcinoma, 24 (5.5%) had a recurrence of disease. Using his criteria, Lohe predicted <1% incidence of lymph node metastasis in microcarcinoma and essentially none in early stromal invasion. Boyce and colleagues have reported a large series with both "microscopic foci" of invasion (360 cases) and "occult invasion" (390 cases). Most (283) of the patients with microscopic foci invasion were treated with simple hysterectomy and only 14 with conization. After 5–15 years of follow-up, only one patient died of the disease. Most (262) of the patients with occult invasion received irradiation therapy. Most of these lesions were greater than 5 mm in depth, and all were characterized by confluent masses of neoplastic cells. Twenty-four of the 390 patients with occult invasion died of the disease in 5 years. Benedet and colleagues reported on 180 patients with microinvasion and occult invasive squamous cell carcinoma of the cervix who were examined by colposcopy during a 10-year period. Colposcopy led to the correct management in 90% of patients with occult invasive carcinoma and in 84% of patients with microinvasive cancer. Colposcopy appeared to be less sensitive in detecting microinvasive lesions than in detecting occult carcinoma. Atypical vessels indicative of early invasive cancer are often subtle and difficult to identify. They are best visualized when the cervix has been bathed in normal saline. In many cases, acetic acid can cover atypical vessels by enhancing white epithelium that obscures the vessels. Östör in Australia has made an extensive review on this subject of the literature published since 1976. As a pathologist, he has critically reviewed many of the parameters that have historically been suggested as important prognostic factors.

0–3 mm Invasion

Östör identified 3683 patients from the literature with <1 mm of invasion. Four patients had lymph node metastasis. With the incidence of lymph node metastasis in this group being essentially 0, it appears that lymphadenectomy has no place in this group of patients. There were 17 invasive recurrences and 16 cancer-related deaths. In several cases that resulted in death, patients refused further therapy or follow-up. Therefore, the death rate in this group of patients appears to be <0.1%, invasive recurrences were approximately 0.4% (Table 3.3). Östör identified 1324 patients who had invasion of 1–3 mm. Of these, 333 definitely had lymphadenectomies with seven nodal metastases. At least two of these probably had >3 mm of stromal invasion. The incidence based on these figures suggests that lymph node metastasis would be approximately 1%. There were 26 invasive recurrences and 6 deaths. Some of these patients probably had >3 mm of invasion and also included some patients with "microinvasive adenocarcinoma". In a review of reports over the last 15 years, most of which occurred within the last decade, Creasman and colleagues identified 1704 patients who had an invasion of 0–3 mm and 17 (1%) recurred. Only three (0.17%) died of their cancer. These recurrences were in patients with squamous lesions.

The management of early invasive lesions (0–3 mm of invasion, Fig. 3.3A–C) has generally been agreed on by the gynecologic oncology community. **Patients with FIGO stage Ia1 and SGO criteria for microinvasion could be treated conservatively with simple hysterectomy, or if continued fertility is desired conization only, provided surgical margins are free of cancer.** Most of the data in the literature concerning patients with 0–3 mm of invasion are based on conservative therapy, although some patients have had lymphadenectomies. From collected series, it would, therefore, appear that the role of vascular space involvement in this group of patients does not predict lymph node metastasis or recurrence. Although still in dispute, a growing number of investigators apparently do not use capillary-like space involvement as an exclusion criterion for this stage.

3–5 mm Invasion

Östör identified 674 patients in this category of which 221 definitely had lymphadenectomies, 6% had nodal metastasis. If most or all of the other patients had lymphadenectomy, which is possible, and the results of all of the nodes were negative, the figure would be close to 2%. Twentyfive (4%) patients developed an invasive recurrence, and 13 (2%) died of their disease. Twenty-three percent of the patients were said to have had capillary-like space involvement. Creasman identified from the literature 264 patients with 3–5 mm invasion who had lymphadenectomy in which vascular space involvement was specifically evaluated. In patients with vascular space involvement, 2 of 83 (2.4%) and 7 of 181 (3.8%) without vascular space involvement had lymph node metastasis. In the literature, 488 patients with 3–5 mm were identified and 15 (3%) developed a recurrence with 9 (1.8%) dying of cancer deaths. The recurrence and death rates in patients with 3–5 mm approaches

TABLE 3.3 Lymph Node Metastases, Recurrences and Deaths in Stage Ia Carcinoma of the Cervix

Invasion Depth (mm)	No. of Patients	Invasion Recurrence	Died of Cancer	No. With CLSI	No. With Positive Nodes
0–3	5007	35 (0.7%)	10 (0.2%)	182 (3.6%)	8/666 (1.2%)
3–5	674	25 (4%)	13 (2%)	124 (18.4%)	14/221 (6.3%)

CLSI, capillary-like space involvement.

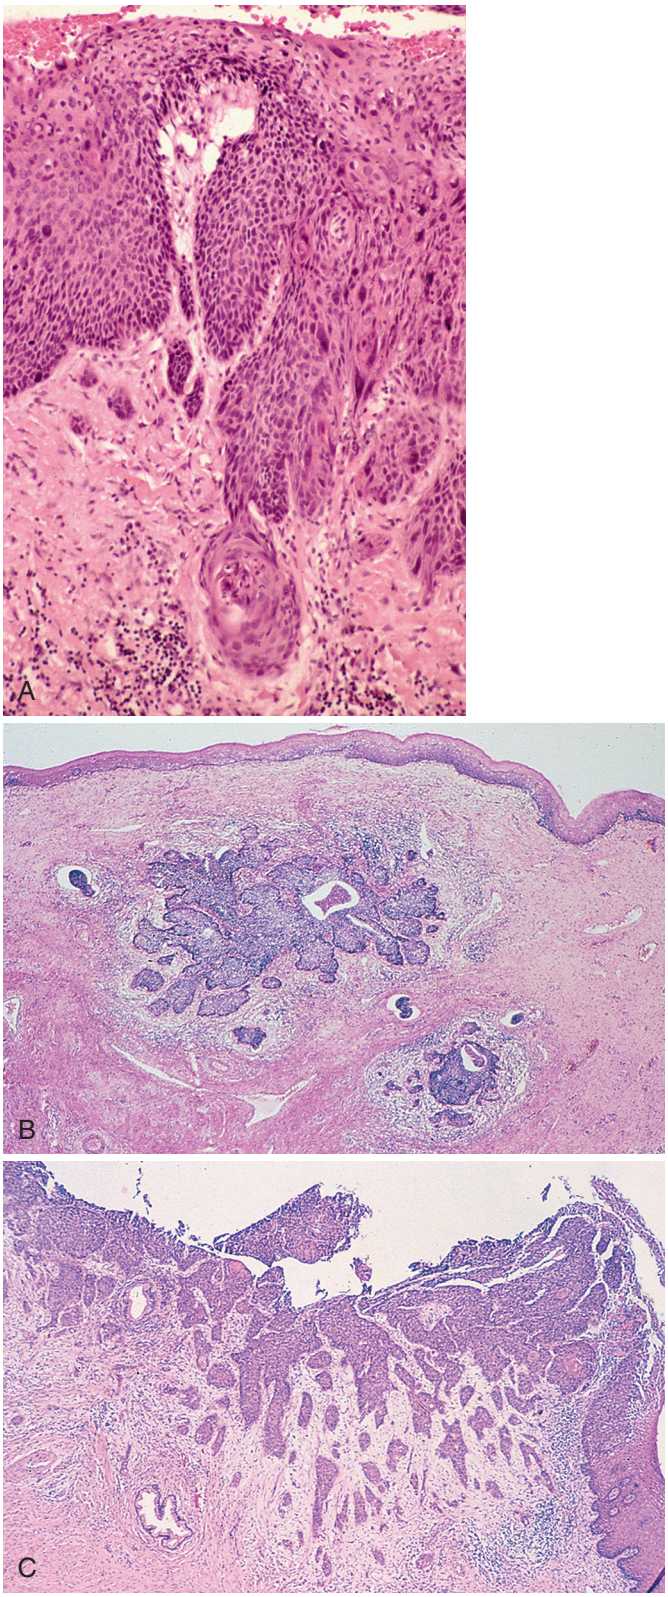

FIGURE 3.3 *A,* Microinvasion (stage Ia1) of squamous cell carcinoma of the cervix. Invasion of less than 1 mm, no confluency or vascular space involvement; true microinvasion. *B,* Microcarcinoma with less than 3 mm of invasion but with vascular space involvement. *C,* Microcarcinoma "spray" type with less than 1 mm of invasion.

those with 0–3 mm invasion. Most, but not all, of patients treated for 3–5 mm invasion were managed with radical hysterectomy and pelvic lymphadenectomy. However, there are patients in this category who have been managed only with conization. In the 3–5 mm range, vascular space status does not appear to correlate with lymph node metastasis. There is limited experience with patients with these clinical lesions, but patients with limited invasion of 3–5 mm have a much greater incidence of lymph node metastasis (7%), which should be treated as a stage Ib cancer.

The data on patients with 3–5 mm invasion still remain fairly limited. With a very low incidence of lymph node metastasis (2–3%), it seems reasonable to evaluate the role of more conservative therapy in this group of patients. This may be done after consultation with the pathologist and gynecologic oncologist. If one is concerned about the 3% incidence of lymph node metastasis, these nodes can be evaluated with laparoscopy or retroperitoneal lymphadenectomy. If there is no evidence of extrauterine disease via these procedures, simple hysterectomy or even conization may be reasonable treatments. Twenty years ago, it was not unusual for investigators to suggest radical hysterectomy and pelvic lymphadenectomy for any degree of stromal invasion. With increased experience, more conservative therapy was found to be just as efficacious as radical therapy. It appears that we are now in the same arena for 3–5 mm today as we were for 0–3 mm two decades ago. Although vascular space involvement does not appear to predict lymph node metastasis with 3–5 mm invasion, anecdotal reports in the literature have suggested that recurrences are higher in patients with capillary-like space involvement but with no metastasis in the lymph nodes.

It may be of significance that with progressively greater depth of stromal invasion, there is an increased risk of angiolymphatic space involvement. In point of fact, Fuller et al from the Memorial Sloan-Kettering Cancer Center detected a linear relationship between depth of cervical stromal invasion and the presence of angiolymphatic invasion. Although vascular space involvement was predictive of recurrence to the same degree it was predictive of nodal metastases, when stratified for the latter, vascular invasion lost its adverse prognostic effects. Östör noted in his review that 496 (14%) of 3597 patients who had capillarylike space involvement did not have an invasive recurrence. Morice et al retrospectively studied the clinicopathologic features of 193 patients who underwent radical surgery and lymphadenectomy for early stage cervical carcinoma, and found that both lymphovascular and nodal status were prognostic factors upon multivariate analysis. It was noteworthy that among a subgroup of 89 patients with a small tumor (<2 cm) and absence of nodal or isthmic involvement, that the overall survival was significantly correlated with the presence of lymphovascular space involvement. Recently, in an analysis of 93 patients who had undergone resection of early stage lesions, Memarzadeh et al demonstrated that the presence of lymphovascular space invasion in the parametria was an independent predictor of metastases in the pelvic ($P < 0.001$) and para-aortic ($P < 0.05$) lymphatic chains, an altogether not surprising finding. Hopefully, the role of lymphovascular space

involvement will be further clarified and possibly even resolved in the future as more data are accumulated.

The Gynecologic Oncology Group (GOG) reported 50 patients with 3–5 mm invasion in the conization specimen. All underwent a radical hysterectomy and pelvic lymphadenectomy. The uterine specimen showed no evidence of residual disease. There were 23% with lymphatic space involvement (LSI), but none of the patients had positive nodes and there have been no recurrences. (Note that the term LSI is used interchangeably with vascular space involvement [VSI].)

In a report from Japan, 402 patients were identified with 0–5 mm invasion. These authors noted that 72 (18%), although had depth of invasion satisfying the FIGO definition, had >7 mm of horizontal spread. As the depth of invasion increased, there was a greater possibility that horizontal spread was >7 mm (6% stage Ia1 and 61% for stage Ia2). Lymph node metastasis was 1.4% for true Ia1 and 3.4% for Ia2 cancers. For those with >7 mm spread, lymph node metastasis was 7.4%. LSI was 18% in those >7 mm compared to 3.6% if <7 mm. Four patients had a recurrence, but three recurrences occurred in those with >7 mm lateral spread. Other authors have noted recurrences and deaths in patients with 0–5 mm invasion; however, when lateral spread was evaluated, it was >7 mm. Tumor volume is an important prediction for metastasis, recurrence, and cancer-related deaths. Now that there are quantifiable perimeters for stage Ia cancers, more precise data can be evaluated with regard to risk and appropriate therapy for stage Ia2 can be considered.

Conservative management for stage Ia2 carcinoma of the cervix does not seem unreasonable in light of the fact that some investigators have suggested that conservative therapy might be feasible for patients with "small stage Ib" cervical cancers. Girardi and colleagues from Graz reported on a series of 69 patients with small stage Ib carcinomas of the cervix. Treatment consisted of conization or simple hysterectomy in 27, radical hysterectomy with lymphadenectomy in 25, radical vaginal hysterectomy in 13, and conization followed by radiotherapy in 4. No patient developed a recurrence during the ensuing 2–35 years. Two of the 25 patients with lymphadenectomy had one positive lymph node each. This study comes from a group of investigators who over the years have meticulously evaluated pathologic specimens and traditionally have been surgically aggressive. Östör reviewed the literature since 1976 with regard to conization as definitive therapy for stage Ia cancers. He identified 655 patients with 0–5 mm invasion treated with conization, which resulted in 12 invasive recurrences and one death.

CLINICAL PROFILE OF INVASIVE CANCER

A substantial and well-publicized screening program is needed to make the public and the profession more aware of cervical cancer as the possible cause of even minimal gynecologic symptoms. All public education should emphasize the prevention and cure of cancer, and a more optimistic attitude would help motivate patients and physicians to seek appropriate action. The need for early diagnosis rests on the incontrovertible fact that definite cure, in actuarial terms, is readily achieved when cervical cancer is minimal—but almost impossible if the tumor is given time to grow and spread to the pelvic wall or into adjacent structures such as the bladder and rectum. The gradient of percentage curability from early invasive cancer to late, grossly invasive disease is such a steep one that even a moderate reduction in tumor size could not fail to create a substantial improvement in curability. It is true, of course, as with other cancers, that some carcinomas of the cervix grow more rapidly than others. The basis for this difference in growth rate is still beyond our knowledge, but it is not beyond our capability to prevent unnecessary growing time. Even the relatively slow-growing malignancy, if given enough time, will become incurable, and the most rapid-growing tumor, if diagnosed while of still moderate dimension, is definitely curable. The earlier that most tumors are detected and treated, the better will be the chance of cure. A Pap smear from a patient with early invasive SCC illustrates a typical multinucleated "tadpole" cell (Fig. 3.4). Cytology and colposcopy are valuable tools in the eradication of cervical cancer. Every opportunity should be taken to disseminate modern concepts of cancer control to schools of nursing and other paramedical organizations because there is still a need for a more coordinated effort in these fields. The burden should not be left with physicians alone. The frequency with which invasive cervical cancer occurs in the United States is unknown, but the best incidence data indicate a rate of approximately 8 to 10 per 100,000/year (Fig. 3.5). The incidence and mortality rates in the United States have been slowly declining (Fig. 3.6). The occurrence of cervical cancer is apparently less frequent in Norway and Sweden than in the United States. However, in the underdeveloped areas of the world, the frequency of cervical cancer is more noteworthy, relative to the overall cancer problem, especially compared with that in the United States (see Table 3.2) and Western Europe.

In many South American and Asian countries, cervical cancer accounts for the largest percentage of cancer deaths in women. One wonders whether nutritional deficiencies in these underdeveloped nations play a role in the etiology of cervical cancer. Orr and colleagues reported that abnormal vitamin levels were more commonly present in patients with cervical cancer. When compared with control values, levels of plasma

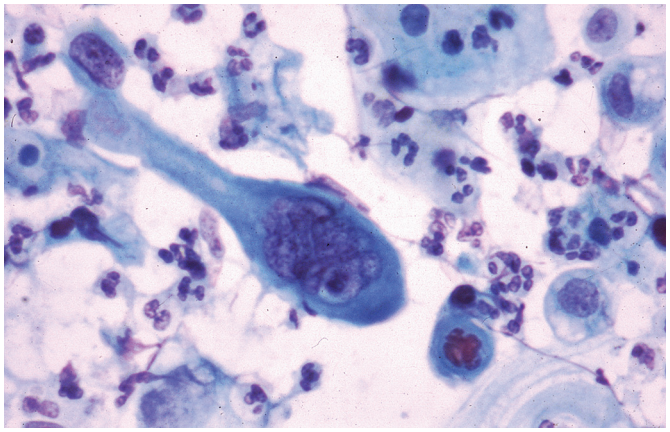

FIGURE 3.4 Multinucleated "tadpole" cell–early invasive squamous cell carcinoma.

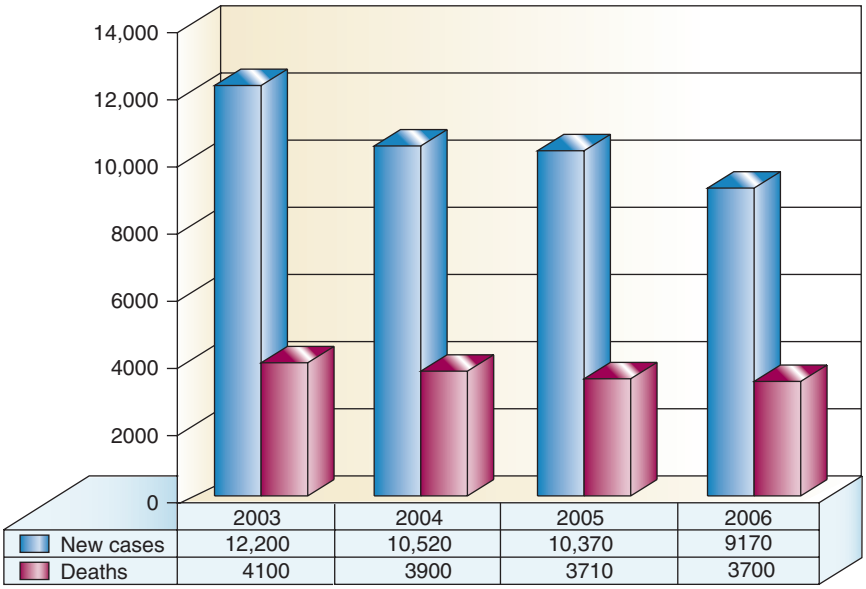

FIGURE 3.6 Cervical cancer in the United States: 2003–2006. (From Jermal, Siegel R, Ward E, et al. Cancer statistics, 2006. *CA Cancer J Clin* 2006;56:106.)

folate, beta-carotene, and vitamin C were significantly lower in patients with cervical cancer. Personal cigarette smoking and exposure to passive smoke as risk factors for cervical carcinoma have been examined in case-control studies. Personal cigarette smoking increases the risk of cervical cancer after adjustment for age, educational level, church attendance, and sexual activity. The adjusted risk estimate associated with being a current smoker was 3.42; for having smoked for 5 or more pack-years, it was 2.81; and for having smoked at least 100 lifetime cigarettes, it was 2.21. The adjusted risk estimate associated with passive smoke exposure for 3 hours or more per day was 2.96. This study, reported by Slattery and colleagues in 1989, has been reinforced by others, confirming a strong association of smoking and increased risk of SCC of the cervix.

Some studies suggest that cancer of the cervix is more frequent among oral contraceptive users; however, these studies may be influenced by confounding factors such as early onset of sexual activity after puberty, multiple sexual partners, and previous history of sexually transmitted diseases. Ursin and colleagues reported a twofold greater risk of adenocarcinoma of the cervix, especially among those who used oral contraceptives for 12 years or more.

Because of the cervix's sensitivity to hormonal influences, it may be considered biologically plausible that oral contraceptives could induce or promote cervical carcinoma. Piver reviewed a large number of early investigations of this issue and failed to show a consistent association. Moreover, these data are based on exposure to oral contraceptive preparations that contained

TABLE 3.4 Histologic Classification of Cervical Cancer

Epithelial Tumors		
Nonglandular	**Glandular**	**Other, Including Mixed**
Squamous cell carcinoma	Adenocarcinoma, usual endocervical type	Adenosquamous
Verrucous carcinoma	Mucinous adenocarcinoma	Glassy cell carcinoma
Warty (condylomatous) carcinoma	Endometrioid adenocarcinoma	Mucoepidermoid carcinoma
Papillary squamotransitional carcinoma	Well-differentiated villoglandular adenocarcinoma	Adenoid cystic carcinoma
Lymphoepithelial-like carcinoma	Adenoma malignum (minimal deviation)	Adenoid basal carcinoma
Sarcomatoid carcinoma	Intestinal-like adenocarcinoma	Small cell carcinoma
	Signet ring cell adenocarcinoma	Classical carcinoid tumor
	Colloid adenocarcinoma	Gestational choriocarcinoma
	Clear cell adenocarcinoma	
	Serous papillary adenocarcinoma	
	Mesonephric adenocarcinoma	
Nonepithelial Tumors		
Mesenchymal Tumors	**Germ Cell Tumors**	**Miscellaneous**
Carcinosarcoma	Mature teratoma	Melanoma
Leiomyosarcoma	Immature teratoma	Lymphoma
Epithelioid leiomyosarcoma	Yolk sac tumor	Primitive neuroectodermal tumor
Extrauterine endometrial stromal sarcoma	Nongestational choriocarcinoma	
Adenosarcoma		
Embryonal rhabdomyosarcoma		
Granulocytic sarcoma (chloroma)

high doses of estrogen and progestin and are no longer available.

In most large series, approximately 75% to 80% of malignant lesions of the cervix are squamous cell, but other lesions are possible (Table 3.4). Most information regarding etiology and epidemiology is pertinent only to the more common squamous cell lesions.

The greatest risk for cervical cancer is not ever having a Pap test or obtaining one infrequently. Everywhere in the world where the incidence of cervical cancer and its death rates have decreased, an active screening program is present. The older patients have a higher incidence of cervical cancer, at least in the United States, and these women have the most infrequent Pap smear screening.

Symptoms

A typical patient with clinically obvious cervical cancer is a multiparous woman between 45 and 55 years who married and delivered her first child at an early age, usually before 20 years of age. Probably the first symptom of early cancer of the cervix is a thin, watery, blood-tinged vaginal discharge that frequently goes unrecognized by the patient. **The classic symptom is intermittent, painless metrorrhagia or spotting only postcoitally** or after douching, although this is not the most common symptom. As the malignancy enlarges, the bleeding episodes become heavier and more frequent, and they last longer. The patient may also describe what seems to her to be an increase in the amount and duration of her regular menstrual flow; ultimately, the bleeding becomes continuous. In postmenopausal women, the bleeding is more likely to prompt early medical attention.

Late symptoms or indicators of more advanced disease include the development of pain referred to the flank or leg, which is usually secondary to the involvement of the ureters, pelvic wall, or sciatic nerve routes. Many patients complain of dysuria, hematuria, rectal bleeding, or obstipation resulting from bladder or rectal invasion. Distant metastasis and persistent edema of one or both lower extremities as a result of lymphatic and venous blockage by extensive pelvic wall disease are late manifestations of primary disease and frequent manifestations of recurrent disease. Massive hemorrhage and development of uremia with profound inanition may also occur and occasionally be the initial presenting symptom.

Gross Appearance

The gross clinical appearance of carcinoma of the cervix varies considerably and depends on the regional mode of involvement and the nature of the particular lesion's growth pattern. Three categories of gross lesions have traditionally been described. **The most common is the exophytic lesion, which usually arises on the ectocervix and often grows to form a large, friable, polypoid mass that can bleed profusely.** These exophytic lesions sometimes arise within the endocervical canal and distend the cervix and the endocervical canal, creating the so-called barrel-shaped lesion. A second type of cervical carcinoma is created by an infiltrating tumor that tends to show

little visible ulceration or exophytic mass but is initially seen as a stone-hard cervix that regresses slowly with radiation therapy. A third category of lesion is the ulcerative tumor (Fig. 3.7), which usually erodes a portion of the cervix, often replacing the cervix and a portion of the upper vaginal vault with a large crater associated with local infection and seropurulent discharge.

Routes of Spread

The main routes of spread of carcinoma of the cervix are as follows:

1. Into the vaginal mucosa, extending microscopically down beyond visible or palpable disease
2. Into the myometrium of the lower uterine segment and corpus, particularly with lesions originating in the endocervix
3. Into the paracervical lymphatics and from there to the most commonly involved lymph nodes (ie, the obturator, hypogastric, and external iliac nodes)
4. Direct extension into adjacent structures or parametria, which may reach to the obturator fascia and the wall of the true pelvis. Extension of the disease to involve the bladder or rectum can result, with or without the occurrence of a vesicovaginal or rectovaginal fistula.

The prevalence of lymph node disease correlated well with the stage of the malignancy in several anatomic studies. Lymph node involvement in stage I is between 15% and 20%; in stage II, it is between 25% and 40%; and in stage III, it is assumed that at least 50% have positive nodes. Variations are sometimes seen with different material. The best study of lymph node involvement in cervical cancer was done by Henriksen (Fig. 3.8). The nodal groups described by Henriksen follow.

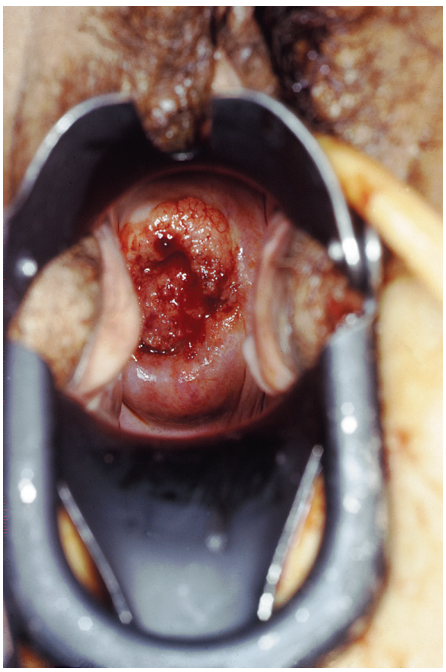

FIGURE 3.7 Ulcerative squamous cell carcinoma of the cervix.

Primary Group

1. The parametrial nodes, which are the small lymph nodes traversing the parametria
2. The paracervical or ureteral nodes, located above the uterine artery where it crosses the ureter
3. The obturator or hypogastric nodes surrounding the obturator vessels and nerves
4. The hypogastric nodes, which course along the hypogastric vein near its junction with the external iliac vein
5. The external iliac nodes, which are a group of six to eight nodes that tend to be uniformly larger than the nodes of the other iliac groups
6. The sacral nodes, which were originally included in the secondary group

Secondary Group

1. The common iliac nodes
2. The inguinal nodes, which consist of the deep and superficial femoral lymph nodes
3. The periaortic nodes

In his autopsy studies, Henriksen plotted the percentage of nodal involvement for treated and untreated patients (Figs. 3.9 and 3.10). Distribution is, as one would expect, with a greater number of involved nodes found in the region of the cervix than in distant metastases. Although the series was an autopsy study, Henriksen found that only 27% had metastasis above the aortic chain. Cervical cancer kills by local extension, with ureteral obstruction in a high percentage of patients.

In 1980, the Gynecologic Oncology Group (GOG) reported the results of a series of 545 patients with cancer of the cervix who were surgically staged within their institutions. This study was prompted because traditional ports of radiation therapy were destined to treatment failure when the disease extended to the periaortic nodes (Fig. 3.11). They found periaortic node involvement in 18.2% of patients with stage IIa disease and up to 33.3% in patients with stage IVa disease. Piver correlated the size of the cervical lesion with the incidence of lymph node metastasis in stage I disease (Table 3.5).

When clinical staging was compared with surgical staging, inaccuracies were found of the magnitude of a 22.9% misstaged occurrence in stage IIb disease and a 64.4% misstaged occurrence in stage IIIb disease. These data raise the question of whether knowing that disease has spread to the periaortic area enables the clinician to institute therapeutic modalities that can

III	47.0	8.6

result in increased salvage. In other words, does the treatment of patients with spread of disease beyond the pelvis result in more cures? Berman and colleagues, reporting the GOG experience with staging laparotomy, indicated that 20% of 436 patients (stages IIb–IVa) were found to have metastatic disease to periaortic nodes. He also reported that 25% of these patients, or 5% of those surgically staged, demonstrated a 3-year, disease-free survival. Most of the patients with known periaortic node involvement received extended postoperative field irradiation.

Cumulative results from many studies utilizing lymphadenectomy in the surgical staging of cervix cancer have shown increased frequency of positive pelvic nodes, as shown in Table 3.6.

GLANDULAR TUMORS OF THE CERVIX

Approximately 75% to 80% of cervical cancers are SCCs, and most of the remaining cases are adenocarcinomas. There appears to be an increase in the frequency of cervical adenocarcinomas, but this may be a result of the decrease in the incidence of invasive squamous cell lesions. With respect to histopathology, a SEER population study conducted on cases registered from 1973 to 2002 noted increasing numbers of adenocarcinomas despite a general decline, suggesting the inefficiency of conventional screening for these tumors. Adenocarcinoma arises from the endocervical mucous-producing gland cells, and because of its origin within the cervix, it may be present for a considerable time before it becomes clinically evident. These lesions are characteristically bulky neoplasms that expand the cervical canal and create the so-called barrel-shaped lesions of the cervix. The spread pattern of these lesions is similar to that of SCC, with direct extension accompanied by metastases to regional pelvic nodes as the primary routes of dissemination. Local recurrence is more common in these lesions, and this has resulted in the commonly held belief that they are more radioresistant than are their squamous counterpart. It seems more likely, however, that the bulky, expansive nature of these endocervical lesions, rather than a differential in radiosensitivity, accounts for the local recurrence. Two controversial issues continue with regard to management of adenocarcinoma of the cervix. First, does this cell type carry a worse prognosis than squamous or adenosquamous cell types? Second, for early-stage disease, which therapy (radical surgery, radiation, or combined treatment) is superior?

Most studies suggest no difference in survival when adenocarcinomas are compared with SCCs after correction for stage. The 1998 FIGO Annual Report, which reported more than 10,000 SCCs and 1138 adenocarcinomas using multivariant analysis, noted no difference in survival in stage I cancers. In a study by Chen and associates of 302 adenocarcinomas, it was noted that in early stages, multivariant analysis noted better survival in patients treated with radical surgery compared with those treated with radiation therapy.

Kjorstad and Bond investigated the metastatic potential and patterns of dissemination in 150 patients with stage Ib adenocarcinoma of the cervix treated from 1956 to 1977. All patients were treated with a combination of intracavitary radium followed by radical hysterectomy with pelvic lymph node dissection. The incidence of pelvic metastases and distant recurrences and the survival rates were the same as those given in previously published reports for SCC treated in the same manner. In one respect, the adenocarcinomas showed a significant difference from the squamous cell cancers. The incidence of residual tumor in the hysterectomy specimens after intracavitary treatment was much higher (30% vs. 11%). Kjorstad and Bond considered this a strong argument for surgical treatment of patients with early stages of adenocarcinoma of the cervix.

Moberg and colleagues reported on 251 patients at Radiumhemmet in Stockholm with adenocarcinoma of the uterine cervix. The 5-year survival rate was compared with that in the total of cervical epithelial malignancies, and the rate was lower in the adenocarcinoma cases, with respective crude 5-year survival rates of 84%, 50%, and 9% in stages I, II, and III, respectively. Combined treatment consisting of two intracavitary radium treatments with an interval of 3 weeks followed by a radical hysterectomy with pelvic lymphadenectomy done within 3 months gave improved 5-year survival in a nonrandomized series. Prempree and colleagues also suggested combined therapy for stage II lesions or for those larger than 4 cm.

A large series of 367 cases of adenocarcinoma of the cervix was reported by Eifel and associates. Their conclusions were that the central control of adenocarcinomas with radiation therapy is comparable to that achieved for SCCs of comparable bulk. They found no evidence that combined treatment (radiation

therapy plus hysterectomy) improved local regional control or survival. In their study, radiation therapy alone was as effective a treatment for most patients with stage I disease. They noted, as others have, that patients with bulky stage I (>6 cm), stage II, or stage III disease, particularly with poorly differentiated lesions or evidence of nodal spread, had a very high rate of extrapelvic disease spread.

Eifel reported the results of 160 patients with adenocarcinoma of the cervix. Of these patients, 84 were treated with radiation therapy alone; 20 were treated with external and intracavitary radiation followed by hysterectomy, and 56 were treated with radical hysterectomy. Survival was strongly correlated with tumor size and grade. There was a 90% survival rate for lesions smaller than 3 cm. After 5 years, 45% of the patients treated with radical hysterectomy had a recurrence. These recurrences were strongly correlated with lymph or vascular space invasion, poorly differentiated lesions, and larger tumor size.

Chen and associates from Taiwan reviewed 3678 cases of cervical cancer treated between 1977 and 1994, of which 302 (8.5%) were adenocarcinoma. A higher proportion of cases with adenocarcinoma were of the lower stages and in the younger patient even within a given stage. Survival was better in all stages in patients with squamous compared with adenocarcinoma (81% vs. 76% in stage I, $P = 0.0039$). When surgery was primary therapy, there was no difference in survival in stage I (83% vs. 80.3% survival of squamous and adenocarcinoma, respectively). Survival with radiation therapy noted 71% vs. 49%, respectively ($P = 0.0039$), in stage I. Survival decreased as age increased within a given stage.

The MD Anderson Hospital group compared 1538 patients with SCC with 229 patients with adenocarcinoma, all stage Ib and treated with radiation. In patients with tumors larger than 4 cm, multivariate analysis confirmed that patients with adenocarcinoma had a significantly poorer survival than did those with SCC (59% vs. 73%). In a study by the GOG, 813 stage Ia2 and Ib cancers were evaluated. All were treated with radical hysterectomy. There were 645 squamous, 104 adenocarcinoma, and 64 adenosquamous cancers. Radiation was given postoperatively to 16% squamous, 13% adenocarcinomas, and 20% of adenosquamous patients. After adjusting for multiple risk factors, survival was worst for adenosquamous cancer compared with squamous and adenocarcinoma (71.8%, 82.1%, and 88%, respectively). A similar finding was noted in a study from Taiwan in which 134 stage Ib or II cervical adenocarcinomas or adenosquamous cancers were compared with 757 similarly staged squamous carcinomas treated with radical hysterectomy. The overall survival (OS) rate was 72.2% for the former compared with 81.2% for the SCCs. The histology was an independent prognostic factor for recurrence-free survival and OS.

STAGING

The staging of cancer of the cervix is a clinical appraisal, preferably confirmed with the patient under anesthesia; it cannot be changed later if findings at operation or subsequent treatment reveal further advancement of the disease.

International Federation of Gynecology and Obstetrics

International classification of cancer of the cervix according to FIGO was recently revised in 2009 (Fig. 3.12):

Stage	Description
0	Carcinoma in situ, intraepithelial carcinoma
I	The carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded)
Ia	Invasive cancer identified only microscopically; all gross lesions, even with superficial invasion, are stage Ib cancers. Invasion is limited to measured stromal invasion with maximum depth of 5 mm and no wider than 7 mm
Ia1	Measured invasion of stroma no greater than 3 mm in depth and no wider than 7 mm
Ia2	Measured invasion of stroma greater than 3 mm and no greater than 5 mm and no wider than 7 mm

The depth of invasion should not be more than 5 mm taken from the base of the epithelium, surface or glandular, from which it originates. Vascular space involvement, venous or lymphatic, should not alter the staging.

Stage	Description
Ib	Clinical lesions confined to the cervix or preclinical lesions greater than stage Ia
Ib1	Clinical lesions no greater than 4 cm
Ib2	Clinical lesions greater than 4 cm
II	Involvement of the vagina but not the lower third, or infiltration of the parametria but not out to the sidewall
IIa	Involvement of the vagina but no evidence of parametrial involvement
IIa1	Clinically visible lesion no greater than 4 cm in greatest dimension
IIa2	Clinically visible lesion greater than 4 cm in greatest dimension
IIb	Infiltration of the parametria but not out to the sidewall
III	Involvement of the lower third of the vagina or extension to the pelvic sidewall; all cases with a hydronephrosis or nonfunctioning kidney should be included unless they are known to be attributable to other causes
IIIa	Involvement of the lower third of the vagina but not out to the pelvic sidewall if the parametria are involved
IIIb	Extension onto the pelvic sidewall or hydronephrosis or nonfunctional kidney
IV	Extension outside the reproductive tract
IVa	Involvement of the mucosa of the bladder or rectum
IVb	Distant metastasis or disease outside the true pelvis

In 2013, using the revised FIGO 2009 staging, Wagner et al. investigated the impact of size within FIGO stages I to IIIB using the 1988 to 2008 SEER Program database. The investigators evaluated a total of 18,649 cases and reported that the

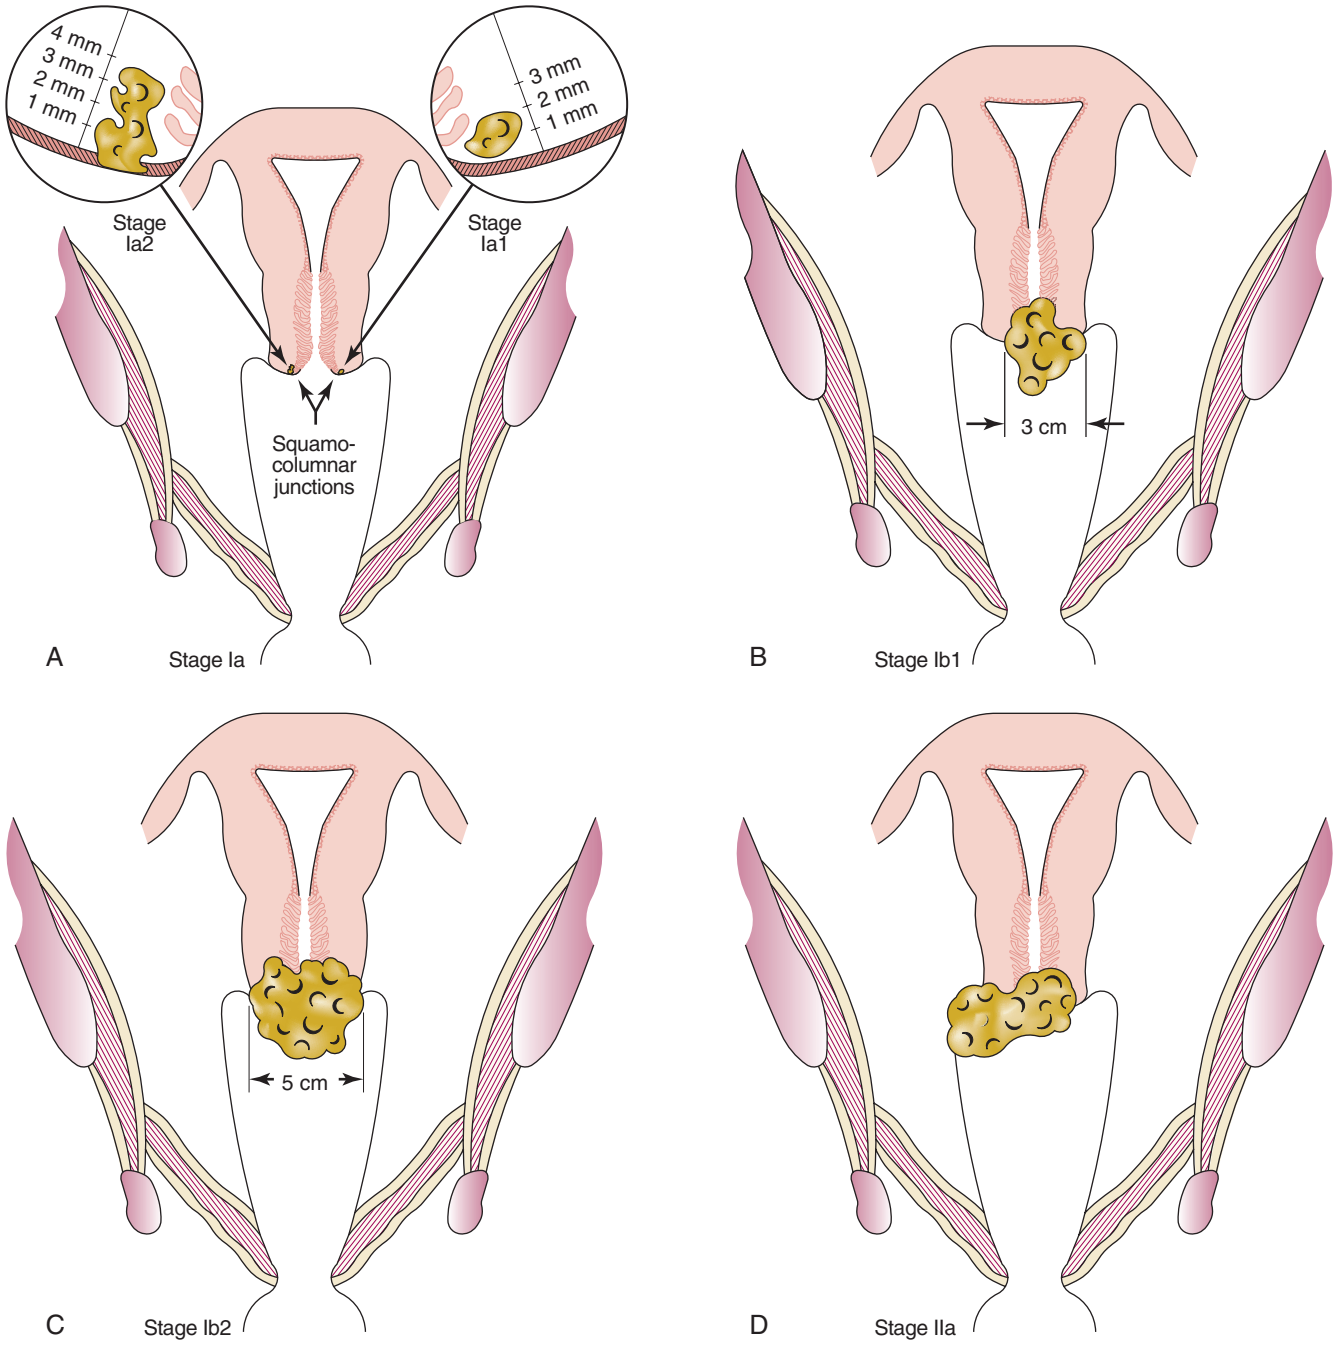

FIGURE 3.12 A–J, Federation of International Gynecologists and Obstetricians stagings and classification of cancer of the cervix. See staging in Appendix A.

Continued

hazard ratios (HRs) were significantly worse for larger tumors on both univariate and multivariate modeling. The prognostic significance of the size subdivisions of 2 cm and 4 cm for stage 1, 4 cm for stage IIB, and 4 cm and 6 cm for stage IIIB were also maintained. These findings were believed to validate the changes to the FIGO system made in 2009.

The clinical evaluation of patients with cervical cancer is outlined in Table 3.7. **The following diagnostic aids are acceptable for determining a staging classification: physical examination, routine radiographs, colposcopy, cystoscopy, proctosigmoidoscopy, IVP, and barium studies of the lower colon and rectum. Other examinations, such as lymphography,** CT scans, magnetic resonance imaging (MRI) examinations, arteriography, venography, laparoscopy, and hysteroscopy, are not recommended for staging because they are not uniformly available from institution to institution. It is important to emphasize that staging is a method of communicating between one institution and another. Probably more important, however, is that staging is a means of evaluating the treatment plans used within one institution. For these reasons, the method of staging

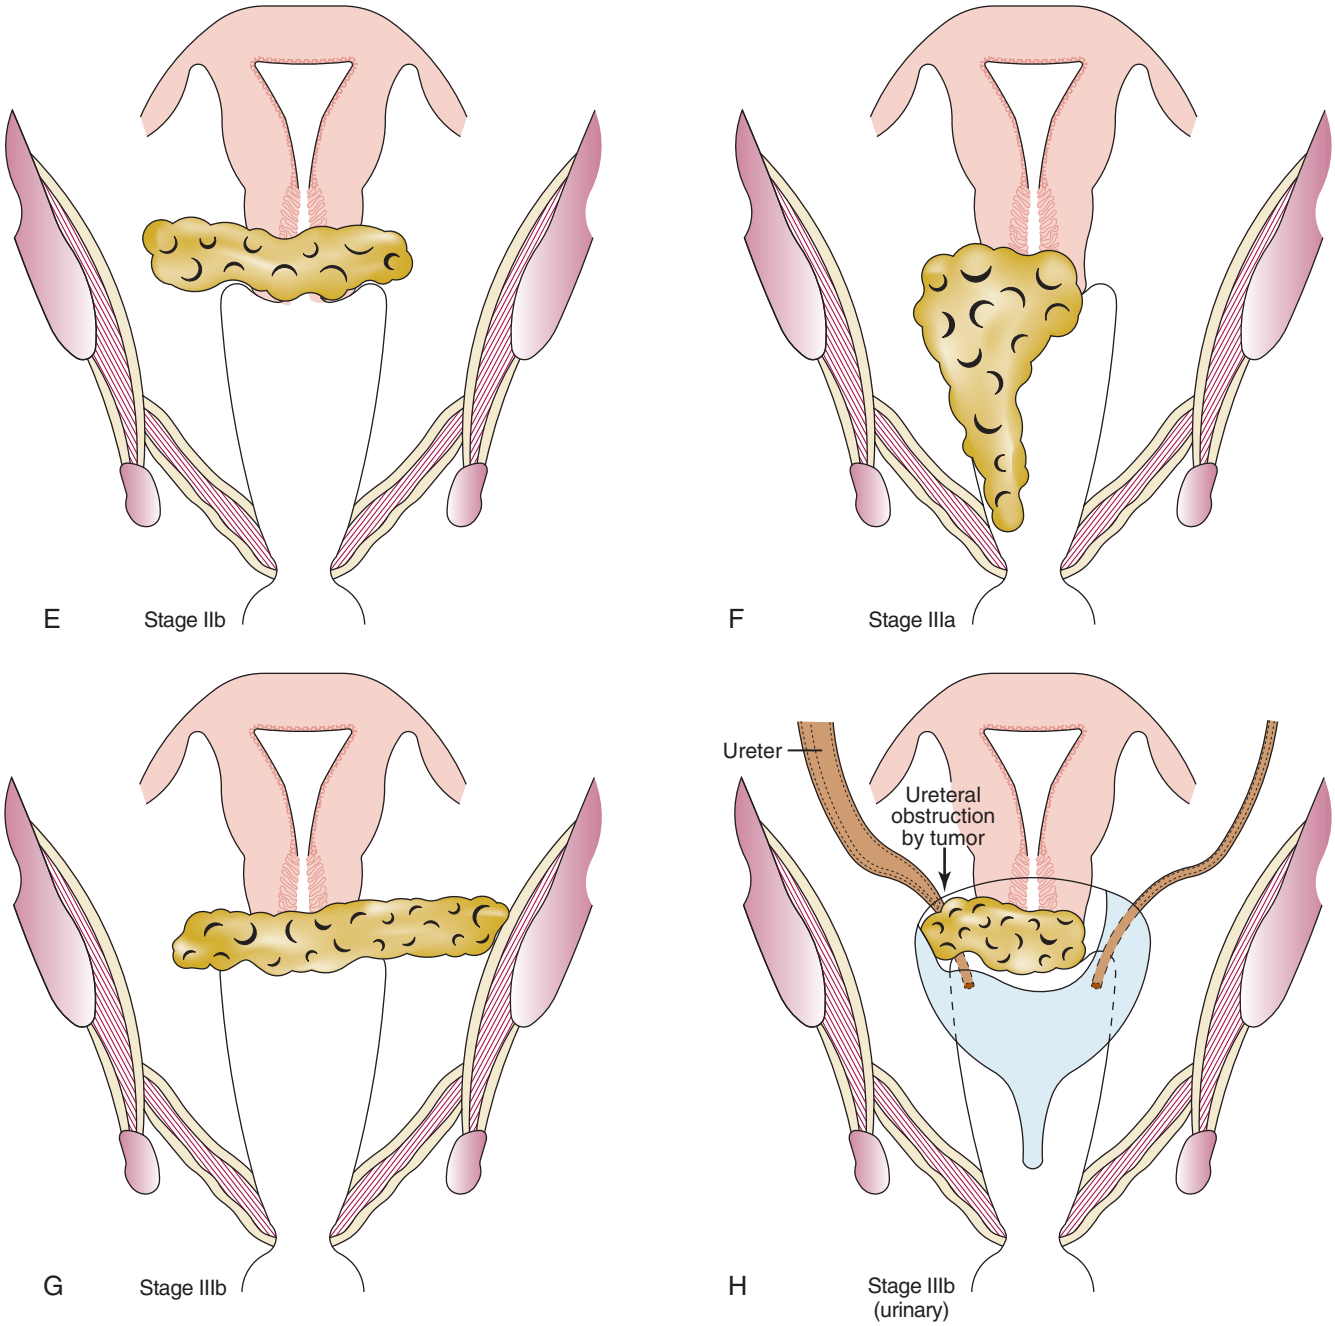

FIGURE 3.12, cont'd

should remain fairly constant. Staging does not define the treatment plan, and therapy can be tailored to the architecture of the malignancy in each patient.

Positron Emission Tomography

In 2005, the Centers for Medicare & Medicaid Services implemented coverage for 18-fluorodeoxyglucose positron emission tomography (FDG-PET) for patients with newly diagnosed and locally advanced cervical cancer undergoing pretreatment staging who have no extrapelvic metastases on conventional imaging studies (Fig. 3.13). It should be noted that all imaging modalities are more specific than sensitive in detecting nodal metastases. **The pooled sensitivity of PET in detecting pelvic nodal metastases in patients with untreated cervical cancer approaches 80% compared with MRI (≈70%) or CT (≈48%).** It is important to recognize that the available studies are limited by low numbers of patients and wide confidence intervals (CIs).

Grosu and colleagues from Munich analyzed the results of clinical studies on the integration of PET in target volume definition for lung, head and neck, GU, and brain tumors. FDG-PET had a significant impact on gross tumor volume and planning target volume delineation in lung cancer and was able to detect lymph node involvement and differentiate malignant tissue from atelectasis. In high-grade gliomas and

TABLE 3.7 Clinical Evaluation of Patients With Newly Diagnosed Cervical Cancer

History	Review of Systems	General Physical Examination
Risk factors (STDs, smoking, OCPs, HIV), prior abnormal Pap tests, previous dysplasia and treatment	Abnormal vaginal bleeding or discharge; pelvic pain, flank pain, sciatica, hematuria, rectal bleeding, anorexia, weight loss, bone pain	Peripheral lymphadenopathy
Evaluation	Common procedures (FIGO)	Alternative procedures
Invasive cancer	Cervical biopsy Endocervical curettage Cervical conization	Histologic diagnosis required
Tumor size; involvement of the vagina, bladder, rectum and parametria	Pelvic examination under anesthesia	MRI pelvis preferred over CT
Anemia	Complete blood count	—
Renal failure	Serum chemistries	—
Hematuria	Urinalysis	—
Bladder involvement	Cystoscopy with biopsy and urine cytology	CT, MRI pelvis
Rectal infiltration	Proctoscopy with biopsy	CT, MRI pelvis; barium enema
Hydronephrosis	IVP	Renal ultrasonography; CT abdomen
Pulmonary metastases	Chest radiography	CT chest; PET scan
Retroperitoneal lymphadenopathy	—	Lymphangiogram, CT, MRI, PET scan

meningiomas, methionine PET helped to differentiate tumor from normal tissue. Furthermore, the investigators suggest that FDG-PET seems to be particularly valuable in lymph node status definition in cervical cancer. With limited experience, several commentators have noted that FDG-PET may be superior to CT and MRI not only in the detection of lymph node metastases but also in the detection of unknown primary cancer and in the differentiation of viable tumor tissue after treatment. The accurate delineation of gross tumor volume suggests the potential for sparing of normal tissue. The imaging of hypoxia, cell proliferation, angiogenesis, apoptosis, and gene expression by new PET tracers such as choline and acetate may lead to the identification of different areas of a biologically heterogeneous tumor mass that can be individually targeted

using intensity-modulated radiotherapy (IMRT). In addition, a biologic dose distribution can be generated permitting dose painting.

A 2007 meta-analysis of 41 studies was undertaken to compare the diagnostic performances of CT, MRI, and PET or PET/CT in patients for detection of metastatic lymph nodes in patients with cervical cancer. Whereas PET or PET/CT showed the highest pooled sensitivity (82%) and specificity (95%), CT showed 50% and 92% and MRI showed 56% and 91%, respectively (Table 3.8). In a recent investigation of 83 women with FIGO stages IB1 to IIIB cervical cancer, F-18 fluorodeoxyglucose-avid pelvic lymph nodes (SUVPLN) was found to be a prognostic biomarker, predicting treatment response, pelvic recurrence risk, and disease-specific survival. Finally, a prospective validation study conducted between 2000 and 2009 enrolled 560 women who underwent pretreatment FDG-PET lymph node staging. Overall, 47% of patients had lymph node involvement by FDG-PET at diagnosis and within a stage, patients with PET-positive lymph nodes had significantly worse disease-specific survival than those with PET-negative lymph nodes ($P<0.001$). The HRs for disease recurrence increased incrementally based on the most distant level of nodal disease: pelvic, 2.4 (95% confidence interval [CI], 1.63, 3.52); paraaortic, 5.88 (95% CI 3.8, 9.90); and supraclavicular, 30.27 (95% CI, 16.56, 55.34).

Vanderperre et al. recently compared surgical staging with PET-CT, PET, and CT imaging of the paraortic lymph nodes in patients with locally advanced disease (ie, FIGO IB2-IVA). The 204 patients studied were divided into the following four groups: positive surgical staging with negative paraaortic imaging ($n = 16$), negative surgical staging ($n = 172$), positive imaging without surgical staging ($n = 20$), and negative imaging without surgical staging ($n = 128$). OS rates at 2 years (median follow-up 31 months) were 40%, 83%, 58%, and 69%, respectively ($P <0.001$ for positive surgical staging and positive imaging without surgical staging vs. the other two groups). The authors noted that despite negative imaging, aortic nodal metastases were present among 8% of patients who underwent surgical staging, with OS being significantly influenced by the presence of paraaortic metastases.

Surgical Staging

Findings uncovered by fusion PET-CT or conventional MR and CT examinations can be used in the planning of therapy but should not influence the initial clinical staging of the lesion. Unfortunately, clinical staging is only of rough value in prognosis because disease distribution and extent are often included under one stage subheading. Clinical staging is enhanced with the liberal use of rectovaginal examinations (Fig. 3.14) in that this type of pelvic examination allows more complete palpation of the parametria and cul-de-sac. The role of surgical assessment of lymph nodes with extraperitoneal, laparoscopic, or robotic lymphadenectomy is expanding. **The ability to perform pelvic and paraaortic lymphadenectomy provides prognostic information, improves direction of radiation therapy (ie, extended-field radiation with positive paraaortic nodes) and**

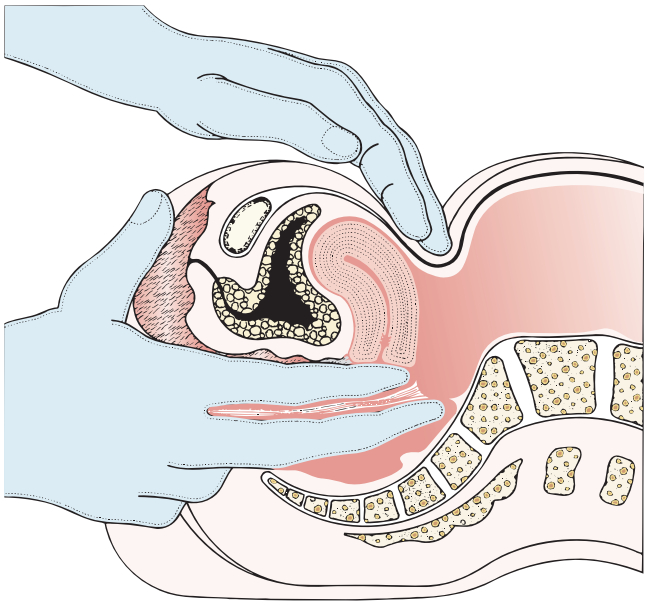

FIGURE 3.14 Technique of rectovaginal examination.

may offer a therapeutic effect particularly in grossly involved lymph nodes. To date, no prospective data on surgical staging of cancers of the cervix exist to indicate a survival advantage to this approach.

Some gynecologic oncologists believe that limited staging procedures are warranted on patients with advanced-stage cervical cancer to place patients on institutional or national group protocols. The status of paraaortic nodes should be known before treatment is initiated in such cases to plan appropriate modalities, such as the extent of the radiation field or concomitant chemotherapy. An extraperitoneal approach for removal of the periaortic nodes is preferred by many clinicians in an effort to reduce morbidity from the procedure. More advanced lesions have been investigated with a retroperitoneal lymphadenectomy to determine the extent of disease before planning radiotherapy fields (Fig. 3.15). Fig. 3.16 illustrates one such approach. With the increased use of PET, it is expected that the indications for surgical staging in cervical cancer will decrease.

TREATMENT OF EARLY-STAGE DISEASE

After the diagnosis of invasive cervical cancer is established, the question is how to best treat the patient. Proposed management algorithms for early-stage disease, locally advanced malignancy, and disseminated tumors appear in Fig. 3.17. Specific therapeutic measures are usually governed by the age and general health of the patient, by the extent of the cancer, and by the presence and nature of any complicating abnormalities. It is thus essential to carry out a complete and careful investigation of the patient (see Table 3.7), and then a joint decision regarding treatment should be made by the radiotherapist and gynecologic oncologist. The choice of treatment demands clinical judgment, but apart from the occasional patient for whom only symptomatic treatment may be best, this choice lies between surgery and radiotherapy (almost always given with cisplatin chemotherapy). In most institutions, the initial method of treatment for locally advanced disease is chemoradiation, both intracavitary and external radiographic therapy. **The controversy between surgery and radiotherapy has existed for decades and essentially surrounds the treatment of stage I and stage IIa cervical cancer** (see Fig. 3.17). For the most part, most patients with stages more advanced than stage I and stage IIa are treated with combination cisplatin and radiotherapy (see Fig. 3.17). The 5-year survival figures from two large series, one treated with radiotherapy alone and the other with surgery, are included here. Currie reported the results of 552 radical operations for cancer of the cervix:

Stage	Patients
Preinvasive carcinoma in situ	555 cases (99.9%)
Stage I	189 cases (86.3%)
Stage IIa	103 cases (75%)
Stage IIb	78 cases (58.9%)
Other stages	41 cases (34.1%)

Some of these patients with positive nodes received postoperative radiotherapy.

In 1981, Zander and colleagues reported results of a 20-year cooperative study from Germany of 1092 patients with stages Ib and II cancer of the cervix treated with radical hysterectomy of the Meigs type and bilateral pelvic lymphadenopathy. Of the 1092 patients, 50.6% had surgery only, with a 5-year survival rate of 84.5% in stage Ib and 71.1% in stage II (most were stage IIa). This correlates well with the figures reported by Currie and Falk. The rest of the patients reported by Zander received postoperative whole-pelvis irradiation therapy. No significant difference could be observed in the survival rates of patients

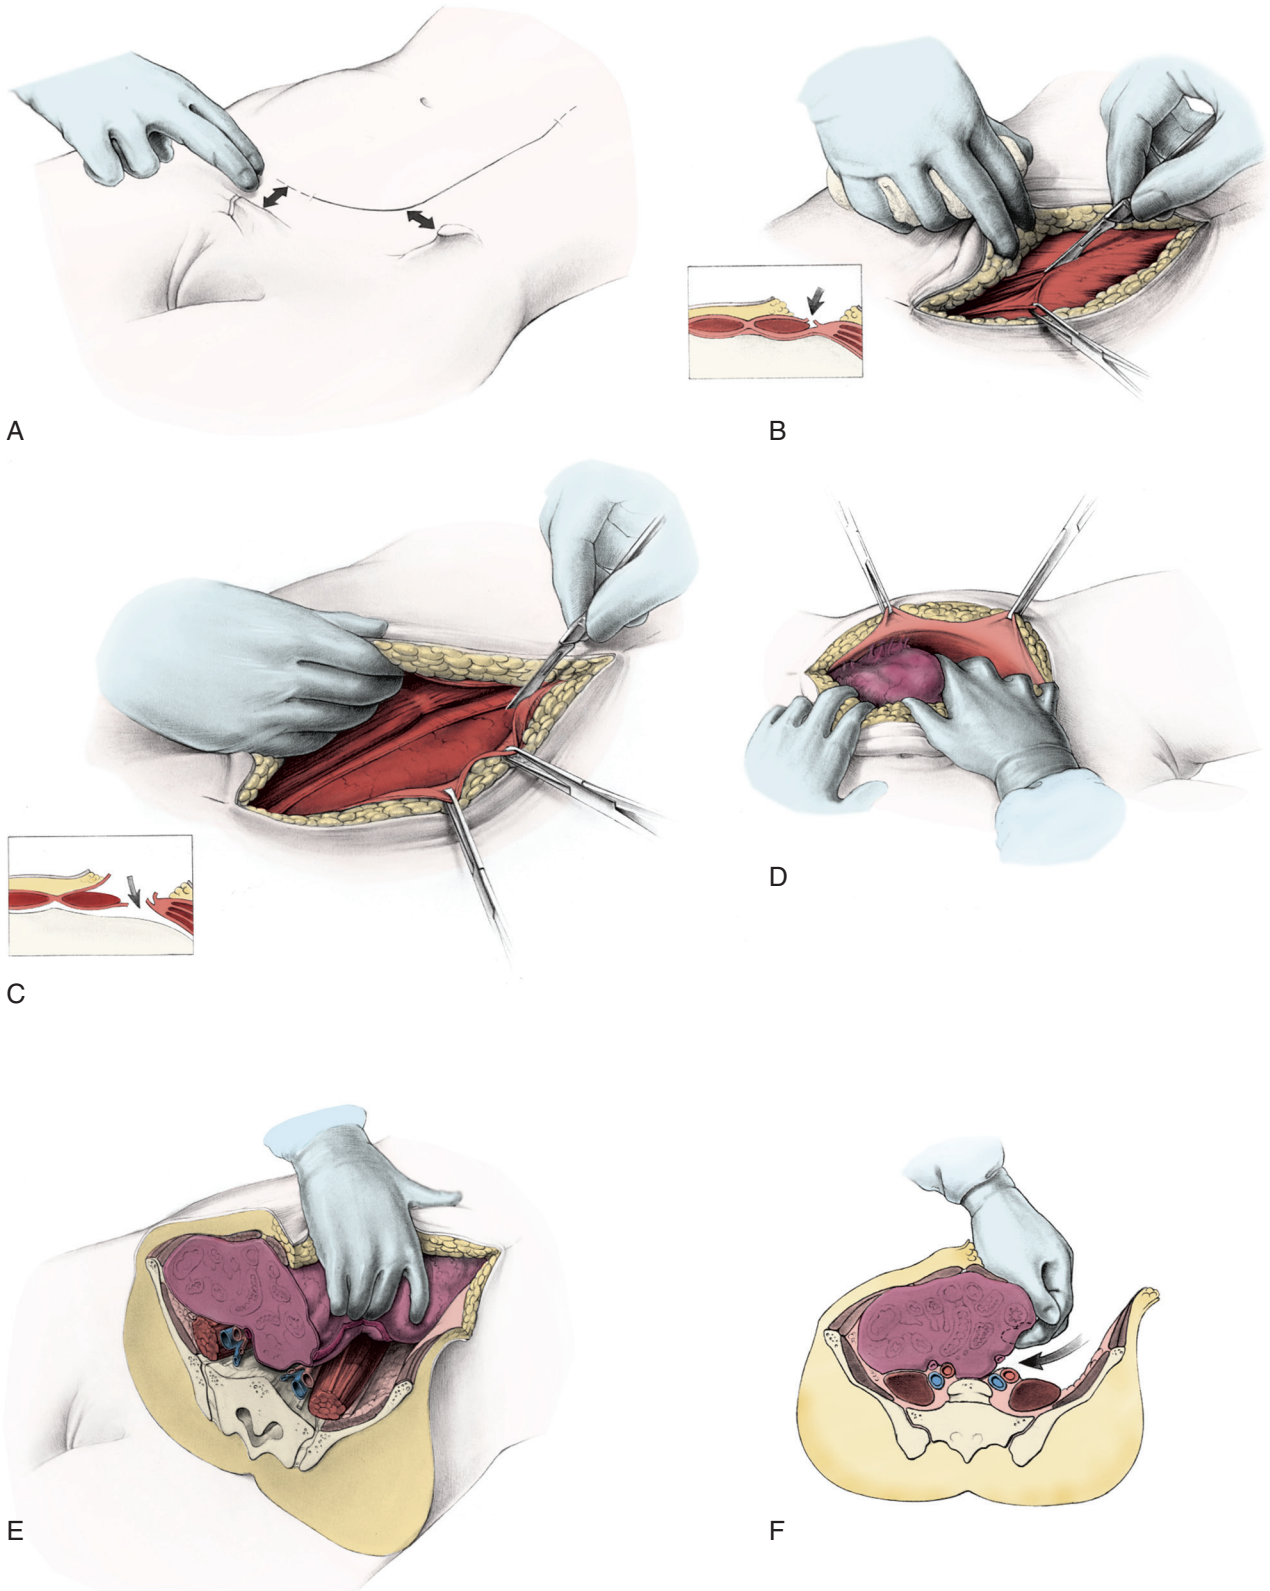

FIGURE 3.16 **A,** Path of incision. First measurement of 2 to 3 cm (two finger widths) above the pubic symphysis; second measurement 2 to 3 cm medial to the anterior superior iliac spine. A diagonal line connects these points. A vertical line is drawn superiorly to 3 to 4 cm above the level of the umbilicus. The incision begins at the lateral margin of the rectus muscle. **B,** Division of the external sheath of the rectus and a cross-section. After the initial incision through the skin, the lateral margin of the sheath is divided with a Bovie along the length of the muscle. On cross-section, an *arrow* points to the ideal point of separation. **C,** Division of the internal sheath of the rectus and a cross-section. The rectus muscle is mobilized medially. The internal sheath is divided carefully to preserve the underlying exposed peritoneum. **D,** Blunt dissection with a hand following the plane of the peritoneum and separating it from the transversalis fascia. **E,** Blunt dissection: perspective cross-section. Dissection along the peritoneum until contact is made with the left ureter. The ureter is preserved with the peritoneum and is mobilized medially as dissection continues. The psoas muscle and the common iliac vessels are exposed. **F,** A cross-section. Proper pathway of dissection along the peritoneum over the psoas.

Avoid damage to the inferior mesenteric artery. **H,** Lymphadenectomy begins along the left common iliac vessels. After medial and superior retraction of the mesentery and beginning about the bifurcation of internal and external iliac vessels, lymph nodes are removed along the length of the left common iliac to the junction with the aorta. **I,** Obturator nodes. Lateral mobilization of the external iliac vessels with a vein retractor. The obturator nerve is identified, and nodes are removed. **J,** The right common iliac. The right common and paraaortic lymph nodes are clipped and removed. The diagram shows deep access to the right common iliac nodes.

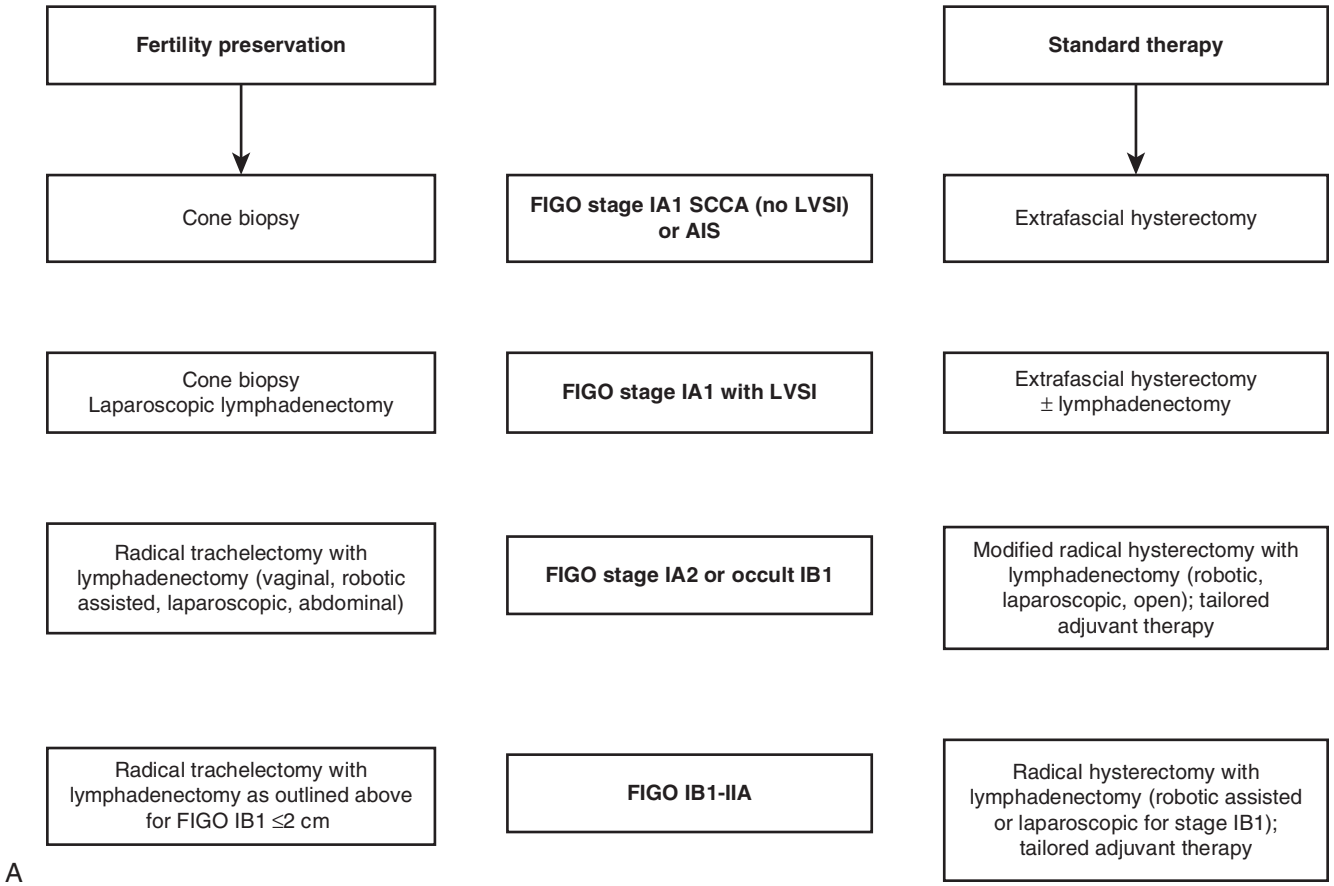

FIGURE 3.17 A and B, Algorithm for therapy.

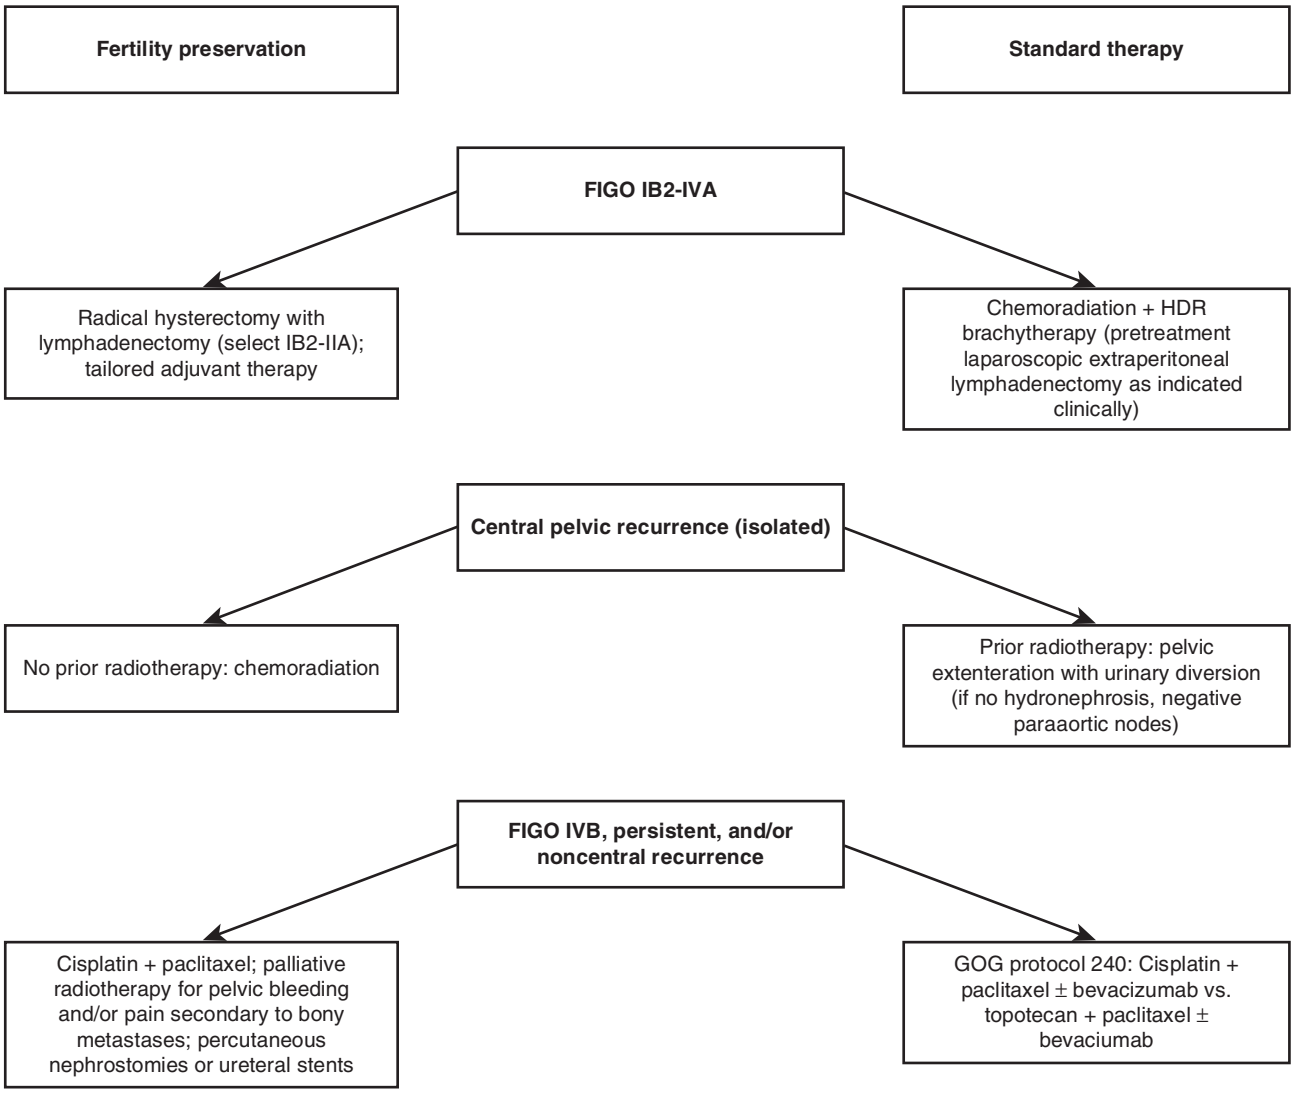

undergoing only surgery compared with those of patients undergoing adjuvant postoperative radiation. In fact, in 199 patients with lymph node involvement, the difference in survival rates of those undergoing only surgery and those undergoing additional postoperative radiation therapy was statistically insignificant.

Landoni and colleagues from the University of Milan conducted a prospective randomized trial in 243 patients comparing class II versus class III radical hysterectomy in stage IB to IIA cervical cancer. Although mean blood loss and transfusions were similar for both arms, mean operative time and late urologic morbidity were significantly lower in patients who underwent class II radical hysterectomy. The use of adjuvant radiotherapy was similar in both arms (54%, 55%). **The recurrence rate (24%, 26%) and overall disease-free survival (75%, 73%) was not significantly different between the arms.** Multivariate analysis confirmed that survival did not depend on the type of operation. This rare phase III surgical trial in early-stage cervical cancer has served as the platform from which our (non–phase III) experience in less radical surgery for early-stage disease is based (eg, radical trachelectomy and cervical conization for fertility preservation in the setting of invasive disease).

In general, in the early stages, comparable survival rates result from both treatment techniques. The advantage of radiotherapy is that it is applicable to almost all patients, but radical surgery of necessity excludes certain patients who are medically inoperable. The possible occurrence of immediate serious morbidity must be kept in mind when this treatment plan is selected. In many institutions, surgery for stage I and stage IIa disease is reserved for young patients in whom preservation of ovarian function is desired and improved vaginal preservation is expected. The modern operative mortality rate and the postoperative ureterovaginal fistula rate both have been reported to be less than 1%, making an objective decision for therapy even more difficult. Other reasons given for the selection of radical surgery over radiation include cervical cancer in pregnancy, concomitant inflammatory disease of the bowel, previous irradiation therapy for other disease, presence of pelvic inflammatory disease or an adnexal neoplasm along with the malignancy, and patient preference. Among the disadvantages of radiation therapy, one must consider the permanent injury to the tissues of the normal organ bed of the neoplasm and the possibility of second malignancies developing in this bed.

Radical Abdominal Hysterectomy With Lymphadenectomy

The use of radical hysterectomy in the United States was initiated by Joe V. Meigs at Harvard University in 1944, and shortly thereafter, the radical hysterectomy with pelvic lymphadenopathy was adopted by many clinics in the United States because of dissatisfaction with the limitations of radiotherapy. Some had found that many lesions were not radiosensitive, and some

B

FIGURE 3.17, cont'd

patients had metastatic disease in regional lymph nodes that were alleged to be radioresistant. Radiation injuries had been reported, and one of the overriding points in favor of surgery was that gynecologists were surgeons rather than radiotherapists and thus felt more comfortable with this treatment. At the time of the popularization of this procedure, modern techniques of surgery, anesthesia, antibiotics, and electrolyte balance had emerged, reducing the enormous morbidity that once attended major operative procedures in the abdomen.

Radical hysterectomy is a procedure that must be performed by a skilled technician with sufficient experience to make the morbidity acceptable (1%–5%). The procedure involves removal of the uterus, the upper 25% of the vagina, the entire uterosacral and uterovesical ligaments (Fig. 3.18), and all of the parametrium on each side, along with pelvic node dissection encompassing the four major pelvic lymph node chains: ureteral, obturator, hypogastric, and iliac. Metastatic lesions to the ovaries are rare, and preservation of these structures is acceptable, especially in young women with small lesions. The procedure is complex because the tissues removed are in close proximity to many vital structures such as the bowel, bladder, ureters (Figs. 3.19 and 3.20), and great vessels of the pelvis. The object of the dissection is to preserve the bladder, rectum, and ureters without injury but to remove as much of the remaining tissue of the pelvis as is feasible.

There is no doubt that in stage I and in the more restricted stage II cases, surgical removal of the disease is feasible. The addition of pelvic lymphadenectomy to the operative procedure caused considerable controversy in the early part of the century. Wertheim removed nodes only if they were enlarged and then not systematically. He believed that when accessible regional nodes were involved, the inaccessible distant nodes were also involved, and removal of suspicious nodes was more for prognostic than therapeutic value. He thought that node involvement was a measure of the lethal quality of the tumor and not merely a mechanical extension of the disease. The operative procedure popularized by Meigs included meticulous pelvic lymphadenectomy. Meigs demonstrated a 42% 5-year survival rate in another series of patients with positive nodes. Lymphadenectomy is now an established part of the operative

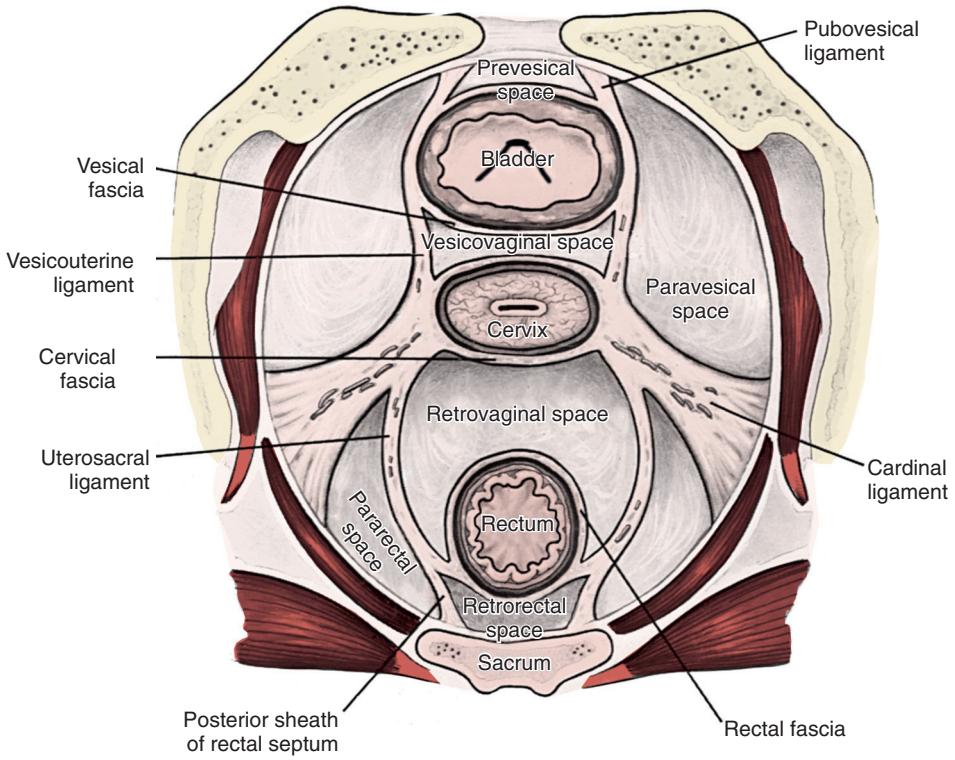

FIGURE 3.18 Cross-section of the pelvis at the level of the cervix.

procedure for any patient with disease greater than stage Ia1. There has been some interest in combining a radical vaginal operation with a retroperitoneal lymphadenectomy, and the results reported by Mitra, Navratil and Kastner, and McCall are surprisingly good. The survival rate in patients with negative nodes is usually in the range of 90% or more.

Rutledge and colleagues devised a system of rating radicality of hysterectomy (Table 3.9) used in treating women with cervical cancer at the MD Anderson Hospital. He suggested that the term "radical hysterectomy" is not adequate to record and communicate the different amounts of therapy attempted and the subsequent risk of complications when different surgeons report their results. These authors believed that describing the technical features of five operations enabled them to evaluate more accurately their results and provided a better understanding of the need to tailor each patient's treatment by using an operation that was adequate but not excessive.

The goal of the class I hysterectomy was to ensure removal of all cervical tissue. Reflection and retraction of the ureters laterally without actual dissection from the ureteral bed allows one to clamp the adjacent paracervical tissue without cutting into the side of the cervical tissue itself. Class I operations are advocated primarily for in situ and true microinvasive carcinomas of the cervix. A class I procedure is also performed after preoperative radiation in adenocarcinoma of the cervix or after preoperative radiation in the so-called barrel-shaped endocervical SCC. The operation described is essentially the extrafascial hysterectomy used routinely at the MD Anderson Hospital.

TABLE 3.9 Rutledge's Classification of Extended Hysterectomy

Class	Description	Indication
I	Extrafascial hysterectomy; pubocervical ligament is incised, allowing lateral deflection of the ureter	CIN, early stromal invasion
II	Removal of the medial half of the cardinal and uterosacral ligaments; upper third of the vagina removed	Microcarcinoma postirradiation
III	Removal of the entire cardinal and uterosacral ligaments; upper third of the vagina removed	Stages Ib and IIa lesions
IV	Removal of all periureteral tissue, superior vesical artery, and three fourths of the vagina when preservation of the bladder is still possible	Anteriorly occurring central recurrences
V	Removal of portions of the distal ureter and bladder	Central recurrent cancer involving portions of the distal ureter or bladder

CIN, Cervical intraepithelial neoplasia.

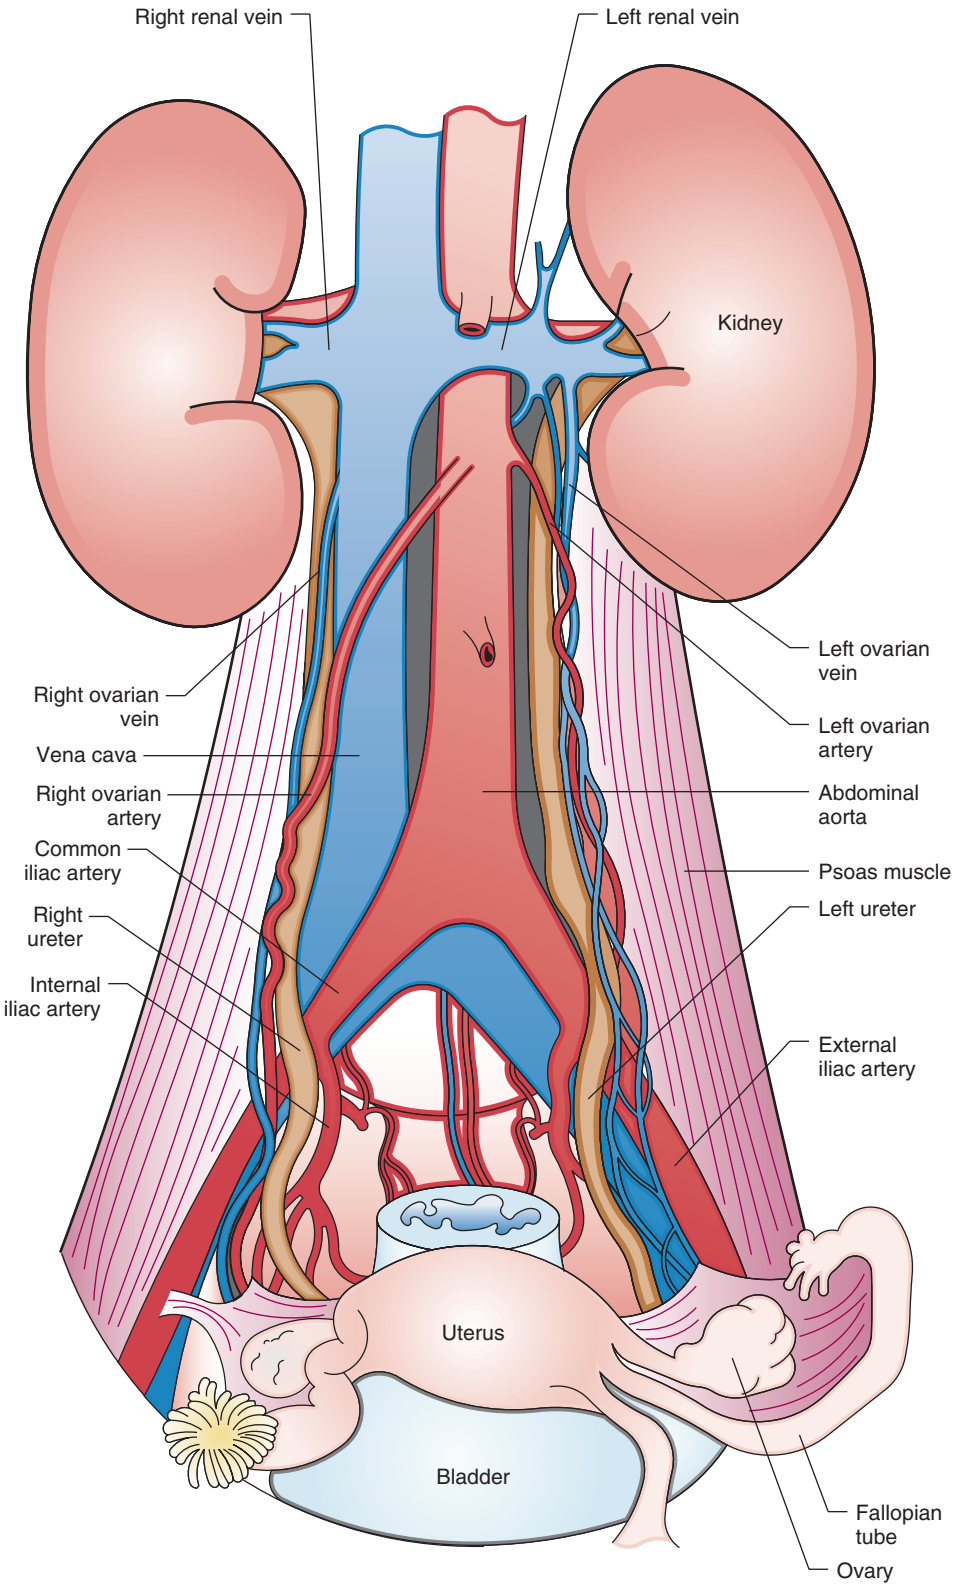

FIGURE 3.19 The retroperitoneal anatomy of the pelvis and lower abdomen illustrating the course of the ureters.

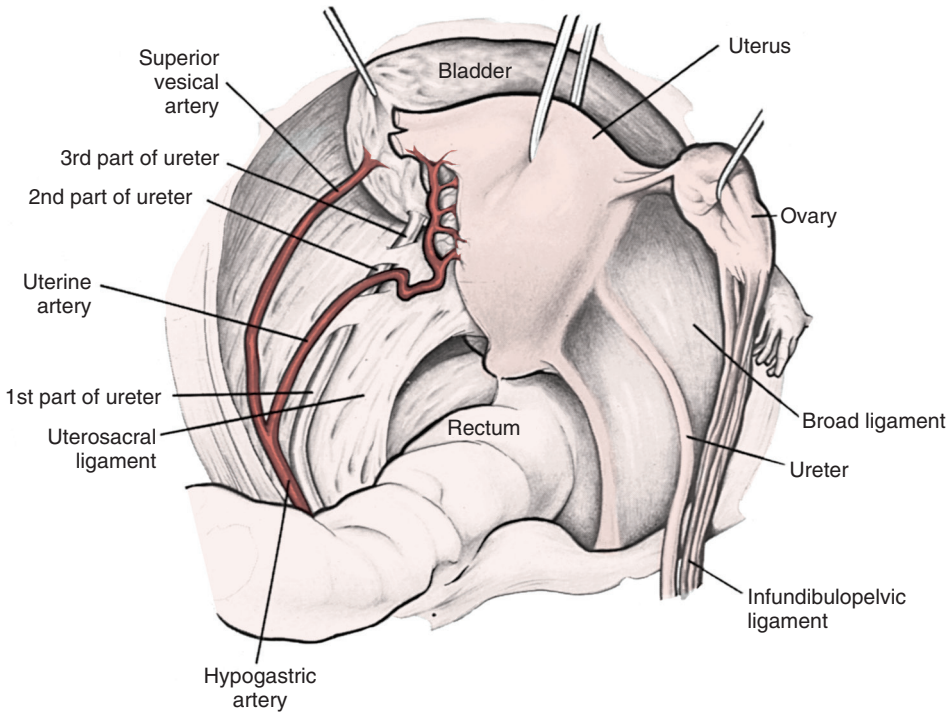

FIGURE 3.20 Relationship of the ureter to the uterosacral ligaments, uterine artery, infundibulopelvic ligament, and uterus.

Class II extended hysterectomy is described as a modified radical hysterectomy. **The purpose of the class II hysterectomy is to remove more paracervical tissue** (Fig. 3.21) **while still preserving most of the blood supply to the distal ureters and bladder.** The ureters are freed from their paracervical position but are not dissected out of the pubovesical ligament. The uterine artery is ligated just medial to the ureter as it lies in "the tunnel," ensuring preservation of the distal ureteral supply. The uterosacral ligaments are transected midway between the uterus and their sacral attachments (Fig. 3.22). The medial halves of both cardinal ligaments are removed, as is the upper 25% of the vagina. A pelvic lymphadenectomy is usually performed with a class II hysterectomy. A class II operation is reported to be suitable for the following conditions:

1. Microinvasive carcinomas in which the depth of invasion is considered greater than early stromal invasion
2. Small postirradiation recurrences limited to the cervix.

The class III procedure is a wide radical excision of the parametrial and paravaginal tissues in addition to the removal of the pelvic lymphatic tissue. The uterine artery is ligated at its origin on the internal iliac artery. In the dissection of the ureter from the pubovesical ligament (between the lower end of the ureter and the superior vesical artery), care is taken to preserve the ligament, maintaining some additional blood supply to the distal ureter. The hazard of fistula formation is decreased by preservation of the superior vesical artery along with a portion of the associated pubovesical ligament. The uterosacral ligaments are resected at the pelvic sidewall. The upper 25% of the vagina is removed (Fig. 3.23), and a pelvic lymphadenectomy is routinely performed. This operation is primarily for patients with stage I or IIa carcinoma of the cervix with or without preservation of ovarian function.

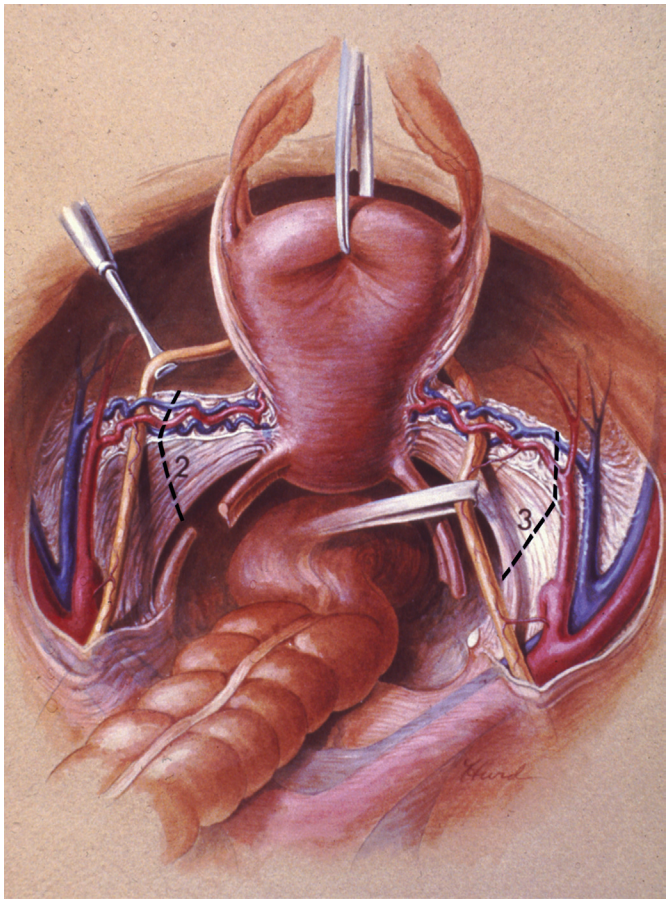

FIGURE 3.21 *Broken lines* identify the point of transection of the cardinal ligaments in class II and class III radical hysterectomy. (Courtesy of Gregorio Delgado, MD.)

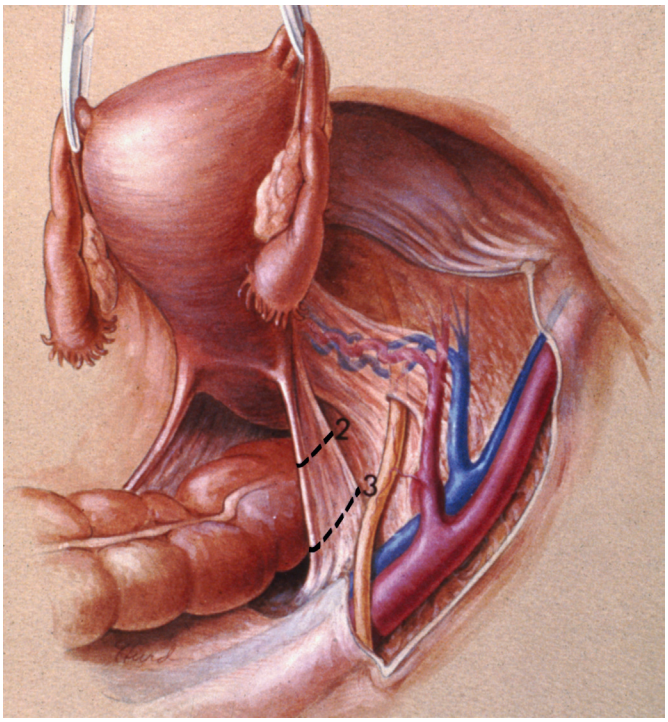

FIGURE 3.22 *Broken lines* identify the point of transection of the uterosacral ligaments in class II and class III radical hysterectomy. (Courtesy of Gregorio Delgado, MD.)

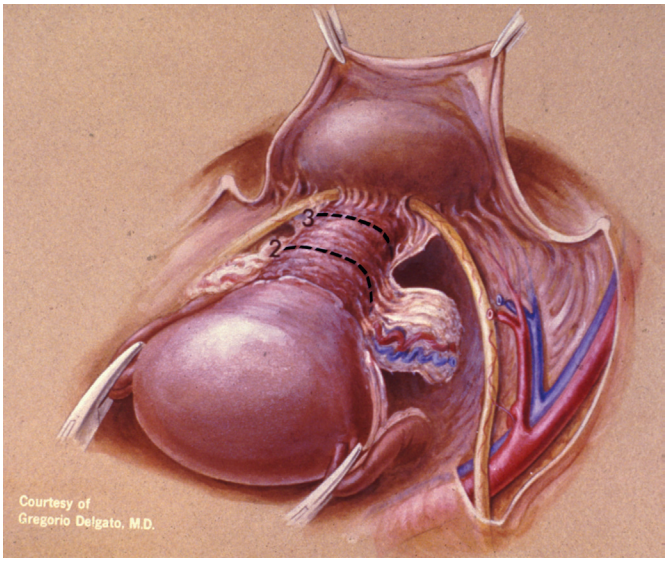

FIGURE 3.23 *Broken lines* illustrate the level of vaginal removal of class II and class III radical hysterectomy. (Courtesy of Gregorio Delgado, MD.)

The aim of the class IV radical hysterectomy is complete removal of all periureteral tissue; a more extensive excision of the paravaginal tissues; and, when indicated, excision of the internal iliac vessels along an involved portion of the medial pelvic wall tissue. This differs from the class III operation in three respects:

1. The ureter is completely dissected from the pubovesical ligament
2. The superior vesical artery is sacrificed
3. 50% of the vagina is removed.

This procedure is used primarily for more extensive anteriorly occurring central recurrences when preservation of the bladder is seemingly still possible. Extension of the dissection laterally is needed when the disease has focally involved the medial parametrium. Sacrificing blood vessels to the bladder is unfavorable because the risk of fistula formation increases significantly. In most cases, these patients are more appropriately treated with an anterior exenteration.

The purpose of the class V hysterectomy is to remove a central recurrent cancer involving portions of the distal ureter or bladder. It differs from a class IV operation because the disease involves a portion of the distal ureter, bladder, or both, which is removed with the disease. A reimplantation of the ureter into the bladder, often as a ureteroneocystostomy, is then performed. This procedure has a rare application to a small, specifically located recurrence when exenteration is considered unnecessary or has been refused by the patient.

The modified Rutledge classification of extended hysterectomies has considerable practical value. It again underlines the necessity for the surgeon to tailor the operative procedure to the disease extent. A stage Ia2 lesion does not need an operative procedure that is as radical as the procedure for a large IIa lesion. This is particularly pertinent in the decision between a class II and class III radical hysterectomy. In many countries, the class II radical hysterectomy (called a modified radical hysterectomy) is combined with a bilateral pelvic lymphadenectomy as standard therapy for early-stage cervical cancer. Indeed, the class III type of radical hysterectomy is a phenomenon of particular prevalence in the Western hemisphere and Asia because of the dual influences of Meigs and Okabayashi. The class III, or Meigs–Okabayashi procedure, is a derivative of the Halstedian principle that a lesion should be removed en bloc with its draining lymphatics; thus, the class III radical hysterectomy calls for removal of all the parametria at the pelvic sidewall and transection of the uterosacral ligaments at the sacrum. Advocates of the modified radical hysterectomy or class II procedure with pelvic lymphadenectomy for stages I and IIa lesions suggest that the intervening lymphatics are not at risk in an early cancer of the cervix. Indeed, spread from the primary lesion to the draining pelvic wall nodes probably occurs as an embolic phenomenon. One virtually never finds a tumor in lymphatics except surrounding the primary lesions. However, it is prudent for the pathologist to take several sections of the most distal portion of the parametria following a class III radical hysterectomy for stage I or IIa cervical cancer in an effort to determine the presence or absence of malignant cells in lymphatics distant from the primary lesion. In the presence of a bulky central lesion, the need for an adequate surgical margin of resection often mandates a more extensive procedure than the typical class II radical hysterectomy. However, preservation of any portion of the lateral parametria appears to be associated with a greatly diminished incidence of bladder atony. Forney reported on 22 women extensively studied after undergoing radical hysterectomy; in 11 women, the cardinal ligaments had been divided completely, and in the other 11, the inferior 1 to

2 cm of these ligaments had been spared. Satisfactory voiding occurred significantly earlier (20 vs. 51 days) in women who had undergone an incomplete transection. In a similar manner, preservation of a portion of the uterosacral ligaments appears to be associated with fewer complaints of postoperative obstipation. Undoubtedly, the preserved tissue contains intact nerve tracts, which avoid the extensive denervation associated with the typical class III type or radical hysterectomy.

Complications

Acute complications of radical hysterectomy include pelvic hemorrhage, urinary tract injury, injury to the genitofemoral or obturator nerves, deep venous thrombosis (DVT), and pulmonary embolism. Although hemorrhage requiring transfusion of blood products is a risk of any radical hysterectomy, this complication may occur more frequently when this procedure is performed in obese patients. Soisson and colleagues reported on 43 women undergoing radical hysterectomy for early-stage cervical cancer. All patients had a body weight at least 25% greater than their ideal weight. Survival was not compromised, and the incidence of serious complications was not increased in obese patients compared with a control group. The operative technique is more difficult; the procedure lasts longer, and surgery is associated with greater blood loss.

Pulmonary embolism is the one complication most likely to cause death in the period surrounding the operative therapy of cervical cancer. This must be kept in mind at all times, and particular care must be exercised during and after surgery to avoid this devastating complication. The operative period is the most dangerous period for the formation of a thrombus in the leg or pelvic veins. Care should be taken to ensure that a constriction of veins in the leg does not occur during the operative procedure, and careful dissection of the pelvic veins should lead to minimal thrombus formation in those structures. Because of the risk of pulmonary embolism and DVT, prophylactic heparin or pneumatic compression boots (or both) are strongly recommended.

Chronic complications after radical hysterectomy include urinary dysfunction, lymphocyst formation, lymphedema, extensive abdominal scarring, fistula formation (vesicovaginal and rectovaginal), compromised sexual function, and loss of fertility. All of these complications are preventable, and the incidence is decreasing steadily (Table 3.10). With highly successful surgical treatment programs in place for early-stage disease, quality of life (QoL) among survivors becomes important.

TABLE 3.10 Complications of Radical Hysterectomy With Approximate Incidences

Complication	Patients (%)
Vesicovaginal fistula	1
Ureterovaginal fistula	2
Severe bladder atony	4
Bowel obstruction (requiring surgery)	1
Lymphocyst (requiring drainage)	3
Thrombophlebitis	2
Pulmonary embolus	1

The major complication after radical surgery for invasive cancer of the cervix is postoperative bladder dysfunction. Reports in the literature by Seski and Carenza and Nobili and Giacobini suggest that bladder dysfunction is a direct result of injury to the sensory and motor nerve supply to the detrusor muscle of the bladder. The more radical the surgery, the greater will be the extent of damage and the more likely postoperative bladder dysfunction will result.

This dysfunction is usually manifested in the patient by a loss of the sense of urgency to void and an inability to empty the bladder completely without the Credé maneuver. Although most patients learn to compensate for the sensory and motor loss and return to near-normal function, patients occasionally need to be taught intermittent self-catheterization, or long periods of constant bladder drainage may be necessary postoperatively. Sophisticated urodynamic studies have shown that a residual hypertonicity in the bladder detrusor muscle and urethral sphincter mechanism sometimes produces dysuria and stress incontinence. Treatment is symptomatic, with near-total recovery in most patients. Limitation of the extent and radicality of surgery, especially in patients with early lesions, can minimize this morbidity. Bandy and colleagues reported on the long-term effects on bladder function after radical hysterectomy (class III) with and without postoperative radiation. In his study, the necessity for bladder drainage of 30 or more days after surgery in 30% of patients was associated with significantly worse long-term residual and other bladder dysfunction. Adjunctive pelvic radiation was associated with significantly more contracted and unstable bladder. In a study reported from Greece of stage Ib cancers, 68 had a Rutledge type III, and 50 had a type II radical hysterectomy. Age, grade, bulky tumor, and lymph node metastasis were similar in the two groups. Postoperative radiation was given to 31% of type III and 64% of type II hysterectomies. Major complications, mainly voiding problems, were significantly more common in those treated with type III hysterectomy; however, the disease-free survival was better in the class III hysterectomy (86.5% vs. 76.5%, $P < 0.05$). This study would suggest type III surgery is better than type II plus radiation.

Ureteral fistulas are now infrequent (0%–3%), primarily as a result of the improvement in techniques, such as avoiding excessive damage to the structure itself and preserving alternate routes of blood supply. With respect to lymphocyst formation, two studies testing the hypothesis that avoiding reperitonealization of the pelvic peritoneum obviates the need for such drainage have been reported; both studies suggest that drainage is not necessary if the peritoneum is left open over the surgical site. Ligation of the lymphatics entering the obturator fossa under the external iliac vein helps reduce the flow of lymph into this area, where lymphocyst formation is prevalent. Lymphocysts, if present, rarely cause injury and are usually reabsorbed if given enough time. Choo and colleagues reported that cysts smaller than 4 to 5 cm usually resolve within 2 months and that only observation is necessary. Surgical intervention is necessary when there is some evidence of a significant ureteral

obstruction. During laparotomy, the surgeon should unroof the lymphocyst and prevent re-formation by suturing a tongue of omentum into the cavity (internal marsupialization). Percutaneous aspiration of the cyst, which is often associated with subsequent infection, should be used cautiously.

Preservation of ovarian function is often desirable for patients who must undergo a surgical procedure for invasive cancer of the cervix. Often, after a careful histologic examination of the operative specimen, including the pelvic lymph nodes, a postoperative recommendation for pelvic radiation is indicated. Standard pelvic placement of preserved ovaries will result in postirradiation ovarian failure; therefore, a procedure for transposition of the ovaries to an extrapelvic site (Fig. 3.24) has been devised. Shielding during postoperative pelvic irradiation is possible with the ovaries so placed. The ovaries receive some radiation but not usually enough to prevent continued steroid production. A word of caution has been interjected by Mann and others regarding the rare occurrence of occult metastases to the ovary in patients with adenocarcinoma of the cervix. The two largest studies suggest that the incidence is between 0.6% and 1.3%. Most patients with metastatic disease in the ovary are postmenopausal or have had gross adnexal pathology or positive pelvic lymph nodes. These guidelines can be helpful in identifying patients for whom preservation of ovarian tissue is unwise. The incidence of occult metastasis to the ovary from SCC of the cervix (stages I and IIa) is so rare that preservation of ovarian tissue does not carry the same concerns. Lateral ovarian transposition will be discussed further in the following section on fertility preservation.

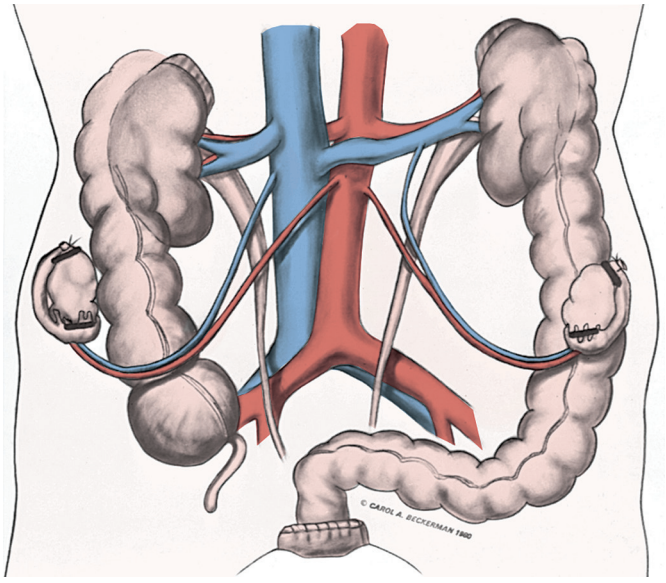

FIGURE 3.24 Diagram illustrating the location of transposed adnexae to a nonpelvic site where they can be spared from postoperative pelvic irradiation. (From DiSaia PJ. Surgical aspects of cervical carcinoma. *Cancer* 1981;48:548. Copyright 1981 American Cancer Society. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley.)

Indications for Postoperative Adjuvant Therapy

Table 3.11 contains data sets from two randomized studies that have established the role for adjuvant therapy after radical surgery based on intermediate and high-risk surgicopathologic factors. In a GOG study (protocol 92) of 277 patients with intermediate risk factors, stage Ib cancers were randomized to radical hysterectomy with or without postoperative irradiation. Of these patients, 137 were randomly assigned to radiation therapy, and 140 were not given further treatment. Based on a previous GOG study, intermediate risk was defined as greater than one-third of stromal invasion, lymph space involvement, and large clinical tumor diameter. (Note that the term *lymph space involvement* is used interchangeably with *vascular space involvement*.) All patients had negative lymph nodes. Four combinations of the risk factors were developed. Tumor size varied to greater than 4 cm. Although the two arms were equal with regard to the four combinations, in which group(s) the recurrences occurred is not stated. Using a one-tail test, there is a greater recurrence-free survival for the combined group (84.6% compared with 72.1%). OS was not significant; 11%

GOG-92 data from Sedlis A, Bundy BN, Rotman MZ, et al. A randomized trial of pelvic radiation therapy versus no further therapy in selected patients with stage IB carcinoma of the cervix after radical hysterectomy and pelvic lymphadenectomy: A Gynecologic Oncology Group Study. *Gynecol Oncol* 1999;73:177-183; GOG 109/SWOG 8797/RTOG 91-12 data from Peters WA 3rd, Liu PY, Barrett RJ 2nd et al. Concurrent chemotherapy and pelvic radiation therapy compared with pelvic radiation therapy alone as adjuvant therapy after radical surgery in high-risk early-stage cancer of the cervix. *J Clin Oncol* 2000;18:1606-1613.

died of cancer compared with 18% of the radical hysterectomy-only group. There was a 10% noncompliance rate in the radiation group. These authors are able to apply this information to clinical practice because more than 90% of patients would be treated without benefit with regard to survival. Data were presented with an intent-to-treat evaluation (see Table 3.11).

Patients with positive pelvic nodes usually receive postoperative whole-pelvis irradiation and chemotherapy (see Table 3.11). Peters and colleagues randomized 268 patients with FIGO stage Ia2, Ib, and IIa carcinoma of the cervix, initially treated with radical hysterectomy and pelvic lymphadenectomy and found to have positive pelvic lymph nodes or positive margins or microscopic involvement of the parametrium, to receive either pelvic radiation therapy alone or concurrent chemoirradiation. Among the 243 patients who were accessible, progression-free survival (PFS) and OS were significantly improved in the patients receiving chemotherapy. The projected PFS at 4 years was 63% with pelvic radiation therapy alone and 80% with concurrent chemoirradiation (HR, 2.01; $P = 0.003$). The projected OS rate at 4 years was 71% with pelvic radiation therapy alone and 81% with concurrent chemoirradiation (HR, 1.96; $P = 0.007$). The combined therapy arm had more frequent grade III and IV4 hematologic and gastrointestinal (GI) toxicity. **This landmark intergroup study of the GOG (protocol 109), the Southwest Oncology Group (protocol 8797), and the Radiation Therapy Oncology Group (protocol 91–12) was one of five randomized trials to be published between 1999 and 2000 attesting to the value of radiosensitizing chemotherapy in the management of cervical cancer (discussed further later).**

Prognostic factors have been evaluated by several authors in patients with early-stage disease who have been treated surgically. In a study by Francke and associates, 105 patients with stage Ib were treated with radical hysterectomy and had negative lymph nodes. Only LSI showed significant correlation with local failure. There were 32 patients with SCC and positive LSI, 17 received postoperative radiation with 0 of 17 recurrences, and 4 of 15 (27%) treated with surgery only developed recurrence. The OS rate at 5 years was 96% in those treated with radiation and 93.3% in those with LSI not treated with radiation. Stockler and colleagues evaluated 194 patients with stage Ib and IIa who were treated with radical hysterectomy and had negative nodes. Nuclear grade 2 or 3 ($P = 0.02$) and small cell squamous histology ($P = 0.001$) were each associated with a fourfold increase in risk of recurrence, but LSI ($P = 0.02$), age younger than 36 years ($P = 0.03$), and either tumor size greater than 28 mm ($P = 0.03$) or surgical clearance less than 5 mm ($P = 0.02$) was associated with a 2.5-fold increase in risk of recurrence. Survival data were not given. Delgado, in reporting a GOG study of 645 women with stage Ib squamous carcinoma, including 100 patients with positive nodes, found depth of invasion, tumor size, and lymph space involvement to be important risk factors for recurrence in multivariate analysis. The group from Boston evaluated 171 patients with lymph node–negative stage Ib and IIa cervical cancer treated primarily with surgery. A total of 116 (68%) patients were treated with surgery only, and 55 (32%) received radiation. Overall, 28 patients (16%) developed recurrent disease with no difference in the two treatment groups. After correction for other factors, patients with LSI who received radiation were less likely to develop recurrence than similar patients treated with surgery only ($P = 0.04$); however, OS was similar in the two groups. In a study from Gateshead, United Kingdom, 527 patients with stage Ib to IIb cervical cancer treated with radical hysterectomy were evaluated. There were 102 (19.3%) with lymph node metastasis. In those with lymph node metastasis, histologic differentiation ($P = 0.009$), and metastatic extent ($P = 0.045$) were the only independent prognostic factors for risk of cervical cancer deaths.

Shibata and colleagues evaluated adjuvant chemoradiation in 37 patients who had undergone radical hysterectomy with pelvic lymphadenectomy. In addition to accepted high-risk surgicopathologic criteria (eg, positive pelvic lymph nodes or positive surgical margins), the investigators also included the presence of lymphovascular space involvement (LVSI) as part of their inclusion criteria for protocol eligibility. Adjuvant chemotherapy consisted of cisplatin (70 mg/m^2 on day 1) and 5-fluoracil (5-FU) (700 mg/m^2/per day on days 1–4) every 4 weeks for a total of three cycles. Pelvic radiotherapy was started concurrently with the first cycle of chemotherapy and administered to a dose of 45 Gy in 25 fractions. The incidence of grade III/IV toxicities included neutropenia (24.3%), nausea and vomiting (8.1%), and diarrhea (18.9%). The 5-year PFS was 89.2%. Both the GOG and the Korean GOG have emphasized the importance of further improvement of outcomes of women found to have high-intermediate surgicopathologic risk factors (eg, large tumor diameter, deep stromal invasion, LVSI) after radical surgery for early-stage disease. A prospective, randomized trial involving adjuvant pelvic radiotherapy versus adjuvant single agent weekly cisplatin-based chemoradiation has recently been designed through collaboration of both cooperative groups.

The optimal adjuvant therapy for patients found to have high-risk surgicopathologic factors has not yet been determined. Specifically, the role of adjuvant chemotherapy in place of or in addition to adjuvant chemoradiation has been the subject of much debate. Takeshima and colleagues treated 65 consecutive patients with FIGO stage IB to IIA cervical carcinoma with adjuvant chemotherapy after radical hysterectomy and pelvic lymphadenectomy. Patients with intermediate-risk factors (stromal invasion >50%; $n = 30$) and those with high-risk factors (positive surgical margin, parametrial invasion, or lymph node involvement; $n = 35$) were treated with bleomycin, vincristine, mitomycin, and cisplatin (three cycles for intermediate-risk cases and five cycles for high-risk cases). Chemotherapy was well tolerated with no significant adverse effects and no cases of severe bleomycin-related pulmonary toxicity. The 5-year disease-free survival was 93.3% for the intermediate-risk group and 85.7% for the high-risk group. All patients with SCCs in the intermediate-risk group and 89.3% of high-risk patients with SCC remained disease free. Despite the absence of adjuvant pelvic radiotherapy, local-regional recurrence occurred in 3.3% of the intermediate-risk group and in 8.6% of the high-risk group. A randomized trial comparing adjuvant chemoradiation

with and without continued systemic "consolidation" platinum-based and taxane-based chemotherapy is being considered by the GOG for patients found to have high-risk surgicopathologic factors after radical surgery.

To summarize, the recommendation for postoperative adjuvant therapy (pelvic radiotherapy with or without radiosensitizing chemotherapy) after radical hysterectomy is based on high-intermediate risk surgicopathologic factors (ie, tumor diameter, depth of stromal invasion, and presence of LVSI) and high-risk surgicopathologic factors (ie, presence of tumor at the vaginal margin, in the parametria, or in the lymph nodes). The major research questions center around limiting the toxicity of chemoradiation, continued intravenous systemic therapy, and the triage of patients with locally advanced resectable lesions (ie, IB2-IIA) to primary chemoradiation versus potentially trimodality therapy (ie, radical surgery followed by adjuvant chemoradiation).

Sexual Function

The subject of sexual function after therapy for cervical cancer is often ignored. Many patients never regain pretreatment sexual function. Patients treated with full pelvic irradiation therapy (ie, external-beam and vaginal brachytherapy) experience decreased sexual function resulting from vaginal stricture formation with obliteration and premature ovarian failure (see forthcoming discussion). Andersen studied the sexual behavior, the level of sexual responsiveness, and the presence of sexual dysfunction of 41 women with uterine cancer compared with a matched group of healthy women. The two groups were similar until the onset of signs of disease, which sometimes occurred long before diagnosis, at which time the patients with cancer began experiencing significant sexual dysfunction. Sexual morbidity therefore begins actually in the prediagnosis period for many patients. Seibel reported on 46 patients who were interviewed more than 1 year after treatment for carcinoma of the cervix to establish the effects of radiation therapy and of surgical therapy on sexual feelings and performance. The patients who were irradiated experienced statistically significant decreases in sexual enjoyment, opportunity, and sexual dreams. The surgically treated group had no significant change in sexual function after treatment. Both groups experienced a change in self-image but did not believe that their partners or families viewed them differently. Myths about cancer and the actual effects of pelvic irradiation were found to have disrupted the sexual marital relationships of many women. Therapeutic programs with counseling and vaginal rehabilitation with the use of estrogen vaginal creams and possibly the use of dilators may be beneficial. Although radical hysterectomy offers an enhanced functional outcome, the procedure does not always leave sexual function undisturbed, with orgasmic problems and dyspareunia resulting from reduced vaginal size having been reported.

Nerve-Sparing Radical Hysterectomy

Lin and colleagues evaluated urodynamic function in 20 women with cervical cancer who underwent radical hysterectomy. Urodynamic parameters measured preoperatively and postoperatively included bladder voiding and bladder storage functions, both of which were found to be significantly impaired in all 20 cases after surgery. **Surgical damage to the pelvic autonomic nerves is likely to be responsible for not only subsequent impaired bladder function but also in defecation problems and sexual dysfunction.** The development of a nerve-sparing procedure that does not compromise the radicality of the operation is highly desirable.

Trimbos and colleagues introduced elements of the Japanese nerve-sparing technique in their Dutch population, citing that in various Japanese oncology centers, it had been recognized that the anatomy of the pelvic autonomic nerve plexus permits a systematic surgical approach to preserve these structures. The investigators first identified and preserved the hypogastric nerve in a loose tissue sheath underneath the ureter and lateral to the uterosacral ligament; next, the inferior hypogastric plexus in the parametrium is lateralized and avoided during parametrial transection; finally, the most distal part of the inferior hypogastric plexus is preserved during the dissection of the posterior part of the vesicouterine ligament. Trimbos and colleagues concluded that the procedure is feasible and safe and deserves further consideration.

An updated series was presented by Maas and colleagues, who observed that the incidence of urinary dysfunction appears to be very low after nerve sparing. These findings have been supported by an Italian series of 23 patients reported by Raspagliesi and colleagues and by two recent Japanese papers for which urodynamic data were recorded for 27 patients. In the study by Sakuragi and colleagues, none of 22 patients for whom the nerve-sparing procedure was performed had urinary dysfunction, compared with three of the five patients for whom the procedure could not be performed.

Nerve-sparing radical hysterectomy is an attractive approach because of improved urogenital, anorectal, and sexual functions. The sympathetic fibers that innervate the uterus, vagina, urinary bladder, and rectum come from T11 to L2 and form the superior hypogastric plexus. The parasympathetic fibers come from S2 to S4 at the pelvic wall as the pelvic splanchnic nerve. These fibers merge and form the inferior hypogastric plexus and branch to innervate the uterus and the urinary bladder. Professor Fujii from the Kyoto University Gynecology Group has gone to great lengths to provide a step-by-step anatomic identification of the nerve-sparing radical hysterectomy (Table 3.12). The first step in the nerve-sparing procedure involves isolation and separation of the deep uterine vein from the pelvic splanchnic nerve (Fig. 3.25). This is then followed by isolation and separation of the hypogastric nerve. Ultimately, the bladder branch from the inferior hypogastric plexus is identified running parallel to the blood vessels in the paracolpium, and the uterine branch from the inferior hypogastric plexus is separated and divided (Fig. 3.26). This procedure can be accomplished only through meticulous division of the posterior leaf of the vesicouterine ligament. Through separation of the inferior vesical vein in this ligament, the bladder branch from the inferior hypogastric plexus can be identified and preserved.

van den Tillaart and colleagues evaluated the feasibility, safety, and local recurrence rate in 122 patients with FIGO stage

IA to IIA lesions and compared them with 124 patients who underwent non–nerve-sparing surgery. Unilateral or bilateral sparing of nerves was possible in 80% of cases in the nerve-sparing group. Operative time and blood loss were less in the nerve-sparing group, but the postoperative courses were similar. The local recurrence rates were not significantly different at 2 years of follow-up. Nerve-sparing surgery was not a significant prognostic factor for local recurrence in univariate and multivariate regression analyses. Neuronavigation systems and robotic-assisted nerve-sparing techniques continue to be under investigation along with the incorporation of the nerve-sparing procedure to radical trachelectomy for fertility preservation.

TABLE 3.12 Comparison of Nerve-Sparing Radical Hysterectomy With Traditional Radical Hysterectomy

	Nerve-Sparing Radical Hysterectomy	Traditional Radical Hysterectomy	*P* Value

Modified from Skret-Magierlo J, Naróg M, Kruczek A, et al. Radical hysterectomy during the transition period from traditional to nerve-sparing technique. *Gynecol Oncol* 2010;116:502-505.

From 2003 to 2005, Roh et al. randomly assigned 92 women with FIGO stage IA2 to IIA disease to conventional radical hysterectomy or nerve-sparing surgery. The patients were well-balanced in clinicopathologic characteristics, and among 86 patients included in final analysis, the frequency of long-term urinary symptoms was higher in the conventional surgery group, with significant deterioration of volume of residual urine and bladder compliance at 12 months. There were no significant differences observed in the 10-year disease-free survival between groups.

In 2009, Querleu and Morrow proposed a new classification system for radical hysterectomy that continues to gain acceptance, particularly in Europe. In this new scheme, four main categories are described according to the extent of removal of the paracervix, using only the ureter, internal iliac vessels, and pelvic wall as reliable landmarks. The new system also incorporates nerve-preservation techniques and paracervical lymphadenectomy in subcategory assignments. In class A, the cervix is removed completely with minimal removal of the paracervix; in class B, the paracervix is removed to the level of the ureter. In class C, the entire paracervix is removed at the pelvic sidewall, and class D describes various exenterative procedures. Class C1 allows for preservation of the autonomic nerves, class D1 includes removal of the vascular parietal system, and class D2 requires removal of muscle and fascia at the lateral pelvic wall.

Cibula et al. have approached the new classification scheme by Querleu and Morrow by developing it further into a

three-dimensional (3D) model using the standard anatomic landmarks for definition of resection margins in longitudinal and transverse dimensions. In their 2011 manuscript, figures included photographs of the resulting 3D anatomic template that presents the parametrial resection in three dimensions along with the nerve-sparing procedure. The investigators intent is to increase adoption of the new classification scheme within the oncologic community and to enhance harmonization of clinical practice as it pertains to radical hysterectomy.

Sentinel Lymph Node Identification

Although the risk of nodal metastases is low in women with small, early cancers (ie, FIGO Ia2 and Ib1 lesions), the need for bilateral pelvic lymphadenectomies must still be emphasized. Controversy has centered on the existence and ability to identify sentinel lymph nodes (SLNs) in cervical cancer. **The rationale for identifying an SLN in cervical cancer is to avoid full pelvic lymphadenectomies, which can result in lymphocyst formation and lower-extremity lymphedema, especially when adjuvant pelvic radiotherapy is given.** Two techniques for sentinel node identification are available. An injection is performed around the tumor using either a blue dye or an isotopic colloid. Ideally, the two techniques are used concomitantly in patients with early-stage lesions (Fig. 3.27).

Dargent and Enria reported the results on 70 consecutive patients. Failure in identification of the SLN occurred in 14 of the 139 attempted dissections. One SLN was detected in 121 dissections, and two SLNs were detected in four dissections. The investigators carried out a systematic pelvic lymphadenectomy after removal of the SN. A metastatic involvement of the SLN was put in evidence in 19 of the 129 retrieved SLNs. The other regional lymph nodes were involved in 13 cases and not involved

in six cases. In the 110 cases in which the SLN was not involved, all of the other regional nodes were free from metastasis.

Table 3.13 contains studies on SLN detection in cervical cancer from 2007 to 2010. Most studies were performed with a combination of blue dye and a radioactive tracer with detection rates ranging from 87.3% to 100%. False-negative rates have ranged from 0% to 22.6%. Darlin and colleagues noted that the technique appears to be an accurate method for identifying lymph node metastases in cervical cancer patients with tumors that are 2 cm or smaller. The investigators recommend that in the case of a unilateral SLN only, a complete lymphadenectomy should be performed on the radionegative side. Although a randomized clinical trial to assess the equivalency of SLN mapping will not be feasible because a sample size of more than 1800 patients will be required to evaluate a decrease in recurrence rate from 15% to 10%, the GOG is prospectively studying the utility of lymphatic mapping and SLN identification in patients with early-stage cervical cancer (GOG protocol 206).

Laparoscopic Radical Hysterectomy With Lymphadenectomy

Advantages of minimally invasive surgery include magnification for improved visualization, decreased blood loss, shorter hospitalization, more rapid recovery to full function, less adhesion formation, improved cosmesis, and decreased wound complications (eg, infection, hernia formation). A type III Wertheim–Meigs radical hysterectomy with bilateral pelvic and aortocaval lymphadenectomies can be accomplished via operative laparoscopy and has been reported by several centers (Table 3.14, Fig. 3.28). Malzoni and colleagues published a series of 77 patients, 60 of whom underwent a class III operation and 17 who underwent a class II operation. The median body mass index (BMI) was 27 kg/m2 (range, 19–35 kg/m^2). Mean operative time was 186 minutes, median blood loss was 57 mL (range, 30–90 mL), and the median hospital stay was 4 days (range, 3–7 days). Chen and colleagues performed 290 laparoscopic radical hysterectomies with lymphadenectomy. The median blood loss was 230 mL (range, 50–1200 mL), and the mean operative time was 162 minutes (range, 110–350 minutes). Positive lymph nodes were detected in 27.1%, and surgical margins were clear in all patients. Postoperative complications occurred in 10.8% and included ureterovaginal fistula ($n = 5$), vesicovaginal fistula ($n = 4$), ureterostenosis ($n = 3$), DVT ($n = 9$), lymphocyst ($n = 4$), lymphedema ($n = 5$), and trocar insertion site metastasis ($n = 1$). Recurrent disease occurred in 16.3% ($n = 48$) at a median follow-up of 36.5 months.

Single-site laparoscopic surgery platforms have been developed and are being evaluated in gynecologic oncology centers.

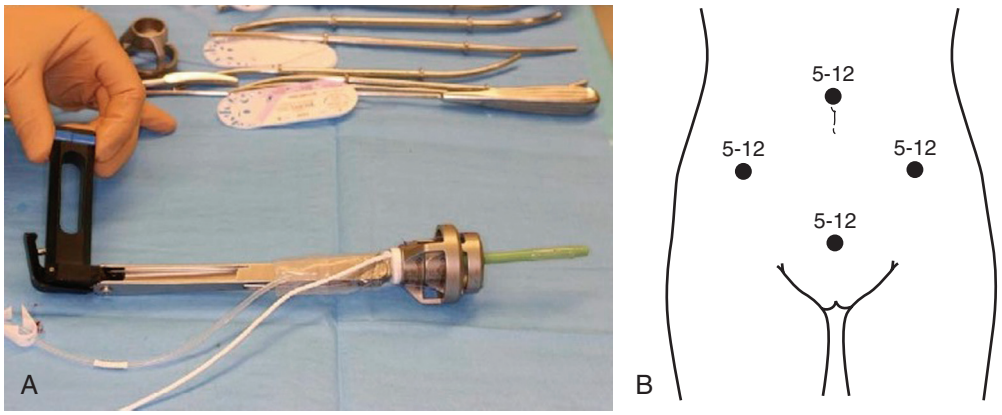

FIGURE 3.28 A, Laparoscopic radical hysterectomy. B, Placement of 5 mm to 12 mm laparoscopoic ports. 5-12, either 5 mm diameter ports up to 12 mm diameter ports. (A: From Frumovitz M, Ramirez PT. Total laparoscopic radical hysterectomy: surgical technique and instrumentation. *Gynecol Oncol* 2007;104(1 suppl):13-6. B: From Abu-Rustum NR, Gemignani ML, Moore K, et al. Total laparoscopic radical hysterectomy with pelvic lymphadenectomy using the argon-beam coagulator: pilot data and comparison to laparotomy. *Gynecol Oncol* 2003;91:402.)

Reports of this technique using the multichannel single-incision laparoscopic surgery port for laparoscopic cases or a single channel Gelport for robotic-assisted cases on the da Vinci Surgical System in the performance of radical hysterectomy with lymphadenectomy using articulating endoscopes and articulating instrumentation are forthcoming.

Robotic-Assisted Laparoscopic Radical Hysterectomy With Lymphadenectomy

Worldwide adoption of a minimally invasive surgical approach for radical hysterectomy with lymphadenectomy using standard laparoscopic techniques has been slow because of technical difficulties, long surgeon learning curve, and long operative time in many cases. The counterintuitive hand movements, two-dimensional visualization, and limited degrees of instrument motion within the body in addition to ergonomic difficulty and tremor amplification constitute additional obstacles. **The development of the robotic-assisted laparoscopic technique using the da Vinci Surgical System has allowed for high-definition 3D visualization, instruments that increase surgical accuracy by mimicking the complex movements of the human hand, enhanced dexterity with tremor abolition, and faster suturing** (Fig. 3.29). In both laboratory drills and in clinical settings, robotic-assisted laparoscopic techniques appear to require a shorter learning curve.

During the preceding 5 years, reports of robotic-assisted laparoscopic radical hysterectomy with lymphadenectomy has started appearing in the literature (Table 3.15). Maggioni and colleagues compared the surgical outcome of robotic radical hysterectomy ($n = 40$) with that of radical abdominal hysterectomy ($n = 40$ historic cases). The two groups did not differ significantly in BMI, stage, histology, or intraoperative complications. The median age did differ significantly (44 years in the robotic cohort vs. 49 years in the historic group; $P = 0.035$). The mean operative time was significantly shorter for the laparotomy group (mean, 200 minutes vs. 272 minutes; $P = 0.0001$), but the

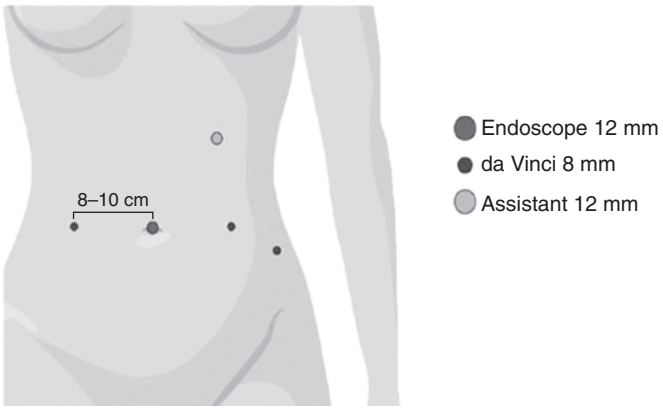

FIGURE 3.29 Robotic port placement (Da Vinci Surgical System). (From Shafer A, Boggess JF. Robotic-assisted endometrial cancer staging and radical hysterectomy with the da Vinci surgical system. *Gynecol Oncol* 2008;111(1 suppl):S18-23.)

mean blood loss was statistically significant in favor of the robotic group (78 mL vs. 222 mL; $P < 0.0001$). A higher number of pelvic lymph nodes was removed via laparotomy (mean, 26 nodes vs. 20 nodes; $P < 0.05$). The mean length of stay was significantly shorter for the robotic group. There were no significant differences in terms of postoperative complications between the two groups.

Finally, Cantrell and colleagues reported their 3-year experience involving 63 patients who underwent successful robotic-assisted laparoscopic type III radical hysterectomy. There was one intraoperative complication (asystole after induction) and two postoperative complications (intensive care unit admission for cardiac evaluation and reoperation for vaginal cuff dehiscence). Thirty-two percent of patients received adjuvant therapy. At a median follow-up period of 12.2 months, there has been recurrence and death of one patient, resulting in a 94% PFS and OS. These survival outcomes did not differ significantly from those of a historic cohort at the investigators' institution.

Robotic-assisted techniques for the management of early-stage cervical carcinoma appear to be feasible, but continued evaluation of oncologic outcomes and a cost–benefit analysis is still needed. Important complications that also require careful evaluation and scrutiny are those that may be specific to robotic techniques, including adverse effects associated with prolongation of steep Trendelenburg position, herniation at 8-mm port sites, vaginal cuff dehiscence, freezing of the robotic arms intraoperatively, and consequences of collisions. In addition, there has been a report of an 8-mm robotic port-site metastasis in a patient who underwent robotic-assisted laparoscopic radical hysterectomy and bilateral pelvic lymphadenectomy for a node-negative FIGO stage IB1 adenocarcinoma of the cervix.

A systematic review and meta-analysis of robotic radical hysterectomy for early-stage disease was recently performed by Shazly et al. Using MEDLINE, EMBASE, and SCOPUS from the time of database inception through February 2015, 26 nonrandomized studies enrolling 4013 women were identified. Robotic radical hysterectomy was associated with significantly less blood loss and blood transfusion, lower febrile morbidity, shorter hospital stay, and decreased wound-related complications compared with abdominal radical hysterectomy. Compared with laparoscopic radical hysterectomy, robotic radial hysterectomy was associated with comparable intra- and postoperative outcomes.

Fertility-Preserving Surgery for Early-Stage Tumors

For patients with microinvasive cervical carcinoma, management depends on the depth of invasion, and select patients may undergo conservative treatment with either cervical conization (FIGO Ia1) or radical trachelectomy with lymphadenectomy (FIGO Ia1 with LVSI, FIGO Ia2, and FIGO Ia adenocarcinoma) (see Fig. 3.17). In addition, patients with FIGO stage Ib lesions smaller than 2 cm with limited endocervical involvement and no pathologic evidence of lymph node metastases may be candidates for radical trachelectomy. In patients who are selected for conservative therapy, there should be no clinical evidence of impaired fertility and a strong desire for future childbearing. In addition, close surveillance should be instituted with scheduled Pap testing, colposcopic evaluation, and endocervical curettage.

Cervical Conization for Adenocarcinoma in Situ and Microinvasive Carcinoma

There has been a movement during the past decade to seriously explore fertility-sparing surgery for patients with adenocarcinoma in situ (AIS) and microinvasive carcinomas. **For many patients with AIS, local excision appears to be sufficient treatment provided ectocervical and endocervical margins are clear and patient compliance with follow-up is demonstrable.** It would appear that cold knife, CO_2 laser, and large loop excision of the transformation zone (LLETZ) conization procedures produce acceptable results; however, these approaches should be reserved for highly selected patients (Table 3.16). Patients with margin involvement should be considered for repeat excisional biopsy. A 2009 meta-analysis composed of 33 studies indicated a recurrence rate for AIS of 2.6% for negative margins and 19.4% for positive margins (odds ratio [OR], 2.48; 95% CI 1.05, 1.622; $P < 0.001$). Invasive adenocarcinoma was more commonly associated with positive margins (5.2%) compared with negative margins (0.1%).

In a study of 85 patients with FIGO stage IA1 SCC treated by electrosurgical conization and cold conization to preserve fertility, there was one recurrence (1.2%) at a median follow-up of 81 months. In a second report containing 75 patients with FIGO stage IA1 SCC, there were no recurrences among the 53 women who underwent conization followed by hysterectomy nor in the 22 who underwent conization alone. As in the case with AIS and microinvasive SCC, conservative fertility-preserving therapy may be considered for select cases of microinvasive adenocarcinoma, although this remains controversial. It would seem that for FIGO stage IA1 adenocarcinomas, conization is safe. When LVSI is present, laparoscopic pelvic lymphadenectomy seems advisable. In summary, for highly selected patients with early-stage disease seen in consultation with a gynecologic oncologist, cold knife cervical conization is a reasonable alternative to preserve fertility provided compliance with follow-up

is not problematic and pathology review has excluded highly aggressive histologic subtypes (eg, neuroendocrine tumors).

Vaginal Radical Trachelectomy With Laparoscopic Lymphadenectomy

Radical trachelectomy involves removing all or most of the cervix along with the bilateral parametria and upper vagina. This procedure allows for preservation of the uterus for childbearing and can be performed vaginally, abdominally, or through a minimally invasive approach (ie, straight-stick laparoscopy or robotic-assisted laparoscopy). Of note, patients with stage Ia2 disease have a 6.3% risk of nodal metastases, so treatment must include a formal pelvic lymphadenectomy.

In 1987, Dargent designed a fertility-preserving operation for stage Ia2 and some Ib1 lesions. A variant of the classical Shauta operation of vaginal radical hysterectomy, the vaginal radical trachelectomy (VRT) is performed in conjunction with bilateral laparoscopic lymphadenectomies. The VRT is performed with division of the uterus underneath the isthmus, and at the completion of the procedure, the uterus is sutured to the vagina. Oncologically, the technique is satisfying because a wide margin around the lesion is obtained containing the parametria and the upper vagina but leaving the body of the uterus in situ.

Plante and colleagues collected more than 600 reports of the vaginal technique from the past decade's literature, including 115 of her own. Oncologic outcomes have been satisfactory with an overall recurrence rate of 4.5% and death rate from disease of 2.5% (Table 3.17). Risk factors for recurrence include lesions 2 cm or larger (29% vs. 1%) and the presence of LVSI (12% vs. 2%). Adenocarcinomas and adenosquamous carcinomas are not clearly associated with an increased risk of recurrence. Patients with neuroendocrine tumors should probably not be offered fertility-sparing surgery. Approximately 10% to 12% of patients selected for VRT are found to have more extensive endocervical disease at the time of surgery or positive nodes on frozen section, leading to abandoning the procedure in favor of adjuvant therapy or completion radical hysterectomy.

Plante and colleagues also tabulated obstetric outcomes for 256 patients (Table 3.18). Approximately 62% of pregnancies after VRT will reach the third trimester, of which 65% will reach term. The preterm delivery rate is in the range of 28%, but only 12% will end with significant prematurity (<32 weeks) in which most neonatal morbidity occurs. Overall, 40% of all pregnancies can be expected to culminate with the birth of a healthy newborn at term.

From Plante M. Vaginal radical trachelectomy: an update. *Gynecol Oncol* 2008;111:S105-S110.

Abdominal approaches to radical trachelectomy may include nerve-sparing, laparoscopic, or robotic-assisted techniques. Potential benefits of the abdominal approach for radical trachelectomy include wider parametrial resection, possible lower intraoperative complication rates, and techniques familiar to most gynecologic oncologists (Fig. 3.30). Cibula and colleagues reviewed the more than 100 reported cases of abdominal radical trachelectomy (ART) in 2008 and then updated their own experience with the abdominal approach in 2009. Specific indications for the abdominal approach have included clear cell carcinoma of the upper vagina, clear cell cervical carcinoma in pediatric patients, cervical cancer in patients with distorted vaginal anatomy, cancer in the cervical stump after subtotal hysterectomy, bulky exophytic cervical cancer, extent and location of cervical cancer that requires increased radicality of parametrial resection (type III), and cervical cancer in the first half of pregnancy. In total, nine live births have been reported, of which at least two were premature deliveries.

Einstein and colleagues compared surgical and pathologic outcomes for 43 adult patients with FIGO stage IB1 lesions who

underwent VRT ($n = 28$) or ART ($n = 15$) (Table 3.19). The median measured parametrial length in the VRT group was 1.45 cm compared with 3.97 cm in the ART group ($P < 0.0001$). Parametrial nodes were only detected in the ART specimens ($n = 8$, 57.3%). There was no difference in histologic subtypes, LVSI, or median total regional lymph nodes removed in the two groups. Median blood loss was greater but not clinically significant in the ART group, and the median operating time was less in the ART group. The two groups did not differ significantly in the overall complication rate. The investigators concluded that the abdominal approach allows for wider parametrial resection, including contiguous parametrial nodes.

Minimally invasive approaches (ie, laparoscopic and robot assisted) to radical trachelectomy were recently studied retrospectively by Vieira et al. One hundred patients from four institutions were identified with early-stage disease and treated via an open approach ($n = 58$) or a minimally invasive approach ($n = 42$). There were no differences in clinicopathologic factors between the two groups, including BMI, histology, FIGO stage, or the presence of lymphovascular space invasion. Intraoperative and postoperative complications did not differ significantly between the two groups. Although the pregnancy rate was higher in the open surgery group (51% vs. 28% $P = 0.018$), the authors note that median follow-up was shorter in the minimally invasive surgery group (25 vs. 66 months). As expected, minimally invasive approaches were associated with less blood loss and shorter hospital stays.

By allowing for the preservation of the body of the uterus and thereby the potential for reproductive function, the radical trachelectomy emerges as a true breakthrough in the management of young women with early-stage cervical cancer (Fig. 3.31). It is currently the fertility-sparing procedure with the most available data supporting its use. Although these results are encouraging, there is lack of level I evidence (ie, randomized controlled trials [RCTs]) comparing safety and survival rates between conservative and radical methods. Therefore, these techniques should be used by fully trained operators. In our opinion, the technique can be considered in conjunction with laparoscopic transperitoneal lymphadenectomy in patients who strongly desire future fertility and harbor a stage Ia1 lesion with LVSI, an Ia2 lesion, or an Ib1 tumor less than 2 cm in diameter.

FIGURE 3.31 Abdominal radical trachelectomy. (From Einstein MH, Park KJ, Sonoda Y, et al. Radical vaginal versus abdominal trachelectomy for stage IB1 cervical cancer: a comparison of surgical and pathologic outcomes. *Gynecol Oncol* 2009;112: 73-77.)

For patients with FIGO stage IB tumors larger than 2 cm, VRT is not recommended because of unacceptable recurrence rates. There are no clear consensus guidelines regarding the safety of abdominal radical trachelectomy, laparoscopic radical trachelectomy, or robotic radical trachelectomy for such patients. One option is to administer neoadjuvant chemotherapy to reduce tumor size. In a recent literature review by Pareja et al., different approaches to radical trachelectomy were analyzed, and the outcome measures appear in the table below:

	ART >2 cm (%)	ART All Sizes (%)	NACT Followed by Surgery (%)	VRT (%)	VRT >2 cm (%)
Pregnancy	—	16.2	30.7	24	—
Recurrence	6	3.8	7.6	4.2	17

ART, Abdominal radical trachelectomy; *NACT,* neoadjuvant chemotherapy; *VRT,* vaginal radical trachelectomy.

Lateral Ovarian Transposition

As described previously, young patients with FIGO stage I to IIa cervical carcinoma who are considered to be at high risk for requiring adjuvant pelvic irradiation (with or without radiosensitizing chemotherapy) should have the ovaries transposed to the paracolic gutters at the time of radical abdominal hysterectomy. The infundibulopelvic ligament is mobilized, and two large metallic clips should be placed in an "X" formation across the mesosalpinges to assist in radiographic localization during radiation treatment planning. Patients with locally advanced carcinomas (ie, FIGO stage Ib2 to IVa) who will receive primary chemoirradiation can undergo lateral ovarian transposition via laparoscopy in anticipation of therapy.

The incidence of ovarian failure following transposition ranges from 28% to 50% when pelvic irradiation is used. There is a tendency to become postmenopausal if the scatter radiation dose at the transposed ovaries is greater than 300 cGy. This scatter radiation dose does not appear to depend on the distance the ovaries are placed from the linea innominata. The risk of premature ovarian failure when adjuvant radiation therapy is not required is approximately 5% in patients who have undergone lateral ovarian transposition. The risk of developing symptomatic ovarian cysts appears to be approximately 5%.

Husseinzadeh and colleagues performed lateral ovarian transposition in 22 patients with invasive cervical cancer, 15 of whom received whole pelvic external radiation therapy. Nine patients also received one or two intracavitary insertions. Ovarian function was measured by the serum gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). Five patients developed postmenopausal symptoms. Ovarian function was preserved in seven patients, all of whom received an average dose of 250 cGy to the ovaries via external radiation and intracavitary insertion(s). FSH values ranged from 3.3 to 38.8 mIU mL-1 (mean, 17.7 mIU mL-1).

TREATMENT OF LOCALLY ADVANCED DISEASE

Radiotherapy

Over the past century, radiotherapy has emerged as a notable alternative to radical surgery, primarily because of improvements in technique. The number of radiation-resistant lesions was discovered to be small, and skilled radiologists limit radiation injury, especially with the moderate dosages used for early disease. Much evidence has been presented that proves that radiotherapy can destroy disease in lymph nodes and in the primary lesion. Over the past 2 decades, radical hysterectomy has been reserved in many institutions for patients who are relatively young, lean, and in otherwise good health. In other areas of the United States, radiotherapy or surgery is used alone when the alternative modality is not available. The relative safety of both treatment modalities and the high curability for stages I and IIa lesions give physicians and patients a true option for therapy.

Radiotherapy for cancer of the cervix was begun in 1903 in New York by Margaret Cleaves. In 1913, Abbe was able to report an 8-year cure. The Stockholm method was established in 1914, the Paris method in 1919, and the Manchester method in 1938. Radium was the first element used; it has always been the most important element in radiotherapy of this lesion. External irradiation was used to treat the lymphatic drainage areas in the pelvis lateral to the cervix and the paracervical tissues.

Successful radiation therapy depends on the following:

1. Greater sensitivity of the cancer cell, compared with the cells of the normal tissue bed, to ionizing radiation
2. Greater ability of normal tissue to recuperate after irradiation
3. A patient in reasonably good physical condition.

The maximal effect of ionizing radiation on cancer is obtained in the presence of a good and intact circulation and adequate cellular oxygenation. Preparation of the patient for a radical course of irradiation therapy should be as careful as the preparation for radical surgery. The patient's general condition should be as well maintained as possible with a diet high in proteins, vitamins, and calories. Excessive blood loss should be controlled, and hemoglobin should be maintained well above 10 g.

Some consideration must be given to the tolerance of normal tissues of the pelvis, which are likely to receive relatively high doses during the course of treatment of cervical malignancy.

The vaginal mucosa in the area of the vault tolerates between 20,000 and 25,000 cGy. The rectovaginal septum is said to tolerate approximately 6000 cGy over 4 to 6 weeks without difficulty. **The bladder mucosa can accept a maximal dose of 7000 cGy. The colon and rectum will tolerate approximately 5000 to 6000 cGy, but small bowel loops are less tolerant and are said to accept a maximal dose of between 4000 and 4200 cGy.** This pertains to small bowel loops within the pelvis; the tolerance of the small bowel when the entire abdomen is irradiated is limited to 2500 cGy. One of the basic principles of radiotherapy is implied here: The normal tissue tolerance of any organ is inversely related to the volume of the organ receiving irradiation. External irradiation and intracavitary radium therapy must be used in various combinations (Table 3.20). Treatment plans must be tailored to each patient and her particular lesion. The size and distribution of the cancer, not the stage, should be treated. Success in curing cancer of the cervix depends on the ability of the therapy team to evaluate the lesion (and the geometry of the pelvis) during treatment and then make indicated changes in therapy as necessary. Intracavitary radium therapy is ideally suited to the treatment of early tumors because of the accessibility of the portio of the cervix and the cervical canal. It is possible to place radium or cesium in close proximity to the lesion and thus deliver surface doses that approximate 15,000 to 20,000 cGy. In addition, normal cervical and vaginal tissue has a particularly high tolerance to irradiation. One therefore has an ideal situation for the treatment of cancer because there are accessible lesions that lie in a bed of normal tissue (cervix and vagina) that is highly radioresistant.

TABLE 3.20 Suggested Therapy for Cervical Cancer

	Whole Pelvis		
Stage	**Radiation Dose (cGy)**	**Brachytherapy (mg/hr)**	**Surgery**
Ial true microinvasive	—	—	Extrafascial hysterectomy
Ia2	2000 (2000 parametrial)	8000 (two applications)	Radical hysterectomy with bilateral pelvic lymphadenectomy as an option
Ib	4000	6000 (two applications)	
IIb	4000–5000*	5000–6000 (two applications)	Consider pelvic exenteration for tumor persistence
IIIa	5000–6000*	2000–3000 or interstitial implant	—
IIIb	5000–6000*	4000 (one application), 5000 (two applications)†	—
IVa	6000	4000 (one application), 5000 (two applications)†	—
IVb	500–1000 pulse two to four times 1 wk apart	Palliative	—

*Patients with larger lesions or poor vaginal geometry merit the higher dose of external radiation.
†Two applications are suggested after whole-pelvis radiation with larger lesions or when the first application has less than optimum dosimetry.

Intensity-Modulated Whole Pelvic Radiotherapy

Traditional external-beam radiotherapy is based on field limits determined by bony landmarks, resulting in generous amounts of healthy tissue being encompassed by large treatment volumes. However, the margins of oncologic security are large, so target motion and the gross tumor volume (GTV) have a negligible impact. With increasing adoption of conformal treatment and attendant steep dose gradients, both the GTV and clinical target volume (CTV) must be precisely defined.

Using variable intensity across the face of the radiation beam to shape isodoses, (IMRT delivers a high tumor dose with minimization of radiation exposure to healthy tissue. Dosimetric advantages can be exploited using a combination of 3D planning and variable radiation intensity in each field. Reductions of both acute and chronic GI and genitourinary (GU) toxicity have been trumpeted among the dosimetric advantages of IMRT and some evidence suggesting that IMRT can spare bone marrow.

Uncertainty exists when considering IMRT for the management of locally advanced cervical cancer, including delineation of the required margins and what the acceptable degree of homogeneity is for the target. Importantly, given the large volume of hematopoietically active marrow in the pelvis and lower lumbar spine, in their review, Fernandez-Otz and Crook propose specific planning constraints be required, including use of a contouring atlas for pelvic volumes as currently used in current Radiation Therapy Oncology Group protocols (now part of NRG Oncology).

Radiation Therapy Oncology Group (RTOG) protocol 0418 established the current role of IMRT in gynecologic cancers to be relegated to the postoperative (ie, adjuvant) setting. The unacceptable toxicity of dose escalation to the pelvis and paraaortic regions using conventional radiotherapy has been prohibitive. However, with IMRT, simultaneous boosts to the target or affected lymph nodes results in an improvement of the therapeutic ratio and the added advantage of shortening the treatment time. Because of cervical-utero movement, the use of IMRT in the setting of the intact cervix requires continued investigation. RTOG protocols require a full bladder and empty rectum to minimize movement, but cervical tumor regression during treatment is also an issue, with a median volume reduction of 46% being reported in the literature. For this reason, Fernandez-Otz and Crook suggest that IMRT should be replanned during the final third of treatment to take advantage of the shrinking GTV.

Ly et al. developed dose-volume histograms of the target volume in a comparison of conventional radiotherapy, 3D conformal radiotherapy, and IMRT for cervical cancer. They reported that the planning target volume dose of the IMRT was significantly higher than the other two modalities and that when more than 30 Gy was administered in IMRT, organs at risk including the small intestine, rectum, bladder, and bone marrow received reduced volumes of radiations. To date, however, there are no head-to-head randomized phase III trials comparing IMRT with conventional radiotherapy in the primary treatment of locally advanced cervical cancer.

Radium and Cesium Therapy

Radium is the isotope that has been used traditionally in the treatment of cancer of the cervix. Its greatest value is that its half-life is approximately 1620 years; therefore, it provides a very stable, durable element for therapy. In recent years, both cesium and cobalt have been used for intracavitary therapy. Cesium has a half-life of 30 years; with the current technology, cesium provides an adequate substitute for radium. Four major technologies for the application of radium in the treatment of cervical cancer continue to be favored among gynecologists. Of these technologies, three are intracavitary techniques using specially designed applicators, and the fourth technique involves the application of radium in the form of needles directly into the tumor. The variations among the three techniques of intracavitary brachytherapy are found in the Stockholm, Paris, and Manchester schools of treatment (Fig. 3.32). The differences are mainly found in the number and length of time of applications, the size and placement of the vaginal colpostats, and radium loading. In the United States, the tendency has been to use fixed radium applicators with the intrauterine tandem and vaginal colpostats originally attached to each other. Over the past 3 decades, a flexible afterloading system, Fletcher-Suit, has gained increasing popularity because it provides flexibility and the safety of afterloading techniques.

The Paris method originally used a daily insertion of 66.66 mg of radium divided equally between the uterus and the vagina. The radium remained in place for 12 to 14 hours, and the period of treatment varied from 5 to 7 days. An essential feature of the Paris method, and a part of the modification of this technique, is the vaginal colpostat, which consists of two hollow corks that serve as radium containers joined together by a steel spring that separates them into the lateral vaginal wall.

The Stockholm technique uses a tandem in the uterine cavity surrounded by a square radium plaque applied to the vaginal wall and portio vaginalis of the cervix. No radium is placed in the lower cervical canal, and vaginal sources are used to cover the cervical lesion. The uterine tandem and vaginal plaque are immobilized by packing and left in place for 12 to 36 hours. Two or three identical applications are made at weekly intervals.

The Manchester system is designed to yield constant isodose patterns regardless of the size of the uterus and vagina. The source placed in the neighborhood of the cervical canal is considered the unit strength. The remaining sources in the corpus and vagina are applied as multiples of this unit and are selected and arranged to produce equivalent isodose curves in each case and an optimal dose at preselected points in the pelvis. The applicator is shaped to allow an isodose curve that delivers radiation to the cervix in a uniform amount. The Fletcher-Suit system (Fig. 3.33) previously mentioned is a variation of the Manchester technique.

An effort is made in the two radium insertions to administer approximately 7000 cGy to the paracervical tissues as the total of the dose from both external and intracavitary irradiation. The isodose distribution around a Manchester system is pear shaped (Fig. 3.34). The maximal total dose delivered by the two radium insertions is a function of the total dose to the bladder and rectum. The total dose received by the rectal mucosa from both radium applications usually ranges between 4000 and 6000 cGy. The nearest bladder mucosa may receive between 5000 and 7000 cGy. When whole-pelvis irradiation is used, the radium dose must be reduced to keep the total dose to the bladder and rectum within acceptable limits.

In conjunction with the development of a system of radium distribution, British workers have defined two anatomic areas of the parametria (see Fig. 3.34) where dose designation can be

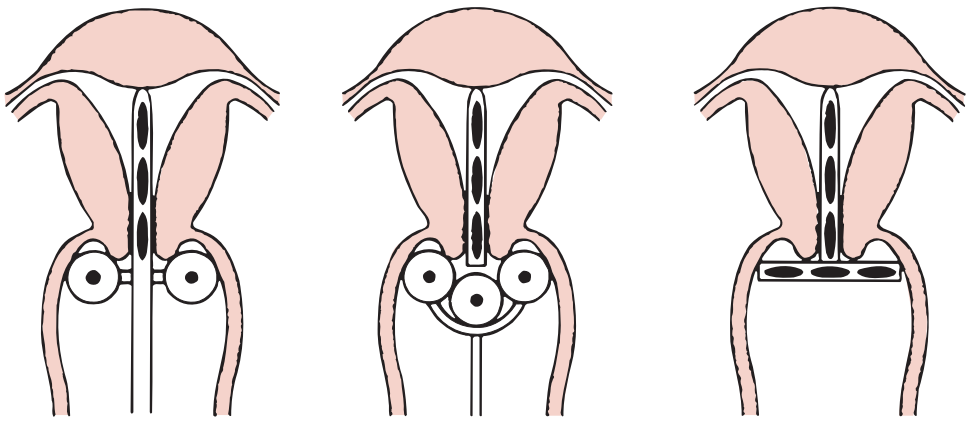

FIGURE 3.32 Three techniques of intracavitary brachytherapy.

FIGURE 3.33 Fletcher-Suit radium applicators: Ovoids and tandem with inserts.

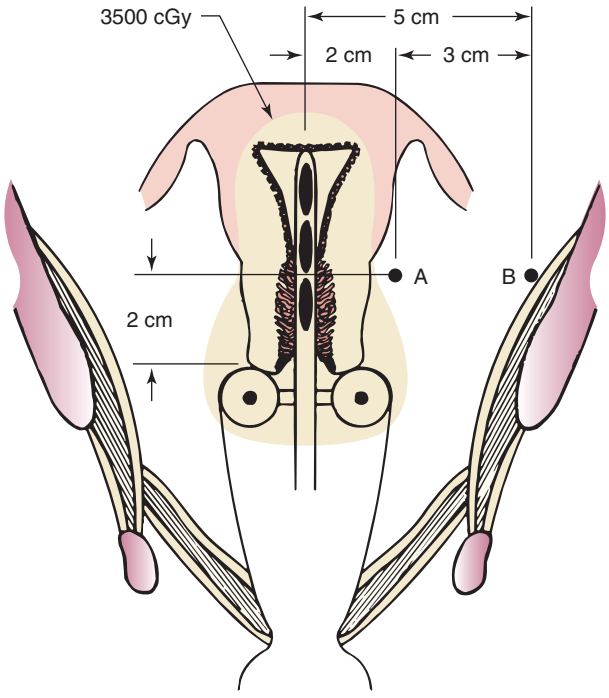

FIGURE 3.34 Pear-shaped distribution of radiation delivered to tissues surrounding a typical radium application with the Manchester type of applicators. Points *A* and *B* are noted as reference points.

correlated with clinical effect. These are situated in the proximal parametria adjacent to the cervix at the level of the internal os and in the distal parametria in the area of the iliac lymph nodes and are designated point A and point B. **The description states that point A is located 2 cm from the midline of the cervical canal and 2 m superior to the lateral vaginal fornix.** The dose at point A is representative of the dose to the paracervical triangle, which correlates well with the incidence of sequelae and with the 5-year control rate in many studies. **Point B is 3 cm lateral to point A.** This point, together with the tissue superior to it, is significant when considering the dose to the node-bearing tissue. It is clear from what has been said relative to points A and B that they can represent important points on a curve describing the dose gradient from the radium sources to the lateral pelvic wall. This gradient is different for the various techniques. In a comparison of the physical characteristics of radio techniques, the ratio of the dose at point A to the dose at point B should help define physical differences. In addition, determining the dose at point A relative to the calculated dose at points identified as bladder trigone and rectal mucosa provides a means of assessing the relative safety of one application over another. The concepts of points A and B have been questioned by many authors, including Fletcher and Rutledge. They remain as imaginary points but seem to provide a framework in which therapy is planned. Again, the distribution of the disease must be the primary guide in planning therapy, and the total dose to either point A or point B is relative only to their position with regard to the disease distribution.

Whole-pelvis irradiation is usually administered in conjunction with brachytherapy (eg, intracavitary radium or cesium) in a dose range of 4000 to 5000 cGy. Megavoltage machines such as cobalt, linear accelerators, and the betatron have the distinct advantage of giving greater homogeneity of dose to the pelvis. In addition, the hard, short rays of megavoltage pass through the skin without much absorption and cause very little injury, allowing almost unlimited amounts of radiation to be delivered to pelvic depths with little if any skin

irritation. Orthovoltage, because of its relatively long wavelength and low energy, has the disadvantage that doses to the skin are particularly high and, in delivering the required amount of radiation to the pelvis, may cause temporary and permanent skin changes. Thus, for pelvis irradiation, high-energy megavoltage equipment has definite advantages over orthovoltage and even low-energy megavoltage equipment.

Interstitial Therapy

In advanced carcinoma of the cervix, the associated obliteration of the fornices or contracture of the vagina may interfere with accurate placement of conventional intracavitary applicators. Poorly placed applicators fail to irradiate the lesion and the pelvis homogeneously. Syed and Feder have revived a solution to this problem by advocating transvaginal and transperineal implants. The technique uses a template to guide the insertion of a group of 18-gauge hollow steel needles into the parametria transperineally (Fig. 3.35). These hollow needles are subsequently "afterloaded" with iridium wires when the patient returns to her hospital room. Theoretically, this technique locates a pair of paravaginal interstitial colpostats in both parametria. This approach appears promising, but long-term studies illustrating an improved survival rate and reasonable morbidity are not available. Also, there is no report reflecting, prospectively, the effectiveness, in comparable groups of patients, of the interstitial technique versus the standard intracavitary approach.

Interstitial therapy may have particular value in the treatment of carcinoma of the cervical stump. Although carcinoma of the cervical stump has become a relatively rare disease, accounting for fewer than 1% of all gynecologic malignancies, it does create difficult problems in terms of optimal geometry for delivery of effective irradiation therapy. In some series of cervical cancer, the incidence of carcinoma of the cervical stump is approximately 10%. Prempree, Patanaphan, and Scott reported excellent results with absolute survival rates of 83.3% for stage I, 75% for stage IIa, and 62.5% for stage IIb using radiation therapy with an emphasis on parametrial interstitial implants in the more advanced diseases. Similar results have been obtained by Puthawala and associates.

Extended-Field Irradiation Therapy

Over the past 2 decades, attempts have been made to improve survival for more patients with advanced cervical cancer by identifying the presence of paraaortic lymph node metastases and applying extended-field irradiation to the area (Fig. 3.36). The en bloc pelvic and periaortic portals extend superiorly as far as the level of the dome of the diaphragm and inferiorly to the obturator foramen. **The width of the periaortic portion of the field is usually 8 to 10 cm, and the usual dose delivered is**

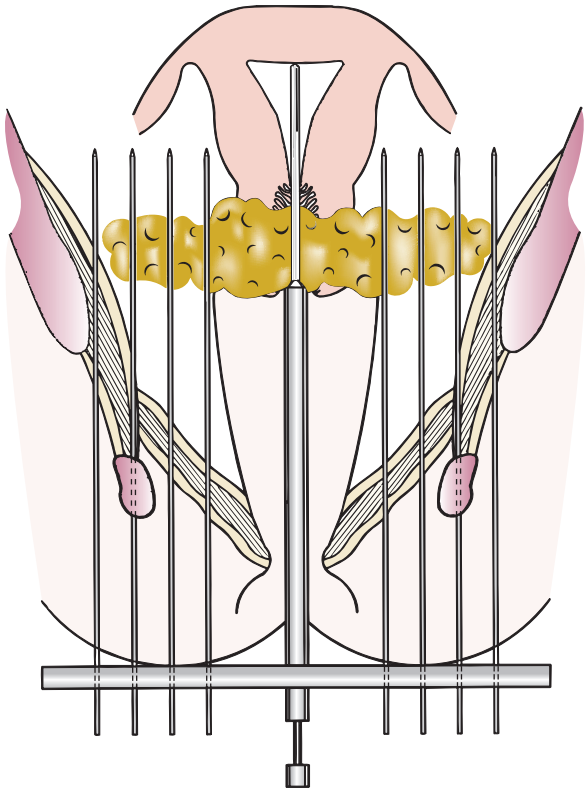

FIGURE 3.35 Diagram of the technique of interstitial therapy for advanced cervical cancer using a Syed-Noblett template.

Ureteral stricture	1

between 4000 and 5000 cGy in 4 to 6 weeks. A booster dose of 1000 cGy is often given to the pelvic field alone. Identification of paraaortic lymph node involvement was initially attempted by use of lymphangiography, but this technique did not find general acceptance because of varied accuracy from institution to institution and from radiologist to radiologist. Surgical localization of periaortic involvement has been more satisfactory.

Several reports have discussed survival and complications in patients with carcinoma of the cervix and periaortic metastases who received extended-field irradiation (Table 3.21). Piver and Barlow of Roswell Park Memorial Institute, Buffalo, reported on 20 women with previously untreated cervical cancer who received radical irradiation to the periaortic lymph nodes and pelvis after the diagnosis of periaortic lymph node metastases had been established by surgical staging. They noted that 90% of these patients received 6000 cGy to the periaortic nodes and pelvis in 8 weeks using a split-course technique. A later report shows that 30% died of complications of this therapy, and 45% died of recurrent disease. Only 25% of patients survived disease free for 16, 18, 24, and 36 months. The criticism may be that the dose is too high, yet a lesser dose might be ineffective, and four patients did survive. It is obvious that a safe yet effective dosage level for extended-field irradiation therapy has not yet been established.

Wharton and colleagues of the MD Anderson Hospital reported on 120 women treated with preirradiation celiotomy. Of these patients, 32 had severe bowel complications, and 20 (16.6%) eventually died as a result of the surgery or of the surgery and irradiation. Four of these patients died immediately as a result of the surgical procedure. Of 64 patients with positive nodes who were irradiated, 17% lived for 13 to 38 months after treatment. No patient had survived for 5 years. Wharton and associates further reported that in 36 women with positive nodes, it was possible to accurately determine the failure sites after completion of the full course of irradiation therapy. In 25 of these patients, distant metastases were the first evidence of treatment failure, 11 had disease or developed recurrence within the treatment fields, and disease of the pelvic wall was found in only two patients.

The role of surgical staging in removal of paraaortic or pelvic nodes in cervical cancer remains controversial. The results of the aforementioned experience would question significant benefit in view of the complications and survival. Retroperitoneal lymphadenectomy, compared with the intraperitoneal approach, has decreased complications mainly as a result of adhesions and possible bowel complications. More recently, patients with advanced disease have had the paraaortic nodes reevaluated so that extended fields could be added if necessary. The laparoscopic approach is currently being evaluated. Less invasive approaches such as lymphangiogram, CT, and MRI studies have also been evaluated. The sensitivity is less, and false-negative results may be as high as 24% in patients with stage IIIB disease. Many gynecologic oncologists will obtain a CT scan and, if the result is positive, do a fine-needle aspiration. If the result is negative, then surgical removal may be done. An alternative is to radiate the paraaortic areas prophylactically. This has been done with little or no survival benefit. All of the studies note that the severe complication rate essentially doubles (5%–10%) when radiation was given to the paraaortic area.

Experience has shown that doses of about 4500 cGy, particularly when administered in daily fractions of 150 to 180 cGy, are safely tolerated by the organs in the periaortic treatment volume, and a complication rate of 5% should be expected. Extraperitoneal surgery appears to be associated with less postradiation morbidity, probably because of reduced bowel adhesions. The issues of the utility of periaortic radiation and surgical staging in the management of cervical carcinoma are closely intertwined. Although many hypotheses have been raised to support or reject the use of surgical staging, it is clear that some patients with biopsy-proven periaortic node metastases can be cured with radiotherapy using extended fields. Approximately 20% of patients who receive extended-field radiotherapy survive cervical cancer metastatic to the periaortic lymph nodes. Rubin and colleagues had a 50% survival rate in a group of patients with stage Ib disease with documented periaortic lymph node involvement. In many reports, the true value of extended-field radiation is clouded because patients with periaortic node involvement often have advanced disease in which any node or regional therapy may have little effect on long-term survival.

The incidence of pelvic recurrence after irradiation alone for stages Ib, IIa, and IIb carcinomas of the cervix increases with the diameter of the tumor. Data from the MD Anderson Hospital showed an improved pelvic control rate, and a small increase in survival, when patients with the bulky, so-called barrel-shaped lesions were treated with preoperative irradiation followed by extrafascial hysterectomy. The subject continues to be controversial, with conflicting studies in the literature. Gallion and colleagues reported on 75 patients with "bulky, barrel-shaped" stage Ib cervical cancer; 32 patients received radiation alone, and 43 patients were treated with radiation followed by extrafascial hysterectomy. The incidence of pelvic recurrence was reduced from 19% to 2%, and extrapelvic recurrence was reduced from 16% to 7% in patients treated by combination therapy, which produced no increase in treatment-related complications. However, Weems and colleagues described 123 such patients treated from two different eras at his institution. Examination of pelvic control rates, and disease-free survival, showed no significant advantage in pelvic control, disease-free survival, or

absolute survival for either treatment group when compared by stage and tumor size. Unfortunately, no large prospective randomized study has been done that could clarify this issue.

Radiation and Chemotherapy

Radiation therapy alone fails to control the progression of cervical cancer in 35% to 90% of women with locally advanced disease. Concurrent chemoirradiation has been used in the treatment of many cancers in an attempt to improve local control and eradicate distant metastases and has been successfully integrated into the therapeutic program of not only cervical carcinomas but also those of the head and neck and anal canal. **The rationale for chemoradiation is based on the finding that tumor radiosensitivity can be enhanced through the formation of DNA-platinum adducts.** There is a correlation of radiosensitivity with platinum sensitivity. Specifically, the therapeutic index may be improved by loading the tumor with platinum salts containing fast atomic ions. Mechanisms of drug–radiation interaction leading to enhanced radiation kill may include modification of the slope of the dose-response curve, inhibition of sublethal damage repair, inhibition of recovery from potentially lethal damage, alterations in cellular kinetics, decrements in tumor volume leading to improved blood supply and tissue oxygenation, and increased radiosensitivity.

Five phase III trials of concurrent chemoirradiation performed by the Gynecologic Oncology Group, the RTOG, and the Southwestern Oncology Group (SWOG) have demonstrated a reduction in the risk of recurrence by up to 50% in patients with locally confined bulky or advanced-stage cervical cancer, regional spread, or high-risk features after hysterectomy (Table 3.22). Three studies compared radiotherapy alone with radiotherapy plus cisplatin-based chemotherapy, one of which addressed the prescription of adjuvant therapy following radical surgery for early-stage tumors (Intergroup Trial, discussed previously). Excluding patients with nodal involvement by CT scan, GOG protocol 123 evaluated the benefit of preoperative chemoirradiation therapy (weekly cisplatin 40 mg/m^2; maximal weekly dose of 70 mg) compared with radiation therapy alone in patients with locally advanced disease confined to the cervix (ie, stage IB2). All patients underwent adjuvant hysterectomy. In this landmark study, the rates of both PFS (P <0.001) and OS (P = 0.008) were significantly higher in the combined therapy group at 4 years. Patients receiving radiosensitizing chemotherapy experienced higher frequencies of grade III and grade IV adverse hematologic effects and adverse GI effects. An update of GOG 123 was provided by Stehman and colleagues in which chemoradiation was found to significantly improve long-term PFS and OS without significantly increasing serious late effects.

TABLE 3.22 Five Pivotal Trials of Chemoradiation in Locally Advanced Cervical Cancer

5-FU, 5-Fluroracil; *PFS,* progression-free survival; *OS,* overall survival; *RT,* radiation therapy.

Morris and colleagues reported the results from RTOG protocol 90-01. In this study, the effects of pelvic radiation plus concurrent cisplatin and 5-FU were compared with pelvic radiation plus extended-field radiation therapy. This was the only trial to include chemotherapy during low-dose-rate brachytherapy. Eligibility requirements for this study differed from the previous GOG studies with the inclusion of patients with FIGO stage IB2 to IIA tumors. The estimated 5-year survival rates were 73% versus 58%, respectively, for patients treated with chemoirradiation therapy versus radiation therapy alone. A significant difference in disease-free survival was also seen in favor of the chemotherapy arm. The addition of chemotherapy to radiation therapy was effective in reducing both the frequency of local recurrences and distant metastases, with the latter observation refuting those detractors who claim that the benefit conferred by radiosensitizing chemotherapy is strictly a function of increasing the relative dose intensity of the radiation that can be delivered to the pelvis. These results have been sustained in an update of RTOG protocol 90-01 with 8 years of follow-up provided by Eifel and colleagues.

Two additional phase III trials have confirmed the superiority of cisplatin-based chemoirradiation for the treatment of locally advanced cervical cancer. Whitney and colleagues published the results of concurrent cisplatin plus 5-FU and pelvic radiation therapy versus hydroxyurea plus pelvic radiation therapy in women with FIGO stage IIB to IVA disease who had undergone surgical staging and were found to have negative common iliac and aortocaval lymph nodes (GOG protocol 85). Among 368 eligible patients, the median follow-up time among survivors was 8.7 years. Disease progression occurred in 43% of patients randomly assigned to cisplatin plus 5-FU versus 53% of patients randomized to hydroxyurea. PFS was significantly better among patients treated with the combined chemotherapy regimen ($P = 0.033$), with 3-year survival rates of 67% (cisplatin–5-FU arm) versus 57% (hydroxyurea).

Rose and colleagues reported the results from the three-arm GOG trial of pelvic radiation therapy plus concurrent single-agent cisplatin versus cisplatin plus 5-FU plus hydroxyurea versus hydroxyurea alone (protocol 120). All patients had FIGO stage IIB to IVA cervical cancer with surgically confirmed negative common iliac and aortocaval lymph nodes. The median duration of follow-up was 35 months for 526 women included in the final analysis. Significant improvements in progression-free and OS were observed in patients randomly assigned to either cisplatin-containing arm. Effectively, the results from GOG protocol 85 and GOG protocol 120 were critical in supplanting hydroxyurea as the radiosensitizer of choice. In 2007, Rose and colleagues provided their own update of GOG 120 in which again it was found that the improvement in PFS and OS observed with cisplatin-based chemoradiation was sustained without significant increases in late toxicity (Table 3.23).

Because the combination of cisplatin plus 5-FU results in added toxicity, weekly single-agent cisplatin dosed at 40 mg/m^2 has emerged as the standard radiosensitizer in locally advanced cervical cancer. At present, radiosensitizing chemotherapy is recommended during that part of the treatment program when external-beam pelvic radiotherapy is administered.

TABLE 3.23 Updates and Ad Hoc Analysis of Pivotal Chemoradiation Trials in Cervical Cancer

Study	Description	Update
Intergroup trial	Adjuvant RT Adjuvant CRT	Absolute 5YS benefit for CRT: tumors >2 cm, ≥2 positive nodes
GOG 123	RT plus adjuvant hysterectomy CRT plus adjuvant hysterectomy	CRT significantly improves long-term PFS and OS; serious late effects not increased significantly
RTOG 9001	RT plus EFRTCRT	CRT: superior OS and DFS (IB–IIB); superior DFS (III–IVA); serious late effects not increased significantly
GOG 120	CDDP–RTCDDP/HU/5-FU–CDDP–HU	CDDP-based CRT improves long-term PFS and OS; no significant increase in late toxicity

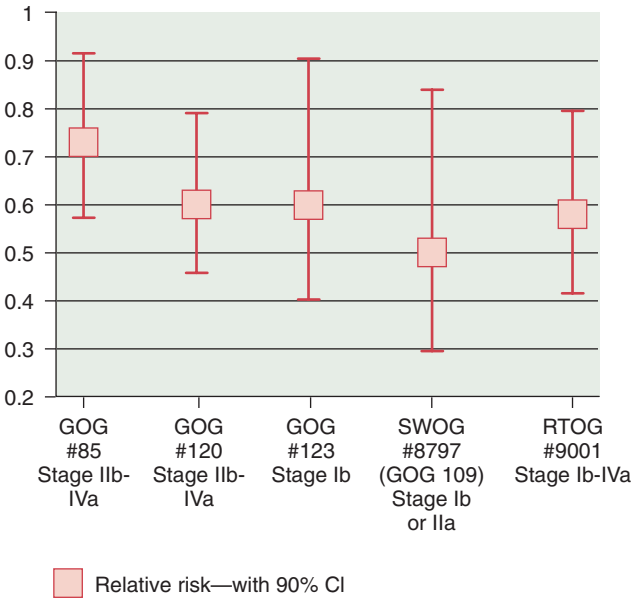

FIGURE 3.37 Relative risk estimate of survival from five phase-III, randomized controlled clinical trials of chemoradiation in women with cervical cancer. *GOG,* Gynecologic Oncology Group; *RTOG,* Radiation Therapy Oncology Group; *SWOG,* Southwestern Oncology Group.

These pivotal phase III trials not only identified a significant survival advantage associated with the addition of concurrent chemotherapy but also were noteworthy in that the degree of benefit achieved with chemotherapy was remarkably similar for each of the four trials that studied chemoirradiation for primary therapy (Fig. 3.37). The results changed the standard of care for the treatment of locally advanced cervical cancer and formed the basis for the 1999 National Cancer Institute (NCI) Clinical

Announcement (Practice Alert) in cervical cancer. At that time, NCI Director Richard D. Klausner, MD, stated the following: "The findings of these five trials are remarkably consistent. They are likely to change the standard of care for invasive cervical cancer."

A meta-analysis of 19 RCTs of chemoradiation versus radiation therapy alone containing a sample of 4580 patients treated from 1981 to 2000 was published in 2001 by Green and colleagues. In their report, the HRs for both PFS and OS favored chemoradiation (HR 0.61; P <0.0001 and HR 0.71; P <0.0001, respectively). The Cochrane review from 2005 analyzed 24 RCTs of 4921 patients. Chemoradiation was associated with a 10% absolute benefit in OS, a 13% absolute benefit in PFS, and a significant benefit was noted for local control. Acute hematologic and GI toxicity were reported more frequently with chemoradiation, but treatment-related deaths attributable to multimodality therapy were rare. Late effects were not able to be adequately determined in the Cochrane review. Most recently, a meta-analysis of 18 randomized trials containing 3517 patients again reported superiority of chemoradiation to radiation therapy alone in terms of relative risk (RR), 3-year survival, and 5-year survival. In this third meta-analysis, although GI toxicity, myelosuppression, and leukopenia occurred more frequently with the use of chemoradiation, there were no significant differences noted between the two modalities in terms of proctitis, cystitis, and nausea or vomiting.

A phase III experience from the Ion Chiricuta Cancer Institute in Romania involved 566 patients with FIGO IIB-IIIB lesions who were randomly assigned to pelvic radiation therapy (46 Gy [gray]) plus high-dose rate brachytherapy (10 Gy) with or without cisplatin (20 mg/m^2 × 5 days). The 5-year survival rate was significantly improved with the use of chemoradiation (74% vs. 64%; P <0.05), as was the local control rate (78% vs. 67%; P = 0.01).

In a 2007 study of practice patterns within the Gynecologic Cancer Intergroup, a global consortium of 14 cooperative groups, the mean external-beam radiation therapy dose was 47 Gy (3.5 Gy SD [standard dose]). The mean total dose to point A was 79.1 Gy (7.9 Gy SD), and the upper border for extended-field radiation therapy among 63% of respondents was T12 to L1. Approximately 85% used high-dose rate systems for vaginal brachytherapy. Of note, all groups reported using concurrent chemotherapy, with weekly cisplatin being the agent of choice for 83%.

The National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology were updated in 2010 for cervical cancer. **For patients with selected bulky tumors, those with FIGO stage IB2 and IIA lesions (>4 cm), and those with FIGO stage IIB to IVA disease, Category 1 treatment constitutes pelvic radiotherapy plus concurrent cisplatin-containing chemotherapy plus brachytherapy.**

The latest phase III trial to study chemoradiation in the locally advanced cervical cancer population was conducted in Mexico by Duenas-Gonzalez et al. In their open-label, randomized phase III trial, the authors studied cisplatin-based chemoradiation followed by brachytherapy with and without concurrent gemcitabine (125 mg/m^2 weekly) and by adjuvant cisplatin (50 mg/m^2 day 1) plus gemcitabine (1000 mg/m^2 days 1 and 8) every 21 days for two cycles. Grade 3 and 4 toxicities were more frequent in the investigational arm (86.5% vs. 46.3%; P <0.001), including two deaths possibly related to treatment toxicity. The PFS at 3 years for the 515 patients enrolled favored the investigational arm (74.4% vs. 65.0%; P = 0.029) and the overall hazard of progression was 0.68 (95% CI, 0.49-0.95; P = 0.0227), and the hazard of death was 0.68 (95% CI, 0.49–0.95; P = 0.0224). Despite these survival figures, the incorporation of gemcitabine into chemoradiation protocols has not been met with great enthusiasm worldwide. Currently, NRG Oncology (the former Gynecologic Oncology Group and Radiation Therapy Oncology Group) in collaboration with the Australian-New Zealand Gynecologic Oncology Group (ANZGOG) is studying the value of four cycles of adjuvant carboplatin plus paclitaxel in this population in the phase III randomized study known as the OUTBACK Trial.

Neoadjuvant Chemotherapy and Other Novel Treatment Approaches

Although multimodality therapy has emerged as the standard of care of patients with locally advanced disease, chemoradiation has some shortcomings related to access, efficacy, and tolerability in certain populations. Neoadjuvant chemotherapy is the most studied alternative treatment modality for FIGO stage IB2 to IVA and is discussed in detail later in this chapter. Other modalities under investigation include proton beam therapy, CyberKnife radiosurgery, IMRT, radiosurgery, radiohyperthermia, and the incorporation of antiangiogenesis and other targeted agents into chemoradiation protocols.

Kagei and colleagues treated 25 patients with FIGO stage IIB to IVA disease with external-beam radiation therapy plus proton beam irradiation. The median total tumor dose was 86 Gy. At a median follow-up period of 139 months (range, 11–184 months), the 10-year OS rates were 89% for stage IIB and 40% for stages IIIB/IVA. Grade IV GI and GU toxicities were reported in 4% of patients. Choi and colleagues treated 30 women with isolated paraaortic nodal metastases with the CyberKnife. Grade III to IV toxicity requiring hospitalization occurred in one patient. The 4-year OS and 4-year local control rates were 50.1% and 67.4%, respectively. A nonrandomized trial comparing 135 women with locally advanced disease treated with IMRT using FDG-PET/CT simulation to 317 non-IMRT patients was reported to have had no significant impact on recurrence-free survival, although the grade III to IV bowel and bladder toxicities were reportedly higher in the non-IMRT cohort (P = 0.0351). Although the radiobiologic rationale for these three investigational modalities is promising, there have been no randomized trials for the population under discussion.

As a result of limited access to sophisticated radiotherapy centers in resource-poor areas of the world, neoadjuvant chemotherapy has emerged as a viable alternative for treatment of women with locally advanced lesions. This approach was popularized by Sardi and colleagues in their "Buenos Aires protocol." In one of the first prospective randomized studies of neoadjuvant chemotherapy in early-stage cervical cancer, Sardi and colleagues reported their final results in 205 cases of stage

Ib carcinoma of the cervix. Patients were treated with radical hysterectomy followed by 50-Gy radiotherapy to the pelvis with or without neoadjuvant chemotherapy. In patients with stage Ib1, neoadjuvant chemotherapy did not improve overall resectability or survival compared with those not receiving chemotherapy. In patients with stage Ib2, there was 83.6% (51 of 61) partial or complete response to chemotherapy. OS after 9 years of follow-up was 61% for the control group (no chemotherapy) and 80% for the neoadjuvant group (P <0.01). Resection was possible in 85% of the control group and 100% in the neoadjuvant group. Patients who responded to neoadjuvant therapy had an OS of 88% compared with 23% for nonresponders. Of interest, the stage Ib1, neoadjuvant groups had an 82% OS compared with 80% for stage Ib2. The control groups' survival rates were 77% and 61%, respectively. Neoadjuvant chemotherapy improved resectability and survival in the patients with stage Ib2. All patients received postoperative radiation.

The Cochrane Collaboration visited this subject originally in 2004 and returned to it recently. In their 2010 report, the authors identified 1072 patients from six trials (Table 3.24). Although PFS was significantly improved with neoadjuvant chemotherapy (HR, 0.76; 95% CI 0.62–0.94; $P = 0.01$), no OS benefit was observed (HR, 0.85; 95% CI 0.67–1.07; $P = 0.17$). Neoadjuvant chemotherapy was associated with a significant decrease in adverse pathologic findings, including lymph node status and parametrial infiltration. Total cisplatin dose and schedule did not influence the findings, nor did stage of disease. The authors concluded that it remains unclear whether neoadjuvant chemotherapy consistently offers a benefit over surgery alone for patients with early-stage or locally advanced cancer.

The latest Cochrane Collaboration review of six randomized trials of neoadjuvant chemotherapy with surgery for women with untreated early or locally advanced cervical cancer providing PFS data ($n = 1027$) and OS data ($n = 1071$) was reported by Rydzewska et al. in 2012. Both parameters were significantly improved among patients receiving neoadjuvant chemotherapy (hazard of progression, 0.75; 95% CI 0.61–0.93; $P = 0.008$) and hazard of death 0.77; 95% CI, 0.62–0.96; $P = 0.02$). The authors emphasized that despite the favorable results associated with neoadjuvant chemotherapy, their analysis was based on a small number of trials, and further research is clearly warranted.

TABLE 3.24 Neoadjuvant Chemotherapy Plus Surgery Versus Surgery Alone: Hazard Ratios and Confidence Intervals for Overall Survival

Study (Year)	Patients (*n*)	HR	95% CI
Sardi et al. (1997)	210	0.53	0.31, 0.92
Katsumata (2006)	134	1.12	0.56, 2.22
Cai (2006)	106	0.74	0.33, 1.65
Napolitano (2003)	288	0.84	0.51, 1.40
Total	**930**	**0.85**	**0.67, 1.07**

A Cochrane Collaboration review identified six randomized controlled trials of radiotherapy versus radiohyperthermia for patients with locally advanced cervical carcinoma during the period from 1987 to 2009. Seventy-four percent of patients treated had FIGO stage IIIB tumors. The HRs for 3-year local recurrence and 3-year survival favored the 43°C hyperthermia arms (HR, 0.48; 95% CI 0.37–0.63; P <0.001 and HR 0.6; 95% CI 0.45–0.99; $P = 0.05$, respectively). There were no significant differences in acute or late-grade III to IV toxicity. The review did indicate that these studies were limited by small numbers and important methodologic flaws.

Finally, a recent Cochrane Collaborative study focusing on the impact of hysterectomy for women with locally advanced disease treated with radiotherapy or chemotherapy or both was reported by Kokka et al. Seven randomized trials were identified involving 1217 patients. Although individual trials did not report a survival advantage among women undergoing hysterectomy after radiotherapy or concurrent chemoradiation, the meta-analysis of three trials ($n = 571$) of neoadjuvant chemotherapy and hysterectomy versus radiotherapy alone found that women who received neoadjuvant chemotherapy plus hysterectomy had a lower risk of death (HR, 0.71; 95% CI, 0.55–0.93).

Targeted therapy has been studied in two chemoradiation protocols. In 2012, the Gynecologic Oncology Group reported in the phase I protocol 9918 that the addition of anti-epithelial growth factor therapy using cetuximab (400 mg/m^2 loading dose followed by 250 mg/m^2) to cisplatin-based chemoradiation was tolerable, but when added to extended-field radiation therapy for treatment of nodal metastases, there were eight dose-limiting toxicities, making the combination not feasible. In RTOG 0417, the antiangiogenesis agent bevacizumab (10 mg/kg IV every 2 weeks) was added to 49 patients treated with cisplatin-based chemoradiation for FIGO stage IB to IIIB disease. The 3-year OS, disease-free survival, and locoregional failure rates were 81.3%, 68.7%, and 23.2%, respectively. The paraaortic nodal failure rate at 3 years was 8.4%.

Suboptimal Treatment Situations

Several clinical situations pose unique challenges in the management of cervical cancer, causing some patients with invasive cancer of the cervix to receive suboptimal treatment:

1. Cancer in a cervical stump
2. Simple hysterectomy in the setting of invasive cervical cancer
3. Poor vaginal geometry for intracavitary radiation.

Cancer that occurs in a cervical stump is fortunately a diminishing problem because supracervical hysterectomies are performed less frequently. Carcinoma occurring in a cervical stump presents a special problem because often an optimal dose of intracavitary radium cannot be applied as a result of the insufficient place to insert the central tandem, which contributes significantly to the radiation dose to the central tumor and to the pelvic sidewall. Radical surgery is also more difficult; the bladder and rectum firmly adhere to the stump and may adhere to each other. Also, the ureters are more difficult to dissect cleanly from the parametrial tissue because of fibrosis from the previous surgery. The net result is an increase in the risk of

significant surgical complications involving the ureters, bladder, and rectum. In modern gynecologic surgery, supracervical hysterectomy is rarely indicated, although in recent years, concerns regarding pelvic support and even sexual function have prompted some surgeons to consider the procedure.

In a report of the MD Anderson Hospital experience with 263 patients with carcinoma of the cervical stump, Miller and colleagues noted a 30% complication rate after full therapy with radiation. Urinary and bowel complications result from post-surgical adhesions; the absence of the uterus, which acts as a shield; and a tendency to emphasize external radiation therapy. We have had a similar experience, resulting in a preference for radical trachelectomy in patients with cancer of the cervical stump in whom stage and medical conditions allow. The increased technical difficulty of performing such a procedure seems to be outweighed by the low complication rate and comparable survival of patients.

A simple hysterectomy performed for invasive cervical cancer is not adequate therapy for most patients. This situation may occur because of poor preoperative evaluation or because the surgery was performed under emergency conditions without an adequate preoperative cervical evaluation. Such a situation may occur in a patient presenting with acute abdomen from ruptured tuboovarian abscesses. In any event, if an extensive cancer is found in the cervix, the prognosis is poor because optimal irradiation cannot be given with the cervix and uterus absent. An even more ominous situation occurs when a hysterectomy is performed with a "cut through" of the cancer—that is, the hysterectomy dissection passes through the cancer. The prognosis is uniformly poor in this event. In the examples just given, surgical cures are not obtained, and the probability of curative radiotherapy is greatly diminished.

In 1968, Durrance reported survival rates of 92% to 100% using postoperative radiation therapy in selected patients with presumed stage I or II disease after suboptimal surgery. Excellent survival rates were also reported by Andras and colleagues in 148 patients who had invasive cervical carcinoma found incidentally in the hysterectomy specimen. Of these patients, 126 were treated with postoperative radiation therapy. Patients with microscopic disease confined to the cervix had a 96% 5-year survival rate. Those with gross tumor confined to the cervix had an 84% 5-year survival. Patients with tumor cut through at the margins of surgical resection, but with no obvious residual cancer, had a 5-year survival rate of 87%. Patients with obvious residual pelvic tumor had a 47% 5-year survival rate. In 1986, Heller and colleagues reviewed the literature and reported equivalent survival rates in 35 patients who were also treated mainly with radiation.

Orr and colleagues have preferred radical parametrectomy, upper vaginectomy, and lymphadenectomy as the treatment of choice after a simple hysterectomy. We also prefer this approach, particularly because many of these patients are young and desirous of preserving optimal sexual function. We are also concerned about postoperative small bowel adhesions and the difficulty of delivering effective irradiation to the medial parametria in the absence of a uterus. Survival rates with either approach appear to be exceptionally good; undoubtedly, this clinical situation creates a bias for smaller lesions that may be easier to eradicate.

Adequate radiotherapy is also compromised in patients who have a vagina or cervix that cannot accommodate a complete intracavitary radiation application. This situation is encountered with atrophic stenotic pelvic structures. These patients are treated by inserting the tandem and ovoids in a compromised manner, such as insertion of the ovoids singly or independently of the central tandem. In any event, standard optimal doses are usually not obtained, and the possibility of sustaining a radiation injury is increased.

NEUROENDOCRINE AND OTHER UNCOMMON TUMORS OF THE CERVIX

Neuroendocrine (small cell) cervical cancer (Fig. 3.38) is a rare malignancy, representing fewer than 5% of all cases of cervical cancer. These tumors provide a therapeutic challenge for the clinician because they are characterized by frequent and early nodal and distant metastases. The pathologist's dilemma results from the large number of pathologic entities all described as "small cell cancers," including fully differentiated small cell nonkeratinizing SCC, reserved cell carcinoma, and neuroendocrine (oat cell) carcinoma. Neuroendocrine carcinomas, which can be identified by characteristic light and electron microscopic criteria, are indistinguishable from oat cell cancers of the lung. In addition, they appear to have the poorest prognosis of the various small cell cancers. Therefore, it is important to distinguish this particular subtype of cancer from the rest and to consider innovative approaches to treatment. **Neuroendocrine markers are commonly used to assist in classification, with up to 80% of tumors staining for synaptophysin, chromogranin, or CD56 (neural cell adhesion molecule).** At least in one series, Pap smear results were abnormal in only one of seven patients.

Abeler and colleagues reported on 26 cases of true neuroendocrine cervical carcinoma. The 5-year survival rate was 14% despite aggressive therapy, including surgery, radiation, and chemotherapy. Viswanathan and colleagues observed a 66%

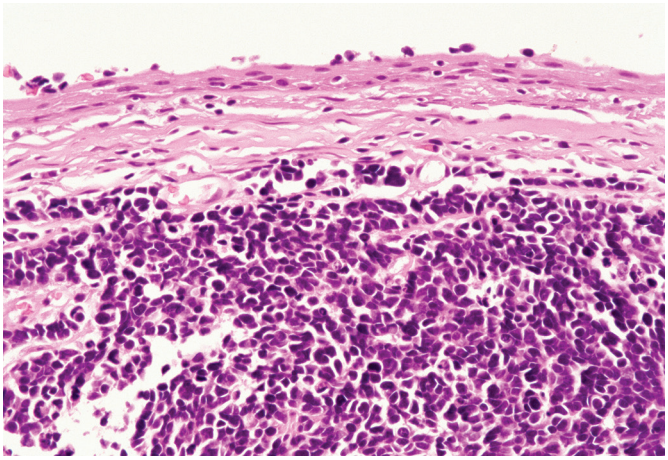

FIGURE 3.38 Small cell carcinoma. (Courtesy of Ibrahim Ramzy, MD, University of California, Irvine (UCI), College of Medicine.)

relapse rate, with a course frequently characterized by the development of widespread hematogenous metastases. Locoregional recurrence outside irradiated fields was also frequently observed. In the group studied, the OS rate at 5 years was only 29%, with none of the patients who had disease more extensive than FIGO stage Ib1 or clinical evidence of lymph node metastases surviving their disease.

In our experience in the 1980s with 14 patients in stage Ib or IIa treated by radical hysterectomy with postoperative radiation therapy, all 14 have experienced recurrence, 12 before the 31st month after therapy. Innovative approaches to treating this subset of unfortunate patients are under study. Recently, Chan and colleagues updated our series and performed a multivariate analysis of different prognostic factors among 34 patients. His group documented that only those with early lesions amenable to extirpation were curable. The role of primary or postoperative radiation with or without chemotherapy is unclear and yields uniformly poor results, particularly in patients with advanced lesions.

Hoskins and colleagues treated 31 patients with small cell neuroendocrine carcinoma (SCNEC) using protocols containing etoposide, cisplatin, and radiation therapy with concurrent chemotherapy with and without the addition of carboplatin and paclitaxel. The reported 3-year failure-free rate for patients with early-stage disease (stage I and II) was 80%. Chang and colleagues have reported that regimens containing a combination of vincristine, doxorubicin, and cyclophosphamide or cisplatin and etoposide constitute active adjuvant therapies after radical hysterectomy. Zivanovic and colleagues examined the outcomes of 17 patients with SCNEC. The estimated 3-year PFS and OS rates were 22% and 30%, respectively. Median OS rates for early-stage disease (IA1–IB2) were 31.2 months and 6.4 months for those with advanced-stage disease (IIB-IV; $P = 0.034$). In the early-stage disease group, the 3-year distant recurrence-free survival rates were 83% for patients who received platinum-based combination chemotherapy and 0% for those who did not receive chemotherapy as part of their initial treatment ($P = 0.025$). These data support the role of chemotherapy for distant control as an addition to radiation therapy for local control. Of interest, combined modality treatment with definitive chemotherapy and radiotherapy are used in the current management of small cell lung cancer, with surgical resection playing a limited role in patients with stage I and stage II disease. It is unclear which patients, if any, should undergo radical hysterectomy for SCNEC of the cervix. Zivanovic and colleagues advise proceeding with combined modality therapy when the diagnosis is established by cervical biopsy, holding surgery in reserve to be used in the adjuvant setting if necessary. It should be recognized that there are advocates of primary radical hysterectomy for patients with early-stage tumors.

Finally, a recent case report by Lyons et al. describing the objective response when a neuroendocrine cervical cancer harboring a Kirsten rat sarcoma viral oncogene homolog (KRAS) mutation was treated with a mitogen-activated protein kinase kinase (MEK) inhibitor emphasizes a potential role for biomarker testing to further guide therapy. Provision of the molecular phenotype of these (and other) tumors is likely to provide the basis for future personalized therapy.

GLASSY CELL CARCINOMA, CARCINOSARCOMA, LYMPHOMA, AND MELANOMA

Glassy cell carcinoma of the cervix has also been classically regarded as a poorly differentiated adenosquamous carcinoma, which is infrequently diagnosed and associated with a poor outcome regardless of the modality of therapy. Many recurrences occur in the first year after therapy, and most have occurred by 24 months. Reported survival rates are more encouraging than are those associated with neuroendocrine carcinomas; rates have been seen to be as high as 50% for stage I disease in some series.

In the SEER report of 6549 cases of cervical carcinoma from 1973 to 1977, there were only 36 cases of cervical sarcoma, which is an incidence of 0.55%. Ninety-six cases of cervical sarcoma were reviewed by Rotmensch and colleagues, and no clear statement could be made regarding management, although surgery was consistently used for early-stage lesions. Laterza and colleagues reviewed the literature and described the outcomes of 33 patients with carcinosarcoma of the cervix, including two of their own (Fig. 3.39). Of 16 patients with stage I disease, eight were reported to be NED after a variety of treatment modalities, including surgery, radiation, or chemotherapy, alone or in combination. The impact of radiotherapy on survival is uncertain. Given the propensity for distinct histologic subtypes to respond to systemic regimens irrespective of organ site of origin (eg, small cell neuroendocrine carcinomas of the cervix and lung, malignant germ cell tumors of the ovary and testis), ifosfamide-based regimens, particularly ifosfamide plus paclitaxel, may be expected to exhibit some activity in this disease, similar to what has been reported in carcinosarcoma of the uterine corpus.

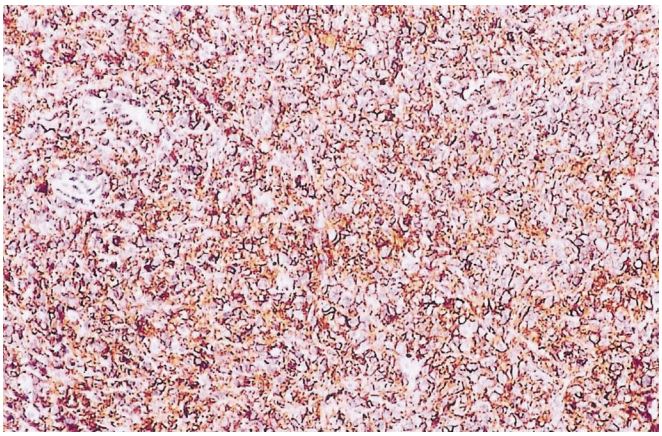

FIGURE 3.40 Lymphoma. (From Szánthó A, Bálega J Já, Csapó Z, et al. Primary non-Hodgkin's lymphoma of the uterine cervix successfully treated by neoadjuvant chemotherapy: case report. *Gynecol Oncol* 2003;89:171-174.)

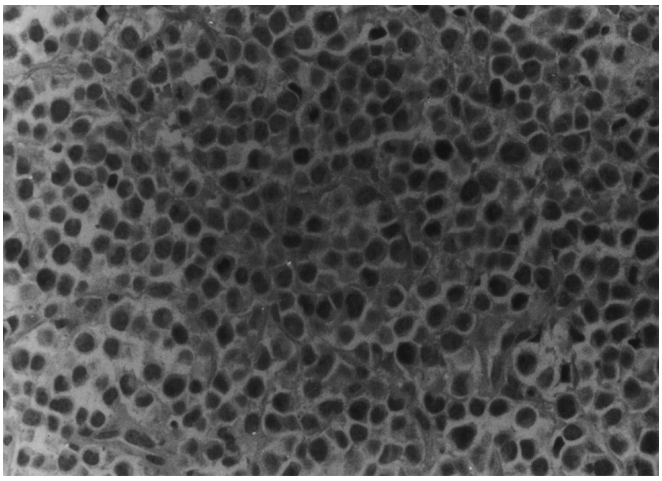

FIGURE 3.41 Melanoma. (From Kristiansen SB, Anderson R, Cohen DM. Primary malignant melanoma of the cervix and review of the literature. *Gynecol Oncol* 1992;47:398-403.)

Biomarker profiling may also be of value to understand the clinical behavior of these rare cancers. In a small series of three women with cervical carcinosarcoma, Gan et al. reported high levels of bcl-2 and surviving expression and decreased apoptosis using an apoptosis index. Dysregulation of apoptosis may facilitate the aggressive behavior of carcinosarcoma.

In contrast to systemic lymphomas, fever, night sweats, and weight loss rarely have been reported in cervical lymphoma (Fig. 3.40). Most present with abnormal vaginal bleeding or discharge, but pelvic pain and dyspareunia may also be present. The differential diagnosis of cervical lymphomas should include benign chronic inflammations, poorly differentiated and small cell cervical carcinomas, sarcomas, and lymphoma-like lesions. Immunophenotyping can be used to make the diagnosis.

The prognosis of extranodal lymphomas is usually poorer than that of nodal lymphomas as a result of inaccurate or delayed diagnosis. Early-stage diagnosis of cervical lymphoma has been associated with favorable outcomes. Some authors have suggested that surgical resection in localized lymphoma may improve survival, although this is unclear. The CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) regimen is the most commonly used regimen.

Malignant melanoma of the uterine cervix is a rare manifestation (Fig. 3.41). A careful survey should be done of the patient's skin and mucous membranes for a possible primary site. Almost 90% of the patients are asymptomatic, and vaginal bleeding is the main complaint among 10%. Most lesions present as an exophytic polypoid cervical mass with obvious coloring. **Immunohistochemistry can be used to identify melanin granules, and positive staining for S100, HMB 45, or Melan-A can help in establishing the diagnosis.** Although there is little consensus on the best approach for therapeutic management, the majority of patients have undergone radical hysterectomy with or without pelvic lymphadenectomy and upper vaginectomy. The efficacy of radiation therapy has not been established, although it has been used in the adjunctive and palliative settings. Likewise, the use of adjuvant chemotherapy is under debate. To date, there have been no reports of immunotherapy, including the use of interferon, for this disease. The 5-year survival rate is very poor, not exceeding 40% of stage I and 14% of stage II.

The therapeutic landscape of cutaneous melanoma has been transformed with the introduction of checkpoint inhibitors (eg, anti-CTLA-4 ipilimumab and the antiprogrammed cell death 1 nivolumab and pembrolizumab). To date, there have been no reports of the efficacy of breaking immune tolerance in cervical melanoma but we may anticipate that they will be forthcoming.

SURVIVAL RESULTS AND PROGNOSTIC FACTORS FOR EARLY-STAGE AND LOCALLY ADVANCED DISEASE

For early-stage tumors, results may imply that one form of therapy (ie, radical surgery vs. radiotherapy) has advantages over the other, but considering the rather wide dispersion that, in fact, may be unrelated to treatment, we must maintain collective open-mindedness about the efficacy of individual therapeutic regimens. The best available figures for the two methods give results that are almost identical, and because the presence of other factors affect the samples being compared, large differences would be necessary to be significant. Individual physicians will probably continue to decide on the basis of personal preferences and comparison of complications and later disabilities.

The recovery rates of patients with operative SCC of the cervix depend on many factors, including the histologically documented extent of the carcinoma. Baltzer and associates studied 718 surgical specimens of patients with SCC of the cervix. Lymphatic and blood vessel invasion significantly influenced survival, blood vessel invasion being much more ominous. In their study, whereas 70% of the patients who demonstrated blood vessel invasion succumbed to the disease,

31% of the patients demonstrating only lymphatic invasion succumbed to the disease process. Other studies have not found prognostic significance for vascular invasion. A definite linkage was noted between the size of the carcinomas and the frequency of metastases. Fuller and colleagues drew similar conclusions. In their study of 431 patients who underwent radical hysterectomy for stages Ib or IIa carcinoma of the cervix at Memorial Sloan-Kettering Cancer Center, they found 71 patients who had nodal spread that correlated closely with increased primary tumor size, extracervical extension of tumor, and the presence of adenocarcinoma. Although these factors were recognized as having prognostic significance, the authors were unable to demonstrate that these detrimental effects could be overcome by postoperative pelvic radiation. Patients receiving postoperative irradiation therapy seemed to have some better local control, but the problem of systemic spread of disease resulted in little overall improvement in survival. In a similar study, Abdulhayogu and associates reported on a series of patients with negative lymph nodes at the time of radical hysterectomy who subsequently developed recurrent disease. They too pointed out the histologic architecture of invasion as an important prognostic indicator. Recurrence was more likely in patients who had deep invasion of the cervical stroma, especially when it extended to the serosal surface (even when the parametria were not involved). Again, the volume of tumor correlated with the eventual prognosis for the patient. They suggested that these patients were in need of postoperative therapy, and radiation therapy for local control was recommended in the absence of any other demonstrated effective adjuvant modality for this set of circumstances. Gauthier and colleagues had similar results and, in a multifactorial analysis of clinical and pathologic factors, demonstrated that the depth of stromal invasion is the single most important determinant of survival.

The role of intraperitoneal tumor spread was evaluated by an Italian group. They evaluated 208 patients with advanced local disease who received neoadjuvant chemotherapy. There were 183 clinically responsive patients who underwent radical surgery; 7 (4%) and 13 (7%) showed macroscopic and microscopic peritoneal tumor, respectively. Multivariant analysis showed that the peritoneal tumor involvement, stage, pathologic parametrial involvement, and lymph node metastasis were independent factors associated with survival. About one-quarter of those with pelvic lymph node metastasis had intraperitoneal involvement compared with only 6% of node-negative patients. If intraperitoneal disease was present, survival was similar, irrespective of stage (Ib–IIb compared with III–IVa).

A study from Austria evaluated 166 patients with stage Ib cancers treated with radical hysterectomy. In a multivariant analysis, microvessel density, lymph node involvement, tumor size, and postoperative radiation remained independent prognostic factors for survival. LSI failed to be a prognostic factor. Of interest, patients with negative lymph nodes but increased microvessel density had similar survival to patients who were node positive but with low microvessel density. A study from Norway evaluated HPV DNA in 97 patients with squamous carcinoma (all stages). When corrected for stage and age, the prognosis was significantly poorer for HPV-18– and -33–positive tumors; however, overall, when all HPV-positive tumors were compared with HPV-negative tumors, no survival difference was noted.

When age was evaluated in the Annual Report, the OS rate in stage I decreased with age. Patients between 15 and 39 years of age in stage II had a worse survival rate compared with older patients. This was true for patients 30 to 49 years of age with stage IV cancers compared with patients of other ages. Mitchell and colleagues reviewed 398 patients with stages I to III cervical cancer of whom 338 patients were 35 to 69 years of age, and 60 patients were 70 years of age or older. Although elderly patients had a higher rate of comorbidity resulting in more frequent treatment breaks and less ability to receive definitive therapy with intracavity radiation, the 5-year actuarial disease-free and cause-specific survival rates were comparable between the two groups.

RECURRENT AND ADVANCED CARCINOMA OF THE CERVIX

It is estimated that approximately 35% of patients with invasive cervical cancer will have recurrent or persistent disease after therapy. The diagnosis of recurrent cervical cancer is often difficult to establish (Table 3.25). The optimal radiation therapy most patients receive makes cervical cytologic findings difficult to evaluate. This is especially true immediately after completion of radiation therapy. Suit, using mammary carcinomas in C3H mice, demonstrated that persistence of histologically intact cancer cells in irradiated tissue was not indicative of the regrowth of a tumor. Radiobiologically, a viable cell is one with the capacity for sustained proliferation. A cell would be classified as nonviable if it had lost its reproductive integrity, although it could carry out diverse metabolic activities. This reproductive integrity was demonstrated by the transplantation "take" rate when histologically viable tumor cells were transplanted into a suitable recipient. It was evident from these experiments in mice that relatively normal-appearing cancer cells can persist for several months after radiation therapy but that these cells are "biologically doomed." Thus, cytologic evaluation of a patient immediately after radiation therapy may erroneously lead to the supposition that persistent disease exists. In addition, subsequent evaluation of the irradiated cervix is difficult because of the distortion produced in the exfoliated cells, often called the *radiation effect*. Thus, histologic confirmation of recurrent cancer is essential. This can be accomplished by

TABLE 3.25 MD Anderson Hospital Central Recurrence Rate for Carcinoma of the Cervix After Treatment With Radiation Therapy

Stage	Patients (%)
I	1.5
IIb	5
IIIa	7.5
IIIb	17

punch or needle biopsy of suspected areas of malignancy when they are accessible. An interval of at least 3 months should elapse after completion of radiation therapy. The clinical presentation of recurrent cervical cancer is varied and often insidious. Many patients develop a wasting syndrome with severe loss of appetite and gradual weight loss over a period of weeks to months. This is often preceded by a period of general good health after completion of radiation therapy. Because most recurrences of cancer occur within 2 years after therapy, the period of good health rarely lasts more than 1 year before the symptoms of cachexia become evident. Diagnostic evaluation at this time of suspected recurrence may include a chest radiograph and CT scan and complete blood count, blood urea nitrogen, creatinine clearance, and liver function tests.

Autopsy studies of the location of advanced recurrent and persistent disease have been reported (Figs. 3.42 and 3.43). After radical hysterectomy, about one-fourth of recurrences occur locally in the upper part of the vagina or the area previously occupied by the cervix. The location of recurrence after radiation therapy showed a 27% occurrence in the cervix, uterus, or upper vagina; 6% in the lower two-thirds of the vagina; 43% in the parametrial area, including the pelvic wall; 16% distant; and 8% unknown. Often one notes the development of ureteral obstruction in a patient who had a normal urinary tract before therapy. Although ureteral obstruction can be caused by radiation fibrosis, this is relatively rare, and 95% of the obstructions are caused by progressive tumor. Central disease may not be evident, and in the absence of other findings, a patient with ureteral obstruction and a negative evaluation for metastatic disease after therapy should undergo exploratory laparotomy and selected biopsies to confirm the diagnosis of recurrence. Patients with ureteral obstruction in the absence of recurrent malignancy should be considered for urinary diversion or internal antegrade ureteral stents.

The definition of primary healing after radiation therapy is a cervix covered with normal epithelium or an obliteration of the vaginal vault without evidence of ulceration or discharge. On rectovaginal examination, the residual induration is smooth

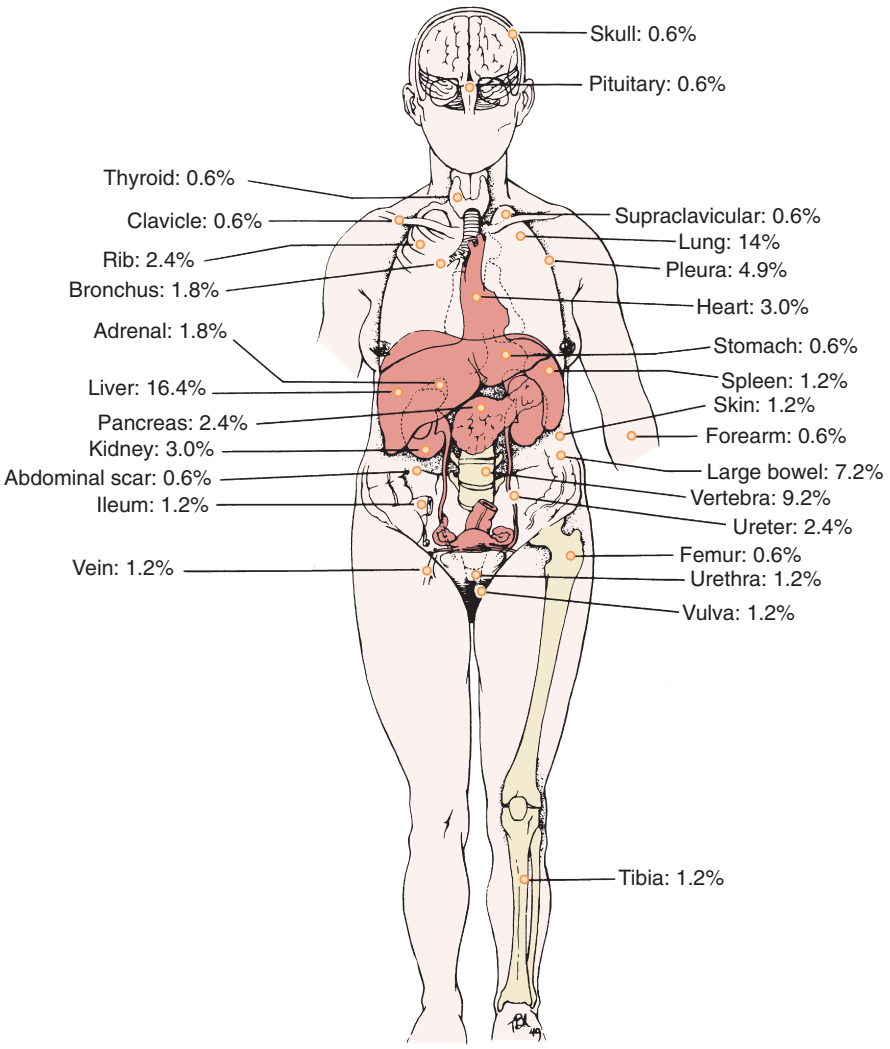

FIGURE 3.42 Metastatic sites of treated patients with cervical cancer and the percentage of involvement. (From Henriksen E. The lymphatic spread of carcinoma of the cervix and of the body of the uterus; a study of 420 necropsies. *Am J Obstet Gynecol* 1949;58:924-942.)

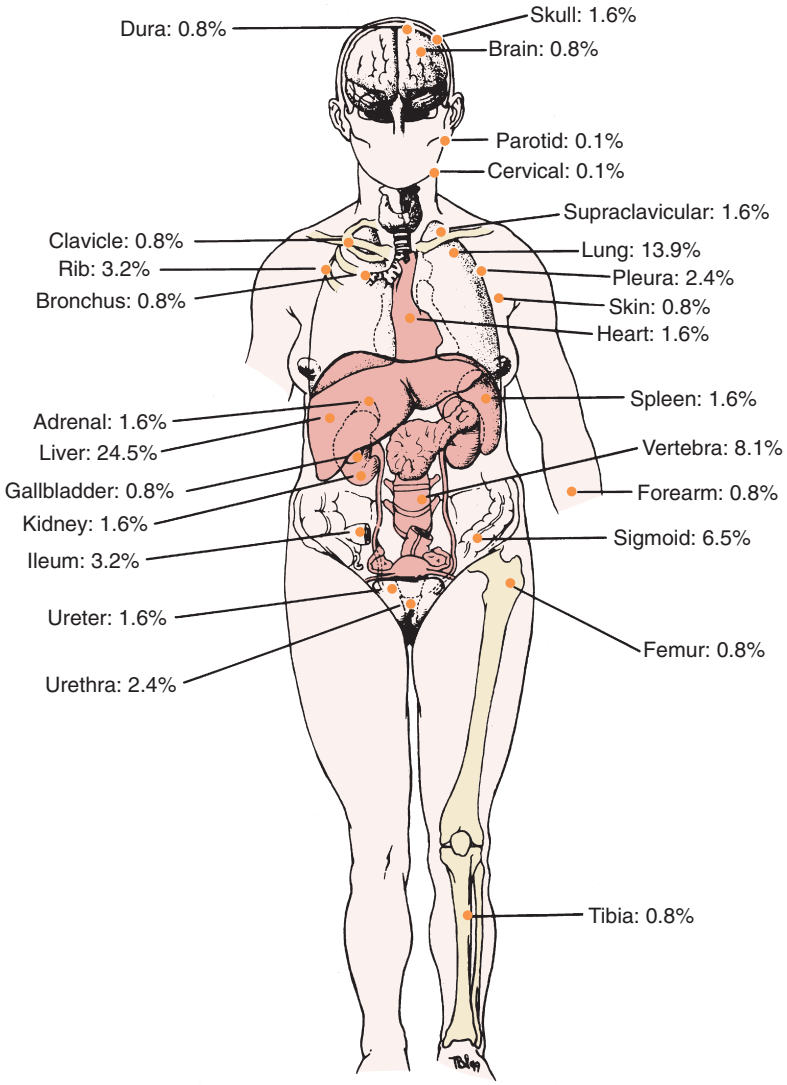

FIGURE 3.43 Metastatic sites of untreated patients with cervical cancer and the percentage of involvement. (From Henriksen E. The lymphatic spread of carcinoma of the cervix and of the body of the uterus; a study of 420 necropsies. *Am J Obstet Gynecol* 1949;58:924-942.)

with no nodularity. The cervix is greater than 2.5 cm in width, and there is no evidence of distant metastasis. The definition of persistent disease after radiation therapy is as follows:

1. Evidence of a portion of the tumor that was clinically present before treatment or
2. Development of a new demonstrable tumor in the pelvis within the treatment period.

The definition of recurrence after radiation therapy is a regrowth of tumor in the pelvis or distally, which is noted after complete healing of the cervix and vagina.

Recurrence after surgery is defined as evidence of a tumor mass after all gross tumor was removed and the margins of the specimen were free of disease. Persistent disease after surgery is defined as persistence of gross tumor in the operative field or local recurrence of tumor within 1 year of initial surgery. A new cancer of the cervix would be a lesion that occurs locally at least 10 years after primary therapy.

The triad of weight loss accompanied by leg edema and pelvic pain is ominous. Leg edema is usually the result of progressive lymphatic obstruction, occlusion of the iliofemoral vein system, or both. The clinician should consider the possibility of thrombophlebitis, but recurrent cancer is more likely. Patients characteristically describe pain that radiates into the upper thigh either to the anterior medial aspect of the thigh or posteriorly into the buttock. Other patients describe pain in the groin or deep-seated central pelvic pain. The appearance of vaginal bleeding or watery, foul vaginal discharge strongly suggests a central recurrence (Table 3.27). These lesions are among the more readily detectable recurrent cervical cancers, and histologic confirmation is easily obtained.

Fewer than 15% of patients with recurrent cervical cancer will develop pulmonary metastasis. When this does occur, patients will complain of cough, hemoptysis, and occasionally chest pain. In many cases, there will be enlargement of

supraclavicular lymph nodes, especially on the left side. Needle aspiration of enlarged lymph nodes can be accomplished easily and avoids the necessity for an open biopsy of the area.

In almost every case, the diagnosis of recurrent cervical cancer must be confirmed histologically. CT-directed needle biopsies have provided us with a tool that avoids the necessity of more elaborate operative procedures. In addition to the standard radiographic evaluations, such as IVP and chest radiograph, the clinician may find more sophisticated studies such as lymphangiography and MRI helpful in localizing deep-seated areas of recurrent cervical cancer.

Bony metastases presenting clinically are particularly rare. In a study of 644 patients with invasive cervical carcinoma, Peeples and colleagues were able to find only 29 cases of remote metastases. Of these, 15 were to the lungs and only 12 were to the bone, which is an incidence of 1.8%. No bony metastases were found at initial staging and diagnosis. The earliest discovery of bone metastasis came 8 months after diagnosis. Therefore, a bone survey was not recommended as part of the staging examination for cervical cancer.

Blythe and associates reported on 55 patients who were treated for cervical carcinoma and who developed bony metastases. Radiographs were diagnostic in all except two of the patients. In 15 patients, a combination of radioactive scans and radiographs was used to establish the diagnosis. The most common mechanism of bony involvement from carcinoma of the cervix was extension of the neoplasia from periaortic nodes, with involvement of the adjacent vertebral bodies. The longest interval from the primary diagnosis until the discovery of bony metastases was 13 years. Of the patients, 69% were diagnosed within 30 months of initial therapy, and 96% died within 18 months. Of the 36 patients treated with radiation therapy, four received complete relief of symptoms, 24 gained some relief, and eight received no relief.

Van Herik and colleagues examined the records of 2107 cases of cervical cancer for recurrence after 10 years. Sixteen (0.7%) patients had a recurrence 10 to 26 years after the initial therapy. Of these patients, 25% had bony metastasis or extension of the recurrence into bone. The finding of metastasis after 10 years correlates with the findings of Paunier and associates, who indicated that 92.5% of deaths resulting from carcinoma of the cervix occur in the first 5 years after diagnosis. In addition, their cumulative death rate curve was flat after 10 years.

Deaths resulting from cancer of the cervix occur most frequently in the first year of observation and decrease thereafter. About half of all the deaths occur in the first year after therapy, 25% in the second year, and 15% in the third year, for a total of 85% by the end of the third year. Because more than three-fourths of the recurrences are clinically evident in the first 2 years after initial therapy, posttreatment evaluation done at frequent intervals during this critical period is mandatory. The patient should be examined every 3 to 4 months, and cervical cytologic testing should be done at these visits. In addition, particular attention should be paid to the parametria on rectovaginal examination to detect evidence of progressive disease. For several months after the completion of radiation therapy, the examiner may observe a progressive fibrosis in the parametria, creating the so-called horseshoe fibrosis. The amount of fibrosis may sometimes be alarming, but smoothness of the induration should be reassuring when compared with the nodular presentation of recurrent parametrial malignancy. Parametrial needle biopsies, with the patient under anesthesia, may be helpful when the palpatory findings are equivocal. Generous use of endocervical curettage at these follow-up visits is recommended, especially when central failure is suspected after radiation therapy. Every follow-up examination should include careful palpation of the abdomen for evidence of periaortic enlargement, hepatomegaly, and unexplained masses. Every follow-up examination should begin with a careful palpation of the supraclavicular areas for evidence of nodal enlargement. This frequently omitted portion of the examination will sometimes reveal the only evidence of recurrent disease.

The prognosis for patients with recurrent or advanced cervical cancer depends on the location of the disease. Of patients with recurrent cervical cancer, the most favorable for therapy after primary irradiation are those with a central recurrence. These patients are candidates for curative radical pelvic surgery, including pelvic exenteration. There will be further discussion of this group of patients later in this chapter. With the advent of sophisticated methods of radiation therapy, including improved methods of brachytherapy and supervoltage external irradiation therapy, patients with pure central recurrence have become a rarity.

Isolated lung metastases from pelvic malignancies have responded in very selected cases to lobectomy. Gallousis reported metastases to the lung from cervical cancer in 1.5% of 5614 cases reviewed, with solitary nodules present in 25% of the cases. A surgical attack for isolated pulmonary recurrence should be considered, especially if the latent period has been longer than 3 years.

Other patients who deserve serious consideration are those with radiation bowel injury. Over the past decade, the limits of human tolerance to radiation therapy have been reached, with treatment techniques for advanced disease that include large extended fields to the periaortic area. Many patients with advanced-stage primary lesions have been treated with large doses of pelvic radiation (6000–7000 cGy), often after intraabdominal surgery. With these techniques, standard radiation therapy can lead to a small but significant number of patients with chronic radiation injury to the large or small bowel. These patients often develop cachexia, which is indistinguishable from the clinical presentation of recurrent and progressive malignancy. These patients are often quickly and superficially diagnosed as having recurrent disease, and no further investigation is initiated. Careful investigation of these patients reveals a history of postprandial crampy abdominal pain causing anorexia and weight loss. The diagnostic evaluations discussed previously reveal no conclusive evidence of persistent malignancy. In most cases, these patients can be returned to health with appropriate bowel surgery, including internal bypass procedures. In every patient suspected of recurrent malignancy, an effort should be made to confirm this suspicion by biopsy (histologic confirmation), and patients who do not have a recurrence and who have radiation bowel injury should be identified.

Management and Prognosis

Persistent or recurrent carcinoma of the cervix is a discouraging clinical entity for the clinician, with a 1-year survival rate between 10% and 15%. Treatment failures are, as expected, much more common in patients with more advanced stages of the disease; therefore, most patients are unlikely candidates for a second curative approach with radical pelvic surgery. Cases of curative therapy applied to isolated lung metastases or lower vaginal recurrences are reported but occur rarely. Unfortunately, most recurrences are suitable for palliative management only.

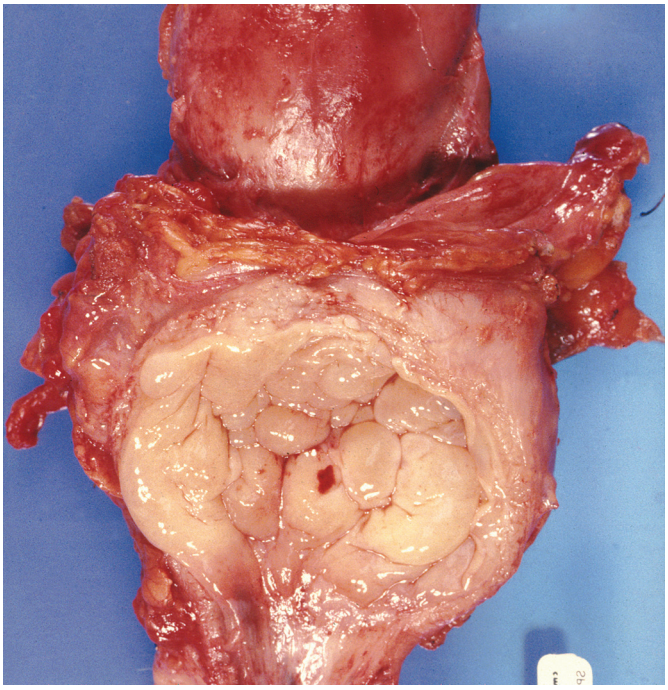
Surgical Therapy: Radical Hysterectomy

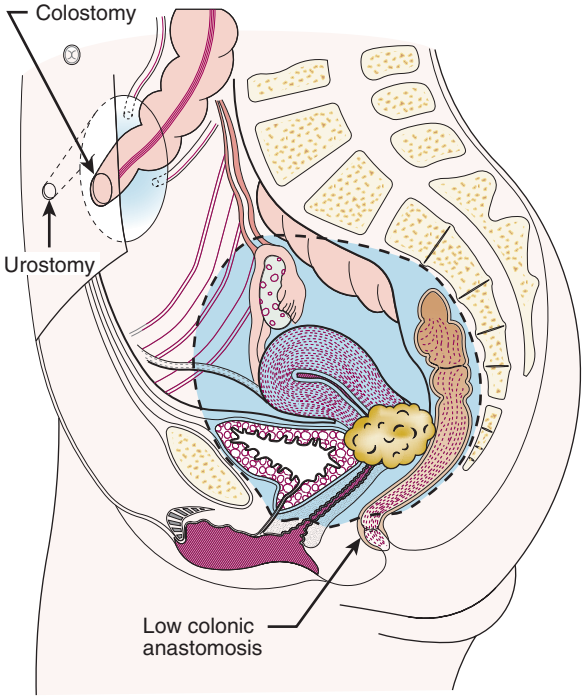
Radical hysterectomy has been reported as therapy for patients with a small recurrent cervical carcinoma after radiation. Coleman's series of 50 patients from the MD Anderson Hospital were treated with radical hysterectomy (type II or III). Severe postoperative complications occurred in 42% of these patients. Of these patients, 28% developed urinary tract injury. The survival rate was 90% at 5 years for patients with lesions smaller than 2 cm as opposed to 64% in patients with larger lesions. Excessive morbidity can be limited if an omental pedicle is placed at the operative site at the end of the procedure, bringing in a new blood supply to the operative field that has undergone previous radiation therapy.

Pelvic Exenteration

In 1948, Brunschwig introduced the operation of pelvic exenteration for cancer of the cervix (Fig. 3.44). Since then, extensive experience with pelvic exenteration has been accumulated, and the techniques and patient selection have steadily improved so that now, 50 years later, this procedure has attained an important role in the treatment of gynecologic malignancies for a selected group of patients. It is now accepted as a respectable procedure that can offer life to selected patients when no other possibility of cure exists. The criticism of this procedure has been lessened by steadily improving mortality and morbidity and a gratifying 5-year survival record. Most important, however, is that patients who survive this procedure can be rehabilitated to a useful and healthful existence.

Although pelvic exenteration has been used for various pelvic malignancies, its greatest and most important role is in the treatment of advanced or recurrent carcinoma of the cervix. **Total exenteration** (Fig. 3.45) **with removal of the pelvic viscera, including the bladder and rectosigmoid, is the procedure of choice for carcinoma of the cervix recurrent or persistent within the pelvis after irradiation.** In select cases, the procedure may be limited to anterior exenteration (Fig. 3.46) with removal of the bladder and preservation of the rectosigmoid or posterior exenteration (Fig. 3.47) with removal of the rectosigmoid and preservation of the bladder. Cogent objections have been raised regarding these limited operations, especially in patients with carcinoma of the cervix recurrent after irradiation, because of the increased risk of an incomplete resection. In addition, patients in whom the bladder or rectum is preserved often have multiple complications and malfunctioning of the





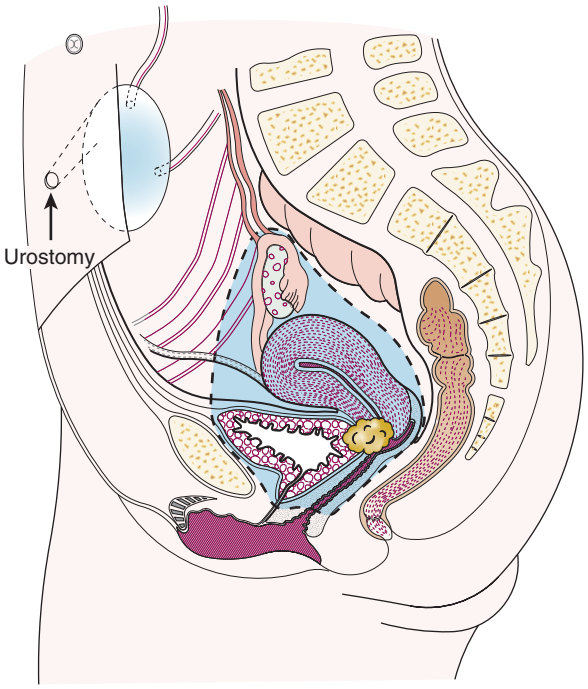


FIGURE 3.44 Specimen from an anterior exenteration done for recurrent cervical carcinoma; the specimen consists of the uterus, vagina, and bladder. (The anterior wall has been opened to expose bullous edema of the trigone.)

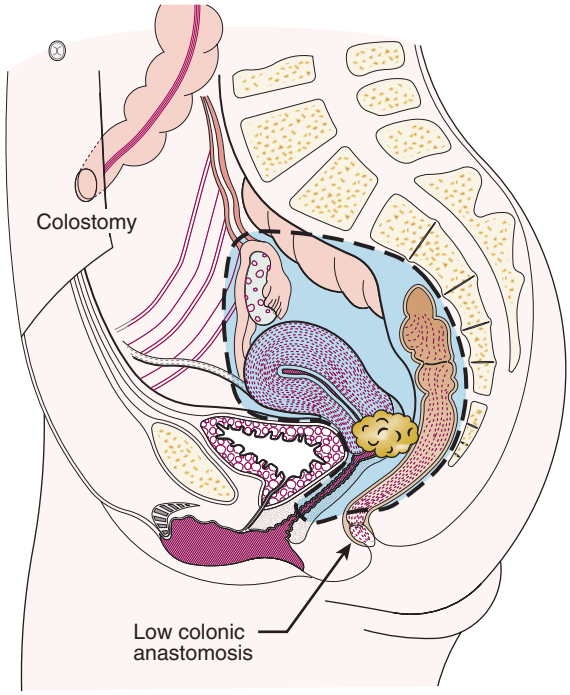

Shaded tissue within the *dashed outline* is permanently removed. Unshaded tissue within the *dashed outline* is first removed and then reconstructed.

FIGURE 3.45 Total exenteration with removal of all pelvic viscera. Fecal stream is diverted via a colostomy, and urinary diversion is via an ileal or sigmoid conduit or a continent pouch. (Modified from DiSaia PJ, Morrow CP, Townsend DE. Cancer of the vulva. *Calif Med* 1973;118:13-8.)

Shaded tissue within the *dashed outline* is permanently removed.

preserved organ. Consequently, some surgeons have completely abandoned subtotal exenterations, and most oncologists use them very selectively.

One of the greatest technical advances in the evolution of pelvic exenteration is the intestinal conduit for diversion of the urinary stream. Originally, Brunschwig transplanted the ureters into the left colon just proximal to the colostomy, thus creating the so-called wet colostomy. The complication rate from this procedure, especially electrolyte imbalance and severe urinary tract infections, was unacceptable. Bricker popularized the use of an ileal segment conduit for urinary diversion. The incidence of both postoperative pyelonephritis and hypochloremic acidosis has been greatly reduced. Furthermore, the patients are dry and comfortable and therefore more easily rehabilitated. More recent developments have resulted in several techniques for creation of a continent reservoir, again using a segment of bowel (Fig. 3.48). Another significant advancement in surgical technique of these patients is the use of the intestinal stapling device. Whereas a permanent colostomy was a standard part of the exenterative procedure, today, it is rare. In many, if not most, cases, reanastomosis with the end-to-end anastomosis stapler can be performed, and the fecal stream continues through the anus.

Patient Selection

Only a few patients with recurrent cancer of the cervix are suitable for this operation (Table 3.26). **Metastases outside the pelvis, whether manifested preoperatively or discovered at laparotomy, are an absolute contraindication to pelvic exenteration. The triad of unilateral leg edema, sciatic pain, and ureteral obstruction is pathognomonic of recurrent and unresectable disease in the pelvis. The triad must be complete, however, to be entirely reliable. Weight loss, cough, anemia, and other aberrations suggestive of advanced disease are not sufficient justifications by themselves to discontinue efforts toward surgical management. Obesity, advanced age, and systemic disease may interdict extensive surgery in direct relation to the severity of these factors. Some patients are unsuitable because of psychological reasons, and a number of women who are otherwise candidates for pelvic exenteration elect to accept the fate of unresected recurrence. If the time from primary treatment to recurrence is short (<2 years), this usually indicates aggressive biologic activity of the tumor, and resectability is usually limited.**

Evaluation studies before surgery include chest radiography, CT scan of the abdomen and pelvis with intravenous contrast, creatinine clearance, liver function tests, and assessment of the patient's hemostatic mechanism. Any suspected disease outside the pelvis noted on any of the diagnostic studies should prompt an attempt at confirmation using a fine-needle biopsy technique. Bone survey and liver scan are not part of the "routine" evaluation.

Preparation for pelvic exenteration is often traumatic to patients with recurrent cervical cancer, especially when the procedure is aborted. The increased use of CT-directed fine-needle aspirants has contributed greatly to lowering the fraction of patients explored who are found to be unexenterable. At

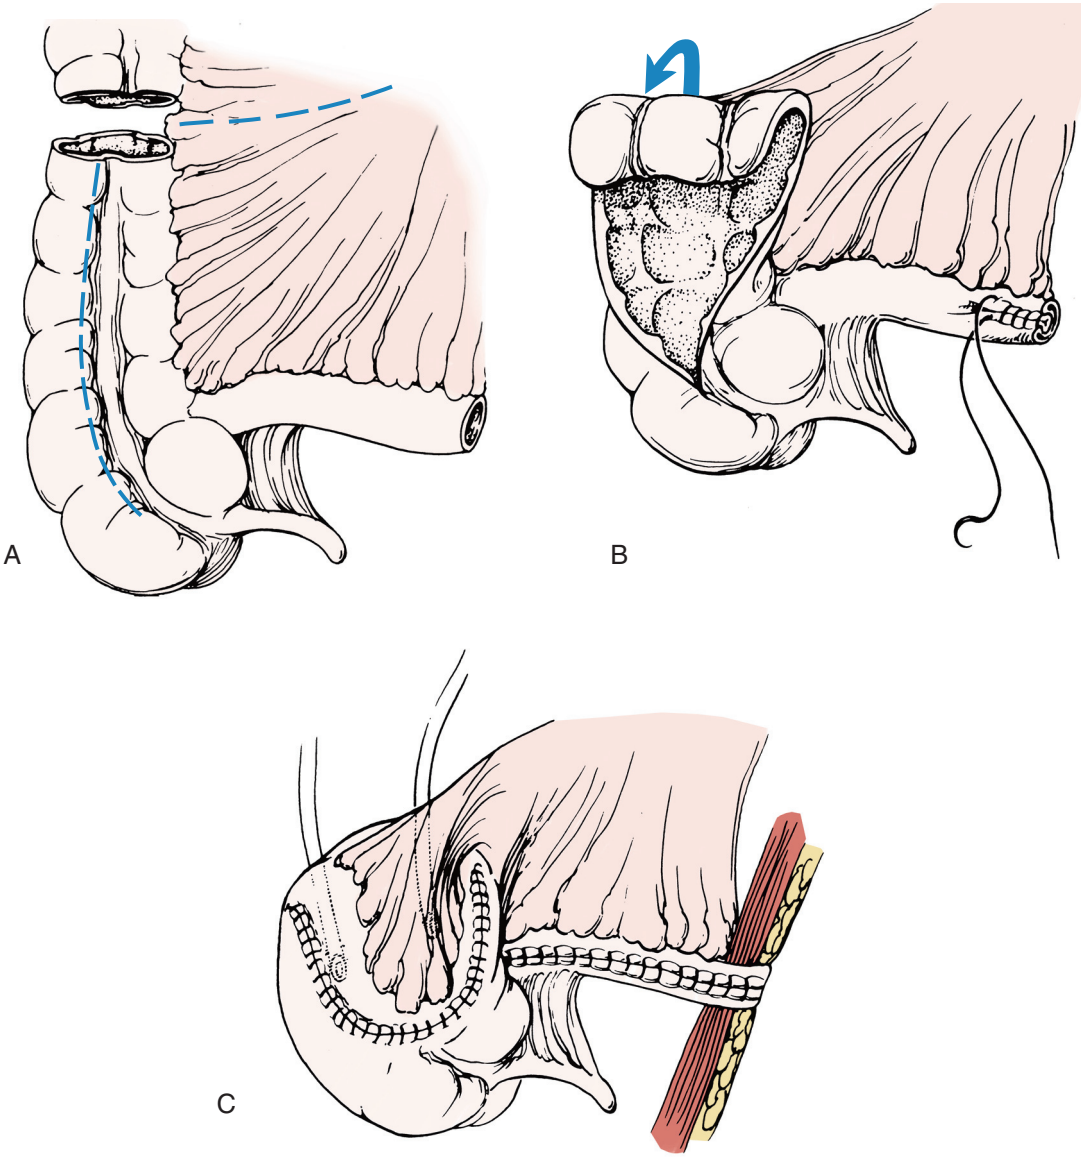

FIGURE 3.48 A–C, Construction of an Indiana pouch from the colon and the terminal ileum. (From Amis ES, Newhouse JH, Olsson CA. Continent urinary diversions: review of current surgical procedures and radiologic imaging. *Radiology* 1988;168:395-401.)

laparotomy, the entire abdomen and pelvis are explored for evidence of metastatic and intraperitoneal cancer (Fig. 3.49). The liver should be carefully inspected visually and by palpation. The lymph nodes surrounding the lower aorta are the first to be sampled if the exploration of the abdomen has revealed no evidence of disease. If the lower aortic area findings are negative, a bilateral pelvic lymphadenectomy is performed.

Morbidity and Mortality

Most of the morbidity and mortality directly related to exenteration occur within the first 18 months after the procedure. Many of the complications can be sequelae to any major surgery. These include cardiopulmonary catastrophes such as pulmonary embolism, pulmonary edema, myocardial infarction, and cerebrovascular accidents. The length of these surgical procedures and the magnitude of blood loss definitely increase the incidence of cardiovascular complications. This category of complications usually occurs within the first week after the procedure. Then there is a period when sepsis is the greatest threat to the patient's health and life. This sepsis usually originates in the pelvic cavity with occurrence of a pelvic abscess or, more commonly, diffuse pelvic cellulitis.

One of the most serious postoperative complications of exenteration is small bowel obstruction related to the denuded pelvic floor. In the past decade, several techniques have been used in an effort to avoid the adherence of small bowel to this large raw surface, including mobilization of omentum (Fig. 3.50) or abdominal wall peritoneum to cover the pelvic floor (Fig. 3.51). When small bowel obstruction does occur, it is appropriately treated with conservative therapy. However, half

TABLE 3.27 Signs and Symptoms of Recurrent Cervical Cancer

Weight loss (unexplained)
Leg edema (excessive and often unilateral)
Pelvic or thigh–buttock pain
Serosanguineous vaginal discharge
Progressive ureteral obstruction
Supraclavicular lymph node enlargement (usually on the left side)
Cough
Hemoptysis
Chest pain

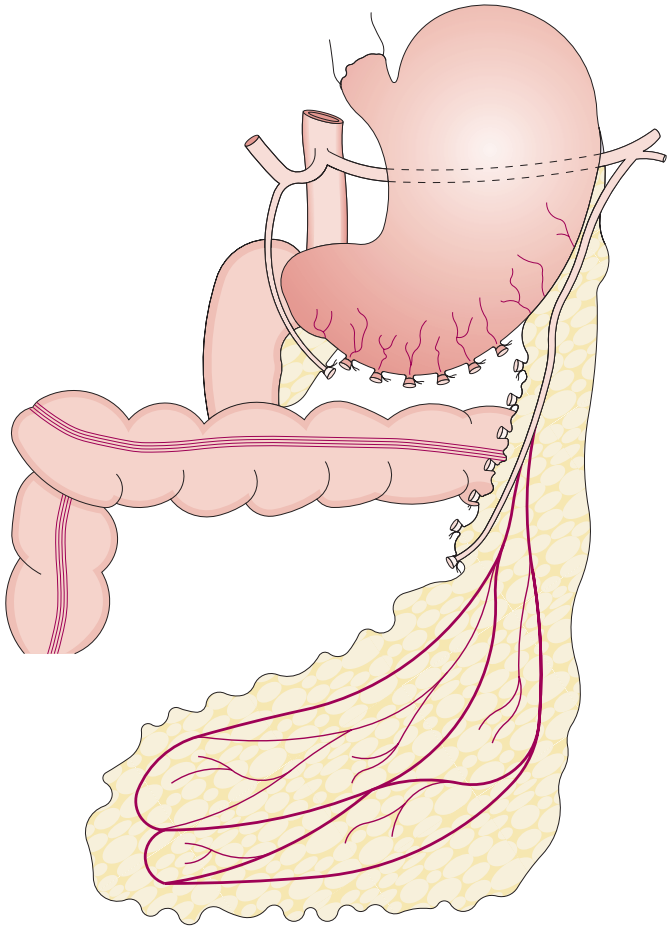

FIGURE 3.50 The omentum has been detached from the right transverse colon and the greater curvature of the stomach, keeping the left gastroepiploic vessels intact and creating a large "tongue of omentum" to cover the pelvic floor.

these patients come to reoperation, and the mortality rate of this group is approximately 50% in some series. The risk of bowel obstruction is increased by the presence of pelvic infection. Both conditions predispose to the development of small bowel fistulas, which always require reoperation and frequently are fatal. In general, complications are more common in patients who have recurrence after radiation therapy. Irradiated tissue is less likely to produce good wound healing, and the formation of granulation tissue is severely retarded.

The long-term morbidity from exenteration is predominantly related to urinary diversion. After the period of susceptibility to sepsis has passed, urinary obstruction and infection become the major nonneoplastic life-threatening complications. Pyelonephritis is common and should be treated promptly and vigorously. Periodic IVPs can be obtained to assess the collecting system for hydronephrosis. A mild degree of obstruction is frequently retained after construction of an ileal conduit, but progressive hydronephrosis will require correction to salvage renal function. The incidence of complications appeared to be less in patients in whom an unirradiated portion of bowel had been used for construction of the conduit.

Survival Results

The 5-year cumulative survival rate after pelvic exenteration varies in the literature from 20% to 62% (Table 3.26). Reported survival rates depend greatly on the circumstances of patient selection for exenteration. Cumulative survival rates are always improved when no patient is exenterated who has a positive pelvic node after pelvic irradiation. In general, however, both morbidity and mortality and the 5-year survival rate have improved steadily over the past 2 decades. The mortality rate in most centers is now well below 5%, and morbidity has been similarly lowered.

In 2009, 60 years after the first description of pelvic exenteration, Marnitz and colleagues surveyed and compared practice patterns in the United States and Germany. The number of exenterations performed in the 21st century was comparable in both countries, with centrally recurrent cervical cancer or persistent tumor after chemoradiation being the main indication. Whereas PET-CT is more commonly used in the United States, MRI is the preferred tool in Germany. Surgical staging is more commonly performed in the United States (61% vs. 32%). Exenteration for FIGO stage IVA disease was more commonly recommended in Germany (43% vs. 0%), as was the operation in the setting of fistulae involving the bladder or rectum (61% vs. 29%). In Germany, interdisciplinary treatment with general surgeons, urologists, plastic surgeons, and radiation oncologists is more common. Although there is a consensus to administer adjuvant therapy after exenteration for patients with positive margins or positive lymph nodes, adjuvant therapy is more frequently recommended in Germany (93%) than in the United States (74%).

In 2010, Spahn and colleagues reported the results of 37 anterior pelvic exenterations and six total pelvic exenterations performed at the University of Wurzburg in Germany. A continent urinary diversion was constructed in 16, and an ileal conduit was constructed in 27. Continent urinary diversion was not associated with higher complication rates than ileal conduit formation. The overall disease-specific 5-year survival rate was 36.5%. Survival correlated significantly with surgical margin status.

For vaginal reconstruction, vascularized muscle flaps are preferred to fill the empty pelvis, and developments in bioengineering tissue are likely to have applications in neovaginal creation. De la Garza and colleagues reported the successful performance of a total pelvic exenteration with a split-thickness

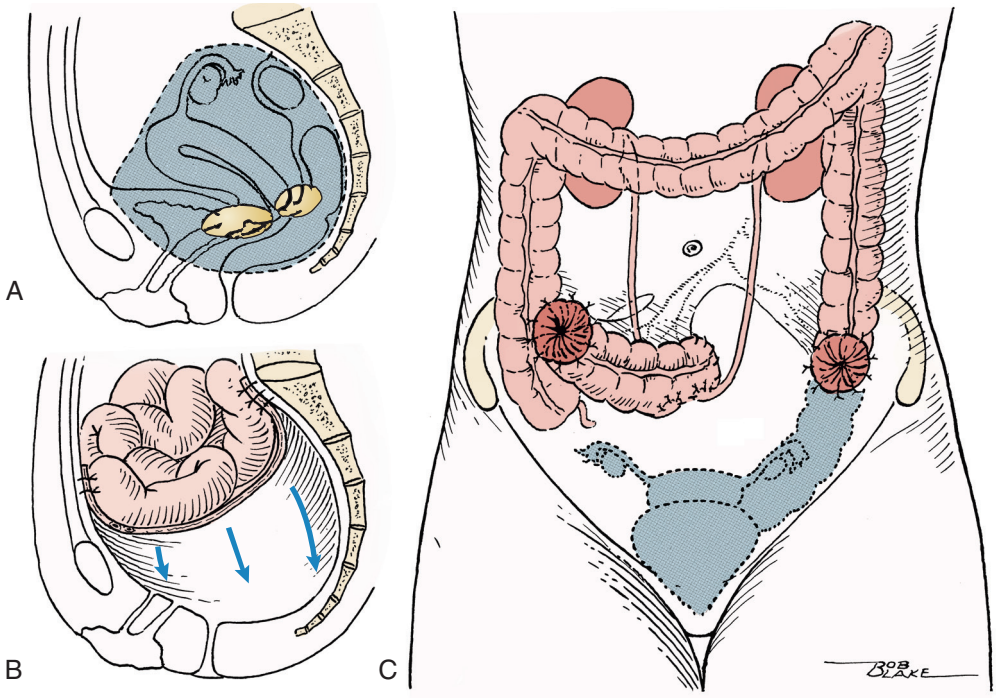

FIGURE 3.51 A, Lateral view of recurrent cancer involving the cervix and upper vagina with extension into the bladder and rectum. The *stippled area* indicates tissue to be removed by exenteration. B, A lateral view after pelvic viscera have been removed. The omental "carpet" is used to keep the intestines out of the pelvis during immediate postoperative period. With time, the omental "carpet" will descend into the pelvis, and the "carpet" will adhere to the pelvic floor. skin graft neovagina, continent orthotopic neobladder, and rectal anastomosis, resulting in no external ostomies and adequate sexual function.

Radiation

With recurrent disease outside the initial treatment field, irradiation is frequently successful in providing local control and symptomatic relief. External irradiation in moderate and easily delivered doses is usually effective in relieving pain from bone metastases. A dose of 3000 cGy delivered over 2 to 3 weeks is often sufficient to relieve pain from vertebral column or long-bone metastases.

Höckel and associates reported their experience with a combined operative and radiotherapy (CORT) for recurrent tumors infiltrating the pelvic wall. Although the combination therapy is not new, these authors surgically remove the recurrence more radically than previously reported. The bony pelvis and neurovascular support of the leg is preserved. Implantation of guide tubes, which exit from the skin for brachytherapy, is done after resection of the tumor. Considerable pelvic reconstruction is usually done. Although the indications and procedure are evolving, in the first 48 patients treated, survival probabilities are 50% and 44% after 3 and 5 years, respectively.

Reirradiation of pelvic recurrences of cervical cancer occurring within the previously treated field is a subject of some controversy. The results after reirradiation of patients with recurrent cervical malignancy have varied considerably. Truelsen reported a 3-year cure rate of 1.7%. Murphy and Schmitz reported a 9% salvage rate in 1956, and Nolan and associates reported on the use of 60Co teleradiation with a 25% salvage rate. At the Roswell Park Memorial Institute, Murphy and Schmitz adopted the policy of reirradiating patients with recurrence, delivering a full or almost full course for a second time. Among the highly selected series of 46 patients, 9% to 10% were living and well at the end of 5 years. Only seven patients had biopsy-proven recurrences before treatment. Others have shown that the results of reirradiation depend on many factors, including the site of recurrence, initial clinical stage, and initial dose of radiation therapy.

Careful perusal of these reports suggests that most patients who benefited from reirradiation were those who received less than optimal radiation during initial therapy. This set of circumstances has become rare in recent times, when more sophisticated radiotherapy is being delivered in many areas of the United States. Therefore, reirradiation for recurrent disease is usually not a worthwhile consideration. The potential for necrosis and fistula formation with even moderate doses of reirradiation in the pelvis by external or interstitial sources can give very unfavorable results.

Recurrence after radical hysterectomy has been treated with radiation. In a study from Holland, 271 patients were treated with radical hysterectomy, and 27 recurred with 14 limited to the pelvis. Of note, adjuvant radiotherapy had been administered in 14 (52%) of the 27. In the four patients with isolated

pelvic recurrence, only one died of disease, but all of the other patients with recurrences died of disease. The survivors were treated with radiation. In a study from the MD Anderson Cancer Center, 50 patients had recurrence after radical hysterectomy and were treated with radiation. OS rate was 33%. In the 16 patients with central disease, 12 (69%) remained disease free. The survival rate of 29 patients with squamous carcinoma was 51% compared with 14% for the 14 patients with adenocarcinoma ($P = 0.05$).

Chemotherapy

The management of disseminated cervical cancer has improved with the development of modern chemotherapy. Fig. 3.17 reviews the treatment of advanced or recurrent disease. Because concurrent platinum-based chemoradiation has become the standard of care for locally advanced disease, many recurrent tumors may therefore be platinum resistant. The GOG has completed eight multicenter, phase III randomized trials to study platinum-based therapies for recurrent and/or metastatic disease (Table 3.28). Drug discovery for the most part has fed into these phase III trial designs through the GOG's phase II series dedicated to exploring the activity and tolerability of cytotoxic compounds in cervical cancer.

The early trials of the GOG for recurrent and metastatic cervical carcinoma were designed to evaluate cisplatin dosing, schedules, and analogs. The next two trials evaluated the addition of ifosfamide, bleomycin, and mitolactol to cisplatin-based therapies. Among some of the lessons learned during the 1980s and 1990s governing chemotherapy for recurrent cervical cancer were that platinum-based therapies were most effective and that cisplatin was more active than carboplatin (19% vs. 15%, respectively). Two ways through which the RR could be increased without prolongation in survival included increasing the platinum dose and/or adding ifosfamide to cisplatin. As a consequence of these first five phase III randomized clinical trials, single-agent cisplatin at 50 mg/m^2 emerged as the standard for recurrent disease, with a documented 19% RR on a 21-day schedule.

The combined regimen of cisplatin in combination with paclitaxel in GOG 169 yielded an impressive 36% RR, improvement in PFS, but no significant impact on OS compared with single-agent cisplatin. The next trial, GOG 179, compared single-agent cisplatin with cisplatin plus topotecan. The improvements observed in RR, PFS, and OS all favored the combined regimen, leading to FDA approval of the cisplatin 50 mg/m^2 plus topotecan 1.75 mg/m^2 days 1 to 3 in this population. In both GOG 169 and GOG 179, RRs were decreased in patients who had received prior platinum (Table 3.29). Because GOG 179 was conducted during the era of chemoradiation and GOG 169 was under way before the adoption of multimodality therapy, 57% of patients on GOG 179 received radiosensitizing platinum compared with 27% on GOG 169.

Gynecologic Oncology Group 204 compared four platinum-based doublets using paclitaxel, topotecan, gemcitabine, and vinorelbine. Because this study was activated before the data from GOG 179 were mature, cisplatin plus paclitaxel was selected as the control arm, primarily because of the 36% RR observed in GOG 169. None of the experimental arms outperformed the reference arm (Table 3.30 and Fig. 3.52). For this reason, cisplatin plus paclitaxel has been selected as the control arm for the succeeding trial, which was activated in April 2009 (GOG 240).

In GOG 240, the experimental arms were designed to answer two critical questions. The first is a chemotherapy question and concerns whether nonplatinum agents would have greater activity in the recurrent setting given the increased usage of

platinum-based chemoradiation initially for locally advanced cancers. Two phase II experiences using nonplatinum doublets have been described. In the United Kingdom, the Scotcerv trial piloted gemcitabine plus Taxotere, which, when presented at American Society of Clinical Oncology (ASCO), was not deemed to be suitable for further development. Tiersten and colleagues reported on their experience with the nonplatinum doublet topotecan plus paclitaxel. It is important to note that the regimen was active in previously irradiated patients (RR, 26%) with acceptable toxicities. The laboratory work by Bahadori and colleagues demonstrating synergy between paclitaxel and microtubule-inhibiting agents (eg, topotecan or vinorelbine) underscored this regimen's potential.[12] This nonplatinum doublet is being studied by the Arbeitsgemeinschaft Gynakologische Onkologie (AGO).

The second question addressed by GOG 240 involves targeted therapy. Tumor angiogenesis as measured by microvessel quantification has been shown to be a prognostic factor in cervical cancer. A small case series by Wright and colleagues described the successful combination of bevacizumab with cytotoxic agents in the recurrent and metastatic setting among previously irradiated patients. Of note, the antiangiogenesis agent bevacizumab in combination with chemotherapy has been FDA approved first- and second-line therapy for metastatic colorectal cancer and untreated non–small cell lung cancer (NSCLC). The drug has also been studied by the GOG in primary advanced and platinum-sensitive recurrent ovarian

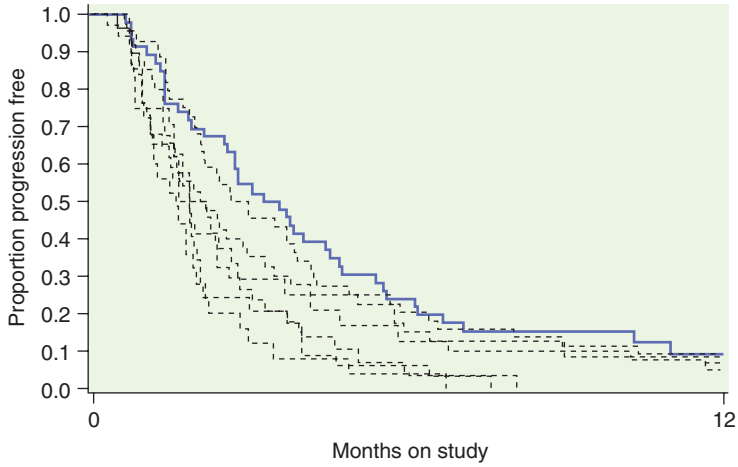

FIGURE 3.53 Progression-free survival curves of bevacizumab from Gynecologic Oncology Group protocol 227C superimposed over progression-free survival curves of other agents studied by the Gynecologic Oncology Group in this patient population. (From Monk BJ, Sill MW, McMeekin DS, et al. Phase III trial of four cisplatin-containing doublet combinations in stage IVB, recurrent, or persistent cervical carcinoma: a Gynecologic Oncology Group study. *J Clin Oncol* 2009;27:4649-4655.)

carcinoma. A phase II evaluation of bevacizumab at 15 mg/kg q21 days was undertaken within the GOG (protocol 227C). The 26% RR of bevacizumab among previously irradiated patients was among the highest RRs noted within the GOG's phase II experience for recurrent cervical cancer (Fig. 3.53).

Given the potential shared tumor biology between NSCLC and cervical cancer, the activity of platinum plus paclitaxel with bevacizumab in NSCLC supported the inclusion of this regimen as one of the experimental arms in GOG 240. Assuming no interaction between the nonplatinum doublet and bevacizumab, a 2 × 2 factorial design was selected to answer both the chemotherapy question and the antiangiogenesis question. The schema for GOG 240 appears in Fig. 3.54. This study also prospectively evaluated important prognostic factors—including African American race, performance status greater than 0, pelvic disease, prior radiosensitizer, and time interval from diagnosis to first recurrence less than 1 year—that have been recently reported by Moore and colleagues in a multivariate pooled analysis of three prior phase III studies in this population (Table 3.31).

At 173 deaths in February 2012, the preplanned interim analysis occurred and was noteworthy for demonstrating that the substitution of topotecan for cisplatin did not significantly improve OS in the GOG 240 population, even among those who were platinum-naïve. However, at 276 deaths in December 2012, the database was locked again and a second analysis performed. **In February 2013, the NCI issued a press release indicating that the open-label, multinational, multi-center, phase III, randomized clinical trial, GOG protocol 240, had met its primary endpoint with the arms administering the fully humanized, antivascular endothelial growth factor (VEGF) monoclonal antibody bevacizumab being associated with a significant survival advantage when compared to chemotherapy alone.** The rationale to target tumor angiogenesis in cervical cancer was based on clinical, pathologic, and molecular phenomenon that characterize HPV-induced cervical carcinogenesis along with therapeutic gains observed with antiangiogenesis drugs in phase I (eg, the fungal derived TNP-470 molecule) and phase II (bevacizumab; oral VEGF receptor tyrosine kinase inhibitor, pazopanib) trials in the recurrent cervical cancer population. In GOG 240, patients were treated every 21 days until progression. The American Society of Clinical Oncology accepted the abstract for the General Plenary 2013 but made a rare exception to their embargo policy and released the abstract into the public domain in March 2013, 3 months before the Annual Meeting. **Importantly, the incorporation of bevacizumab (15 mg/kg) with cisplatin–paclitaxel and with topotecan–paclitaxel led to a significant 3.7-month improvement in OS (17 vs. 13.3 months; HR, 0.71; 98% CI, 0.54–0.95; one-sided $P = 0.004$), a significant improvement in PFS (8.2 vs. 5.9 months; HR, 0.67; 95% CI, 0.54–0.82; two-sided $P = 0.002$), and superior ORR (48% vs. 36%; relative probability of response, 1.35; 95% CI, 1.08–1–1.68; two-sided $P = 0.008$)** (Fig. 3.55)**.** Each of these gains was clinically meaningful and was not accompanied by a significant deterioration of QoL when measured by three QoL instruments that had undergone prior prospective validation in this population. **A vaginal fistula rate of 8.6% was observed among patients who received bevacizumab, all of whom had been previously irradiated.**

The results of GOG-240 led directly to US FDA approval on August 14, 2014 (without an Oncology Drugs Advisory Committee [ODAC]) for the population studied, as well as approval by regulatory agencies throughout the world, including the United Kingdom's Cancer Drug Fund; the European Union's European Medicines Agency; SwissMedic; and the Ministries of Health in Israel, Australia, Hong Kong, five Middle Eastern nations, Brazil, and 10 Latin American countries, including Mexico. The National Comprehensive Category Network (NCCN) Cervical Cancer Treatment Guidelines have listed both bevacizumab-containing triplets studied in GOG 240

GYNECOLOGIC ONCOLOGY GROUP PROTOCOL 240

A randomized phase III trial of cisplatin plus paclitaxel with and without bevacizumab versus the nonplatinum doublet, topotecan plus paclitaxel, with and without NCI-supplied bevacizumab, in stage IVb, recurrent, or persistent carcinoma of the cervix.

Activation Date – April 6, 2009 Target Accrual = 450

Study Chair: Krishnansu S. Tewari, MD (ktewari@uci.edu) Statistician: Michael Sill, PhD Pathologist: Helen Michael, MD
Co-Chairs: Harry J. Long, MD (Medical Oncology), Richard T. Penson, MD (Quality of Life), Michael J. Birrer, MD, PhD (Translational Research)
Scientific Collaborations: Steven Waggoner, MD. David H. Moore, MD. Kathleen M. Darcy, PhD, Bradley J. Monk, MD

PRIMARY OBJECTIVES
1. To determine whether the addition of bevacizumab to chemotherapy improves overall survival
2. To determine whether the non-platinum chemotherapy doublet consisting of topotecan plus paclitaxel improves overall survival compared with the regimen involving cisplatin plus paclitaxel
3. To determine the frequency and severity of adverse events as assessed by CTCAE version 3.0 for the regimens administered

SECONDARY OBJECTIVES
1. To estimate and compare the progression-free survival of patients treated by the regimens investigated on this study
2. To estimate and compare the proportion of patients with tumor responses by the regimens investigated on this study

HEALTH-RELATED QUALITY OF LIFE OBJECTIVES
To determine whether the addition of bevacizumab to chemotherapy or the substitution of cisplatin with topotecan improves the health-related QoL as measured by the FACT-Cx TOI and produces favorable toxicity profiles

ELIGIBILITY
Primary stage IVB or recurrent or persistent carcinoma of the cervix
Measureable disease
GOG PS 0-1

Cycles repeated q21 days to progression or toxicity

RANDOMIZE

REGIMEN I
Paclitaxel 135 mg/m^2 IV 24h d1
CDDP 50 mg/m^2 IV d2 OR
Paclitaxel 175 mg/m^2 IV 3h 1
CDDP 50 mg/m2 IV d^2 OR
Paclitaxel 175 mg/m^2 IV 3h d1
CDDP 50 mg/m^2 IV d1

REGIMEN II
Paclitaxel 135 mg/m^2 IV 24h d1
CDDP 50 mg/m^2 IV d2

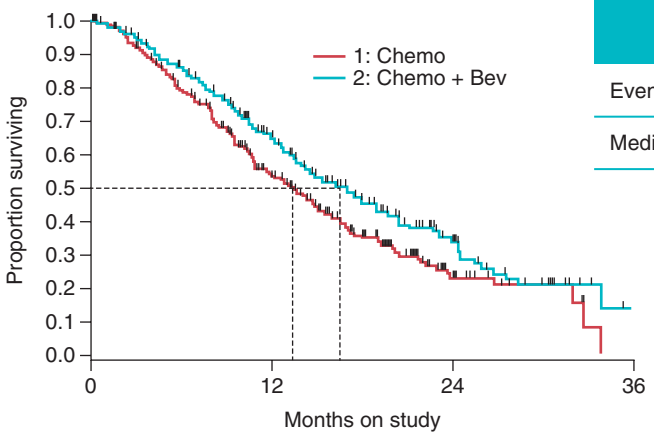
REGIMEN IV
Paclitaxel 175 mg/m^2 IV 3h d1
Topotecan 0.75 mg/m^2 30min d1–3
Bevacizumab 15 mg/kg IV d1

GOG Gynecologic Oncology Group



EXPLORATORY OBJECTIVE A: PROGNOSTIC MARKERS FOR PREDICTIVE MODELING
To evaluate the impact of age, race, performance status, stage, histology, grade, disease site, prior chemotherapy with primary radiation, and time to recurrence on RR, PFS, and OS

EXPLORATORY OBJECTIVE B: IMPACT ON SMOKING
To determine the prevalence of active smoking extent of nicotine dependence and to determine if smoking is an independent risk factor for PFS in this cohort

TRANSLATIONAL RESEARCH OBJECTIVES
1. To isolate circulating tumor cells recovered from blood and determine their association to measures of clinical outcome
2. To correlate angiogenesis markers in plasma, biomarkers of hypoxia, and single nucleotide polymorphisms with measures of clinical outcome
3. To develop an optimal prognostic model for PFS and OS using clinical covariates, smoking status, and various biomarkers

US NIH, 2010.

(cisplatin–paclitaxel–bevacizumab and topotecan–paclitaxel–bevacizumab) as Category 1.

We are seeing increasing evidence that therapy for metastatic cervical carcinoma does not need to be solely palliative. Qui and colleagues reported in 2007 on long-term survivors who presented with supraclavicular metastases. Additionally, in 2009, Takano and colleagues reported complete remissions in two patients with metastatic and recurrent cervical cancer. Before recurrence, one patient had received chemoradiation for locally advanced disease, and the other had been treated with adjuvant pelvic radiation after hysterectomy. Of note, both of these patients were treated with weekly paclitaxel (80 mg/m^2) plus carboplatin (area under the concentration vs time curve [AUC] 2.0) (days 1, 8, and 15) and weekly bevacizumab (days 1, 8, 15, and 21). Notwithstanding significant unanticipated toxicities, the ongoing trials of the Arbeitsgemeinschaft Gynakologische Onkologie (AGO; ie, German Society of Gynaecologic Oncology), Japan Clinical Oncology Group (JCOG), and Gynecologic Oncology Group (GOG) have been positioned to further refine therapeutic options for this disease.

Targeted Therapies

Biologic therapy is attractive in cervical cancer because of the homogeneity of the disease brought on by virally driven carcinogenesis. Several translational studies indicate that in addition to the VEGF-dependent angiogenesis axis (discussed later), other important signal transduction pathways to consider targeting include the PI3KC/Akt/mTOR pathway, the Notch signaling pathway, and patients harboring homologous recombination deficiencies for whom poly-ADP-ribose polymerase (PARP) inhibitors may be active.

Angiogenesis Inhibitors

As discussed earlier, biologic therapy in the form of angiogenesis inhibitors may be useful in retarding tumor growth and progression and even eliminating small-volume residual disease. Evidence that angiogenesis plays an important role in locally advanced cervical cancer has accumulated in recent years. In one study of 111 patients, Cooper and colleagues identified tumor angiogenesis (as reflected by the tumor microvessel density [MVD]) as a significant prognostic factor within a Cox multivariate analysis, where it was associated with poor locoregional control and OS. Conversely, among 166 women who underwent radical hysterectomy for stage Ib tumors, Obermair and colleagues demonstrated enhanced 5-year survivorship when the MVD was less than 20 per high power field (HPF) (90% vs. 63% with MVD >20 HPF). The VEGF receptor expression has also been shown to correlate with MVD in cervical carcinomas.

Several small-molecule inhibitors are actively being studied in cervical cancer, although none of these agents is currently approved in cervical cancer. Pazopanib is an oral tyrosine kinase inhibitor with antiangiogenic activity. It targets VEGFR, PDGFR, and c-Kit. Another oral tyrosine kinase inhibitor, lapatinib, targets EGFR and HER2. Given existing evidence supporting a role for angiogenesis in cervical cancer and the observation that overexpression of EGFR correlates with poor outcome in this disease, Monk and colleagues studied these drugs in 230 patients with measurable stage IVB persistent or recurrent cervical carcinoma not amenable to curative therapy and at least one prior regimen. The randomization scheme included pazopanib 800 mg/day ($n = 74$) vs. lapatinib 1500 mg/day ($n = 78$) vs. pazopanib 400 mg/day plus lapatinib 1000 mg/day ($n = 78$). The futility boundary was crossed for the combined regimen at the planned interim analysis, and this arm was discontinued, leaving a total of 152 patients in the monotherapy arms. Pazopanib improved PFS (HR, 0.66; 90% CI 0.48, 0.91; $P = 0.013$) and OS (HR, 0.67; 90% CI 0.46, 0.99; $P = 0.045$; median OS for *P* is 50.7 weeks; L is 39.1 weeks) with RR for pazopanib of 9% and that of lapatinib of 5%. Pazopanib was generally well tolerated, with the most common grade III adverse effect reported being diarrhea.

One year after presentation of the GOG 240 results that demonstrated a survival advantage associated with the integration of bevacizumab with chemotherapy, Symonds et al. presented data on their randomized, blinded, phase II trial of Cediranib in Recurrent Cervical Cancer (CIRCCa). Cediranib is a tyrosine kinase inhibitor of VEGF receptors 1, 2, and 3. Patients received cediranib 20 mg orally daily or matched placebo in combination with carboplatin AUC5 and paclitaxel 175 mg/m^2 three times weekly. This was continued until documented disease progression or inability to tolerate adverse events. A total of 69 patients was randomized and 79% completed six cycles of chemotherapy. Median PFS for the cediranib and placebo arms were 35 weeks and 30 weeks, respectively (HR, 0.61; 80%CI, 0.41–0.89; $P = 0.046$). No significant difference in OS was demonstrated. The overall response rate with cediranib was 66% (80% CI, 53%–77%) compared with 42% with placebo (80% CI 30%–55%). Cediranib showed significantly more grade 3/4 neutropenia than placebo (31% vs. 9%, $P = 0.019$). Additionally, 50% experienced grade 2, 3, or 4 diarrhea, and 34% experienced grade 2, 3, 4 hypertension. Given its manageable toxicity but lack of demonstrated improvement in OS, further assessment of this agent may be warranted.

Immunotherapy

As discussed earlier, the therapeutic landscape of advanced melanoma has been effectively transformed through the introduction of checkpoint inhibitors. Clinical trials using the anti-programmed death cell 1 drugs pembrolizumab and nivolumab are currently being planned or are underway through the NRG Oncology cooperative group.

Therapeutic Human Papillomavirus Vaccine

Therapeutic vaccines target virus-infected cells using epitopes of major histocompatibility complex (MHC)–processed peptides. Through interaction with CD8+ lymphocytes and MHC I pathways, they engage the cellular machinery, resulting in production of cytotoxic T lymphocytes. The HPV oncoproteins E6 and E7 can be targeted for the development of antigen-specific vaccination. Molecular strategies to design a therapeutic vaccine can be based on bacterial or viral vectors, peptides, proteins, DNA, and even dendritic cells. They may be useful in inducing regression, halting progression of preinvasive disease, or eradicating subclinical residual neoplastic disease after therapy.

With respect to prophylactic HPV vaccines, in 2003, the World Health Organization convened a gathering of experts from both developing and developed countries to identify the appropriate endpoint measurements for HPV vaccine efficacy. The general consensus was that it would be desirable to have a globally agreed, measurable efficacy endpoint for considering deployment of HPV vaccines in public health settings. Because of the temporal lag between infection and the manifestation of invasive carcinoma, it was determined that a surrogate endpoint would be used to define the efficacy of HPV vaccines. Because persistent infection with the same high-risk HPV subtypes is considered a predictor for both moderate- or high-grade cervical dysplasias and invasive cervical cancer, it was determined that cervical intraepithelial neoplasia (CIN), rather than invasive cancer, would serve as the endpoint after HPV vaccine introduction.

Garcia and colleagues from the University of Arizona conducted a randomized, multicenter, double-blind, placebo-controlled trial in 161 women with biopsy-confirmed CIN II to III. Subjects received three intramuscular doses of placebo or ZYC101a, a vaccine containing plasmid DNA-encoding fragments derived from HPV-16 and -18 E6 and E7 oncoproteins. The vaccine was well tolerated and had demonstrable efficacy in promoting resolution of CIN II to III in women younger than age 25 years. Recently, Einstein and colleagues presented data from their phase II trial using the novel therapeutic vaccine HspE7. The fusion protein consists of a *Mycobacterium bovis* BCG heat shock protein (Hsp65) covalently linked at its C terminus to the entire sequence of HPV-16 E7. With an excellent safety profile on record, 32 HIV-negative women with CIN III were vaccinated. The investigators observed a 48% resolution of CIN III, 19% partial responses, and 33% of subjects with stable disease over a 4-month follow-up period.

A study by ADVAXIS conducted in India demonstrated no improvement in survival when cisplatin was added to their HPV-16 E7-based therapeutic vaccine. The immunotherapy platform being used by ADVAXIS is composed of an attenuated *Listeria monocytogenes* live vector that secretes an antigen-adjuvant fusion protein composed of truncated listeriolysin O and HPV-16 E7 oncoprotein. Through a shared evolution during which time *Listeria* has infected humans and humans in turn have acquired immunity to this bacterium, a profound, genetic ally-conserved, pathogen-associated immune mechanism has developed. Importantly, the first stage of GOG 265 (the open-label phase II trial of ADXS-HPV monotherapy in women with recurrent or persistent and metastatic cervical cancer) was notable for having a minimum of six patients alive (out of 26) at 12 months, allowing the trial to proceed to the second stage and is currently planning to enroll up to 38 additional patients. ADXS-HPV has also been greenlighted to be studied in HPV-induced head and neck carcinoma. At present, GOG Partners is developing a trial to study adjuvant ADXS-HPV in high-risk women treated with chemoradiation for locally advanced disease.

Human Papillomavirus–Targeted Tumor-Infiltrating T Cells

Stevanovic recently reported promising results from a small trial conducted at the NCI for women with metastatic cervical cancer who had been previously treated with platinum-based chemotherapy or chemoradiotherapy. Nine women were treated with a single infusion of tumor-infiltrating T cells selected when possible for HPV E6 and E7 reactivity (HPV-TILs). Cell infusion was preceded by lymphocyte-depleting chemotherapy and followed by administration of aldesleukin. Three of nine patients experienced objective tumor responses (two complete responses and one partial response). At the time of publication, the two complete responses were ongoing at 22 and 15 months after treatment. Importantly, HPV reactivity of T cells in the infusion product correlated positively with clinical response. Patients whose serum showed no reactivity did not respond to a single infusion of HPV-TILs. This approach using a novel autologous T-cell vaccine continues to be studied in this population.

Endometrial Hyperplasia, Estrogen Therapy, and the Prevention of Endometrial Cancer

Lisa M. Landrum, MD, PhD, Rosemary E. Zuna, MD, Joan L. Walker, MD

OUTLINE

Introduction
Clinical Presentation
Endometrial Hyperplasia: Pathologic Diagnostic Criteria
Management Decisions for Atypical Endometrial Hyperplasia (Endometrial Intraepithelial Neoplasia)
Management of Endometrial Hyperplasia Without Atypia
Prevention of Endometrial Cancer
Benefits and Risks of Estrogen Replacement Therapy
Quality of Life, Vasomotor Symptoms, and Sexual Function
Osteoporosis
Colorectal Cancer
Cardiovascular Disease
Estrogen Replacement Therapy for Endometrial and Breast Cancer Survivors
Estrogen Replacement Therapy for Endometrial Cancer Survivors
Hormonal Therapy for Breast Cancer Survivors

KEY POINTS

1. Atypia is the most worrisome feature in endometrial hyperplasia.
2. Complex hyperplasia with atypia has a concomitant risk of malignancy of more than 40%, many of which are high grade.
3. Estrogen therapy is the most effective treatment of postmenopausal vasomotor symptoms.
4. Estrogen is effective in the prevention and treatment of osteoporosis.

INTRODUCTION

The endometrium is a very dynamic tissue in reproductive age women. It is continuously changing in response to hormonal, stromal, and vascular influences, with the intended goal of implanting an embryo and supporting the nutritional needs of the developing pregnancy. Whereas estrogen stimulation is associated with the growth of proliferative endometrium (Fig. 4.1), progesterone produced by the corpus luteum after ovulation inhibits proliferation and stimulates formation of secretory endometrium (Fig. 4.2). Without conception and human chorionic gonadotropin (hCG) production, the corpus luteum fails to produce progesterone, and hormonal withdrawal allows endometrial breakdown and menses to occur. Continuous estrogen stimulation of the endometrium bypasses the normal recycling of the endometrium. Menarche and menopause represent transition times of varying lengths in women's lives when the absence of ovulation predisposes them to unopposed estrogen stimulation because no corpus luteum forms to secrete progesterone. Some women (≈5%) have polycystic ovarian disease, which is a prolonged anovulatory condition prone to estrogen excess. Obesity during menopause also produces a state of excess estrogen production. This is due to the peripheral conversion, in the adipose tissues, of androgens secreted from the adrenal glands and ovaries into an estrogen, estrone, by the enzyme aromatase.

Unopposed estrogen stimulation yields a continuous spectrum of change from proliferative endometrium (Fig. 4.3) through many variations of endometrial hyperplasia until a malignant neoplasm develops. Endometrial cancer is defined by the ability to invade local tissue and metastasize (Fig. 4.4). Endometrial lesions show glandular and stromal variations in continuous change, presenting the challenge of classifying endometrial hyperplasia into distinct, reproducible categories that predict neoplastic risk, as well as response to progesterone therapy. Histopathologic classification of endometrial lesions provides a stratification of risk for progression to cancer by defined endometrial changes.

Understanding the pathophysiology of excess unopposed estrogen production helps the clinician better predict which women are at risk for endometrial cancer and provides windows of opportunity for implementation of prevention strategies. Selective estrogen receptor modulators (SERMs) such as tamoxifen and raloxifene and, more recently, aromatase inhibitors are widely used as both treatment and chemoprevention of breast cancer. These drugs have toxicities that the obstetrician/

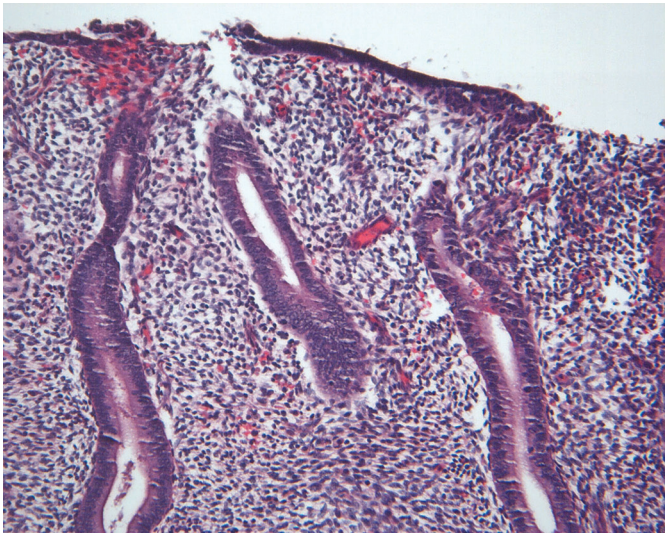

FIGURE 4.1 Proliferative endometrium. Simple tubular endometrial glands are set in a prominent stroma. This pattern is associated with normal estrogen stimulation in a cycling woman (hematoxylin and eosin, 100× original magnification).

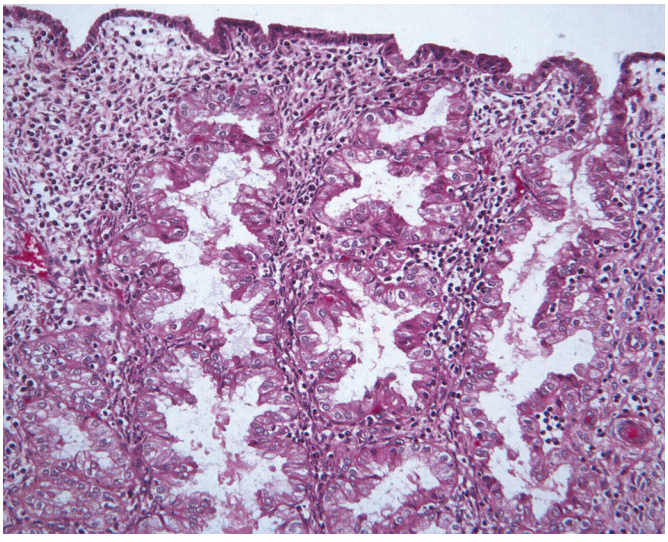

FIGURE 4.2 Secretory endometrium. Endometrial glands are present with a sawtooth pattern. Each gland is an individual unit set in endometrial stroma. The epithelium has intracytoplasmic glycogen secretion that is eventually extruded into the gland lumen (hematoxylin and eosin, 100× original magnification).

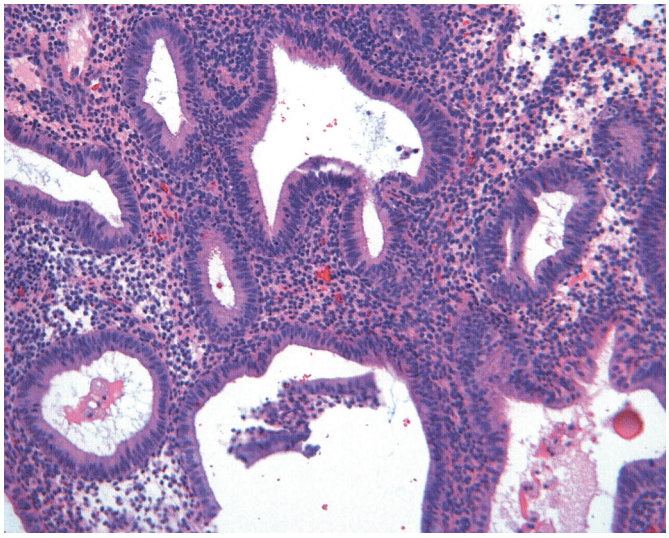

FIGURE 4.3 Benign endometrial hyperplasia (formerly simple hyperplasia without atypia). The endometrium shows an increase in the glandular epithelium usually caused by unopposed estrogen stimulation. This results in irregular and unpredictable gland outlines that are often cystic. There is abundant stroma, so that the gland-to-stromal ratio is little altered from normal (hematoxylin and eosin, 100× original magnification).

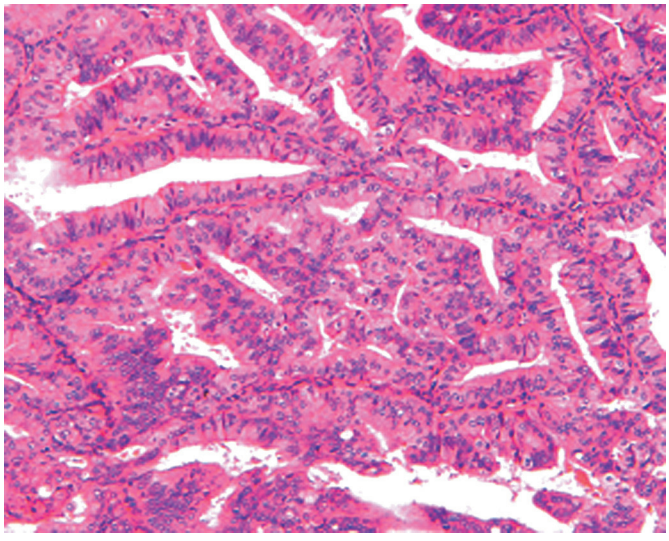

FIGURE 4.4 Endometrioid adenocarcinoma. Well-differentiated (International Federation of Gynecology and Obstetrics G1) endometrioid adenocarcinomas typically show a "back-to-back" glandular arrangement with little intervening stroma. The glands are lined by tall columnar cells (hematoxylin and eosin, 200× original magnification).

gynecologist will be required to manage. Although tamoxifen is an antiestrogen in breast tissue, it paradoxically has estrogen-like properties in the endometrium and increases the risk of endometrial cancer. It is also associated with thromboembolism and stroke. Although tamoxifen provides protection against bone loss, osteoporosis, and fractures, it does not appear to carry increased risk of myocardial infarction. There does appear to be an association with cataracts. Aromatase inhibitors block the cytochrome p450 CYP-19 enzyme responsible for the peripheral conversion of androgens to estrogens and result in estrogen deficiency. This accelerates menopausal bone loss, which could lead to osteoporosis and fractures; therefore, prevention of these toxicities is important when they are prescribed. Other side effects include hot flashes, sweats, edema, myalgias, and fatigue. Unfortunately, both tamoxifen and aromatase inhibitors accentuate menopausal symptoms.

Preventive health maintenance must balance all risks and benefits while maintaining quality of life and symptom control,

and this is the central theme in this chapter. Many women want active control over these very important choices, balancing quality of life and their sexuality with factors such as cancer prevention and cardiovascular risk reduction.

CLINICAL PRESENTATION

The scientific explanation for the low incidence rates for endometrial hyperplasia is that it is a lesion that is usually unrecognized and asymptomatic until cancer develops. Until endometrial cancer screening becomes routine and cost effective, the true prevalence of the precursor lesions will remain unknown. Women with endometrial hyperplasias are identified by endometrial biopsy performed because of abnormal vaginal bleeding (menorrhagia or postmenopausal bleeding) or because a thickened endometrial stripe is found on transvaginal ultrasonography when ordered for another reason such as the identification of endometrial cells in the Pap test of a woman older than the age of 40 years.

There is evidence of exogenous or endogenous unopposed estrogen stimulation of the endometrium in most women with endometrial hyperplasia. The most common causes of excess estrogen are obesity, polycystic ovarian disease, or a prolonged perimenopause with anovulatory bleeding patterns. Some women have an ovarian neoplasm producing the estrogen stimulation, which is the classic presentation of a granulosa cell tumor. The development of hyperplasia secondary to anovulation at menarche is very uncommon and should be easily reversible, with normalization of cyclic menses with oral contraceptive pills. The age at presentation depends on the source of the excess estrogen. Endometrial hyperplasias and cancers that are associated with estrogen stimulation have a good prognosis. Endometrial cancers in women without evidence of excess estrogen are usually not associated with hyperplasia and can be associated with a tumor suppressor gene abnormality such as p53 associated uterine papillary serous carcinomas (Figs. 4.5 and 4.6). These are aggressive tumors, behaving similar to ovarian cancer with higher mortality rates.

Office endometrial biopsy has replaced the dilation and curettage (D&C) procedure for the diagnosis of endometrial hyperplasia or carcinoma. Historically, there was thought to be potential benefit of curettage as therapy, as well as providing more tissue for accurate histologic diagnosis. The use of "hormonal curettage" in which medical therapy with progesterone is followed by the withdrawal bleed provides the same benefit without the surgical cost or risk. Repeat office endometrial biopsy at 3-month intervals can reassure the patient and the clinician of the therapeutic effect of the hormonal therapy. An argument can be made that hysteroscopy and D&C for abnormal bleeding would potentially be more effective in identifying endometrial cancers, but there is no evidence that D&C reduces a woman's mortality risk. This outpatient office evaluation and management has become the usual and safest way to manage these patients until there is evidence that a hysterectomy is required. These management decisions are discussed further in later sections of this chapter.

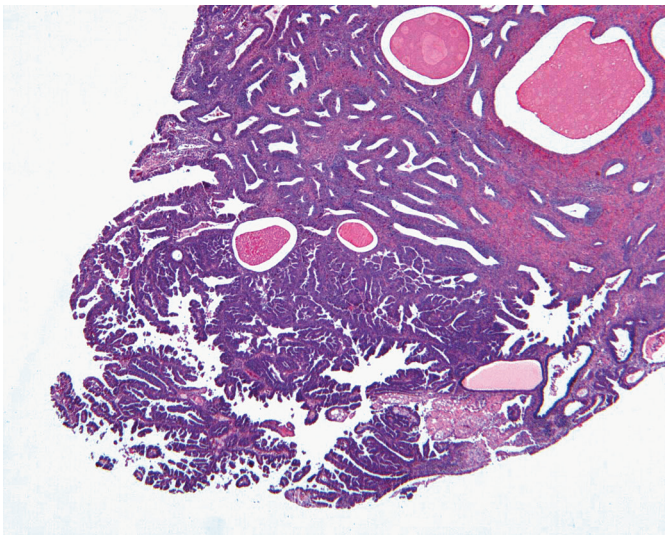

FIGURE 4.5 Endometrial serous carcinoma in a polyp. There is an irregular, complex pattern of papillary epithelium arising in the tip of an endometrial polyp (hematoxylin and eosin, 20× original magnification).

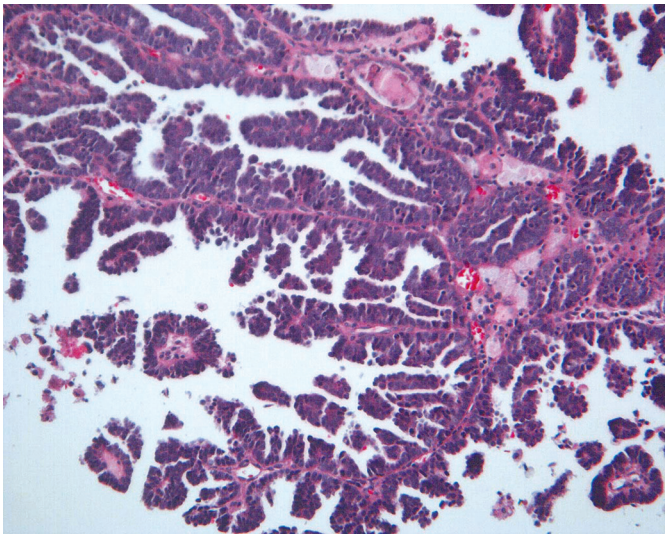

FIGURE 4.6 Endometrial serous carcinoma. This tumor shows a complex pattern of highly atypical cells with large irregular nuclei and prominent nucleoli. Typically, the tumor shows a papillary configuration, with abnormal epithelium covering a thin connective tissue core (hematoxylin and eosin, 100× original magnification).

ENDOMETRIAL HYPERPLASIA: PATHOLOGIC DIAGNOSTIC CRITERIA

There are currently two systems of nomenclature for endometrial precursors, the 1994 World Health Organization (WHO94) schema and the endometrial intraepithelial neoplasia (EIN) system. Recently, the American College of Obstetrics and Gynecology and the Society of Gynecologic Oncology have published their "Committee Opinion" endorsing the EIN system but the community pathologists are not yet using this system. The International Society of Gynecological Pathologists (ISGYP),

TABLE 4.1 Classification of Endometrial Hyperplasia

Simple hyperplasia
Complex hyperplasia (adenomatous)
Simple atypical hyperplasia
Complex atypical hyperplasia (adenomatous with atypia)

From World Health Organization, Kurman RJ, ed. *Blaustein's Pathology of the Female Genital Tract*, ed 4, Springer, NewYork, 1994.

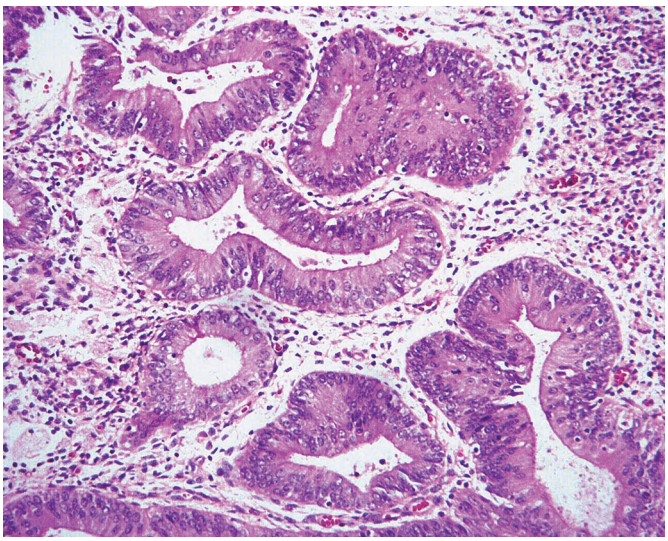

FIGURE 4.7 Endometrial intraepithelial neoplasia (formerly atypical complex hyperplasia). The tissue shows a marked increase in the gland-to-stromal ratio with complex glandular outlines and nuclear atypia in the lining epithelium (hematoxylin and eosin, 100× original magnification).

International Federation of Gynecology and Obstetrics (FIGO), a schema is commonly used to classify endometrial hyperplasia into four categories based on architectural structure and cytologic features. The architecture is either simple or complex, and the cytologic features are described as with or without atypia. This yields four separate diagnoses (Table 4.1): simple hyperplasia without atypia (see Fig. 4.3), complex hyperplasia without atypia, simple hyperplasia with atypia, and complex hyperplasia with atypia (AEH) (Fig. 4.7). The terms *adenomatous* and *cystic-glandular hyperplasia* have been discarded, and when the abbreviation AEH is used, it refers to atypical endometrial hyperplasia (AEH), which reflects the two categories of hyperplasia with cytologic atypia (simple hyperplasia or complex hyperplasia with atypia). The presence of atypia appears to be the most important criteria for progression to adenocarcinoma or the coexistence of endometrioid adenocarcinoma. The rates of coexisting endometrioid adenocarcinoma with AEH are reported to be as low as 13% and as high as 43%.

The pathologic diagnosis of these lesions is usually made with a small sampling of the endometrium in the office using an endometrial biopsy device. This small tissue sample then has to be categorized by the pathologist. A prospective study of the reproducibility of the diagnosis of AEH (both simple and complex) was undertaken by the Gynecologic Oncology Group (GOG). Women with the diagnosis of AEH who agreed to have a hysterectomy within 12 weeks of diagnosis of AEH were enrolled. The study population included 302 eligible cases with a median age of 57 years; 31% were 50 years of age or younger. The endometrial biopsy specimens were re-reviewed by three gynecologic pathologists independently (study panel diagnosis) in a blinded protocol. They agreed to categorize the endometrium as normal (cycling, menstrual, or atrophic), nonatypical hyperplasia (disordered proliferative, simple or complex hyperplasia), atypical hyperplasia (simple or complex), adenocarcinoma, or inadequate for evaluation. Two of three study pathologists had to agree on one of the above five diagnoses for a study panel diagnosis to be established. Correct diagnosis was determined by consensus agreement on the hysterectomy specimen during a simultaneous panel review with a multiheaded microscope. The results found only 40% of the cases had all three pathologists in agreement. The reproducibility was lowest for the diagnosis of AEH (kappa 0.28), and better for adenocarcinoma (kappa 0.51). Reproducibility was best for D&C (kappa 0.47; confidence interval [CI] 0.41:0.53) compared with small sampling devices (kappa 0.26–0.36). Two of three study panel members agreed with the referring institution diagnosis of AEH in 38% of cases. The study panel diagnosis was less severe in 25% of cases and adenocarcinoma in 29% of cases. The most important outcome for this study was the finding that 43% of the enrolled participants were found to have adenocarcinoma in their uteruses at the time of hysterectomy. The second most important finding was the rate of adenocarcinoma in each study panel majority diagnosis category: normal or nonatypical hyperplasia, 14 of 74 (18.9%); AEH, 45 of 115 (39.1%); and adenocarcinoma, 54 of 84 (64.3%). The uterine examination revealed the presence of some risk factors for metastatic disease present in 43 cases, including myometrial invasion or grade 2 or 3 lesions.

The natural history of simple hyperplasia without atypia is likely to follow a benign course. It is often seen in women near menopause when anovulatory cycles are common. The removal of the estrogenic stimulation or treatment with progestogens favorably influences the outcome. The majority of lesions will regress (60%) without treatment, and 84% will regress with progestin therapy. Only 3% are believed to progress to cancer. In the absence of atypia, the goal of treatment is to prevent progression to cancer in a small population of patients and to control abnormal uterine bleeding. The duration of treatment and best agent for progestin therapy have not yet been identified; however, medroxyprogesterone acetate (MPA) is typically used because there is the most clinical experience with it. Other progestin preparations that have been effectively used in hyperplasia without atypia include levonorgestrel-releasing intrauterine device and estrogen-progestin contraceptives in patients who desire to retain fertility. Complex hyperplasia is also expected to regress (56%) when atypia is not present. Atypical hyperplasia has a 36% progression rate, and even with progestins, 27% have been reported to progress, but it is uncertain if this is coexistent cancer that is eventually identified. Fifty-five percent of atypical hyperplasia is expected to regress with

progestin therapy. A study among Finnish women notes that a treatment regimen including continuous progestin rather than cyclical (10–14 days/month) progestin appears to reduce risk of endometrial cancer in a postmenopausal population. It is assumed that unless the estrogen stimulation ceases, the progestin therapy may need to be lifelong. Alternatively, a hysterectomy is necessary to prevent the development of endometrioid adenocarcinoma (Fig. 4.4) or type I cancer (estrogen dependent). This estrogen-induced cancer is the most common histologic type and the least aggressive form of uterine malignancy and should be preventable, as well as successfully treated when detected.

The EIN system developed by International Endometrial Collaborative Group classifies endometrial precursors based on their clonal origin, noninvasive growth patterns, and risk of concurrent carcinoma. For a diagnosis of EIN to be made, the following criteria must be met: area of glands exceeds the stroma, cytology differs between the crowded focus and the normal background endometrium, the size of the lesion exceeds 1 mm and benign pathology with overlapping features such as polyps or effects of exogenous estrogen can be eliminated. This system is not universally adopted at this time, but there is some evidence that the clinical outcome prediction and the interobserver reproducibility using EIN may be improved over the 1994 WHO schema.

Endometrial carcinomas of the serous papillary variety arise in a background of atrophic endometrium. These cancers are not associated with excess estrogen and have been classified as type II (estrogen independent) endometrial cancers. Serous papillary adenocarcinoma is less likely to be identified at an early stage compared with endometrioid histologic types. These lesions are typically associated with mutations in the p53 tumor suppressor gene that results in accumulation of inactive p53 protein in the cell (Fig. 4.8). Unlike normal cells or most endometrioid cancers, immunostaining with antibodies to p53 will be positive in the majority of serous cancers. Endometrial hyperplasia is not a precursor to serous carcinoma. Rather, the precursor has been identified as endometrial intraepithelial carcinoma (EIC). Serous EIC (Fig. 4.9) can even be multifocal with disease found in the ovaries, fallopian tubes, and peritoneal cavity when no invasive component is found in the uterus. Comprehensive surgical staging is recommended because of the difficulty in establishing the diagnosis of invasive cancer intraoperatively. Postoperative therapy can be recommended after adequate histologic evaluation.

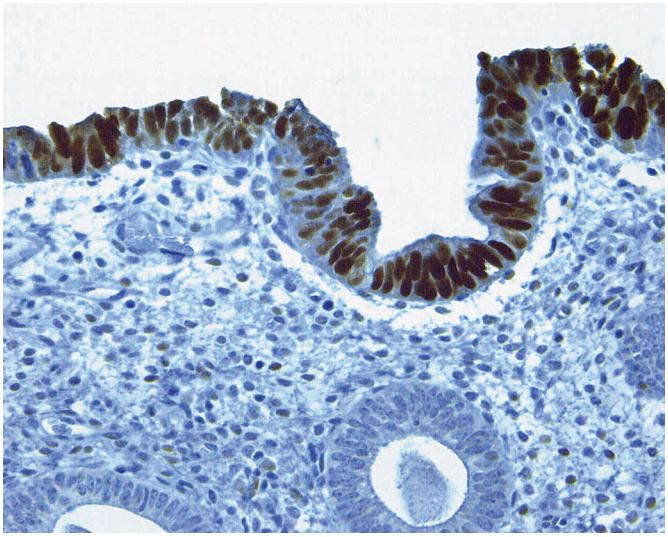

FIGURE 4.8 p53 immunostain of endometrial intraepithelial neoplasia. Endometrial serous carcinoma is typically accompanied by p53 mutations that allow accumulation of p53 protein in the cells that can be identified by immunostaining. Normal cells do not stain positively for p53 because the amount of normal protein is below the threshold of the staining test (immunoperoxidase stain for p53 with DAB chromogen, 200× original magnification).

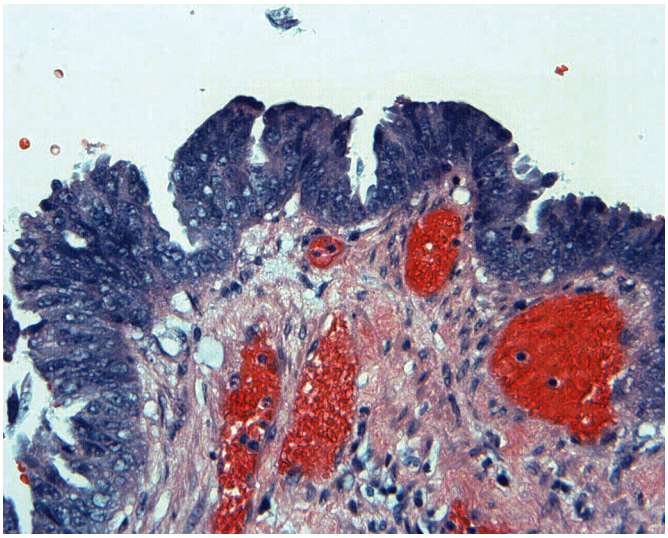

FIGURE 4.9 Endometrial intraepithelial carcinoma. This is the precursor lesion for serous carcinoma of the endometrium with markedly atypical, crowded epithelium with little architectural abnormality. This lesion is often observed on the surface of otherwise benign endometrial polyps (hematoxylin and eosin, 100× original magnification).

MANAGEMENT DECISIONS FOR ATYPICAL ENDOMETRIAL HYPERPLASIA (ENDOMETRIAL INTRAEPITHELIAL NEOPLASIA)

The patient's age, fertility plans and need for contraception, comorbidities, and personal preferences play a role in the management of these lesions. Hysterectomy is indicated when fertility is not desired and AEH is identified. AEH is commonly found with coexisting undiagnosed cancer already present in the uterus or progressing to endometrial cancer in untreated women. As previously discussed, the GOG reported that 43% of 306 women who had a community-based diagnosis of AEH on endometrial biopsy and proceeded without medical treatment to hysterectomy had endometrial cancer on final pathology. Although 63% (77 of 123) of the cancers identified were grade I lesions confined to the endometrium, 31% were

myoinvasive, and 11% had deep myometrial invasion into the outer 50% of the myometrium. It is possible that future validation of a new EIN scoring system or another molecular marker will allow more precise predictability for the neoplastic potential and the coexistence of cancer before hysterectomy.

The complexity of the surgical management of AEH is underappreciated. Intraoperative decision making, using frozen section to determine the operative interventions, is never ideal, considering difficulty of the diagnosis and the variety of skill and expertise of the pathologist and gynecologists. It is to be expected that the postoperative diagnosis of cancer will be obtained in a substantial number of these cases. The recommendation is that the patient should be informed of the 20% to 45% risk of underlying malignancy, and hysterectomy is required for the final diagnosis. The patient should be counseled about the desire to keep her ovaries or have them removed based on her age, family history, and other medical conditions or comorbidities. Genetic counseling and testing for Lynch syndrome may also be reasonable as a factor to consider in this decision-making process. Vaginal hysterectomy may be all that is required, or laparoscopically assisted hysterectomy with bilateral salpingo-oophorectomy can be considered. For the vast majority of patients with AEH, lymphadenectomy and complete surgical staging results in overtreatment and increased surgical risk. Endometrial cancers associated with AEH are usually low-grade, early stage lesions with a low risk of lymphatic metastasis. The risk of a high-risk uterine cancer in women with a biopsy of AEH ranges from 5% to 7%. In the event that high-grade cancer or deep myometrial invasion is found, reoperation may be offered for comprehensive surgical staging and removal of retained ovaries. Staging can usually be accomplished laparoscopically. This should be necessary in approximately 15% of the cases when cancer is identified and depends on the entire health history of the individual. Staging based on intraoperative assessment of myometrial invasion and grade of tumor is an appropriate strategy for institutions experienced in this approach. Supracervical hysterectomy, morcellation, and endometrial ablation are unacceptable for treatment of AEH because of the high prevalence of occult endometrial cancer in these patients. Women who desire childbearing, refuse hysterectomy, or have medical conditions that make hysterectomy an undesirable first choice can be treated hormonally. Megestrol 160 mg/day, in divided doses, has been the drug of choice with acceptable results even in the face of complex endometrial hyperplasia with atypia. It is unclear whether the treatment should be continuous or cyclic, but there are theoretical advantages to the endometrial shedding provided by the progesterone withdrawal bleed. The endometrium needs to be reevaluated histologically, by office biopsy or D&C, at approximately 3-month intervals for at least 1 year. Lifelong prevention strategies must be emphasized with the patient. The pathologist finds the evaluation of the endometrial sampling more straightforward if it is not complicated by exogenous hormonal influences. For this reason, it is best to withdraw the patient from the progestogen for 7 to 14 days to allow withdrawal bleeding before endometrial biopsies. The biopsy or D&C should be scheduled for after the withdrawal bleeding ceases.

In 2012, a systematic review identified 391 subjects from 45 studies with hyperplasia or grade 1 endometrial cancer who desired fertility and were treated with progestins. Seventy-eight percent of patients demonstrated a response to therapy with 53% of patients demonstrating a durable, complete response. The complete response rate was significantly higher for those with hyperplasia at 65% than for those women with carcinoma (48%). The American Congress of Obstetricians and Gynecologists (ACOG) Practice Bulletin on endometrial cancer includes this general guideline: The new Endometrial Intraepithelial Neoplasia ACOG Practice Bulletin (May 2015) offers multiple options for women with contraindications for hysterectomy, including medroxyprogesterone acetate, depot medroxyprogesterone, micronized vaginal progesterone, megestrol acetate, or levonorgestrel intrauterine system.

Women with AEH and endometrial cancer who desire to maintain their fertility may be treated with progestin therapy. After therapy, they should undergo serial complete intrauterine evaluation approximately every 3 months to document response. Hysterectomy should be recommended for women who do not desire fertility.

Local therapy of the endometrium with a progestin-containing intrauterine device (Mirena) is encouraging. In a recent multicenter randomized trial in Norway, 170 women with endometrial hyperplasia were randomized to one of three treatment arms: levonorgestrel intrauterine system (LNG-IUS), oral MPA 10 mg administered 10 days per cycle, or continuous oral MPA 10 mg/day for 6 months. At the end of 6 months, women in all treatment regimens showed significant therapeutic response, but the highest numbers of responders were noted in the LNG-IUS group (100%) and the continuous MPA group (96%) compared with the cyclical MPA group (69%). Gallos et al. reported a 12-year comparative cohort study of 344 patients with endometrial hyperplasia who received conservative management with progestins for complex or AEH because of desire for fertility or who were medically unsuitable for surgery. For the group of women treated with LNG-IUS ($n = 250$), 94.8% achieved regression of hyperplasia compared with 84% of women treated with oral progestins. Of note, the patients with a body mass index of 35 or greater were most likely to have a relapse of hyperplasia or fail to regress to a normal endometrium. In conclusion, management decisions in women with AEH are complex and require an understanding of the risk of invasive endometrial adenocarcinoma, the reproductive desires of the patient and her comorbidities, and the risks for surgical management. Ideally, minimally invasive techniques can be used to complete hysterectomy with bilateral salpingo-oophorectomy. The finding of adenocarcinoma in the uterus requires consultation with a gynecologic oncologist to determine whether observation, reoperation for surgical staging, or adjuvant therapy based on uterine factors should be considered.

MANAGEMENT OF ENDOMETRIAL HYPERPLASIA WITHOUT ATYPIA

The diagnosis of simple or complex hyperplasia without atypia requires hormonal management and is not an indication for

TABLE 4.2 Hormonal Treatment for Endometrial Intraepithelial Neoplasia*

Hormonal Agent	Dosage and Length
Medroxyprogesterone acetate	10–20 mg/day or cyclic 12–14 days per month
Depot medroxyprogesterone	150 mg intramuscularly every 3 months
Micronized vaginal progesterone	100–200 mg/d or cyclic 12–14 days per month
Megestrol acetate	40–200 mg/day
Levonorgestrel intrauterine system	52 mg in steroid reservoir over 5 years

*Previously known as atypical endometrial hyperplasia.
Modified from Committee on Gynecologic Practice, Society of Gynecologic Oncology. Endometrial intraepithelial neoplasia. ACOG Committee Opinion No. 631. American College of Obstetricians and Gynecologists. *Obstet Gynecol* 2015;125(5):1272-1278 and Trimble CL, Method M, Leitao M, Lu K, et al. Management of endometrial precancers. hysterectomy. These lesions are generally reversible with progestogen (synthetic progestin or progesterone). The classification of progestogens is seen in Table 4.2. The initial approach is generally to treat in a cyclic fashion with the progestin given for 14 days of the month to deliver predictable cyclic withdrawal menses. Women, including teenagers who are premenopausal and sexually active, are usually best treated with a regimen that provides contraception such as Depo-Provera or oral contraceptives. Women who want to conceive are likely to be anovulatory and require ovulation induction agents after withdrawal bleeding is produced with a progestogen. Reassurance can be obtained from a reduction of menstrual flow and a bleeding pattern that is appropriately timed with the cyclic therapy. It is extremely important to counsel anovulatory women about the lifelong risk of endometrial cancer and methods for surveillance and prevention. Twenty-five percent of endometrial cancers occur in the premenopausal age range, and 5% are in women 40 years of age and younger. These cancers may be part of the polycystic ovarian syndrome or the anovulatory transition before menopause, and are all theoretically preventable with proper counseling and active management. Premenopausal endometrial cancer patients should also be counseled about the possibility of Lynch syndrome. A family history should be taken, and if endometrial and colon cancers are frequent in the family, the patient should be referred to genetic counseling. Colonoscopy is often recommended to endometrial cancer patients because of the association with colon cancer. There is a dramatic rise in the incidence rate of endometrial hyperplasia and endometrial cancer at 45 years of age and peaking at 65 years of age. This is likely because of the combined effects of estrone (estrogen) production in the peripheral adipose tissue, particularly in obese women, and to the absence of progesterone that is caused by the loss of ovulatory function in menopause.

PREVENTION OF ENDOMETRIAL CANCER

Endometrial stimulation by estrogens unopposed by progestins leads to endometrial hyperplastic conditions in a dose- and time-dependent manner. Experimental evidence has been obtained from prospective clinical trials conducted to identify the appropriate doses and schedules of hormone replacement therapies. Kurman reported a randomized trial of 1176 postmenopausal women receiving 1 mg of estradiol orally and either placebo or various doses of norethindrone acetate. Women treated with estradiol alone (247 evaluable participants) for 12 months had a 12.2% rate of simple hyperplasia without atypia, 1.6% had complex hyperplasia without atypia, and 0.8% had complex atypical hyperplasia. Norethindrone acetate at all doses used in this trial nearly eliminated that risk. The North American Menopause Society support the addition of a progestogen whenever estrogen is prescribed for menopausal symptoms in women with an intact uterus for the prevention of estrogen-induced hyperplasia and adenocarcinoma. Unfortunately, progestogen has undesirable side effects, and women have been known to discontinue this component of their prescribed hormone replacement (see Table 4.2).

The prevention of endometrial cancer has been complicated by the publication and early closure of the estrogen plus progestin (E + P) component of the Women's Health Initiative (WHI). This randomized placebo-controlled clinical trial evaluated conjugated equine estrogens (CEEs), 0.625 mg, plus MPA, 2.5 mg orally per day (hormone replacement therapy [HRT]). This trial enrolled 16,608 women with a range of 50 to 79 years of age for an average of 5.2 years to determine the primary outcomes of coronary heart disease (CHD), invasive breast cancer, and a global index (including stroke, pulmonary embolism [PE], endometrial cancer, colorectal cancer, hip fracture, and death from other causes). In May 2002, the data safety monitoring committee recommended premature closure of the trial because of the adverse outcomes of breast cancer and cardiovascular complications, including CHD, stroke, and PE. Of note, the overall mortality rate was not affected. The absolute excess risk per 10,000 person-years attributable to HRT was seven CHD events, eight strokes, eight PE, eight invasive breast cancers, and a reduction of five hip fractures. These risks need to be reviewed with women choosing HRT.

The WHI trial with CEE alone versus placebo had a very different outcome. There was a nonsignificant reduction in breast cancer risk ($P = 0.06$), and the CHD risk was unaffected (hazards ratio [HR], 0.91; CI 0.75–1.12), strokes were increased (HR, 1.39; CI 1.10–1.77), and hip fractures were reduced (HR, 0.61; CI 0.41–0.91). This places women with intact uteruses and their physicians in a difficult situation of balancing the risks. Women with uteruses can decide to accept the potential risks of the addition of a progestin or may choose to take unopposed estrogen and follow the endometrium yearly with transvaginal ultrasonography or endometrial biopsy. Unopposed estrogen use gives a woman a relative risk (RR) of endometrial cancer of three times the general population for less than 5 years of use and RR of 10 after 10 years of use. The risk decreases but remains elevated after discontinuing the drug. Alternatively,

other progestins and progesterone formulations are available that may carry a different but as yet unknown risk of breast cancer. Micronized progesterone is available as oral 100- or 200-mg capsules (Prometrium) and has been approved by the Food and Drug Administration (FDA) for use in combination with estrogen for relief of menopausal symptoms. The dosage of 200 mg for 12 days per month in a cyclic fashion causes withdrawal bleeding in a predictable manner. The regimen of CEE 0.625 mg/day with oral micronized progesterone at a dose of 200 mg/day for 12 days per month failed to see any increase in endometrial hyperplasia with 3 years of follow-up. A vaginal progesterone gel is available that is only FDA approved for infertility use but has been studied in small numbers of menopausal women. An additional provocative alternative is to use the progestin-containing intrauterine system (Mirena is FDA approved for contraceptive use only) and unopposed estrogen, which has been studied prospectively in menopausal women. These women were only followed for 1 year, and they were able to convert proliferative endometrium to atrophic endometrium while using continuous estradiol 50 mcg/day via the transdermal route.

The official position statement of the North American Menopause Society is that a progestogen should be added to estrogen therapy for all postmenopausal women with intact uteruses. The type, route, or regimen can be individualized to minimize side effects while providing adequate endometrial protection.

BENEFITS AND RISKS OF ESTROGEN REPLACEMENT THERAPY

Quality of Life, Vasomotor Symptoms, and Sexual Function

The WHO and the Stages of Reproductive Aging Workshop (STRAW) working group define menopause as the permanent cessation of menstrual periods that occurs naturally or is induced by surgery, chemotherapy, or radiation. Menopausal transition is the time of an increase in follicle-stimulating hormone and increased variability in cycle length. Postmenopause begins at the time of the final menstrual period but is not recognized until 12 months of amenorrhea has occurred. The National Institutes of Health in the "State of the Science Conference Statement: Management of Menopause-Related Symptoms" defines menopausal symptoms as vasomotor symptoms, vaginal dryness and painful intercourse, and sleep disturbance. Estrogen is the most consistently effective therapy for vasomotor symptoms, vaginal dryness, sleep disturbances, and improved quality of life, and a subset of women may find an improved mood with estrogen therapy. Testosterone has been demonstrated to improve libido, especially in women who have undergone oophorectomy; however, the long-term risks have not been studied. Antidepressants, clonidine, and gabapentin have been studied in treatment of hot flashes with some efficacy.

Symptom control is the most common reason for initiating estrogen therapy and remains undisputed as the most appropriate indication for prescribing estrogen at the time of natural or surgical menopause. The epidemiology community recommendations are that the patient should be told that hormone replacement should be for symptom control only, prescribed at the lowest effective dose, and for the shortest duration of use possible. Women should consider tapering off after 5 years of use to avoid the adverse events of thromboembolic disorders, breast cancer, stroke, and cardiovascular events (myocardial infarction, death). Women must be active participants in the decision-making process regarding estrogen use or estrogen plus progestogen use. They must experience the symptoms, recognize the reasons they are choosing to use these agents, and actively make the decision that the benefit is worth the small risk. Their own social situation or individual risk profile may influence their personal decisions.

The WHI reported the symptoms manifested by 8405 women between 8 to 12 months from the date the HRT participants were asked to discontinue CEE plus medroxyprogesterone acetate. These women were mailed a survey, and 21.2% responded that they had moderate-to-severe vasomotor symptoms, which was significantly different (CI 4.92–6.89) compared with placebo. They also reported pain and stiffness (Adjusted odds ratio [AOR] 2.16), and these symptoms were reported by more than 10% of respondents. Other withdrawal effects were feeling tired, difficulty sleeping, and a feeling of bloating or gas. Depression was also significantly increased after withdrawal of hormone replacement (P <0.001).

The WHI documented the beneficial effects experienced from HRT in women with uteruses. Relief of hot flashes (85.7%), night sweats (77.6%), vaginal or genital dryness (74.1%), and joint pain or stiffness (49.1%) compared with placebo effects ranged from 57.7% to 38.4%, respectively. Women taking HRT were more likely to complain of breast tenderness (9.3%) and vaginal bleeding (51%) than those on placebo (2.4% vs. 5%, respectively).

In conclusion, the data summarized in the WHI are not generalizable to 45- to 55-year-old women with menopausal symptoms. These women must prioritize their own situations and health risks and quality of life benefits. Most will find the best symptom relief from estrogen use. Alternatives to estrogen include progestogens, antidepressants (venlafaxine, paroxetine, fluoxetine), clonidine, and the anticonvulsant gabapentin. Over-the-counter remedies frequently used include isoflavones, black cohosh, and vitamin E. None of the alternatives resolve the entire menopausal syndrome, including sexual dysfunction.

Estradiol may also be delivered by a silicone ring placed in the vagina (Estring, Femring). The Estring (Pfizer US Pharmaceuticals) contains 2 mg of estradiol and on average 0.02 mg/day is released over a 90-day period. Studies have demonstrated a median plasma estradiol increase from 4.5 pmol/L before insertion to 12.5 pmol/L at steady state. The comparison with a 0.05 mg Estraderm patch was 10-fold greater serum concentrations of estradiol in users of the patch. A study of endometrial thickness in 60 postmenopausal women over a 12-month period showed a thickness of 2.8 mm before Estring and 2.6 mm thickness after 12 months of use. This is reassuring to women unable to tolerate progestins. Another randomized controlled study (RCT) demonstrated a decrease in urinary

tract infections with the use of Estring. The use of Estring may be preferred for women wanting local therapy for vaginal dryness symptoms and an inability to take progestins or a history of breast cancer. Femring is available when an increase in vaginal dose is desired.

Estrogen alone does not always resolve the sexual dysfunction complaints after bilateral salpingo-oophorectomy. Testosterone has been demonstrated in clinical trials to help with decreased sexual desire, arousal, and orgasmic response, but at present, there is no FDA approval for libido in women. A recent study evaluated the efficacy and safety of testosterone treatment in 814 postmenopausal women with hypoactive sexual desire not receiving estrogen therapy. Patients were randomized to receive testosterone by patch (150 or 300 mcg/day) or placebo. At 24 weeks, efficacy was measured, and the group of women receiving 300 mcg/day of testosterone reported significantly greater sexual satisfaction compared with the placebo group and the group treated with 150 mcg/day of testosterone. The rate of adverse events related to androgens, specifically unwanted hair growth, was also highest in this group. Furthermore, breast cancer was diagnosed in four women treated with testosterone compared with none of the women who received placebo. The long-term effects of testosterone, including effects on the breasts, remain unclear. The FDA has recently approved flibanserin to treat acquired, generalized hyposexual desire disorder in premenopausal but not postmenopausal women.

Osteoporosis

Osteoporosis is a disease characterized by low bone mass and microarchitectural deterioration of bone tissue, which leads to increased bone fragility and increased fracture risk. Low bone mass is related to a low peak bone mass (mainly under genetic influence) and to decrease in bone mass, which occurs after menopause and with aging. Menopause induces an accelerated bone loss within 5 to 8 years followed by a linear rate of bone loss. Bone density readings are standardized to healthy women of similar age. Osteopenia is defined as bone loss of greater than 1 standard deviation (SD) from the mean, and osteoporosis is bone loss greater than 2 SDs from the mean.

Osteoporosis prevention strategies should begin before 40 years of age because of a decline from peak bone mass. An even more dramatic loss of bone occurs at menopause with the loss of estrogen support of osteoblastic activity. Women should take active measures to protect their bones by regular weight-bearing exercise (at least 30 minutes three times a week), calcium supplementation (1500 mg elemental calcium for postmenopausal women), and adequate vitamin D supplementation (800–1200 IU/day). At menopause, a baseline bone density is recommended and then repeated every other year unless osteopenia or osteoporosis is detected. Estrogen replacement therapy (ERT) has been the traditional main strategy to prevent this deterioration in bone strength. A number of medications are approved by the FDA for the prevention or treatment of osteoporosis. Bisphosphonates such as alendronate (Fosamax), risedronate (Actonel), and ibandronate (Boniva) act by preventing bone resorption by blocking the action of osteoclasts. Gastrointestinal side effects (reflex, esophagitis, esophageal ulcers) have been a primary concern for patients taking oral bisphosphonates. These drugs should be taken first thing in the morning on an empty stomach with a full 8-oz glass of water. The patient should then wait a full hour before eating or taking any other medications. Lying down or eating before the recommended time increases risk for gastrointestinal distress. There are also theoretical concerns that prolonged therapy with bisphosphonates leads to oversuppression of bone remodeling, which allows microdamage to accumulate and increase skeletal fragility. Microscopic crack frequency is increased in animals treated with high doses of bisphosphonates, although this has yet to be demonstrated in biopsies taken from postmenopausal women treated with long-term use. SERMs such as raloxifene (Evista) bind with high affinity to estrogen receptors and promote estrogen-like activity on bone. Unfortunately, raloxifene has the same thromboembolic risk of estrogen without the benefit of menopausal symptom relief. Drugs approved for treatment only include calcitonin (Miacalcin), which is administered by nasal spray, and teriparatide (Forteo), which is administered through daily subcutaneous injections. Both of these pharmacologic agents serve to increase bone formation.

Two anatomic areas are of interest in the bone remodeling process. The first is the axial skeleton, which is composed primarily of trabecular bone. The second is the appendicular skeleton, which is composed primarily of cortical bone. The remodeling cycle is the same in both types of bone. However, because of the greater surface area, approximately 40% of trabecular bone, as opposed to 10% of the cortical bone, is in "turnover" each year. The osteoclast is responsible for the resorption of old bone, which results in the formation of a resorption cavity. Osteoblasts are then attracted to the cavity, where they secrete osteoid, which is primarily type I collagen. The collagen is mineralized mainly with calcium, thus producing new bone with an appropriate mechanical strength. Under normal circumstances, the amount of bone removed is replaced with fresh bone; however, this process can become uncoupled if osteoclasts remove more bone than can normally be replaced by osteoblasts, resulting in net loss of bone mass. In menopausal women, accelerated bone loss is associated with high bone turnover rate and increased osteoclast activity. Estrogen may inhibit osteoclast activity and increase proliferation of osteoblasts as well as collagen production.

The beneficial effects of estrogen in preventing or treating postmenopausal osteoporosis are well recognized. At the same time, there is growing recognition that osteoporosis is a major public health problem in the United States. It is estimated that approximately 8 million women in the United States have osteoporosis and another 14 million are at risk because they have low bone mass. Osteoporosis causes more than 1.5 million fractures each year, including 300,000 hip, 700,000 vertebral, and 200,000 wrist fractures. These fractures are seen mainly in women. For a 50-year-old woman, the lifetime risk of fracture of any of the three is 40%. Traditional risk factors for osteoporosis include estrogen deficiency; fair complexion; high caffeine intake; low calcium intake; small, thin build; smoking; inadequate physical activities; and multiple disease processes

and drugs. The acute and long-term medical care expenses associated with these fractures cost the nation an estimated $17 billion in 2005. The cumulative cost over the next 2 decades is estimated to be $474 billion. An excess mortality rate associated with hip fracture is 12% to 20% during the first year after the injury. Fewer than half of patients with hip fractures ever return to their prefracture activity level. Many require assistance and have lost their independence and require long-term domiciliary care. Vertebral fractures may be asymptomatic in 50%, but successive fractures can lead to loss of height, kyphotic distortion of posture, and chronic back pain. Approximately 10% of patients with hip fractures die of surgical complications within 6 months of fracture. Approximately 25% of all white women older than 60 years of age have spinal compression fractures resulting from osteoporosis. The risk of hip fracture is 20% by the age of 90 years, and hip fractures are about 2.5 times more common in women than in men. An increased rate of loss of both cortical and cancellous bone is associated with menopause. In a follow-up study of 82 postmenopausal women 5 to 10 years after their first examination, Meema and coworkers concluded that (1) as a group, menopausal women lost bone, and the beginning of this loss is less related to age than to loss of ovarian function; (2) the rate of loss was not significantly correlated with age; and (3) the bone loss was prevented by estrogen administration (ie, 0.625 mg of conjugated estrogens).

Nachtigall and associates conducted a 10-year double-blind prospective study to evaluate the effects of ERT. They took a sample population of 84 pairs of randomly chosen postmenopausal patients who were matched for age and diagnosis. Half of the patients received conjugated estrogens and cyclic progesterone, and the other half received a placebo. The estrogen-treated patients whose therapy was started within 3 years of menopause showed improvement or no increase in osteoporosis. The patients in the control group demonstrated an increase in osteoporosis. A subsequent report by the same authors showed that there was no statistically significant difference in the incidence of thrombophlebitis, myocardial infarction, or uterine cancer in the two groups. Indeed, there was a lower incidence of breast cancer in the treated group. Estrogen-treated patients did show a higher incidence of cholelithiasis. The low number of cases precludes drawing any real conclusions from the data on diseases of low frequency. The study excludes a high incidence of complications from estrogens.

In another crossover study comparing the effects of estrogen–progestin therapy with those of placebo, bone mineral content increased during the 3 years of combination hormone therapy but continued to decrease in the placebo-treated group (Fig. 4.10). When the placebo was given to some of the estrogen-progestin group, bone density decreased, but the placebo-treated women had an increase in bone mineral content after being given estrogen–progestin therapy. Other factors are also important in preventing osteoporosis, such as adequate dietary calcium, exercise, and vitamin D. Many case control studies have noted considerable protection from hip fracture with HRT (Table 4.3).

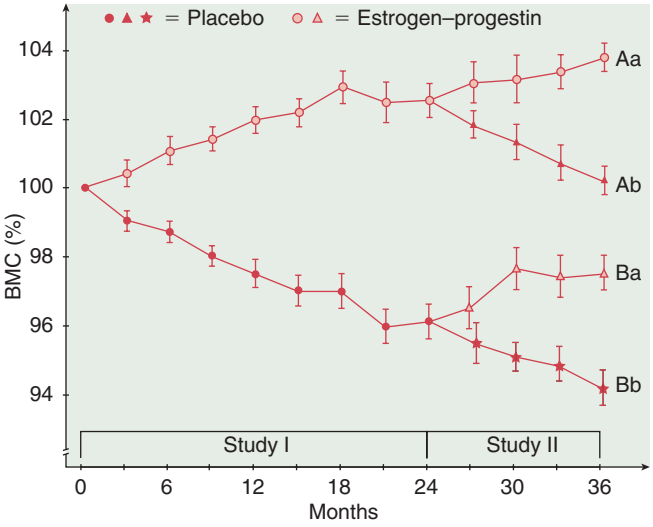

FIGURE 4.10 Estrogen–progestin versus placebo crossover study. Bone mass in postmenopausal women in response to randomization to estrogen plus progestin supplementation versus placebo at time zero and again at 24 months. Women were 49 to 51 years of age and were taking 500 mg of calcium daily. (From Christiansen C, Christensen MS, Transbøl I. Bone mass in postmenopausal women after withdrawal of oestrogen/gestagen replacement therapy. *Lancet* 1981;1(8218):459-461.)

Colorectal Cancer

Colorectal cancer is the third most common cancer and the third leading cause of cancer deaths in US women. Several epidemiologic studies have noted that HRT may reduce the risk of colorectal cancers. The WHI demonstrated an HR of 0.63, demonstrating slight protection from colorectal cancer in their E + P arm but not in the estrogen alone study (HR, 1.08). There appear to be some biologic reasons why estrogen may be protective. Bile acids are thought to initiate or promote malignant changes in the epithelium of the colon. Exogenous estrogen decreases secondary bile acid production. Estrogen also decreases serum levels of insulin-like growth factor-1, which is an important mitogen associated with colorectal cancer. Both case-control and prospective studies have been reported. Kampman and associates reported the largest case-controlled study with 815 colon cancer and 1019 population base controls

in postmenopausal women. After adjusting for multiple risk factors, they noted an 18% decrease in risk of colon cancer in HRT users compared with the nonusers (RR, 0.82; CI 0.67–0.99). In the large study of the American Cancer Society, 897 deaths from colon cancer were identified during 7 years of follow-up of 422,373 postmenopausal women. The authors reported a 29% decrease in risk of colon cancer deaths in hormone users compared with nonusers (R, 0.71; CI 0.61–0.83). In the review and meta-analysis by Grodstein and colleagues, 18 studies were evaluated. They found a 20% decrease of colon cancer in ERT users compared with the nonusers (RR, 0.8; CI 0.72–0.92) and a 19% decrease in rectal cancer (RR, 0.79; CI 0.72–0.92). Ten studies provided data on timing of hormone use. Current users had an RR of 0.66 (CI 0.59–0.74) compared with that of the nonusers. In the Nurses' Health Study, current users noted an RR of 0.65; in past users, the RR was 0.84 (nonsignificant). Among past users, the decreased risk continued during the first 4 years after quitting ERT; however, 5 years or more after stopping ERT, the risk was similar to that of nonusers (RR, 0.92; CI 0.70–1.21). The effect of ERT on colon cancer risk was evaluated in the California Teachers Study among 56,864 postmenopausal women. There was noted to be significantly lower risk for colon cancer in women who had used ERT within the past 15 years than women that had never used hormones (RR, 0.64; CI 0.51–0.80). Five studies evaluated the duration of current use and found similar apparent protection for all women currently on ERT, regardless of duration. Four studies evaluated ERT and colorectal adenoma. Most studies noted a significantly decreased risk of development of adenomas in women on ERT. This decrease did not appear to be caused by increased surveillance (sigmoidoscopy) in the ERT users. In several, but not all, studies, there was a suggestion that colorectal cancers increased in women who were taking tamoxifen.

Most recently, extended follow-up data from the WHI was published that reviewed both incidence and mortality of colorectal cancer in women treated with E + P. This analysis revealed that, although fewer colorectal cancers were diagnosed in the E + P group, the patients more commonly had positive lymph nodes and advanced stage at diagnosis, translating into more deaths. So, although the incidence of colorectal cancers was lower, the mortality rate was greater. These data address the importance of not only identifying the incidence of colorectal cancer but also the influence of tumor characteristics, stage, and mortality rate. Overall, the findings do not suggest a clinically meaningful benefit in reducing mortality from colorectal cancer.

Cardiovascular Disease

Cardiovascular morbidity (ie, heart disease and stroke) constitutes the most frequent cause of death among women in the United States. It is estimated to account for approximately 292,188 deaths in the United States in 2009—that is, one in every four female deaths. Cardiovascular risks factors can be found, and potentially modulated, in women. High cholesterol levels are present in 50% of women, and high blood pressure is observed in 32% of all women, with 45% of black women having high blood pressure. The prevalence of cardiovascular diseases increases dramatically with age, starting at a low level of 17.6% for women 35 to 44 years of age, 36.6% for women 45 to 55 years of age, 56.5% for women 55 to 64 years of age, and 75% for women 65 to 74 years of age. The possible effects of estrogen and progestin on the incidence of cardiovascular disease in women is the subject of ongoing research. Most of the cohort studies suggest that ERT effectively diminishes the risk of cardiovascular disease in women who are 50 to 60 years of age, but protection decreases with age (Table 4.4). Unfortunately, the studies (WHI, Heart and Estrogen/Progestin Replacement Study [HERS]) reveal that initiating estrogen therapy in women with established vascular disease (mean ages of 63–67 years) will not prevent cardiovascular events or deaths. These studies are unable to be generalized to estrogen use in the younger perimenopausal age groups, and the cohort and epidemiologic studies reveal some benefit, but use of progestin consistently decreases benefit.

Prevention of cardiovascular disease includes smoking cessation, blood pressure control, weight control, exercise, and blood sugar and cholesterol control. Blood cholesterol level is the main risk factor for cardiovascular disease in postmenopausal women. A high positive correlation has been found between levels of low-density lipoprotein (LDL) and coronary morbidity. Conversely, the level of high-density lipoprotein (HDL) shows a high negative correlation with the probability of coronary disease and with the extent of damage to the coronary vessels. Matthews has shown the beneficial effects of ERT on LDL and HDL levels. In a prospective study, he showed clearly a corresponding rise in HDLs and a decrease in LDLs in postmenopausal patients treated with ERT. The association of increased HDL and decreased LDL levels with reduced risk of cardiovascular disease is well documented for both men and women.

Lobo reported on the impact of different dosages of MPA on metabolism and hemostasis in postmenopausal women treated with conjugated estrogens. In this prospective, double-blind study, 525 women were randomized to five treatment regimens at 26 sites in the United States and Europe. All participants received 0.625 mg of conjugated estrogens daily for up to 13 cycles; four groups also received MPA, either 2.5 or 5 mg/day continuously or 5 or 10 mg/day for the last 14 days of each cycle. Effects on lipid and carbohydrate metabolism and coagulation were evaluated.

All of the treatment groups experienced increases in HDL cholesterol (HDL-C), the HDL2-C subfraction, and apolipoprotein A-1 compared with baseline; however, at each time point, the increases from baseline in the conjugated estrogens–only group were significantly greater than were those for the conjugated estrogens–MPA groups. Additionally, all treatment groups had significant decreases in LDL cholesterol (LDL-C) and apolipoprotein B. Decreases from baseline in total cholesterol (TC) levels were significantly greater than were those in the conjugated estrogens–only group. HDL3-C levels increased significantly from baseline in the conjugated estrogens–only group but not in the other treatment groups. Triglyceride levels increased significantly in all groups. The mean increase in the MPA-treated groups was less than that in the conjugated estrogens–only treatment group. Although MPA modified some of the effects of conjugated estrogens on lipid metabolism, the direction of changes in lipid parameters was unaltered.

Additional data on the conjugated estrogens regimen were reported in the results of the Postmenopausal Estrogen/Progestin Intervention (PEPI) trial. In this 3-year, randomized, double-blind, placebo-controlled trial, the investigators evaluated differences in selected heart disease risk factors among 875 postmenopausal women who received placebo, conjugated estrogens, or one of three conjugated estrogens–progestin regimens. One of the regimens used in this study was identical to that present in conjugated estrogens.

The investigators reported that after 3 years of therapy, women taking the conjugated estrogens regimen experienced significant increases in HDL-C levels compared with those taking the placebo. However, the increases were significantly less than those experienced by women taking conjugated estrogens alone. Compared with the placebo, LDL-C values were significantly decreased in women taking the conjugated estrogens, with no significant difference between groups. TC levels decreased significantly among women taking the conjugated estrogens regimen compared with those taking the placebo. Significant increases in serum triglyceride levels occurred in all treatment groups compared with the placebo group. There were no significant changes in blood pressure, fasting insulin levels, or 2-hour insulin levels between treatment groups. Treatment groups had significant increases in 2-hour glucose levels and significant decreases in fasting glucose levels compared with the placebo group. In paired comparisons, women in the placebo group had greater increases in fibrinogen than did women in the active treatment groups; no significant differences were present among the active treatment groups. Among their findings, the investigators concluded that "… oral estrogen taken alone or with MPA … is associated with improved lipoprotein and lower fibrinogen levels compared with placebo and the magnitude of these differences is likely to be clinically significant."

Multiple studies have evaluated HRT and CHD. In 1998, an overview by Barrett-Connor and Grady included 25 studies. Overall, the RR of CHD for women who took ERT compared with those who never took ERT was 0.70 (CI 0.65–0.75). When HRT was evaluated, the RR was 0.66 (0.53–0.84) compared with the nonusers. This analysis evaluated cohort case control and angiographic studies. The apparent benefit is limited mainly to current or recent use. These findings are consistent across diverse populations and various study designs.

The US National Health and Nutritional Examination Survey (NHANES-1) evaluated HRT and death from all cardiovascular disease in 1944 white women 55 years of age or older who were monitored for up to 16 years. After adjusting for risk factors of CHD, the risk of death from CHD was 0.66 (0.48–0.90) in the HRT users. The study by Ettinger and associates noted similar findings. In their patient population followed for 25 years, the death from any cause in HRT users compared with nonusers was 0.54, which was mainly due to a reduction in CHD (RR, 0.40) and other cardiovascular diseases (RR, 0.27).

Many studies, including the PEPI RCT, have noted that estrogen therapy in postmenopausal women decreased serum TC, LDL, and Lp(a) lipoproteins. HDL and triglyceride concentrations increase. The route of administration does affect serum lipids. Transdermal application has less effect on the serum lipid concentrations than the oral route. The type of progestins can also affect the serum lipids. Synthetic progestins tend to blunt the beneficial effects on the HDL but not decrease it below the baseline. Micronized progesterone does not decrease HDL compared with estrogen alone. Estrogen tends to decrease plasma fibrinogen concentrations as it does anticoagulant proteins, antithrombin III, and protein S. There also appears to be a decrease in the antifibronolytic protein plasminogen B activator inhibitor type I with an overall increased potential for fibrinolysis. In some reports, factor VII was also lowered with estrogen. The net effect on coagulation depends on the type of estrogen, dose, and duration of treatment.

The Global Consensus Statement on menopausal hormone therapy released a statement in 2013 recommending the use of estrogen therapy as the most effective treatment for vasomotor symptoms associated with menopause, and the benefits are more likely to outweigh the risks before age 60 years. Estrogen is effective and appropriate for the prevention of osteoporosis-related fractures in at risk women before age 60 years. They recommend the lowest dose and shortest treatment duration to achieve goals. This statement is based on the results of a round table meeting between representatives of the major international menopausal societies to reach consensus on core recommendations regarding HRT.

Two large trials (WHI and HERS) have now demonstrated that estrogen cannot protect against myocardial infarction or death in women with preexisting heart or vascular disease. In fact, the thromboembolic properties of estrogen likely increase risk when preexisting vascular lesions are present, predisposing women to stroke, myocardial infarction, and death. The WHI demonstrated in a trial of 16,608 women randomized to combined estrogen plus progestin (HRT) versus placebo at a mean age of 63.6 years. The absolute excess risk per 10,000 person-years attributable to HRT was seven CHD events, eight strokes, eight PEs, eight invasive breast cancers, and a reduction of five hip fractures. The WHI trial also had women without uterus treated with CEE alone versus placebo (n= 10,739), and they had a very different outcome. There was a nonsignificant reduction in breast cancer risk (P = 0.06), and CHD risk was

unaffected (HR, 0.91; CI 0.75–1.12), strokes were increased (HR, 1.39; CI 1.10–1.77), and hip fractures were reduced (HR, 0.61; CI 0.41–0.91).

The HERS was designed to determine if HRT could reduce cardiovascular events in women with known coronary artery disease (CAD). A total of 2763 women with preexisting CAD and an average age of 67 years were enrolled and randomized to conjugated estrogen 0.625 mg plus MPA 2.5 mg/day versus placebo. After 4.1 years of follow-up, there was no significant difference in the primary outcomes of CHD events or in any secondary outcome. There was a time trend of higher risk of events in the first year of use and a decrease in events in years 3 through 5. HERS II was a longer term follow-up study of the same participants that could not substantiate any benefit of HRT with longer use. It has been speculated that the initial increase in risk of cardiovascular events with HRT might be due to prothrombotic effects of the hormonal therapy. There may be a beneficial effect on the inhibition of progression of atherosclerosis because of the effects on lipoprotein cholesterol; therefore, those who were doing well on the medication were not asked to discontinue it. The conclusion of HERS and HERS II was that postmenopausal hormone therapy should not be used to reduce the risk for CHD events in women with CHD.

Manson et al., for the WHI investigators, published the summary of CHD outcomes. This report also emphasized the increased risk of CHD events during the first year of use and recommended against prescribing HRT for the prevention of cardiovascular disease. The problems with these trials are that the participants were older than the usual women prescribed HRT, and they were recruited because of their increased risk of CAD events. This makes the results of HERS and WHI applicable to a similar population of high-risk women, and the conclusions may not be generalizable to younger women initiating HRT at the onset of menopausal symptoms. Prevention of CAD may have a different pathophysiology than the progression from CAD to death. The epidemiologic and cohort data are criticized for the likely enrollment of healthier and more active women and may also not represent all women of a similar age.

Cardiovascular risk reduction recommendations are smoking cessation, exercise, and weight control along with blood pressure and cholesterol management. Aspirin has recently been shown to lower the risk of stroke without affecting the risk of myocardial infarction or death from cardiovascular causes in most women. In this randomized trial of 39,876 healthy women 45 years of age or older, participants received 100 mg or aspirin or placebo on alternate days for 10 years and were monitored for cardiovascular events. There was a 17% reduction of strokes for the entire study population randomized to aspirin (RR, 0.83; CI 0.69–0.99; $P = 0.04$). There was benefit for prevention of myocardial infarction only in women 65 years of age and older at enrollment (RR, 0.66; CI 0.44; 0.97; $P = 0.04$). The conclusion of this study is that physicians should perform a careful risk assessment to determine who is likely to benefit from aspirin versus likely to be harmed by the increase of gastrointestinal hemorrhage requiring transfusion ($P = 0.05$)

The 2013 ACOG committee recommended that HRT should not be used for the primary or secondary prevention of CHD, but rather women should be prescribed estrogen or estrogen plus a progestogen (when a uterus is present) at the onset of moderate or severe menopausal symptoms. The dose should be the lowest necessary to achieve the symptom control desired, and the duration of therapy should be 5 years or less. Discontinuation of this medication is not without side effects, and withdrawal symptoms may be minimized by a tapering schedule over a long period of time. It is accepted, however, that when a woman is on therapy, the risk of continuing such treatment is low, and the risk is greatest during the first year or two after initiating treatment, especially when preexisting vascular disease may already be present.

ESTROGEN REPLACEMENT THERAPY FOR ENDOMETRIAL AND BREAST CANCER SURVIVORS

Estrogen Replacement Therapy for Endometrial Cancer Survivors

Historically, HRT has been contraindicated for patients who have been treated for cancer of the uterus. Although estrogen administration has not been shown to have adverse effects on patients who have been treated for endometrial cancer, many physicians continue to be reluctant to administer this medication to these women. No data in the literature substantiate the detrimental effects of estrogen in these patients. It is not unusual for women with endometrial cancer to have severe symptoms because of withdrawal of estrogen at the time of their diagnosis and surgical treatment.

The GOG conducted a prospective trial to evaluate the potential risk of estrogen replacement in women after treatment of endometrial adenocarcinoma. This randomized clinical trial of ERT (CEE 0.625 mg orally per day, Premarin) compared with placebo in women treated for stage I and II endometrial cancer closed after the WHI was halted prematurely in 2002 because of decrease in accrual and lack of feasibility. Before study closure, 1236 eligible women were randomized, and the median follow-up was 35.7 months. The median age at endometrial cancer diagnosis was 57 years (range, 26–91 years). Compliance with medication for the entire treatment period was 41%, and for those on the ERT arm, 71% knew to which arm they had been randomized. A summary of the results on the ERT arm demonstrated endometrial cancer recurrence in 14 patients (2.3%); eight patients (1.3%) developed a new malignancy, one of which was breast cancer. There were 26 deaths (4.2%) on the estrogen arm; five were due to endometrial cancer. An important finding is that women with stage I and II endometrial cancer are more likely to die of causes unrelated to the cancer diagnosis; therefore, other health issues must take priority when planning for preventive health maintenance (Table 4.5). Women on the placebo arm of this study suffered 19 deaths (3.1% not statistically different), and four were due to endometrial cancer. Ten placebo patients developed a new malignancy (1.6%), three of which were breast cancer. Although there were no significant

differences in recurrence between the ERT and placebo arms for all comers, further investigation suggested that racial disparities in outcome may exist. With a median follow-up of 3 years, recurrent disease was noted in 5 of 56 black patients on the ERT arm compared with only 8 of 521 white patients. The RR of recurrence among blacks in the ERT group was 11.2 (95% CI, 2.86–43.59; $P = 0.0005$) after adjustment for age, body mass index, and tumor grade.

This study was admittedly underpowered for the endpoints of new breast cancer or endometrial cancer recurrence, but at least women can be informed that the rate of recurrence of endometrial cancer was equally low on each arm of this study. The exception to this may lie with ERT for specific subgroups. Although the number of outcome events was limited in this study, these findings suggest that the use of ERT in black women should be judicious and given only after appropriate patient education. The decision to prescribe estrogen must be individualized based on symptom control and quality of life concerns that only the patient can assess.

Many physicians do not hesitate to give ERT in patients with well-differentiated or superficially invasive cancers because recurrences are generally very low in these patients. There is greater hesitancy to treat poorly differentiated or deeply invasive cancers with ERT. This is also true for patients with extrauterine disease. The belief is that because recurrence is more frequent, ERT may increase the risk. The data suggest the opposite. Patients with high-risk factors and taking ERT had a lower recurrence rate than did those who were not taking ERT. Although theoretically a possible advantage, it does not appear that the addition of a progestin to estrogen is beneficial. We initially followed this routine of a combination of E + P; however, for several years now, we have not done so, and we have noticed no difference in outcomes.

The optimal time to begin ERT after treatment has not been determined. Some suggest waiting for at least 2 years because most patients who will develop recurrences will have done so. The data currently suggest no benefit in waiting. Within a few days of surgical treatment, many patients will develop disturbing vasomotor symptoms. These symptoms can be prolonged with subsequent adverse symptomatology, such as vaginal thinness and dryness, which can lead to unpleasant intercourse. As a result, symptoms can be treated as soon as they become troublesome.

In 1993, the ACOG released the following statement: "In women with a history of endometrial cancer, estrogens could be used for the same indications as for any other woman, except that the selection of appropriate candidates should be based on prognostic indicators and the risk the patient is willing to assume." In the absence of good prospective studies, this statement appropriately leaves the issue with the patient and the physician.

Fear of medicolegal liability because of the contraindication of estrogen in breast and endometrial cancer in the package insert requires that physicians document a lengthy discussion of the risks and benefits and have the patient actively participate in the decision and understand the process of informed consent needed for this therapy.

Hormonal Therapy for Breast Cancer Survivors

Women diagnosed with breast cancer are faced with many challenging decisions, especially if they are premenopausal. They are asked to review their family history to determine if they may have developed breast cancer because of a genetic predisposition (*BRCA1* or *BRCA2* gene) transmitting risk of familial breast and ovarian cancer. Genetic counseling and testing may then be recommended to properly counsel the patient and her family members about the benefits and risks of prophylactic mastectomy and bilateral salpingo-oophorectomy. This places premenopausal breast cancer patients in the unique position of being asked to undergo surgery to remove their ovaries to prevent ovarian cancer, when they may be told they cannot take estrogen replacement for the menopausal symptoms that will occur postoperatively. Appropriate estrogen or testosterone replacement (or both) after premenopausal oophorectomy is not condoned in this population by oncologists. The challenges to the patient's emotional well-being while facing a life-threatening illness with new menopausal symptoms, sexual dysfunction, and potential problems with her marriage all at the same time, are overwhelming. The benefits to bilateral salpingo-oophorectomy in a *BRCA1* or *BRCA2* carrier are the potential reduction in risk of breast cancer recurrence, as well as the 90% risk reduction from ovarian cancer. If symptom control from the surgery was feasible, this would be a great benefit. The risks of estrogen and androgen withdrawal can be decreased libido, lubrication, hot flashes, insomnia, and depression, and some women conclude that the benefit is not worth the risk. For this reason, the age at which prophylactic oophorectomy should be planned is not known in genetic carriers and must be individualized. Some allow patients a reversible trial period of Depo-Lupron to simulate menopause to help them with this decision-making process.

The treatment of breast cancer may consist of tamoxifen, aromatase inhibitors, local radiation, and chemotherapy. Some argue that the purpose of the chemotherapy is to destroy ovarian function. Oophorectomy may be able to replace the benefit of chemotherapy, but this has not yet been adequately scientifically compared. Women are also eligible for treatment with aromatase inhibitors if they are menopausal, which has demonstrated a 43% reduction in breast cancer recurrence after completion of 5 years of tamoxifen.

There is increasing concern for the long-term morbidity of the standard breast cancer therapies, which are poorly captured in research trials. Women report cognitive function impairment from chemotherapy, as well as fatigue, weight gain, osteoporosis, and sexual dysfunction. Further study is required in this area to determine prevention strategies, including bone density testing frequency, calcium and vitamin supplementations, benefits of bisphosphonates, bone density monitoring, and prevention of cognitive dysfunction and sexual dysfunction.

The use of tamoxifen for the treatment or prevention of breast cancer has many known consequences, including thromboembolic disease, strokes, and endometrial cancer. The expected annual rate of endometrial cancer in breast cancer patients is 1 per 1000. Patients taking tamoxifen have an excess risk of 2 per 1000 or a total risk of 3 per 1000 per year. Studies on the appropriate monitoring of women on tamoxifen have demonstrated that transvaginal ultrasonography and routine annual endometrial biopsies increase a woman's risk. The current recommendation is to "do no harm" by conducting a routine annual gynecologic examination with cervical cytology and inquire about symptoms such as bleeding or discharge.

For many years, it has been stated that ERT in patients who have had breast cancer is absolutely contraindicated, yet the data are inconsistent in substantiating this admonition. During the past couple of decades, there has been increasing evidence that ERT can protect against osteoporosis and colon cancer, and recent data suggest benefits in the prevention of Alzheimer disease, macular degeneration, and tooth loss. Because the benefits of ERT are substantial and no data are available to note detrimental effect in patients with breast disease, these authors firmly believe that a reappraisal of the admonition against ERT in patients with breast cancer is needed. Historically, it has been the dictum that women who have had breast cancer should not, under any circumstances, receive ERT. When one looks in the literature for data to support this recommendation, there is a huge void. In 1989, Wile and DiSaia suggested that in the absence of prospective study of ERT in breast cancer survivors, one could analyze situations when these patients were exposed to high levels of estrogens at a time when they may have been harboring breast cancer cells. These situations were defined as pregnancy coexistent with breast cancer, pregnancy subsequent to breast cancer, breast cancer in previous and current users of oral contraceptives, and breast cancer in women receiving ERT. After extensive evaluation of these situations, there appears to be very little, if any, relationship. A total of 234,190 new cases of breast cancer were projected to be diagnosed in the United States in 2015. More and more of these individuals fortunately are surviving their cancer; in many, long-term survival of more than 90% of these patients can be expected. Because many will survive their cancer, they will experience old age. We must address the advisability of HRT in this setting.

In fact, some data suggest that ERT in breast cancer patients is not deleterious. Historically, we must remember that before cytotoxic agents, postmenopausal women with metastatic or recurrent cancer received estrogen as a first line of therapy. We now understand that its effectiveness depended to a certain extent on the receptor status of the cancer. At least seven prospective, randomized double-blind studies have compared estrogen with tamoxifen in patients with recurrent or metastatic breast cancer. The response rate of estrogen and tamoxifen is essentially the same. In prospective randomized studies comparing estrogen and tamoxifen as adjuvant therapy, the recurrence rate was essentially the same. It appears that we have a very short medical history memory.

At least six retrospective studies have evaluated HRT in women with breast cancer. These patients were recurrence free at the time, and they were given estrogen to combat vasomotor symptoms or to prevent the chronic illness of cardiovascular disease, osteoporosis, and colon cancer. In this selected group of more than 500 patients, there have been 30 (6%) recurrences and only seven (1%) deaths. In the authors' study of 145 patients in which patients with in situ, stage I to IV cancer were treated, there have been 13 (9%) recurrences. Patients with both node-positive and node-negative disease were treated. Of the 96 node-negative patients, 11 recurred, but only one of 34 node-positive patients to date has had a recurrence. Recurrence was noted in 1 of 15 patients in whom the lymph nodes were not pathologically evaluated. It appears that evaluation of the receptor status in patients who had this performed did not have an impact one way or the other with regard to recurrences (Table 4.6).

In addition, there have been three case-controlled studies and three cohort-type studies (Table 4.7) in which recurrences and deaths were similar in both the patients in the ERT and control groups. A cohort study of 125 patients with breast cancer who received HRT after cancer therapy were compared with 362 patients with breast cancer who did not receive HRT. Patients were matched for stage, age, and year of diagnosis. All stages were included, although 78% had carcinoma in situ (CIS) (14%) or stage I and II cancers. There was a survival advantage for HRT users compared with non-HRT users with

an odds ratio of 0.28 (CI 0.11–0.71). Six endometrial cancers were subsequently diagnosed in the patients who took HRT.

In 1997, two randomized clinical trials were started in Sweden to assess the risks of HRT after a diagnosis of breast cancer. Interestingly, these similarly designed trials in a homogenous population of Swedish women arrived at different conclusions. The HABITS (Hormonal Replacement Therapy After Breast Cancer—Is It Safe?) trial was designed as a randomized, non-placebo noninferiority study to compare combined estrogen–progesterone treatment for menopausal symptoms with best management without HRT in women previously treated for stage 0 to 2 breast cancer. Patients were treated for 2 years and then asked to stop treatment. After a median follow-up of 4 years, there was an increased risk of a new breast cancer event in the HRT group compared with the group without HRT with a relative hazard of 3.5 (CI 1.5–8.1). Of 219 patients in the HRT group, 26 new breast cancer events were noted. In the no HRT group, there were eight new breast cancer events in 215 women. This corresponds to an absolute difference of 14% in the cumulative incidence of a new breast cancer event at 5 years. Based on these findings at the interim analysis, the decision was made that HRT represented an unacceptable risk for women with a history of breast cancer, and the trial was terminated in 2003.

The Stockholm trial was a randomized open study in postmenopausal women with a history of breast cancer randomized to receive HRT with a cyclic estrogen–progesterone regimen for 5 years ($n = 188$) or no HRT ($n = 190$). In contrast to the HABITS trial, the Stockholm trial found that the risk of breast cancer recurrence was not associated with the use of HRT in patients with early stage breast cancer with a risk hazard of 0.82 (CI 0.35–1.9). Despite these findings, the Stockholm steering committee prematurely closed this trial based on considerations related to patient safety and difficulty recruiting patients in light of the HABITS results. It is unclear why these two similarly designed studies arrived at different conclusions, but with significant heterogeneity between the two studies ($P = 0.02$), it is unlikely that this can be explained by chance alone. It should be noted that the proportion of lymph-node positive patients was higher in the HABITS trial compared with the Stockholm trial (26% vs. 16%, respectively). Furthermore, only 21% of patients in the HABITS trial received adjuvant tamoxifen therapy compared with 52% of patients in the Stockholm trial. The distinctions in these clinical characteristics may have contributed to the differences in results of the two studies.

In conclusion, the risk of recurrent breast cancer in postmenopausal women receiving ERT is unclear. In postmenopausal women with previously treated breast cancer, consideration of ERT is an option but must be reviewed with caution. In other words, there must be informed consent. Women are interested in information for which they can make informed decisions. To not even discuss replacement therapy with these individuals is not in their best interest. In the United States today, more than 36,000 women who are younger than 50 years of age will develop breast cancer. Most, if not all, will go on cytotoxic chemotherapy, and a significant number will become amenorrheic even though they are younger than 35 years of age. Unfortunately, if amenorrhea occurs while they are on chemotherapy, permanent ovarian failure occurs in the vast majority. Even in the very young (younger than 40 years of age), 86% will have ovarian failure. We therefore are seeing an increasing number of young women who are going through chemotherapeutic-induced premature menopause. A significant number of these women will be cured of their breast cancer; however, because of the premature menopause, they may have significant vasomotor symptoms that are much greater than those expected with natural menopause. Long-term benefits of replacement therapy may even be greater because of the premature menopause. These patients should be made aware of the rationale for replacement (ie, the benefits and risks) so that intelligent decisions can be made. Breast cancer patients may be the ideal candidates for the vaginal slow-release forms of estradiol rings. Estring contains a very low dose of estradiol, which can successfully treat vaginal atrophy symptoms and only increase plasma estradiol levels to one tenth the amount of a 0.05 Estraderm patch. If menopausal symptoms remain intolerable, Femring has a higher estradiol dose of 0.05 mg/day and may provide some relief of symptoms as well.

Adenocarcinoma of the Uterine Corpus

William T. Creasman, MD, David Scott Miller, MD, FACOG, FACS

OUTLINE

Incidence
Epidemiology
Diagnosis
Pathology
Tumor Grade
Prognostic Factors
Treatment
Surgical Management of Endometrial Cancer
Radiation Therapy
Drug Development
Special Circumstances
Follow-Up

KEY POINTS

1. Adenocarcinoma of the endometrium is the most common gynecologic malignancy and is increasing in incidence. The mortality rate form this disease is also increasing.
2. Classically, endometrial cancer is divided into two histologic types: type I is endometrioid, and type II is consists of uterine papillary serous carcinoma (UPSC), clear cell (CC), and other more aggressive histologic types.
3. The mainstay of treatment is surgery with removal of the uterus tubes and ovaries with staging.
4. Adjuvant therapy is often given. Radiation or chemotherapy is used depending on the clinical scenario.
5. Endometrial cancer is commonly inherited through a DNA mismatch repair defect, which is known as Lynch syndrome. All patients with endometrial cancer should be evaluated for this possibility.

INCIDENCE

In the United States, cancer of the uterine corpus is the most common malignancy unique to women. It was estimated by the American Cancer Society that uterine cancer will develop in approximately 60,050 women in 2016 in the United States, making it the fourth most common cancer in women. The increased incidence of carcinoma of the endometrium has been apparent only during the past 3 decades. In reviewing the predicted incidence for the 1970s, the American Cancer Society noted a 1.5-fold increase in the number of patients with endometrial cancer; however, there was a decline in incidence during the late 1980s. In the past several years, the incidence has remained constant. During the period of increased incidence, predicted deaths from this malignant neoplasm actually decreased slightly. More recently, deaths from uterine cancer have increased. In 1990, the American Cancer Society estimated 4000 deaths from this cancer, increasing to 10,470 in 2016. An estimation of the most common new cancers and the percentage of female deaths for 2009 in the United States is shown in Fig. 5.1. The increased use of estrogen has been implicated in the apparent increased incidence during the 1970s and early 1980s; however, Norway and Czechoslovakia report a 50% to 60% increase, respectively, in endometrial cancer even though estrogens are rarely prescribed or are not generally available there. However, the increasing prevalence of overweight and obesity in women, especially in developed countries, may account for this apparent increase. Regardless of the reason for the increased number of women with corpus cancer, this malignant neoplasm has become an important factor in the care of the female patient.

EPIDEMIOLOGY

Endometrial adenocarcinoma occurs during the reproductive and menopausal years. The mean age for patients with adenocarcinoma of the uterine corpus is 63 years; most patients are between the ages of 50 and 59 years (Fig. 5.2). Approximately 5% of women will have adenocarcinoma before the age of 40 years, and **20% to 25% will be diagnosed before menopause.** Bokhman suggested that there are two pathogenic types of endometrial cancer. **The first type arises in women with obesity, hyperlipidemia, and signs of hyperestrogenism, such as anovulatory uterine bleeding, infertility, late onset of menopause, and hyperplasia of the stroma of the ovaries and endometrium. The second pathogenic type of disease arises in women who have none of these disease states or in whom**

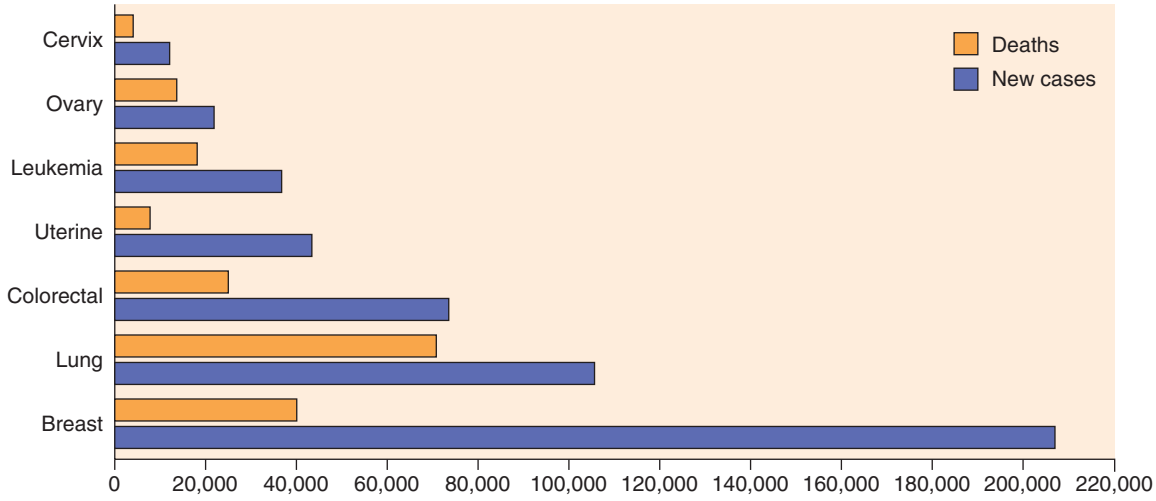

FIGURE 5.1 Common new cancer cases and deaths in women for 2010 in the United States. (Modified from American Cancer Society. *Cancer Facts and Figs. 2010*. Atlanta, 2010, American Cancer Society.)

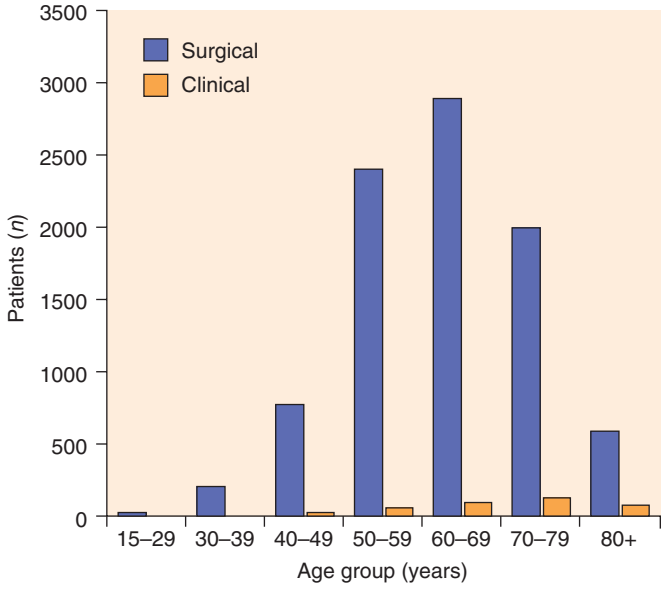

FIGURE 5.2 Carcinoma of the corpus uteri; patients treated in 1999 to 2001. Age distribution by mode of staging. (Modified from Creasman WT, Odicino F, Maisonneuve P, et al. Carcinoma of the corpus uteri. FIGO 26th Annual Report on the Results of Treatment in Gynecological Cancer. *Int J Gynecol Obstet* 95(1):S105-S143, 2006.)

TABLE 5.1 Endometrial Cancer Risk Factors

Risk Factors	Risk
Obesity	2.5–4.5×
Nulliparity	
Compared with one child	2×
Compared with five or more children	3×
Late menopause	2.4×

TABLE 5.2 Multiple Risk Factors

	Risk	
Nulliparous		Parous
Top 15% in weight	5× more than	Lower two thirds in weight
Menopause at 52 years		Menopause before 49 years

the disease states are not clearly defined. Bokhman's data suggest that patients with the first pathogenic type mainly have well-differentiated or moderately differentiated tumors, superficial invasion of the myometrium, high sensitivity to progestins, and a favorable prognosis (85% 5-year survival rate in his material). The patients who fall into the second pathogenic group tend to have poorly differentiated tumors, deep myometrial invasion, a high frequency of metastatic disease in the lymph nodes, decreased sensitivity to progestin, and poor prognosis (58% 5-year survival rate).

Multiple risk factors for endometrial cancer have been identified, and MacMahon divides them into three categories:

- Variants of normal anatomy or physiology
- Frank abnormality or disease
- Exposure to external carcinogens

Obesity, nulliparity, and late menopause are variants of normal anatomy or physiology classically associated with endometrial carcinoma. These three factors are evaluated in regard to the possible risk of developing endometrial cancer in Table 5.1. If a patient is nulliparous and obese and reaches menopause at age 52 years or older, she appears to have a fivefold increase in the risk of endometrial cancer above that of a patient who does not satisfy these criteria (Table 5.2).

The type of obesity in patients with endometrial cancer has been evaluated. In a study from the University of South Florida, **it was noted that women with endometrial cancer had greater waist-to-hip circumference ratios, abdomen-to-thigh skin ratios, and suprailiac-to-thigh skin ratios than those of**

matched control women. As these ratios increased, the relative risk (RR) of endometrial cancer increased. The researchers concluded that upper-body fat localization is a significant risk factor for endometrial cancer. In a large multicenter case-control study of 403 endometrial cancer cases and 297 control cases, Swanson and associates confirmed and amplified these findings. Women whose weight exceeded 78 kg had a risk 2.3 times that of women weighing less than 58 kg. For women weighing more than 96 kg, the RR increased to 4.3. Upper-body obesity (waist-to-height ratio) was a risk factor independent of body weight. Patients in the highest quartile of both weight and waist-to-thigh circumference had a risk of 5.8 times. The amount of body fat has been associated with decreased circulating levels of both progesterone and sex hormone–binding proteins. There was a strong inverse association between sitting height and risk of endometrial cancer. This may be related to sex hormone–bound globulin (SHBG), which appears to be depressed in women with endometrial cancer. The level of SHBG is progressively depressed with increasing upper-body fat localization. With lower SHBG, there is a higher endogenous production of non–protein-bound estradiol. Because endometrial cancer is related to obesity, dietary habits appear to be important. Data suggest that the levels of estriol, total estrogens, and prolactin were lower and those of SHBG were higher in postmenopausal women who were vegetarians. In a case-control study, Levi and colleagues evaluated dietary factors in 274 patients with endometrial cancer and 572 control subjects from two areas in Switzerland and northern Italy. Extensive dietary history was obtained. Their data confirmed the relationship between obesity and endometrial cancer. In relation to diet, they noted an increased association with total energy intake. After correction for total energy intake, a risk was present with the frequency of consumption of most types of meats, eggs, beans, added fats, and sugar. **Conversely, significant protection was noted with an elevated intake of most vegetables, fresh fruits, whole grain bread, and pasta.** This reflected a low risk with increased intake of ascorbic acid and beta-carotene. Of dietary interest is that the intake of olive oil seemed beneficial in Switzerland but resembled other added fats in the Italian women. It has been previously noted that the amount and type of dietary fat influence estrogen metabolism because estrogen reabsorption from the bowel seems to be increased by diets rich in beef or fats.

Diabetes mellitus and hypertension are frequently associated with endometrial cancer. Elwood and colleagues reported an RR of 2.8 associated with a history of diabetes after controlling for age, body weight, and socioeconomic status. High levels of insulin-like growth factor I, coupled with elevated estrogen levels, are thought to have neoplastic potential that accounts for the observed increased risk of endometrial cancer. High blood pressure is prevalent in older obese patients but does not appear to be a significant factor by itself, even though 25% of patients with endometrial cancer have hypertension or arteriosclerotic heart disease.

As extensively detailed in Chapter 4**, the relationship of unopposed estrogen and endometrial cancer is well documented. Fortunately, the addition of a progestin appears to be protective. The adequacy of progesterone is important in prevention of endometrial cancer.** In a study from Sweden, at the end of 5 years, excess risk of endometrial cancer was 6.6, but with combined estrogen progestin (E + P), the RR was 1.6 for 11 to 15 days of progestin, 2.9 for 10 days of use, and 0.2 if continuous E + P was given. The Million Women study from the United Kingdom reported its findings of endometrial cancer and hormone replacement therapy (HRT). This study, which first reported on HRT and breast cancer, has been severely criticized mainly on methodology factors. The study had an average follow-up of 3.4 years, during which 1320 incident endometrial cancers were diagnosed. At time of recruitment, 22% of HRT users (total number was 320,953 women) last used continuous combined therapy, 45% last used cyclic combined therapy with progestogen usually added for 10 to 14 days per month, 19% last used tibolone, and 4% used estrogen alone. **Compared with nonusers, the RRs of endometrial cancer were 0.71, confidence interval (CI) 0.56 to 0.90, $P = 0.005$; 1.05, CI 0.91 to 1.22; 1.79, CI 1.43 to 2.25, $P < 0.001$; and 1.45, CI 1.02 to 2.06, $P = 0.04$, respectively.** Of note, the adverse effects of tibolone and estrogen only were greatest in the nonobese women, and the beneficial effects of combined HRT were greatest in obese women. Although the risk of unopposed estrogen is present, women taking estrogen who develop endometrial cancer appear to have favorable prognostic factors. Several but not all studies suggest that risk factors such as multiparity and obesity are lower in the estrogen users. **Stage of disease and histologic grade appear to be lower in estrogen users.** With correction for stage and grade, estrogen users still have less myometrial invasion than nonestrogen users do. The poor prognostic subtypes, such as clear cell carcinoma and adenosquamous cancer, appear less frequently in estrogen users. As a result, **survival rates with estrogen-related endometrial cancer are much better than those of non–estrogen-related cancers.** In fact, some studies note just as good if not better survival in estrogen users than in women with nonestrogen, nonendometrial cancers.

Data indicate that the use of combination oral contraceptives decreases the risk for development of endometrial cancer. The Centers for Disease Control and Prevention evaluated endometrial cancer cases of all women aged 20 to 54 years from eight population-based cancer registries and compared them with control patients selected at random from the same centers. A comparison of the first 187 cases with 1320 control cases showed that **women who used oral contraceptives at some time had a 0.5 RR of developing endometrial cancer compared with women who had never used oral contraceptives.** This protection occurred in women who used oral contraceptives for at least 12 months, and **protection continued for at least 10 years after oral contraceptive use.** Protection was most notable for nulliparous women. **These investigators estimated that about 2000 cases of endometrial cancer are prevented each year in the United States by past or current use of oral contraceptives.** Of interest, cigarette smoking appears to decrease the risk for developing endometrial cancer. In a population-based case-control study of women aged 40 to 60 years, Lawrence and associates found a significant decline in RR of endometrial carcinoma with increased smoking ($P > 0.05$).

The RR decreased by about 30% when one pack of cigarettes was smoked per day and by another 30% when more than one pack was smoked per day. The effects of smoking did not appear to vary with menstrual status or exogenous estrogen. There was a fourfold increase in smoking-related odds ratio with body weight; the greatest reduction in risk by smoking was in the heaviest women. However, the estimated risk increased 12-fold in overweight women who were nonsmokers and whose primary source of estrogen was peripheral conversion of androgen to estrogen. Although smoking apparently reduces the risk for development of early-stage endometrial cancer, this advantage is strongly outweighed by the increased risk of lung cancer and other major health hazards associated with cigarette smoking.

Incidence and survival are higher in white women compared with black women. Reasons for these differences are unexplained. An analysis of the Gynecologic Oncology Group (GOG) database evaluated this factor in 600 white and 91 black women with clinical stage I or stage II endometrial cancer. A larger number of the African American women were diagnosed after age 70 years, and they had a higher proportion of UPSC and clear cell histologic types; the black women also had more advanced disease, grade, vascular space involvement, depth of invasion, and lymph node metastases than the white women did. The survival rate (5-year) was 77% for white women and 60% for black women. Survival difference remained even in high-risk groups such as grade III tumors (59% vs. 37%, respectively). The unadjusted hazard rate was 2.0, which was statistically significant. With adjustment for age, cell type, and extent of disease, the RR dropped to 1.2. **The adjusted risk rate suggests that race is not a significant factor; nevertheless, race does denote an increased risk for poor prognostic factors, which clinically may be important.**

Tamoxifen is used to prevent or treat breast cancer. Tamoxifen was first introduced in clinical trials in the early 1970s and was approved in 1978 by the US Food and Drug Administration (FDA) for treatment of advanced breast carcinoma in postmenopausal woman. Tamoxifen, although labeled an antiestrogen, is known to have estrogenic properties and truly is a weak estrogen. Women receiving tamoxifen also appear to have some protection from osteoporosis and heart disease (decreased lactate dehydrogenase and cholesterol), similar to women receiving estrogen replacement therapy. Extensive experience with this drug has been reported. It is estimated that more than 4 million women in the United States have taken tamoxifen for almost 8 million women-years of use. One of its major benefits is that in women taking tamoxifen, there has been a substantial decrease in the incidence of a second cancer in the opposite breast compared with similar women who were taking a placebo.

The Early Breast Cancer Trialists Collaborative Group (EBCTCG) has produced an important meta-analysis of 194 randomized trials of adjuvant chemotherapy or endocrine therapy with at least 15 years of follow-up. The analysis evaluated the effects of adjuvant tamoxifen on breast cancer recurrence and survival. It was shown that 5 years of tamoxifen therapy, compared with no adjuvant therapy, reduced the 15-year probability of breast cancer recurrence (from 45% to 33%) and breast cancer mortality (from 35% to 26%). In addition, tamoxifen has been shown to provide a preventive benefit in women at risk for developing breast cancer.

There has been a considerable amount of discussion in the literature concerning the association of tamoxifen with endometrial cancer. At least three studies (Fisher and colleagues, Powels and colleagues, and Veronesi and colleagues) evaluating the prophylactic use of tamoxifen in women without breast cancer have reported an association between tamoxifen use and endometrial cancer. In addition, several cases of endometrial cancer have been described in women receiving tamoxifen. In a prospective, randomized study of the National Surgical Adjuvant Breast and Bowel Project (NSABP), 2843 patients with node-negative estrogen receptor–positive invasive breast cancer were randomly assigned to receive a placebo or 20 mg/day of tamoxifen. An additional 1220 tamoxifen-treated patients were registered and given the drug. The average time in the study was 8 years for the randomly assigned patients and 5 years for the registered patients. Of the 1419 patients randomly assigned to tamoxifen, 15 developed uterine cancer, of which two were sarcomas. One patient randomly assigned to receive tamoxifen did not take the drug and developed endometrial cancer 78 months after randomization. In the placebo group, two developed endometrial cancer; however, both were receiving tamoxifen at the time of their uterine malignant disease. One patient had a breast recurrence and was prescribed tamoxifen, and the other was given tamoxifen after colon cancer. Two of the patients with endometrial cancer had been taking tamoxifen for only 5 and 8 months before their diagnosis of uterine disease was made. Five patients in the tamoxifen group developed endometrial cancer after the drug had been discontinued for 7 to 73 months. In the registered patients who received tamoxifen, eight uterine tumors (seven endometrial) were subsequently diagnosed. Three of these patients had been taking tamoxifen for less than 1 year (2 months, 2 months, and 9 months). The authors determined the average annual hazards ratio (HR) of endometrial cancer per 1000 women in their population of patients. This was 0.2 per 1000 in the placebo group and 1.6 per 1000 for the randomized tamoxifen-treated patients. In the registered patients receiving tamoxifen, the average annual hazard rate was 1.4 per 1000, similar to that of the randomized tamoxifen-treated group. The hazard rate of endometrial cancer in the placebo group was low compared with the Surveillance, Epidemiology, and End Results (SEER) data and with previous NSABP randomized tamoxifen–placebo studies; these data suggest that the average annual hazard rate is 0.7 per 1000.

These data, based on a limited number of patients with endometrial cancer while receiving tamoxifen, suggest that there may be an RR of 2.3 for development of endometrial cancer while receiving tamoxifen. This does not take into account the well-known fact that women who develop breast cancer are at an increased risk for development of endometrial cancer irrespective of subsequent treatment. The RR of 1.72 to more than 3 has been reported. The risks and benefits of the prevention of recurrences and new breast cancer in comparison to new endometrial cancers were evaluated in the NSABP study. **The benefits suggest that 121 fewer breast-related events**

per 1000 women treated with tamoxifen were seen compared with 6.3 endometrial cancers per 1000 women. Therefore, the benefit from tamoxifen is apparent.

It was initially suggested that the rate of endometrial cancers associated with tamoxifen use might be equal to that associated with unopposed estrogen replacement therapy. Because tamoxifen is a weak estrogen, similar characteristics of endometrial cancer were also implied (ie, well-differentiated superficially invasive cancers). Barakat and associates reviewed five studies, including the study by Magriples, the NSABP, their own data from Memorial Sloan-Kettering Hospital, and two studies from overseas. A total of 103 patients were evaluated in regard to histologic features, grade of tumor, International Federation of Gynecology and Obstetrics (FIGO) staging, and deaths from uterine cancer; **an increase was not found in poor prognostic histologic findings, tumor differentiation, or stage compared with what would be expected in a similar group of non–tamoxifen-treated patients with uterine cancer.** Jordan, in an evaluation of the SEER data and of tamoxifen-associated endometrial cancer in the literature, reported similar findings.

It is suggested that all women, irrespective of whether they are taking tamoxifen, should have yearly gynecologic examinations. The endometrium should be evaluated if the patient is symptomatic. We concur with the American College of Obstetricians and Gynecologists (ACOG) committee opinion that does not recommend endometrial sampling or ultrasound evaluation of the endometrium just because an individual is taking tamoxifen. This possible concern of tamoxifen and endometrial cancer may lessen in the near future because the aromatase inhibitors (AIs) may appear to be better than tamoxifen in the prevention of recurrent or contralateral breast cancer. Several clinical trials have demonstrated the comparable if not greater efficacy of AIs compared with tamoxifen. Although tamoxifen remains an option for adjuvant therapy for postmenopausal women, AIs are thought to be more effective in preventing breast cancer recurrence in the first 2 years after surgery. AIs reduce estrogen levels in postmenopausal women by inhibiting or inactivating aromatase, the enzyme that synthesizes estrogens from circulating androgens. AIs should be avoided in premenopausal women, including those who have experienced chemotherapy-induced amenorrhea. Whereas tamoxifen is a partial agonist, AIs are not agonists and are not associated with estrogenic-related thromboembolic events and uterine cancers. The activity of third-generation agents anastrozole, letrozole, and exemestane is generally considered comparable. Although AIs are associated with a significant risk of osteoporosis, they do not increase the risk of gynecologic problems. In one large adjuvant therapy trial (the Anastrozole, Tamoxifen Alone or in Combination Trial [ATAC]), anastrozole was associated with fewer cerebrovascular events (2.0% vs. 2.8%), endometrial cancers (0.2% vs. 0.8%), thromboembolism (3% vs. 4%), hot flashes (41% vs. 36%), and vaginal bleeding (5% vs. 10%) compared with tamoxifen. The role of AIs as prophylaxis is being investigated, but data are lacking at the present time.

Although most cases of endometrial cancer are sporadic, hereditary endometrial cancer has been identified in association with hereditary nonpolyposis colon cancer (HNPCC), also known as Lynch II syndrome. This is an autosomal-dominant inherited cancer that involves a germline mutation in one of the genes in the DNA mismatch repair gene family, which includes *MSH2, MLM1,* and *MSH6*. Fortunately, HNPCC accounts for only 1% to 5% of all colorectal cancers but it is associated with a 39% to 54% lifetime risk of developing colon cancer. **There is a lifetime risk of 30% to 61% of developing endometrial cancer in those with HNPCC.** There is also an increased risk of ovarian cancers and other nongynecologic cancers. In a study by Lu and associates, they noted that about half the time, the endometrial or ovarian cancer appeared before the colon cancer. In both instances, the age at diagnosis was in the early 40s. There was a median of 11 years between the gynecologic cancer and the colon cancer. About 14% of the time, the gynecologic and colon cancers were diagnosed simultaneously. Several "red flags" should prompt an evaluation for HNPCC. These include any individual with a personal or family history of colon cancer at an early age of onset (usually before age 50 years) or endometrial cancer at an early age of onset (premenopausal or before age 50 years) and two or more HNPCC-related cancers in an individual or family. Assessing a patient's risk for hereditary cancer is an important process, beginning with screening for the "red flags" of hereditary colon (and endometrial) cancer. Individuals with any of the "red flags" should enter into a discussion about genetic testing to determine if this is appropriate for them. Medical management strategies can be tailored depending on the genetic testing results and may include increased surveillance, chemoprevention, and prophylactic surgery. The Cancer Study Consortium suggests colonoscopy every 1 to 3 years beginning at age 25 years in individuals with this hereditary disorder. The data suggest that if surveillance is done, survival rates are improved. **Women should be offered surveillance with ultrasound and endometrial sampling from age 25 to 35 years, although there are no data to suggest this will improve survival if endometrial cancer is diagnosed by these means.** As reported by Schmeler and colleagues, risk-reducing surgery consisting of removal of the uterus and bilateral ovaries has been shown to decrease the risk of uterine and ovarian cancer in these high-risk patients.

DIAGNOSIS

Routine screening for uterine adenocarcinoma and its precursors is not recommended. Women receiving HRT (estrogen and progesterone) do not need endometrial biopsy before institution of therapy or during replacement therapy unless abnormal bleeding occurs. Monthly withdrawal bleeding after progestin is not considered abnormal bleeding. However, break through bleeding should be evaluated. **The use of continuous estrogen alone increases the risk of adenocarcinoma. Estrogen plus progesterone appears to decrease the risk of adenocarcinoma and therefore is the preferred treatment.** In asymptomatic high-risk patients, periodic screening may be advisable. All postmenopausal women with uterine bleeding must be evaluated for endometrial cancer, although only 20% of these patients will have a malignant genital neoplasm. **As the patient's age increases after menopause, there is a progressively increasing**

probability that her uterine bleeding is caused by endometrial cancer. Feldman and associates found that age was the greatest independent risk factor associated with endometrial cancer or complex hyperplasia. In women aged 70 years or older, the odds ratio was 9.1. If complex hyperplasia was present, the odds ratio increased to 16. When a woman was older than 70 years, her chance of having cancer when vaginal bleeding was present was about 50%. If she was also nulliparous and had diabetes, the risk was 87%. A perimenopausal patient who may have abnormal uterine bleeding indicative of endometrial cancer is frequently not evaluated because the patient or her physician interprets her new bleeding pattern as resulting from menopause. **During this time in a woman's life, the menstrual periods should become lighter and lighter and farther and farther apart.** Any other bleeding pattern should be evaluated with carcinoma of the endometrium in mind. A high index of suspicion must be maintained if the diagnosis of endometrial cancer is to be made in a young patient. Prolonged and heavy menstrual periods and intermenstrual spotting may indicate cancer, and endometrial sampling is advised. Most young patients who develop endometrial cancer are obese, in many instances massively overweight, often with anovulatory menstrual cycles.

Historically, fractional dilation and curettage (D&C) has been the definitive diagnostic procedure used in ruling out endometrial cancer. **Today, most advocate the routine use of the endometrial biopsy as an office procedure to make a definitive diagnosis and spare the patient hospitalization and an anesthetic.** Several studies have indicated that the accuracy of the endometrial biopsy in detecting endometrial cancer is approximately 90%. Cytologic detection of endometrial cancer by routine cervical Papanicolaou (Pap) smear has generally been poor in comparison with the efficacy of the Pap smear in diagnosing early cervical neoplasia. Several studies in the literature indicate that only one-third to half of the patients with adenocarcinoma of the endometrium have abnormal Pap smear results on routine cervical screening. The main reason for the poor detection with the cervical Pap smear is that cells are not removed directly from the lesion. When a cytologic preparation is obtained directly from the endometrial cavity, malignant cells are present in higher numbers than those found if routine cervical or vaginal smears are obtained. Techniques that obtain only a cytologic preparation are generally inadequate if they are used alone.

Several commercial apparatuses are available for sampling the endometrial cavity on an outpatient basis. If diagnosis of endometrial cancer can be made on an outpatient basis, the patient can avoid hospitalization and a minor surgical procedure. Devices that remove tissue for histologic evaluation have generally been good if tissue is obtained from the endometrial cavity. Stovall and colleagues used the Pipelle instrument to evaluate 40 patients known to have endometrial cancer. Ninety percent of the women were postmenopausal. Only in one patient was cancer not identified with the Pipelle. This patient had a prior D&C that revealed a grade I lesion. The Pipelle diagnosis was atypical adenomatous hyperplasia, and the hysterectomy specimen revealed a focus of adenocarcinoma in situ. The pathologist noted that the obtainable tissue was acceptable for analysis in 100% of patients. Discomfort was recorded as mild in 80%, and only two patients (5%) reported severe pain. Goldchmit and coworkers reported similar accuracy with the Pipelle in 176 consecutive patients undergoing D&C. Whereas endometrial biopsy and D&C appear to be equivalent in terms of diagnosing cancer, the accuracy of endometrial biopsy appears to be inferior to D&C in predicting final posthysterectomy tumor grade. In a recent study by Leitao and colleagues, 18% of endometrial biopsy specimens were upgraded on final hysterectomy specimen, but only 9% of D&C specimens were upgraded. In symptomatic patients in whom inadequate tissue (or no tissue at all) is obtained for pathologic evaluation, a D&C must be considered.

Hysteroscopy has been suggested as adjuvant in making the diagnosis of endometrial cancer and in establishing the extent of disease. Hysteroscopy has been used frequently in the evaluation of patients with abnormal uterine bleeding and has the advantages of allowing the physician to see the pathologic lesion and direct biopsy, identify other competing diagnoses (fibroids, polyps), and perform the procedure on an outpatient basis. Clark and colleagues analyzed data from 65 primary studies on the use of hysteroscopy to diagnose endometrial cancer and endometrial disease (cancer, hyperplasia, or both), including more than 26,000 women. All of the patients had abnormal premenopausal or postmenopausal uterine bleeding. Using endometrial histologic findings as a reference, a positive hysteroscopy result was associated with a 72% probability of endometrial cancer, but a negative result reduced this probability to 0.6%. The corresponding probabilities for endometrial disease were 55% with a positive result and 3% with a negative result. The accuracy of hysteroscopy tended to be higher among postmenopausal women and in an outpatient setting. They concluded that hysteroscopy is highly accurate and thereby clinically useful in diagnosing endometrial cancer in women with abnormal uterine bleeding and is moderately useful in diagnosing endometrial disease. Because many patients with endometrial cancer can be diagnosed with office biopsy, that is our preferred first diagnostic step. If the biopsy result is negative and further evaluation is needed, we proceed to hysteroscopy. With its use, surgeons can direct biopsies of focal lesions that might be missed by D&C. Hysteroscopy can also be used to evaluate the endocervical canal.

Ultrasonography has been suggested as a diagnostic tool in evaluating women with irregular bleeding, particularly postmenopausal patients (Fig. 5.3). The endometrial stripe as seen with transvaginal ultrasonography appears to be indicative of endometrial thickness. Several studies suggest that if a thin endometrial stripe is present, a histologic diagnosis is not necessary because atrophic endometrium would be present. Granberg and associates evaluated 205 women with postmenopausal bleeding, 30 postmenopausal asymptomatic women, and 30 postmenopausal patients with known endometrial cancer. In the two groups of 60 patients, the endometrial thickness was 3.2 (mean) versus 17.7, respectively. In the group of 205 women, 18 were found to have endometrial cancer. No cancers were present in the endometrium that had an endometrial thickness

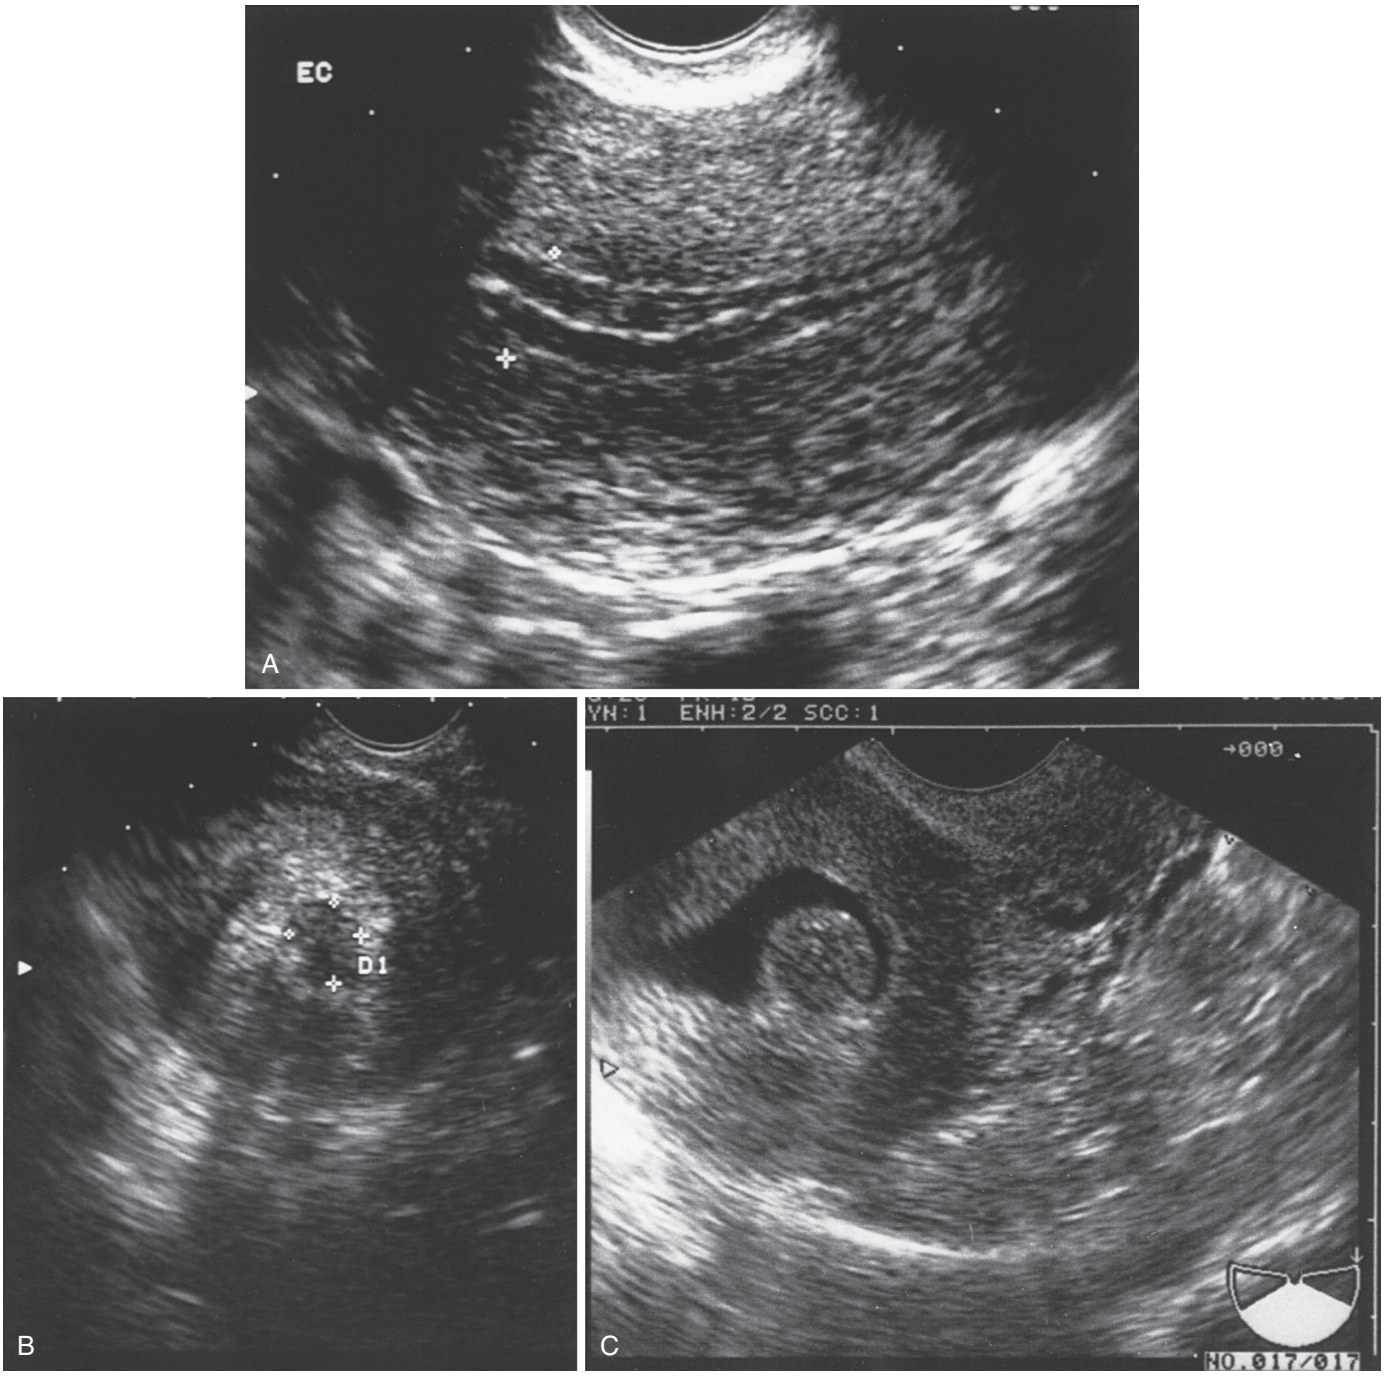

FIGURE 5.3 A, Ultrasound image of the uterus showing the "triple line" indicating the thickness of the endometrium. B, Ultrasound of the uterus showing a "thickened endometrium" of more than 10 mm. C, Saline instillation of the endometrial cavity notes a well-defined submucous fibroid and not thickened endometrium.

of 8 mm or less. There was considerable overlap of endometrial thickness by all histologic groups. The authors noted that if a cutoff of 5 mm was used, no false-negative findings were present. With this measurement, the positive predictive value was 87%, with specificity of 96% and sensitivity of 100% for identifying endometrial abnormalities. It has been suggested that if ultrasonography could save a large number of endometrial biopsies, there would be a large cost savings with less discomfort to the patient. As previously noted, significant pain with the newer disposable endometrial biopsy techniques affects only a small number of patients, and a certain number of patients, because of considerable endometrial thickness, will require endometrial sampling anyway. Clark and colleagues investigated the cost-effectiveness of initial diagnostic strategies

for postmenopausal bleeding. A decision analytic model was constructed to reflect current service provision, which evaluated 12 diagnostic strategies using endometrial biopsy, ultrasonography (4- and 5-mm endometrial thickness cutoff), and hysteroscopy. Diagnostic probability estimates were derived from systematic quantitative reviews, clinical outcomes from published literature, and cost estimates from local and National Health Service sources. The main outcome measure was the cost per additional life year gained (£/LYG). Compared with carrying out no initial investigation, a strategy based on initial diagnosis with ultrasonography using a 5-mm cutoff was the least expensive (£11 470/LYG). Initial investigation with endometrial biopsy or ultrasonography using a 4-mm cutoff was comparably cost-effective (<£30,000/LYG vs. ultrasonography with a 5-mm cutoff). The strategies involving initial evaluation with test combinations or hysteroscopy alone were not cost-effective. They concluded that women presenting for the first time with postmenopausal bleeding should undergo initial evaluation with ultrasonography or endometrial biopsy.

Unfortunately, endometrial cancer has been identified when the endometrial thickness is less than 5 mm. Although studies may evaluate several hundred patients, most do not have many cancer patients included. Wang and associates reviewed the ultrasounds of 52 women who were diagnosed with UPSC, clear cell and other high-grade carcinomas. Of the 52, 34 (65%) had a thickened endometrium measuring 5 mm or more; in nine (17%) the endometrium was less than 5 mm, and in an additional nine women (17%) the endometrium was indistinct. In the women with a nonthickened endometrium, other ultrasound abnormalities were noted: intracavitary fluid or lesion, myometrial mass, enlarged uterus, or adnexal mass. **Multiple factors can affect endometrial thickness. These include estrogen use, E + P use, body mass index (BMI), diabetes, poor histotype, race, and postmenopausal status.** The Committee on Gynecologic Practice of the ACOG issued an opinion on the role of transvaginal ultrasonography in the evaluation of postmenopausal bleeding. They concluded that women with postmenopausal bleeding may be assessed initially with either endometrial biopsy or transvaginal ultrasonography. This initial evaluation does not require performance of both tests. Transvaginal ultrasonography can be useful in the triage of patients in whom endometrial sampling was performed but tissue was insufficient for diagnosis. When transvaginal ultrasonography is performed for patients with postmenopausal bleeding and an endometrial thickness of less than or equal to 4 mm is found, endometrial sampling is not required. Meaningful assessment of the endometrium by ultrasonography is not possible in all patients. In such cases, alternative assessment should be completed. When bleeding persists despite negative initial evaluations, additional assessment is indicated.

The reliability determining endometrial thickness in postmenopausal patients does not appear to be applicable to women taking tamoxifen. **In all studies, the endometrium in a tamoxifen-treated patient is considerably thicker than in a non–tamoxifen-treated patient.** Histologic evaluation revealed an atrophic endometrium in a large number of these tamoxifen-treated patients. Lahti and colleagues evaluated 103 asymptomatic postmenopausal patients (51 receiving tamoxifen and 52 control participants) with ultrasonography, hysteroscopy, and endometrial histologic examination. In the tamoxifen group, 84% had an endometrial thickness on ultrasonography of 5 mm or more versus 19% in the non-tamoxifen group (51% vs. 8% >10 mm, respectively). Hysteroscopy findings noted that 28% of uterine mucosa was atrophic versus 87% in the non-tamoxifen control group. Histopathologic examination noted atrophic endometrium in 60% of tamoxifen-treated patients versus 79% of control subjects. **The biggest difference between the two groups was the finding of polyps in 18% of the tamoxifen group versus 0% of the control group; this appears to be a frequent finding in the tamoxifen-treated patient.** So-called megapolyps measuring up to 12 cm have been described. Other uterine diseases have been attributed to tamoxifen, including increased uterine volume, lower impedance to blood flow in uterine arteries, endometriosis, focal periglandular condensation of stromal cells, and epithelial metaplasia. Data now suggest that the markedly thickened endometrium (≤40 mm) in patients receiving tamoxifen is not thickened endometrium but proximal myometrium.

Ultrasonography has also been evaluated as a means for determining depth of myometrial invasion. Gordon and associates studied 15 known patients with endometrial cancer by ultrasonography and magnetic resonance imaging (MRI). By use of criteria of greater than 50% myometrial wall involvement as deep invasion and less than 50% as superficial invasion, ultrasonography was judged to be more accurate than MRI in five studies; MRI was better in three, both were equally accurate in four, and neither was accurate in three. It has been suggested by some that ultrasonography can accurately predict myometrial invasion in about 75% of cases. Although knowing the depth of invasion preoperatively would be important information to the clinician, the data from studies as noted before would currently appear to be too premature or too costly to use routinely. **We prefer to evaluate depth of myometrial invasion intraoperatively with gross examination or frozen section.**

Pathology

Careful evaluation of the uterus by the pathologist is essential for proper diagnosis and treatment of corpus cancer (Fig. 5.4). Gross inspection of a bivalved uterus at the time of hysterectomy can offer an impression of the size of the lesion, its location (involvement of fundus, lower uterine segment, or cervix), and the depth of tumor penetration into the myometrium (depth of invasion). A clinically enlarged uterus may be caused by increasing tumor volume, but this should not be the only gauge for significant local disease. Obviously, many patients can have enlarged uteri because of factors other than adenocarcinoma. Carcinoma of the endometrium may start as a focal discrete lesion, as in an endometrial polyp. It may also be diffuse in several different areas, in some situations involving the entire endometrial surface. As the tumor grows, it can become larger or spread within the endometrium or myometrium. Endometrial cancer may disseminate to regional lymph nodes, by embolization or direct extension into the pelvis or vagina, or hematogenously to distant organs (Fig. 5.5). The risk of spread

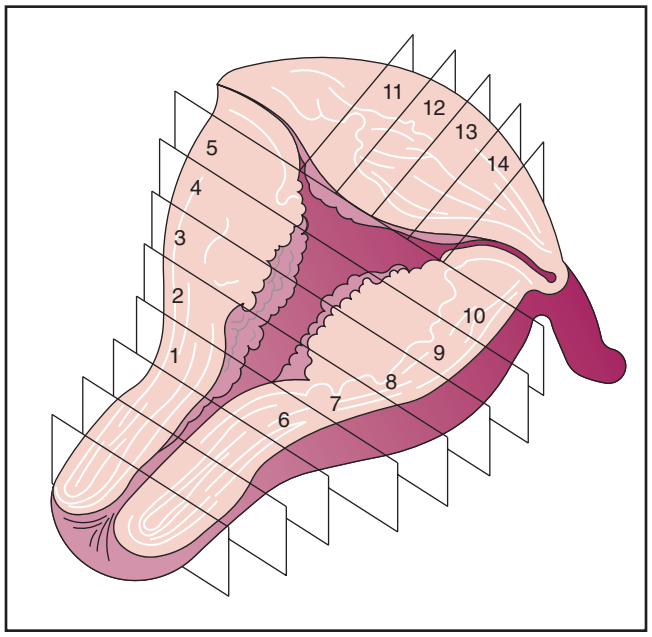

FIGURE 5.4 Pathologic evaluation of endometrial cancer. (Courtesy of Paul Underwood, MD.)

is related to several factors, including depth of invasion into the myometrium, tumor grade, and histologic type.

Adenocarcinoma, the most common histologic type, is usually preceded by a predisposing lesion, atypical endometrial hyperplasia (Table 5.3)**. Only hyperplasias with cellular atypia are considered precursors of adenocarcinoma of the endometrium.** For most patients with endometrioid-type tumors, particularly grade I or II lesions, and hyperplasia, hyperestrogenism is the etiologic basis. Pathologically, endometrial cancer is characterized by the presence of glands in an abnormal relationship to each other, with the hallmark of little,

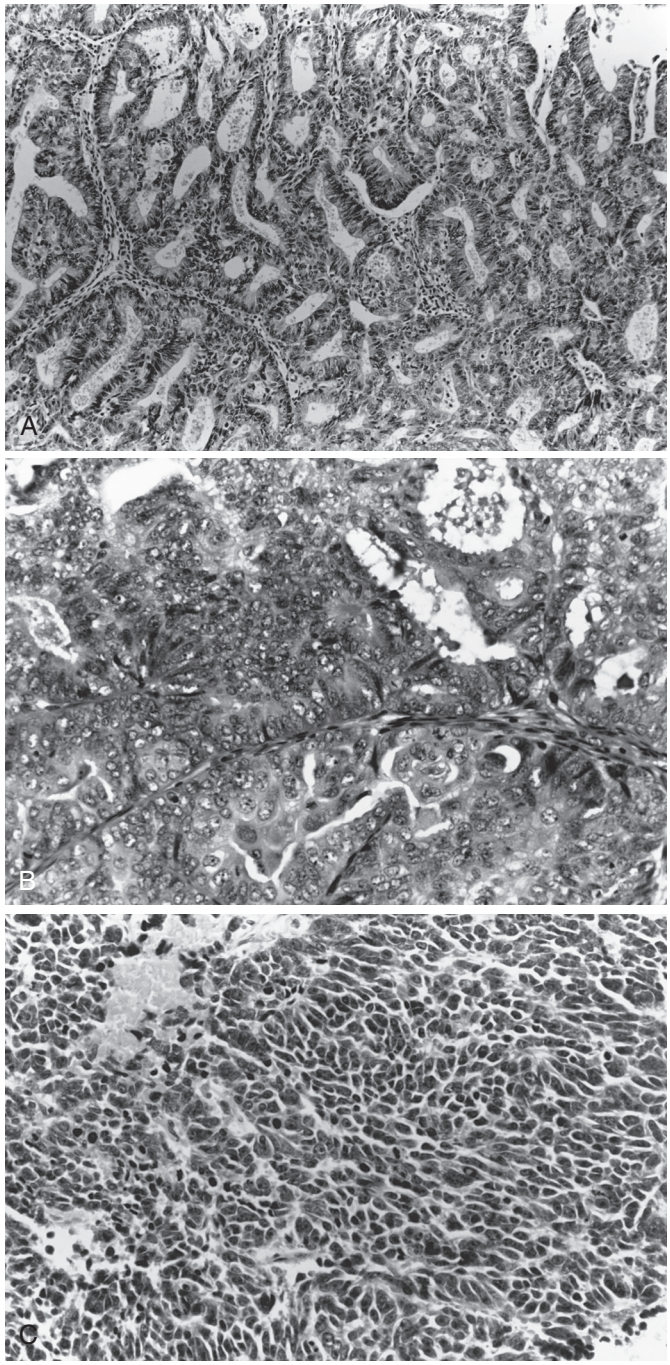
if any, intervening stroma between the glands. There can be variations in the size of the glands, and infolding is common. The cells are usually enlarged, as are the nuclei, along with nuclear chromatin clumping and nucleolar enlargement. Mitosis may be frequent. Differentiation of adenocarcinoma (mild, moderate, and severe, or grades I–III) is important prognostically and is incorporated into FIGO surgical staging (Fig. 5.6). Most studies suggest that 60% to 65% of all endometrial cancers are of this subtype.



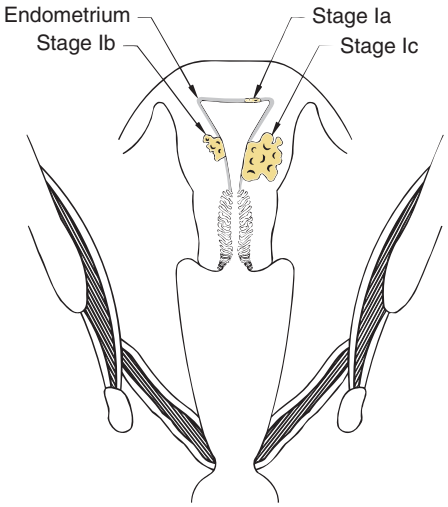


FIGURE 5.6 Histologic patterns of differentiation in endometrial carcinoma. **A,** Well-differentiated (G1). **B,** Moderately differentiated (G2). **C,** Poorly differentiated (G3). (Courtesy of Gregory Spiegel, MD.)

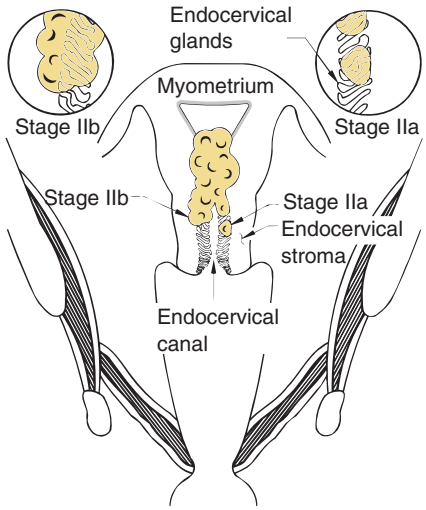

For almost a century, it has been recognized that a squamous component may be associated with an adenocarcinoma of the endometrium. This occurs in about 25% of patients. Historically, patients with a squamous component were further stratified according to whether the squamous component appeared benign (designated adenoacanthoma [AA]) or malignant (designated adenosquamous carcinoma [AS]). It was suggested that AA indicated a good prognosis and those with AS had a poor survival. Today, this distinction has been questioned concerning its prognostic importance. **Zaino and coworkers, in reporting data from the GOG, suggest that the notation of squamous component irrespective of differentiation does not affect survival.** Patients with clinical stage I and stage II cancers were evaluated, and 456 with typical adenocarcinoma (AC) and 175 with squamous differentiation (AC + SQ) were identified. The latter were subdivided into 99 with AA and 69 with AS. Multiple known prognostic factors were compared with differentiation of glandular and squamous component of the tumor. Age, depth of myometrial invasion, architecture, nuclear grade, and combined grade were similar for AC and AC + SQ, although patients with AA were better differentiated than those with AS and had less myometrial invasion. Both glandular and squamous differentiation correlated with frequency of pelvic and paraaortic node metastasis. Nodal metastasis, when it was stratified for grade and depth of invasion, was similar in AC and AC + SQ patients. **The differentiation of squamous component is closely correlated with the differentiation of the glandular element, and the glandular element is a better predictor of outcome.** It would therefore appear that the previous designation of AA and AS has no added predictive property than differentiation of glandular component and probably should be dropped as a diagnostic term. **The authors suggest the term *squamous differentiation* instead, with differentiation of the glandular component noted as the important prognostic factor.** Subsequently, Abeler and Kjorstad reviewed 255 cases and made the same recommendations.

Secretory adenocarcinoma (Fig. 5.7) is an uncommon type of endometrial cancer. It usually represents well-differentiated carcinoma with progestational changes. It is difficult to differentiate it from secretory endometrium. Survival is good and comparable to that associated with the pure adenocarcinoma. Although it is an interesting histologic variant, the separation of the entity as it relates to treatment and survival is probably not warranted.

Increasing emphasis has been placed on the importance of the **histologic subtype serous adenocarcinoma of the uterus, known as uterine papillary serous carcinoma (UPSC). This subtype represents fewer than 10% of all adenocarcinomas but is a highly aggressive carcinoma of the uterus.** Unlike the more common variants, UPSC is not associated with hyperestrogenism and frequently develops in the setting of atrophic endometrium. **It is more commonly seen in older and nonwhite patients. Hendrickson, in the early 1980s, noted that in more than 250 endometrial cancers, only 10% had histologic features of UPSC, but these accounted for 50% of all treatment failures.** The histopathologic appearance resembles a high-grade serous carcinoma of the ovary that has a

propensity for vascular or lymphatic vascular space involvement (LVSI). Well-formed papillae are lined by neoplastic cells with grade III cytologic features (Fig. 5.8). Differentiation between papillary architecture and syncytial metaplasia with benign endometrial alterations must be made because **the papillary architecture alone does not designate UPSC.** The uterus may appear grossly normal but can have extensive myometrial invasion. Most UPSC tumors are aneuploid and have a high S-phase, and can be pure or admixed with other histologic types (endometrioid, clear cell, carcinosarcoma).

Clear cell carcinomas (Fig. 5.9) are also infrequent in number but have distinct histologic criteria. Clear cell tumors are characterized by large polyhedral epithelial cells that may be admixed with typical non–clear cell adenocarcinomas. Some authorities accept the mesonephritic-type hobnail cells as part of this pattern, but others believe that this histologic type should be excluded from the clear cell category. Silverberg and DeGiorgi and Kurman and Scully suggested a worse prognosis for clear cell adenocarcinoma than for pure adenocarcinoma. This was confirmed in studies by Christopherson and coworkers. Even in stage I disease, only 44% of patients with clear cell carcinomas survive 5 years. Neither the FIGO classification nor nuclear grade correlates with survival. Photopulos and associates, in a review of their material, noted that their patients with this entity were older and tended to have a worse prognosis. They did note that patients with stage I clear cell carcinomas had a 5-year survival rate similar to that of patients with stage I pure adenocarcinoma of the endometrium.

Tumor Grade

In addition to histologic type, pathologists assign a measure of tumor differentiation, known as grade, to endometrial cancers. Grade I lesions are well differentiated, are frequently associated with estrogen excess, closely resemble hyperplastic endometrium, and are generally associated with a favorable prognosis. Grade III lesions are poorly differentiated, do not resemble normal endometrium, and frequently have a poorer prognosis. Grade II tumors are moderately well differentiated and have an intermediate prognosis. Both architectural criteria and nuclear grade are used to classify. Architectural grade is related to the proportion of solid tumor growth, with grade I having an adenocarcinoma in which less than 5% of the tumor growth is in solid sheets, grade II having 6% to 50% of the neoplasm arranged in solid sheets of neoplastic cells, and grade III having greater than 50% of the neoplastic cells in solid masses. Regions of squamous differentiation are excluded from this assessment. The FIGO rules for grading state that notable nuclear atypia, inappropriate for architectural grade, raises the grade of a grade I or grade II tumor by one. By convention, serous and clear tumors are considered grade III or high-grade tumors.

PROGNOSTIC FACTORS

After hysterectomy and lymph node dissection, clinicopathologic characteristics are commonly used to predict risk of recurrence and to optimize therapy. Multiple factors have been

		IIIC1 Positive pelvic nodes
		IIIC2 Positive paraaortic lymph nodes with or without positive pelvic lymph nodes
Stage IV*		Tumor invades bladder and/or bowel mucosa and/or distant metastases
	IVa	Tumor invasion of bladder and/or bowel mucosa
	IVb	Distant metastases, including intraabdominal metastases and/or inguinal lymph nodes

*Includes grades 1, 2, or 3.
†Endocervical glandular involvement only should be considered as stage I and no longer as stage II.
‡Positive cytology has to be reported separately without changing the stage.

identified for endometrial carcinoma that has prognostic value (Table 5.4). Essentially all reports in the literature agree stage (extent of disease spread), grade of tumor, and depth of invasion are important prognostic considerations. Before 1988, endometrial cancer was clinically staged with stage assignments based on uterine size and clinical extent of disease. Because of the considerable discrepancy between the clinical extent of disease spread and pathologic spread noted after surgical staging, FIGO adopted a surgical-pathologic staging classification in 1988. In 2009, FIGO updated the staging system (Table 5.5). FIGO staging classification attempts to categorize patients into prognostic groups based on extent of disease and tumor grade.

Stage of Disease: Depth of Invasion, Cervical Involvement, Adnexal Involvement, and Nodal Metastasis

Staging of patients with malignancies is designed to have prognostic value by classifying the size and extent of tumor. The survival rate in regard to stage of disease has been consistent,

and Table 5.6 and Fig. 5.10 show the 5-year survival rate reported by FIGO (FIGO 1988 staging). The patterns of disease spread in endometrial cancer was evaluated in a prospective study performed by the GOG (GOG protocol 33) and reported by Creasman. This study is required reading for physicians who care for patients with endometrial cancer. GOG protocol 33 was a surgical-pathologic study of 621 patients with clinical stage I endometrial cancer who were uniformly treated with total abdominal hysterectomy (TAH), bilateral salpingo-oophorectomy (BSO), peritoneal cytologic evaluation, and selective pelvic and paraaortic selected lymphadenectomy. Before this study, it was presumed most patients with endometrial cancer were at risk for nodal metastases, and nearly all patients required some form of pelvic radiation therapy (either preoperatively or postoperatively). The study demonstrated important relationships between pathologic factors and risk of nodal disease. For example, factors associated with nodal disease included higher tumor grade, deeper myometrial invasion, cervical involvement, (+) cytology, and LVSI. Because of this study, FIGO accepted a surgical-based staging system, including lymphadenectomy, of endometrial cancer in 1988.

For endometrial cancer, FIGO staging reflects the progression of disease within the uterus and at extrauterine sites. Approximately 75% of patients with endometrial cancer present with disease limited to the uterus (Table 5.7). For stage I disease, depth of tumor invasion into the myometrium is an important prognostic factor. **The degree of myometrial invasion is a consistent indicator of tumor virulence** (Fig. 5.11). DiSaia and

associates noted that recurrences were directly related to depth of myometrial invasion in patients with stage I cancer treated primarily with surgery (Table 5.8). The Annual Report of FIGO demonstrated a decrease in the survival rate as myometrial penetration increased (Table 5.9). Lutz and coworkers determined that the depth of myometrial penetration was not as important as the proximity of the invading tumor to the uterine serosa. Patients whose tumors invaded to within 5 mm of the serosa had a 65% 5-year survival rate, but patients whose tumors were more than 10 mm from the serosa had a 97% survival rate. The depth of myometrial invasion is associated with the other prognostic factors, such as the grade of the tumor. As noted by DiSaia and associates, the survival rate of patients with poorly differentiated lesions and deep myometrial invasion is poor in contrast to that of patients who have well-differentiated lesions but no myometrial invasion. This suggests that virulence of the tumor may vary considerably, and as a result, therapy should depend on the combination of prognostic factors.

Location of the tumor within the endometrial cavity is important because tumors low in the cavity may involve the cervix earlier than fundal lesions. The prognosis for women with cervical involvement (stage II) is worse than with stage I disease. Cervical involvement is often a surrogate marker for extrauterine disease spread or for risk of local recurrence. Data from GOG 33 showed that those with disease of the lower uterine segment had a higher incidence of pelvic lymph node metastases (16%) than do those with only fundal disease (8%). There is a similar frequency of paraaortic nodal metastases: a 16% incidence from disease of the lower uterine segment and a 4% incidence when only fundal disease is present. Previously, endocervical curettage (ECC) was commonly used to determine whether the patient had cervical involvement. Many false-positive results occur with this technique, however. In addition, the prognostic significance of endocervical glandular spread (formerly stage IIa) has been challenged. The new surgical staging adopted by FIGO in 2009 includes only patients with cervical stromal invasion in the stage II category. In some cases, cervical biopsy or ECC is required in the pretreatment planning of a patient with suspected cervical involvement.

Patients with stage III or IV disease may have a heterogeneous mix of disease characteristics. It is well recognized that endometrial cancer can and frequently does metastasize to the adnexa. Patients with adnexal or serosal involvement are categorized as having stage IIIA disease and are considered to have a higher risk of peritoneal recurrence. In GOG 33, 5% of patients had adnexal involvement. Adnexal metastasis was significantly associated with involved pelvic (32%) and paraaortic (20%) lymph nodes. In a large surgical trial comparing laparoscopy with open staging (GOG Lap 2 trial), 5% of 2616 patients enrolled were found to have stage IIIA disease (FIGO 1988 staging). In an analysis of 222 patients with clinical stage I carcinoma of the endometrium reported by DiSaia and colleagues, 16 (7%) were found to have metastasis in the adnexa. This finding correlated with many but not all of the other prognostic factors. Spread to the adnexa did not seem to be related to the size of the uterus. The grade of the disease did not appear prognostically important in regard to this in that 6% of patients with grade I tumors had adnexal disease compared with only 10% if poorly differentiated carcinoma was present. The depth of invasion did appear to be significant, however, in that only 4% of patients with only the endometrium involved had adnexal spread compared with 24% who had adnexal metastases if deep muscle was involved. If tumor was limited to the fundus of the uterus, only 5% of patients had disease in the adnexa; however, if the lower uterine segment or the endocervix was involved, one-third had spread to the adnexa. When metastasis was present in the adnexa, 60% of patients had malignant cells in the peritoneal cytologic fluid compared with only 11% if the adnexa were not involved. Recurrences appeared in only 14% of these individuals who did not have metastasis to the adnexa compared with recurrences in 38% of patients with adnexal metastasis.

Metastatic spread to lymph nodes (stage IIIC) has prognostic and therapeutic implications. It is clear that lymphadenectomy, to date, is the most sensitive way to identify nodal disease. The GOG 33 study demonstrated that as the depth of tumor invasion or tumor grade increased, the frequency of pelvic and paraaortic nodal metastases also increased (Tables 5.10 and 5.11). For all 621 patients, 58 (9%) had positive pelvic nodes, and 34 (6%) had positive paraaortic nodes. Patients with grade 1, 2, and 3 tumors had pelvic nodal metastases of 3%, 9%, and 18% respectively. Similarly, patients with no myometrial invasion, inner one-third, middle one-third, and outer one-third invasion had 1%, 5%, 6%, and 25% pelvic nodal disease, respectively. The highest risk group included patients with grade III tumors and outer one-third invasion who had pelvic nodal involvement in 34% of cases (Table 5.12). Without a lymphadenectomy, one may grossly estimate the probability of nodal involvement based on these data to select for or against the use of adjuvant therapy. This strategy potentially results in undertreatment or overtreatment of patients, however. In two large prospective randomized trials, routine lymphadenectomy resulted in the identification of more patients with nodal disease (9%–13%) compared with when only clinically suspicious nodes were removed (1%–3%). It is clear that patients with nodal disease have a poorer prognosis (3- to 5-year survival rate of 50%–75%) and different patterns of failure (nodal, distant) than patients with negative nodes (3- to 5-year survival rate of 80%–95%, vaginal cuff failures predominate). Patients with nodal involvement include those with pelvic nodal disease (IIIC1) or any paraaortic involvement (IIIC2). The substaging was created in 2009 given the belief of different outcomes associated with different levels of nodal involvement. The number of involved nodes and the extent of resection of grossly involved nodes also affect outcome. In addition, Mariani and McMeekin have suggested that patients with positive nodal

disease plus other stage III defining features (positive cytology, adnexal or serosal involvement) have a much poorer prognosis than those with nodal disease only. Patients with stage IV or distant disease spread (intraperitoneal, lung, liver) have a particularly poor prognosis, with 5-year survival rate of less than 20%. The extent of surgical resection has been suggested to alter the prognosis in patients with advanced-stage disease. As with ovarian cancer, the extent of resection of disease reflects the biology of the tumor, aggressiveness of the surgery, and response to postoperative therapies.

Tumor Grade

The degree of histologic differentiation (tumor grade) of endometrial cancer is a sensitive indicator of prognosis and is included in FIGO stage assignment. The Annual Report on the Results of Treatment in Gynecological Cancer has evaluated survival in regard to grade in patients with clinical stage I adenocarcinoma of the endometrium (Table 5.13). Tumor grade is inversely related to survival decreases; as grade increases, survival is poorer. In their review of 244 patients with stage I disease, Genest and colleagues noted that patients with grade I disease had a 5-year survival rate of 96%. This dropped to 79% and 70% for grade II and grade III, respectively. Data presented by Morrow for outcomes in patients enrolled on GOG 33 show that recurrence-free survival markedly diminishes with increasing grade, with progression-free survival (PFS) at 48 months being approximately 95%, 85%, and 68% for grade I, II, and III tumors, respectively. Grade of tumor also correlates with other factors of prognosis. Table 5.14 shows the relationship between differentiation of the tumor and depth of myometrial invasion as reported by Creasman from the GOG 33 study. As the tumor becomes less differentiated, the chances of deep myometrial involvement increase. However, exceptions can occur: Patients with a well-differentiated lesion can have deep myometrial invasion, but patients with a poorly differentiated malignant neoplasm might have only endometrial or superficial myometrial involvement.

Lymphovascular Space Involvement

Hanson and colleagues described 111 patients with stage I endometrial cancer and found capillary-like space (CLS) involvement in 16. This was most frequently found in patients with poorly differentiated tumors with deep invasion. These patients had a 44% recurrence rate compared with 2% if the CLS was not involved. This was an independently significant prognostic factor. In the GOG study of 621 patients, it was shown that 93 (15%) had CLS involvement. **The incidences of pelvic and paraaortic node metastases were 27% and 19%, respectively.** This compares with a 7% occurrence of pelvic node metastasis and a 3% occurrence of paraaortic node metastasis when there is no CLS involvement. In risk models predicting risk of recurrence in node-negative, early-stage endometrial cancer, the GOG has suggested that LVSI is an important risk factor. In the Post-Operative Radiation Therapy in Endometrial Cancer (PORTEC) trial, LVSI was considered a factor associated with distant site of failure.

Tumor Size

Schink and coworkers evaluated tumor size in 91 patients with stage I disease. The incidence of lymph node metastases in

patients with tumor size less than 2 cm was only 6%. If the tumor was larger than 2 cm in diameter, there were nodal metastases of 21% and up to 40% if the entire endometrium was involved. Patients with lesions greater than 2 cm in size and less than half myometrial invasion had no nodal metastasis. Using multivariate analysis, the authors showed that tumor size was an independently significant prognostic factor. Watanabe and associates did not find cancer size was predictive of lymph node metastasis. Gynecologic oncologists from the Mayo Clinic have developed a risk model predicting nodal metastases and have suggested that grade I and II tumors that are smaller than 2 cm are particularly low risk for nodal disease.

Peritoneal Cytology

The importance of peritoneal cytology in endometrial cancer is controversial. In GOG 33, 76 (12%) had malignant cells identified by cytologic examination of peritoneal washings. Of these patients, 25% had positive pelvic nodes compared with 7% of patients in whom no malignant cells were found in peritoneal cytologic specimens ($P > 0.0001$). It is true that peritoneal cytology, to a certain degree, mimics other known prognostic factors—that is, if peritoneal cytologic specimens are positive, other known poor prognostic factors may also be identified. In addition, data from GOG 33 also suggested that the RR for recurrence with positive cytology was 2.4 ($P = 0.02$).

Given the relationship of positive cytology with other known risk factors, it is important to evaluate data sets coming from patients who undergo complete surgical staging. Saga and colleagues reported on a series of 307 (32 with positive cytology, 275 with negative cytology) patients with endometrioid-type cancer, all who underwent complete staging and had negative lymph nodes. The authors reported that 5-year survival rate was 87% with positive cytology compared with 97% with negative cytology. Most patients with positive cytology received chemotherapy postoperatively. Havrilesky et al. reported on experience from Duke University. Patients with positive cytology alone ($n = 37$) were compared with patients with adnexal or serosal involvement ($n = 20$). The 5-year survival rate was similar between the groups (62% positive cytology, 68% adnexal or serosal disease), but in a multivariable analysis, cytology was an independent predictor of recurrence and poorer survival. This study included patients with nonendometrioid histologies, and lymphadenectomy was not routinely performed. In another review of the literature, Wethington demonstrated that in endometrioid-type tumors with low risk factors (superficial invasion, grade I or II); the recurrence rate was only 4%. By comparison, 32% of patients with higher grade tumors or deeper invasion and positive cytology had a recurrence. These results suggest that for at least a subset of cytology patients, the risk of recurrence approximates that driven by other uterine factors (depth of invasion, tumor grade). In 2009, FIGO dropped cytology as a stage IIIA defining characteristic.

Milosevic and colleagues reviewed 17 studies. In 3820 patients, the prevalence of positive cytologic findings was 11%. **The three largest studies totaling more than 1700 patients (Haroung and associates, Turner and colleagues, Morrow and coworkers) using multivariate analysis noted that the finding of malignant cells on cytologic examination was independently significantly associated with either recurrence or reduced survival.** Pooled odds ratio for the entire series was 4.7 (CI, 3.5–6.3) for disease recurrence. All studies note the highest correlation of malignant cytologic specimens with extrauterine disease. **It does appear that with multivariate analysis, the presence of malignant cells is an important prognostic factor even when disease is limited to the uterus.**

Optimal therapy has not been determined to date. Historically, intraperitoneal ^{32}P or oral progestins have been used to manage disease in patients with positive cytology. Today, uterine risk factors are largely used to define postoperative adjuvant therapy independent of cytology status and, increasingly, in otherwise low-risk patients (endometrioid-type tumors, negative nodes), observation is often considered. Chemotherapy has also been used in the adjuvant setting for patients with positive cytology.

Molecular Indices

Hormone receptors. Historically, estrogen and progesterone receptors were the first "targets" describing the molecular biology of endometrial cancer. Using multivariate analysis to analyze hormone receptor status, Creasman and associates noted that in stage I and stage II cancers, progesterone receptor–positive status was a highly significant, independently prognostic factor in endometrial cancer. Without progesterone receptor status in the model and with the evaluation of estrogen receptor status in its stead, estrogen receptor–positive status was an independent prognostic factor but not to the degree of progesterone receptor–positive status. Hormone receptor status may closely mirror grade, however.

Today there is an explosion of research into the molecular makeup of endometrial cancer. Cytogenetic studies have described gross chromosomal alterations, including changes in the number of copies of specific chromosome. The extent of abnormalities in a given tumor is relatively low. About 80% have normal diploid DNA content. Aneuploidy in 20% is usually associated with high-grade, extrauterine disease, high-risk histotypes, and poor prognosis. So-called loss of heterozygosity occurs at a relatively low frequency compared with other solid tumors. When chromosomal loss of heterozygosity does occur, underlying molecular genetic defects have been observed on 17p and 10q that correlate with mutational inactivation of *TP53* and *PTEN*, respectively. **Individual tumors with a greater number of gains and losses are associated with a poorer prognosis, and some changes seen in cancer are also present in atypical hyperplasia but not simple hyperplasia lesions.**

Mutational activation or aberrant expression of some oncogenes has been described but to a lesser degree than tumor suppressor genes. The *RAS* gene family is the most commonly identified oncogene aberration in human cancers and is present in 10% to 30% of endometrial cancers. This mutation appears to occur early in the neoplastic process, and the incidence is the same in endometrial hyperplasia. Correlation of *RAS* mutation to survival has produced conflicting results. About 10% to 15% of endometrial cancer has overexpression of ERBB-2

(HER2/neu) protein. **Overexpression appears to be confined to high-grade or advanced-stage tumors.**

The *FMS* oncogene encodes a tyrosine kinase, which serves as a receptor for macrophage colony-stimulating factor (m-CSF). Expression of *FMS* correlates with advanced-stage, high-grade, and deep myometrial invasion. Expression of *C-MTC,* which has been observed in normal endometrium and endometriosis, has a higher expression in secretory endometrium. Several studies suggest amplification is present in a fraction of endometrial cancers.

Mutation of TP53 tumor suppressor gene, the most common genetic abnormality currently recognized in human cancers, is present in 10% to 30% of endometrial cancers. Overexpression or mutation (or both) is associated with prognostic factors. In a study of more than 100 endometrial hyperplasia specimens, TP53 mutation was not present. PTEN mutation analysis in endometrial cancer indicates that this gene is somatically inactivated in 30% to 50% of all tumors, the most frequent molecular genetic alteration defined in endometrial cancer. There does appear to be a correlation between microsatellite instability and PTEN mutation. PTEN mutation is observed in 20% of endometrial hyperplasias, suggesting that this is an early event in the development of some type I endometrial cancers.

Inherited mutations in gene encoding DNA mismatched repair proteins, primarily MSH2 and MLM1, are responsible for HNPCC, for which endometrial cancer is the second most common cancer in women with these mutations. Cancers in these individuals are characterized by frame shift mutations in multiple microsatellite repeat sequences throughout the genome. This instability is also seen in 20% of sporadic endometrial cancers. In these sporadic cancers, acquired mutation in mismatched repair genes is rare. Endometrial cancers that exhibit microsatellite instability tend to be type I, which has a more favorable prognosis. This microsatellite instability is present in some cases of complex hyperplasia associated with endometrial cancer but is not seen in UPSC cancers.

Type I endometrial cancers are commonly described to include tumors seen in obese and nulliparous women, are well differentiated, are superficially invasive, and frequently carry a good prognosis. These tumors also share several common molecular changes and tend to have the following genetic features: diploid, low allelic imbalance, K-RAS, MLH1 methylation, and PTEN. In contrast, type II with poor prognostic pathologic features have aneuploid, high allelic imbalance, K-RAS, TP53, and HER2/neu changes.

Recently, array-based technology has allowed a more comprehensive characterization of endometrial cancers. It should be noted that these new technologies are in their infancy, although multiple papers using these techniques have been reported, many with DNA microassay. The effects of exogenous PTEN expression in endometrial carcinoma cell lines lacking PTEN function has been studied by Matsushima-Nishiu and associates. They observed increased expression in 99 genes and repression of 72 genes, many of which are known to be involved in cell proliferation, differentiation, and apoptosis, suggesting the potential power of expression profiling identifying molecular pathways affected by critical cancer-related genes. Proteomic profiling, which is the study of intact and fragmented proteins and their function, is being evaluated. Newer technologies allow the creating of proteomic fingerprints that reflect in serum what is happening in the end organs. The biochip is playing a major role in this evaluation. As little as 1 μL of serum can be evaluated, and this technology is very sensitive to low molecular weight protein regions. The results of The Cancer Genome Atlas (TCGA) Research Network has further improved our understanding of the molecular characteristics of endometrial cancer. They described four molecular subtypes, including (1) POLE (ultra-mutated) tumors, (2) microsatellite unstable tumors, (3) copy-number high tumors with mostly TP53 mutations, and (4) a remaining group without these alterations. For protocol 210, the GOG has collected material (tissue, serum, urine) on a large number of endometrial cancer patients stored in its tumor bank for in-depth research using these newer technologies, which will hopefully allow us to understand the malignant process.

Correlation of Multiple Prognostic Factors

The GOG 33 protocol identified the extent of disease spread identified at surgery correlated with outcomes. Although single factors were associated with recurrence, the combination of factors could also establish risk. For example, Morrow showed that patients with no risk factors (LVSI, cervical involvement, adnexal involvement, nodal disease) had a very low risk of recurrence, but 20% with one, 43% with two, and 63% with three or more factors recurred. In multivariate analysis, patients with disease limited to the uterus were at increased risk for recurrence if there were deep myometrial invasion, vascular space involvement, or positive washings. Fig. 5.11 is the author's attempt to compartmentalize these risk factors into risk categories for predicting prognosis and guiding decisions for adjuvant therapy. The lines between categories are somewhat porous, consistent with most clinical situations.

Data from three randomized trials evaluating the use of postoperative pelvic radiation therapy have been useful in shaping models predicting risk of recurrence after surgery. Aalders identified a subset of the 95 of 540 (18%) patients enrolled in a randomized trial of vaginal cuff brachytherapy with or without pelvic radiation therapy with grade III tumors and greater than 0% myometrial invasion to be particularly notable for risk of recurrence. Patients with these factors had a pelvic recurrence rate of 20% with vaginal brachytherapy alone compared with 5% with the combination of pelvic and vaginal radiation. It is interesting that approximately 15% of patients with these tumor characteristics failed at a distant site, regardless of radiation technique. The PORTEC trial compared pelvic radiation therapy with observation after hysterectomy without lymph node dissection in patients with endometrial cancer. In this trial of 714 patients, a subset of patients with grade III tumors (10%), age older than 60 years (72%), or greater than 50% depth of invasion (59%) was identified in which having two of three factors defined a high-risk group. The locoregional failure rate was 23% in this group who underwent surgery followed by observation compared with 5% after pelvic radiation therapy. There was no difference in distant sites of recurrence

TABLE 5.15 High-Intermediate Risk Model: Early-Stage Endometrial Cancer

Age	Risk Factor
Any age + 3 factors	LVSI
≥50 years + 2 factors	Grade II or III tumor
≥70 years + 1 factor	Outer one-third invasion

LVSI, Lymphovascular space invasion.
Modified from Keys HM, Roberts JA, Brunetto VL, et al. A phase III trial of surgery with or without adjunctive external pelvic radiation therapy in intermediate risk endometrial adenocarcinoma: a Gynecologic Oncology Group study. *Gynecol Oncol* 2004;92:744-751.

(~5% each group) or in cancer-related deaths (8% observation, 11% radiation). The GOG conducted a randomized trial (GOG 99) of observation versus pelvic radiation in a group of patients with surgically documented negative nodes and any amount of myometrial invasion. Depending on patient age and number of risk factors (LVSI, grade I or II tumor, outer one-third myometrial invasion) (Table 5.15), a high-intermediate (H-IR) risk group could be identified. The H-IR group accounted for one-third of all patients enrolled but two-thirds of recurrences. Perhaps equally important was the identification that two-thirds of the patients enrolled who did not have H-IR features had an incredibly low risk of recurrence (2%–3%), suggesting that in addition to defining high-risk groups, low-risk groups that may avoid postoperative adjuvant therapy may also be identified.

The value of risk models is that they can be applied to an individual patient incorporating all of the information (age, uterine characteristics) to provide a reasonable estimate of risk of recurrence and probability of benefit of selected adjuvant therapy. Research is under way to identify molecular markers that may augment clinical-pathologic information in establishing risk. Other cancer types (breast, prostate, bladder) have well-validated disease-specific nomograms predicting risk and benefit to adjuvant therapy. Similarly, developed and validated models for endometrial cancer are needed.

TREATMENT

Surgical Management of Endometrial Cancer

We prefer to sample the endometrium in symptomatic postmenopausal patients as the first diagnostic technique. **If histologic findings are "negative," the patient is observed. A D&C is done only if the patient continues to be symptomatic after the negative biopsy result.** After a tissue diagnosis of endometrial cancer is established, the patient should be assessed for surgical options of therapy. Most patients require routine blood counts (CBC), metabolic profile, and a metastatic evaluation with chest radiography. Routine use of computed tomography (CT) or MRI scans has not shown to be useful and should be reserved for unusual situations (high-risk tumor types, evidence of intraperitoneal disease, positive chest radiograph). Most patients with endometrial cancer are candidates for definitive surgery, including surgical staging (lymphadenectomy). Routes

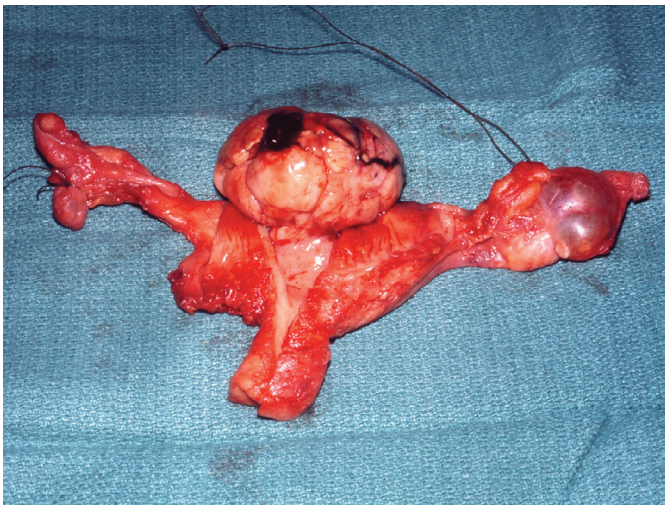

FIGURE 5.12 Total abdominal hysterectomy and bilateral salpingo-oophorectomy showing large polypoid adenocarcinoma of the endometrium with deep myometrial invasion.

of hysterectomy include vaginal, abdominal, laparoscopic (total or assisted), and robotic and have broadened the surgical options for patients.

The surgical evaluation of most patients with endometrial cancer requires a thorough inspection of the peritoneal cavity, collection of cytologic washings, and pelvic and paraaortic lymphadenectomy (PALA) in addition to hysterectomy. Cytologic evaluation of peritoneal fluids, or washings, has been a common surgical step in staging endometrial cancer because of associations with extrauterine disease and prognosis. After the peritoneal cavity is opened, an assessment of the amount of peritoneal fluid in the pelvis is made. If none is present, 100 to 125 mL of normal saline solution is injected into the pelvis. This can be done easily with a bulb syringe. The saline solution is admixed in the pelvis, withdrawn with the syringe, and sent for cytologic evaluation. We continue to recommend that peritoneal cytologic evaluation be performed in all patients undergoing surgery for endometrial cancer, although FIGO no longer uses cytology as a stage-defining characteristic. Omental biopsy may be considered in patients with gross spread to the omentum or adnexa or in cases with high-risk histologies such as serous or clear cell tumors. Approximately 10% of all patients will be found with nodal metastasis when surgically staged, but only 1% to 3% will be found to have nodal disease if nodes are evaluated only when clinically suspicious. In a large GOG study of 621 staged patients, 6% of patients with clinical stage I disease were noted to have intraperitoneal disease.

The definitive treatment for patients with endometrial cancer is hysterectomy. The hysterectomy should be extrafascial, and removal of the upper vagina does not appear to decrease vault recurrences (Fig. 5.12). Extirpation of the uterus removes the primary tumor and can provide important information that can be used to estimate risk of spread to lymph nodes or risk of recurrence. Removal of the adnexa is thought to be important given that approximately 5% of endometrial cancers have metastatic disease to the ovaries, fallopian tubes, or both.

In addition, synchronous ovarian and endometrial cancers are not infrequent, particularly in younger patients. Historically, total abdominal hysterectomy (TAH) and bilateral salpingo-oophorectomy (BSO) have been the hallmarks of therapy for endometrial cancer. There are no data to suggest that the route of hysterectomy influences recurrence-free or overall survival (OS) outcomes for patients; as such, the hysterectomy (abdominal, laparoscopic, and robotic) is the safest and facilitates rapid recovery and thus is suggested.

Several studies note the role of vaginal hysterectomy in highly selected patients with endometrial cancer for whom surgical staging cannot be performed safely (morbid obesity, significant cardiopulmonary medical comorbidities, advanced age). Because factors associated with the choice of vaginal hysterectomy (morbid obesity, medical comorbidities) are often associated with favorable uterine characteristics (low-grade lesions, smaller uterus), it is not surprising that survival rates are comparable to those of the abdominal approach. Chan and coworkers reviewed 51 medically compromised patients treated with vaginal hysterectomy and reported 3- and 5-year disease-specific survival rates of 91% and 88%, respectively. Of note, approximately 50% of women could not have the ovaries removed at the time of vaginal hysterectomy. Smith evaluated 63 patients with obesity or medical comorbidities and found that vaginal hysterectomy was safe and well tolerated in this patient population. Vaginal hysterectomy may represent a reasonable tradeoff for patients who may not tolerate other approaches or for whom surgical staging is not being considered (atypical hyperplasia, some patients with grade I cancers).

Over time, there has been a more widespread use of lymphadenectomy in the management of patients with endometrial cancer. Lymph node dissection provides the best estimate of spread of disease (vs. palpation or use of imaging studies), the lymph node status is prognostically important (as evident from the different survival rates seen with different stages of disease), and patients who are found to have positive or negative nodes receive different postoperative therapy vs. patients with unknown status of lymph nodes. In a joint statement by ACOG and the Society of Gynecologic Oncologists (SGO) in 2005, both organizations suggested that most women with endometrial cancer should undergo systematic surgical staging, including bilateral pelvic and PALA. Today, debate continues as to which patients (all, none, or some) benefit most from lymphadenectomy and the technique (pelvic, pelvic and paraaortic, level of paraaortic dissection) that should be performed.

The extent of the lymph node dissection is thought to be important. Early studies were conducted with selective lymphadenopathy or lymph node sampling (only visibly enlarged lymph nodes are selectively removed). Some data suggest that a true lymphadenectomy (complete skeletonization of vessels) should be performed. It seems intuitive that a sufficient number or distribution of nodes needs to be removed to represent an adequate sampling. When lymphadenectomy is done, the retroperitoneal spaces in the pelvis are opened in routine fashion. The vessels are outlined, and the lymph node–bearing tissue along the external iliacs from the bifurcation to the inguinal ligament is removed. The obturator fossa anterior to the obturator nerve is cleaned of lymphoid tissue. Lymph nodes along the common iliacs are also removed. The left and right paraaortic nodes are approached by retracting the small intestine into the upper abdomen and incising the peritoneum over the upper common iliac artery and lower aorta. The main vessels are outlined, and the ureter is retracted laterally. On the right, the tissue overlying the vena cava and the aorta are removed en bloc, beginning at the bifurcation of the aorta and extending caudad. On the left, the left common nodes are frequently quite lateral. Using this technique, one should have a total of 20 to 30 pelvic and paraaortic lymph nodes available for histologic evaluation. The upper limit of the dissection (unless enlarged nodes are noted above this area) is usually the inferior mesenteric artery (IMA), but some surgeons suggest that the dissection should extend to the level of the renal vessels.

The extent of nodal dissection to include paraaortic nodes is also thought to be important in endometrial cancer. There appear to be two nodal drainage basins—pelvic and paraaortic. Studies indicate that when lymph nodes are positive, approximately 50% to 60% of the time paraaortic nodes are involved. In a retrospective study from the Mayo Clinic, 137 patients at high risk for nodal involvement who underwent PALA (PAL+) were compared with those who did not undergo surgical evaluation of the paraaortic nodes (PAL–). **The 5-year survival rate was 85% for PAL+ patients compared with 77% for PAL– patients. In 51 patients with pelvic or paraaortic node metastasis, survival was 77% for PAL+ patients compared with 42% in the PAL– group. It is generally thought that the rate of isolated paraaortic lymph node metastasis is less than 5%; metastasis isolated to the paraaortic lymph node and metastasis above the IMA are seen.** Mariani and colleagues reported on a study of 482 patients with endometrial cancer at the Mayo Clinic. A total of 281 underwent lymphadenectomy to the renal vessels, and 22% had positive lymph nodes; of these, 51% had both positive pelvic and paraaortic nodes, 33% had positive pelvic nodes only, and 16% had isolated involvement of the paraaortic nodes. Of note, 46% of those with isolated paraaortic lymph nodes were only positive above the IMA, and 77% had at least one metastatic node located above the level of the IMA. However, the authors do report that there were no positive lymph nodes detected in those with grade I or II tumors with a tumor size of smaller than 2 cm with less than 50% invasion, raising the question of the benefit of lymphadenectomy in the truly low-risk group. Abu-Rustum and colleagues demonstrated a 1% risk of isolated paraaortic lymph node metastasis in both the low- and high-grade tumors. Based on these and other reports, PALA does have an important role in comprehensive staging. For high-risk patients, the data suggest even a therapeutic role for paraaortic lymph node dissection. However, prospective trials are needed to confirm this concept for patients with early-stage endometrial cancer with high-risk features.

Since 1988 when FIGO changed endometrial staging from clinical to surgical, there have been questions raised as to whether the lymphadenectomy is only diagnostic, which is an important determinate, or whether it also could be therapeutic. **Kilgore and associates, in evaluating 649 patients, noted that those who underwent multiple-site lymph node removal had**

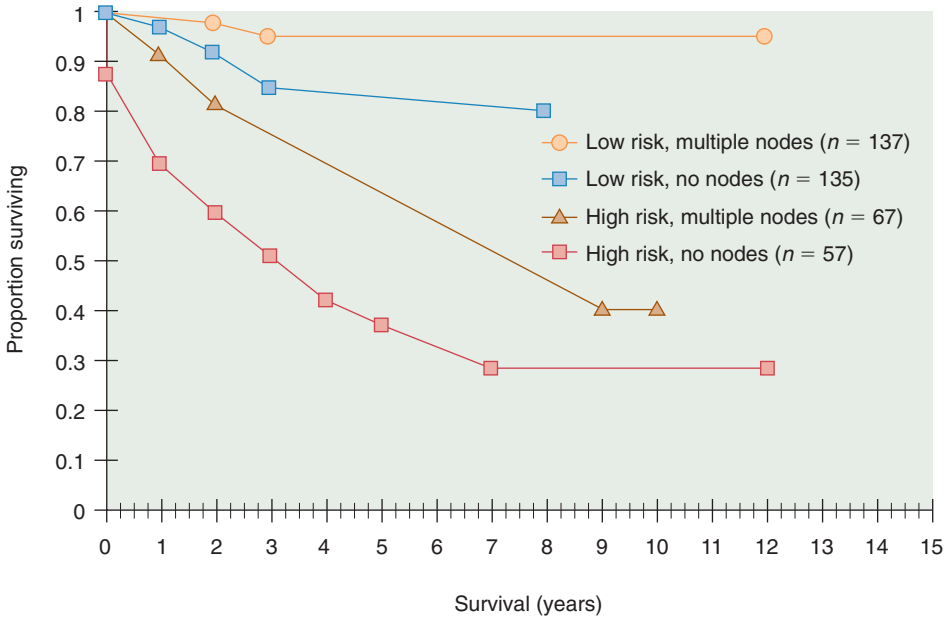

FIGURE 5.13 Survival by nodes sampled and risk groups: multiple-site pelvic node sampling versus no nodes. Low-risk group, $P = 0.026$; high-risk group, $P = 0.0006$. (From Kilgore LC, Partridge EE, Alvarez RD, et al. Adenocarcinoma of the endometrium: survival comparisons of patients with and without pelvic node sampling. *Gynecol Oncol* 1995;56:29.)

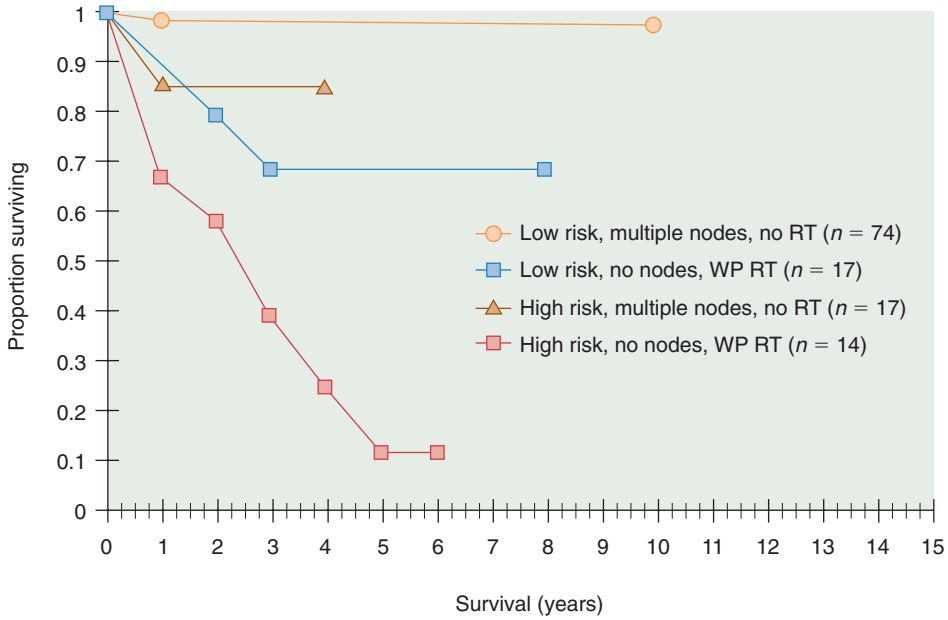

FIGURE 5.14 Survival comparisons of multiple-site pelvic node sampling with whole-pelvic (WP) radiation therapy (RT): multiple nodes without RT versus no nodes plus WP RT. Low-risk group, $P = 0.003$; high-risk group, $P = 0.041$. (From Kilgore LC, Partridge EE, Alvarez RD, et al. Adenocarcinoma of the endometrium: survival comparisons of patients with and without pelvic node sampling. *Gynecol Oncol* 1995;56:29.)

significantly better survival rates than those patients who had no lymph nodes removed (Figs. 5.13 and 5.14). Lymph node removal resulted in a better survival rate than for those without lymph node removal plus postoperative radiation. Cragun and colleagues reported that patients with grade III or poorly differentiated cancers with more than 11 lymph nodes removed had an improved survival (hazard ratio [HR], 0.25) and PFS (HR, 0.26) compared with those with fewer than 11 lymph nodes removed. However, the number of lymph nodes removed was not predictive of survival outcome in those with grade I and II tumors. This association between lymphadenectomy and improved survival remained when controlling for adjuvant radiation treatment, emphasizing the impact of extensive lymph node dissection. A retrospective review by

Chan and colleagues of more than 12,000 patients showed an increased 5-year survival rate for the intermediate- and high-risk group that underwent an extensive lymph node dissection. However, there was no benefit of nodal dissection seen in the low-risk group.

Removal of nodes involved by tumor has been supported as a therapeutic option. In a study reported by Havrilesky et al., 91 patients were identified with stage IIIc disease. There were 39 with microscopic involvement of the lymph nodes and 52 with grossly enlarged nodes. After surgery, 92% received some type of adjuvant therapy with 85% receiving radiation therapy. **The survival rate (5 years) was 58% in the 39 with microscopic lymph nodes, 48% in 41 patients with grossly positive lymph nodes completely resected, and only 22% in the 11 with unresected lymph nodes. The authors believed that these data suggested a therapeutic benefit for lymphadenectomy. Similarly, in a small study of 41 patients, Bristow and coworkers noted disease-free survival was improved if patients with bulky adenopathy underwent complete resection of involved nodes compared with patients who had gross residual disease in lymph nodes remaining after surgery (37.5 vs. 8.8 months; $P = 0.006$).** Onda and colleagues carried out thorough pelvic and paraaortic lymphadenectomies on 173 patients with stage I to III endometrial cancer. The average numbers of lymph nodes removed were 38 pelvic and 29 paraaortic. There were 30 patients (17%) with positive nodes: 10 to pelvis only, two paraaortic only, and 18 with metastasis to both pelvic and paraaortic nodes. Selected patients received radiation therapy with extended fields, combination chemotherapy, or both. In the 10 patients with only pelvic metastasis, the 5-year survival rate was 100%; it was 75% in those with paraaortic involvement. **The authors suggest that, although postoperative treatment may contribute to these excellent results, systematic pelvic and PALA was a contributing factor.**

One of the important effects of lymph node dissection is that it identifies that most patients with negative lymph nodes are at very low risk for recurrence. As such, lymph node dissection has allowed for modifications of postoperative therapy away from pelvic radiation therapy. In one study, Mohan and associates evaluated 159 stage I patients who had full pelvic lymphadenectomy (PLA) and received vaginal brachytherapy rather than the more traditional pelvic radiation. In general, vaginal brachytherapy is a quicker therapy (1–3 days vs. 5–6 weeks for pelvic radiation) and is associated with fewer side effects. In the Mohan study, the 15-year OS was 92%, and the recurrence rate was 4%, all at distant sites. **Podratz and associates reviewed four studies that used thorough lymphadenectomies in moderate- and high-risk patients who did not receive postoperative radiation therapy. There were 20 recurrences (7%) in 305 patients; only five recurrences were local or regional, with four being in the vagina. Those four did not receive postoperative brachytherapy but were salvaged with subsequent radiation.**

The disadvantages of a lymph node dissection include that the performance of lymph node dissection requires a specially trained surgeon, has the potential to increase complications (postoperative ileus, lymphedema), and has not been prospectively validated to improve outcomes. Two recent phase III trials compared the use of lymph node dissection or not in patients with endometrial cancer. In a large multicentric study (ASTEC study), 1408 patients were randomly assigned to abdominal hysterectomy or bilateral salpingo-oophorectomy with or without PLA. A median follow-up period of 37 months was obtained. There was no difference in survival between the two groups. This was an intent-to-treat study and has been criticized as having a relatively large noncompliance in regard to lymphadenectomy and subsequent therapy. In the lymphadenectomy arm, almost a half had no nodes or a small number (≤9) removed. This study was further complicated by the fact that many of these patients were secondarily randomly assigned into a postoperative radiation study, not taking into consideration surgical findings. PALA was not the standard management, although some patients had these nodes removed.

The second study was published by Pierluigi Benedetti Panici. The Italian study randomly assigned 514 stage I patients to systematic PLA or no lymphadenectomy. Although 13% of patients in the lymphadenectomy arm had known metastasis versus 3% in the no-lymphadenectomy arm, there was no difference in recurrence or OS. The protocol required a minimum of 20 lymph nodes to be removed; however, the lymphadenectomy was limited to the pelvis, although PALA could be removed at the discretion of the surgeon. Postoperative radiation was left to the discretion of the treating physician. Adjuvant therapy was similar in the two groups. Whether or not this had an effect on survival is unknown because this was not standardized.

A study from Japan (SEPAL study) was published in early 2010. This was a study of PLA ($n = 325$ patients) versus PALA ($n = 346$ patients) in endometrial cancer. It was not a randomized study; however, one hospital did only pelvic nodes and the other pelvic and paraaortic. Lymphadenectomy was certainly adequate for using the number of lymph nodes removed as a parameter. The survival rate was significantly better ($P > 0.001$) in women receiving the PLA and PALA. This was seen in intermediate- and high-risk patients but not in low-risk patients. In a multivariant analysis, the PLA plus PALA reduced the risk of death compared with PLA only. In the high-risk group, patients receiving chemotherapy plus PLA plus PALA had a better survival than patients receiving chemotherapy plus PLA only. PLA plus PALA and adjuvant chemotherapy were independently associated with improved survival.

The Cochrane Database subsequently concluded that there was no overall statistical difference between PFS and OS in patients who had a lymphadenectomy versus those who did not but did report more morbidity for those patients who had a lymphadenectomy. Cochrane only considered the ASTEC and the Italian study in reaching this conclusion. The extent of the lymphadenectomy appears to be critical in evaluating studies in determining an appropriate surgical procedure for patients with endometrial cancer. Multiple studies confirm that both pelvic and paraaortic lymph nodes are at risk for metastasis.

Patients with stage II carcinoma of the endometrium, because of extension of disease into the endocervix, will have a greater propensity for lymph node metastasis. For example, in the GOG 33 protocol, 16% of patients with cervical involvement had positive pelvic lymph nodes versus 8% with a fundal

location of tumor. Even in patients with occult cervical involvement, 19% of patients had lymph node metastases. In addition, parametrial and vaginal involvement are thought to be more common when the cervix is involved. As such, surgery in the form of radical hysterectomy and lymphadenectomy has been advocated when there is gross cervical involvement with tumor. Because many cases of cervical involvement are occult and only recognized after surgery, simple hysterectomy with lymphadenectomy appears to be adequate surgery in most cases. Postoperative radiation therapy can be planned, depending on surgical-pathologic findings, including use of pelvic radiation or vaginal cuff brachytherapy, both, or neither.

In 1993, Childers and others pioneered laparoscopic lymph node removal in conjunction with vaginal hysterectomy and bilateral salpingo-oophorectomy. In the hands of those who acquired those surgical skills, the outcomes appeared comparable, and some advantages were gained, such as short hospitalization and rapid postoperative recovery. A large GOG study comparing the laparoscopic approach versus laparotomy has been completed. Walker and colleagues published the results of GOGLAP2, which randomly assigned patients between laparoscopic versus open laparotomy surgical staging. Laparoscopy was initiated and completed without conversion in 74%. Conversion from laparoscopy to laparotomy was secondary to poor visibility in 15%, metastatic cancer in 4%, and bleeding in 3%. Patients randomly assigned to undergo laparoscopy had significantly fewer moderate to severe postoperative (14% vs. 21%) complications and similar rates of intraoperative complications. Length of hospital stay was significantly shorter for those randomized to undergo laparoscopy (median 3 days vs. 4 days), but operative time was significantly longer (median, 204 minutes vs. 130 minutes). Pelvic and paraaortic nodes were removed in 92% of patients undergoing laparoscopy and 96% of patients undergoing laparotomy, and cytology was performed in 96% vs. 98%. Neither treatment arm demonstrated an improved ability to detect metastatic disease. Quality-of-life evaluation found a better body image and return to normal activities for the patients undergoing laparoscopy. Laparoscopic surgical staging is feasible and safe for patients with uterine cancer and results in fewer complications and shorter hospital stays. A reduction in paraaortic node evaluation is a potential risk of laparoscopic staging. Recurrence rates were lower than anticipated; the estimated 3-year recurrence rate was 11% with laparoscopy and 10% with laparotomy, and the estimated 5-year OS rate was almost identical in both arms (90%). Today, advancements of laparoscopic surgery, including use of a robotic surgical platform, have been suggested as the next step. Robotic surgery offers three-dimensional graphics, improved ergonomics, and greater dexterity of surgical instruments. Robotic surgery may extend the applications of laparoscopy, especially in obese patients or patients in whom a vaginal component is more difficult. However, no randomized trials have confirmed equivalence or superiority of robotic assistance.

Surgical staging has now been accepted as standard therapy in patients with endometrial cancer unless clinical conditions suggest otherwise. Of the 6260 patients with endometrial cancer reported to the last Annual Report of FIGO, 94% were surgically staged. It is appreciated that institutions reporting to the Annual Report are academic ones and that most patients with endometrial cancers, at least in the United States, have their primary surgery at academic hospitals. Because endometrial cancer staging has been determined by surgical staging, it has been suggested by some that these are patients who are at low risk (ie, grade I) for lymph node metastasis and that lymphadenectomy is not worthwhile. Increasing data suggest that even in grade I disease, as noted on endometrial biopsy, a significant number of patients have full surgical staging findings that would have an impact on further therapy. **Ben-Shachar and colleagues, in evaluating 181 grade I endometrial cancers, found that 19% had grade change on hysterectomy specimen, 11% had extrauterine disease, 4% had lymph node metastasis, and 26% on final evaluation had high-risk intrauterine factors. Of note, the authors believed because of full surgical staging that 12% needed and received adjuvant therapy, and 17% who may have received postoperative treatment did not based on full surgical findings.** Geisler and associates found in 349 patients that of those with grade I lesions, 16% had positive nodes and 3% had positive paraaortic nodes only. Of all positive nodes, **31% occurred in grade I lesions. As a result of these and other studies, many believe that all patients with endometrial cancer should have the benefit of full surgical staging, which includes peritoneal cytology, bilateral pelvic lymphadenectomy and PALA, and total abdominal hysterectomy and bilateral salpingo-oophorectomy.** Obviously, complete evaluation of the entire peritoneal cavity and its contents should be performed, and any suspicious areas should be pathologically evaluated.

Straight and associates reported on a large number of patients who were surgically staged. Low-risk factors, stage IaG1 and 2, were present in 103 patients. None received postoperative therapy, and none had recurred. **Intermediate risk was defined as stage IaG3 and all stage I and Ic cancers. There were 440 patients of whom 93% received no further therapy. Twenty-eight patients received postoperative therapy, and one (4%) had a recurrence compared with 5% of those not radiated.** The latter patients received therapy at the time of recurrence, and 62% were successful. **The Annual Report (2003) noted 5-year survival rates with surgery only of 93%, 91%, 73%, 79%, and 73%, respectively, for stages Ia, Ib, Ic, and IIa, and IIb. This compares with 89%, 91%, 83%, 83%, and 75%, respectively, if surgery plus postoperative radiation is used.** There is a suggestion that in stage Ic, the survival rate is somewhat better when postoperative radiation is added than surgery alone. What factors went into decision making regarding postoperative therapy is unknown. In a multi-institutional study, 220 surgically staged Ic patients were identified. High-risk histotypes were excluded. Adjuvant radiation was used in 99 (45%), 56 brachytherapy only, and 19 whole-pelvis radiation, and 24 received both. **OS rates between those treated with surgery and surgery plus radiation was similar (92% vs. 90%).**

Radiation Therapy

Radiation therapy has been the mainstay of adjuvant therapy for endometrial cancer. Historically, nearly all patients received

some form of preoperative or postoperative radiation therapy given the perception of risk for recurrence was high. Whereas GOG 33 defined relationships between depth of invasion and tumor grade and extrauterine spread after surgical staging, it also showed that most patients were not at risk for extrauterine disease spread. As such, the routine use of pelvic radiation therapy became increasing questioned. To date, four large prospective randomized studies have compared external pelvic radiation with observation or vaginal brachytherapy in women with endometrial cancer (Table 5.16). Aalders and colleagues compared vaginal cuff brachytherapy with or without pelvic radiation in 540 patients with early-stage endometrial cancer. Patients did not undergo lymph node dissection. The addition of pelvic radiation therapy reduced local failures (2% vs. 7%), but there was no difference in 5-year survival rate between the groups (89% pelvic, 91% brachytherapy). Onsrud et al. updated the long-term follow-up for these patients. After a median 20.5 years of follow-up, no statistically significant difference was revealed in OS rate between treatment groups. However, women younger than age 60 years had significantly higher mortality rates after external-beam radiotherapy (EBRT) (HR, 1.36; 95% CI, 1.06–1.76) than the control group. The risk of secondary cancer increased after EBRT, especially in women younger than age 60 years (HR, 2.02; 95% CI, 1.30–3.15). The authors concluded that there was no survival benefit of external pelvic radiation in early-stage endometrial carcinoma. In women younger than age 60 years, pelvic radiation decreased survival and increased the risk of secondary cancer. Thus, adjuvant EBRT should be used with caution, especially in women with long life expectancies.

In the Dutch PORTEC trial, Creutzberg et al. enrolled 714 patients with grade I lesions with greater than 50% myometrial invasion, grade II lesions with any amount of invasion, or grade III with less than 50% invasion. Patients were randomly assigned postoperatively to receive either external radiation or observation. None of the patients were surgically staged, and all histologies were eligible. In the 654 eligible for follow-up, **local and regional recurrences were less frequent in the radiation therapy group (4% vs. 14%) than in the observational group, but the 5-year survival rates were similar, 81% versus 85%, respectively.** Long-term follow-up is also available for this trial. As published by Creutzberg et al., after 15 years, there remained no survival advantage and a trend for long-term risk of second cancers. EBRT should be avoided in patients with low- and intermediate-risk EC.

The GOG performed a phase III trial, #99, of surgery with or without adjunctive external pelvic radiation in intermediate-risk endometrial adenocarcinomas. These included all women with any degree of myometrial invasion, any grade, and no evidence of lymph node metastasis (stage Ib, IC, IIA occult, and IIB occult). All patients were required to have surgical staging with histologic evaluation of the lymph nodes. A total of 202 received no radiation (NAT), and 190 received pelvic radiation. The median follow-up period was 69 months. There were 15% total recurrences in the NAT group compared with 6% to 8% in the radiation group ($P = 0.007$). Local recurrences were 9% versus 2%, respectively. The OS at 48 months was 86% for NAT and 92% for radiation, with intercurrent diseases accounting for half or more of the deaths in both groups. **Deaths from disease were 8% in both the NAT versus radiation group.** Grade III and IV toxicity by treatment was 5% versus 14% in the NAT and radiation, groups, respectively. In 12 of the 13 women who had isolated vaginal recurrences, the NAT arm were treated with radiation, and five have died of disease. An high intermediate (H-IR) subgroup appeared to derive the best benefit from pelvic radiation, with 27% of H-IR patients followed with observation compared to 13% after pelvic radiation, recurring. All other eligible patients were considered low–intermediate risk and had recurrence rates less than 1% to 3% regardless of the use of radiation therapy. The most recent data from a pooled trial of the MRC ASTEC and NCIC CTG EN.5 randomized trials also showed no survival advantage for adjuvant EBRT in the treatment of endometrial cancer (5-year survival rate ~84% both groups). In this study including 906 patients randomly assigned to pelvic radiation or observation, 30% of patients underwent lymphadenectomy, and 50% received vaginal brachytherapy. Pelvic radiation reduced local failures (6% with observation vs. 3% after pelvic radiation). In a subsequent Cochrane review on the use of adjuvant radiation therapy for stage I endometrial cancer, the authors concluded that there is no survival advantage with routine use of pelvic radiation therapy and that benefits must be balanced against the toxicity and morbidity of therapy. In addition, risk factors within stage I groups (grade III, outer 50% invasion) should be considered in an effort to better select populations who may get the best benefit.

Essentially all studies evaluating pelvic radiation therapy show improved local control rates compared to observation. The local control, however, is largely a result of reduction in

TABLE 5.17 Survival Rate in Stage I Carcinoma of the Endometrium With Regard to Grade and Treatment

TABLE 5.18 Recurrences in Stage I Carcinoma of the Endometrium With Regard to Depth of Invasion and Treatment

Recurrence	Surgery and Radium	Surgery and External Radiation
Endometrium only	6/88 (7%)	0/4 (0%)
Inner and mid thirds	3/68 (4%)	9/29 (31%)
Outer third	3/9 (33%)	11/24 (46%)

Modified from DiSaia PJ, Creasman WT, Boronow RC, Blessing JA. Risk factors in recurrent patterns in stage I endometrial carcinoma *Am J Obstet Gynecol* 1985;151:1009.

vaginal cuff recurrences. A considerable amount of data has been collected to evaluate vaginal recurrence and survival rate with surgery alone or combined therapy when mainly preoperative application of brachytherapy and surgery were used. Data have also been evaluated concerning the grade of the tumor (Table 5.17) and, in some instances, the depth of myometrial involvement (Table 5.18). In patients who had postoperative irradiation, there appeared to be a lower incidence of vaginal vault recurrences, although there does not appear to be much difference in the grade I and grade II lesions. Vaginal vault recurrence did not appear to affect survival. Recently, results of a randomized prospective trial comparing adjuvant EBRT versus vaginal brachytherapy in 427 patients with intermediate-risk early-stage endometrial cancer have been reported (PORTEC-2). No differences in recurrence rate (vaginal failure 2% with pelvic radiation, 0.9% with vaginal brachytherapy) or OS (3-year survival rate ~90% both groups) were observed between the two treatment arms, suggesting that patients with intermediate-risk early-stage endometrial cancer can be treated with adjuvant vaginal brachytherapy alone. Although these findings have led many clinicians in the United States to move away from the routine use of EBRT in early-stage endometrial cancer, it is important to note that in the patients who did not undergo a lymph node dissection, pelvic failure rates were higher in vaginal brachytherapy group (3.5% vs. 0.7%), and the study excluded higher risk patients such as those with grade III or deeper invasion tumors. The most recently reported study comparing pelvic radiation followed by vaginal cuff brachytherapy to vaginal cuff brachytherapy alone for "medium-risk" endometrial cancer by Sorbe et al. showed results similar to PORTEC-2, demonstrating that pelvic radiation reduced locoregional relapse rates (1% vs. 5%, $P = 0.013$) with no difference in OS. Sorbe et al. also reported a randomized trial of vaginal brachytherapy versus no further treatment in patients with low-risk endometrial cancer (grade I or II endometrioid cancer with <50% invasion). There was no significant reduction in vaginal recurrence in the group receiving brachytherapy (3% vs. 1%).

Chemotherapy

The role of chemotherapy in endometrial cancer is evolving. Traditionally reserved for patients with recurrent or disseminated cancer, chemotherapy has become increasingly used in the first-line management of patients with advanced-stage and high-risk early-stage disease. Historically, radiation therapy has been the adjuvant of choice for patients at risk of recurrence. Although the overall prognosis of patients in adjuvant radiation trials has been favorable, 3% to 23% of patients have a recurrence at distant sites, demonstrating the need for effective systemic therapy.

Drug Development

Progestins have been an important systemic therapy given response rates in up to one-third of patients and low toxicity. The identification of active cytotoxic chemotherapy regimens has led to a reevaluation of chemotherapy. Phase II studies have identified several single agents with activity in advanced or recurrent endometrial cancer. In a report of the GOG experience, Thigpen and colleagues noted that 37% with advanced or recurrent cancer experienced an objective response with use of doxorubicin alone. Unfortunately, response lasted only 7 months. The Eastern Cooperative Oncology Group achieved only a 19% response rate in its doxorubicin trial; however, a dosage lower than the GOG dosage was used. When one evaluates the doxorubicin data, one notes that only about 10% of patients who received this drug had a complete response rate. Patients designated as giving a partial response had survival rates no greater than those of patients who had no response to this cytotoxic agent. Likewise, phase II studies have identified platinum agents (cisplatin, carboplatin) and taxanes (paclitaxel) to have significant activity.

Combining two or more active agents has been an important strategy. Phase III studies have shown better response rates when the agents were combined compared with used alone. Several chemotherapy combinations have been used in recurrent or advanced endometrial cancer. The GOG, in a randomized trial, #107, compared doxorubicin with or without cisplatin. The combination produced tumor response in 66% versus 35% for the single agent, with median progression-free intervals of 6.2 and 3.9 months, respectively. **The GOG reported a 45% response rate (22% complete response) for the combination of doxorubicin and cisplatin in advanced or recurrent endometrial cancer compared to 17% response for doxorubicin alone.** The European Organization for Research and Treatment of Cancer Gynecological Cancer Cooperative Group (EORTC-GCCG) compared doxorubicin alone with doxorubicin and

cisplatin. Response rate was 17% and 57%, respectively. The GOG (GOG 163) has compared doxorubicin and cisplatin with doxorubicin and paclitaxel (24-hour infusion) with filgrastim in advanced or recurrent endometrial cancer. A total of 317 patients randomly assigned to the two regimens. Response rates were similar (40% vs. 43%). PFS was median 7.2 versus 6 months, and OS was median 12.6 versus 13.6 months. Toxicities were also similar. **A phase III study by the GOG (177) compared doxorubicin plus cisplatin with or without paclitaxel plus filgrastim (TAP) in advanced endometrial cancer. There were 273 women registered, and objective responses were 57% versus 34% (P <0.01); PFS (median, 8.3 vs. 5.3 months, P <0.01) and OS (median, 15.3 vs. 12.3 months, P = 0.037) were improved with the triple combination TAP regimen.** This study marked for the first time a statistically significant improvement in response rate, PFS, and survival with a combination regimen in endometrial cancer. However, the three-drug regimen required a 2-day treatment and the use of growth factors on day 3 and was associated with moderate peripheral neuropathy. The GOG has presented a randomized trial, #209, comparing the three-drug TAP regimen with carboplatin plus paclitaxel (TC). PFS (median TC vs. TAP, 14 vs. 14 months; HR, 1.03) and OS (median TC vs. TAP, 32 vs. 38 months; HR, 1.01) results for TC were not inferior to TAP. Health-related quality of life differences, when they were present, favored TC over TAP by a small margin.

Advanced Disease

Drug development trials are largely designed to assess the efficacy of new drugs or combinations in patients with incurable disease (recurrent, disseminated). The concept of using chemotherapy in patients with advanced but potentially curable disease was once considered controversial. Treatment of patients with stage III or IV disease depends largely on the extent of surgical resection. Patients with stage III or IV disease and resection to less than 1 to 2 cm residual may be treated with curative intent with chemotherapy, radiation, or a combination of the two. The GOG studied patients (GOG 122) with stage III or IV endometrial cancer with 2 cm or less residual disease (distant metastases were excluded). After surgery, patients were randomly assigned to receive doxorubicin and cisplatin every 3 weeks for eight courses or whole-abdominal radiation with 3000 cGy to the whole abdomen. A boost to the pelvic and paraaortic lymph node region (1500 cGy) could be given for positive nodes. As reported by Randall et al., 2 years after therapy, the OS rate was improved by 11%, and the cancer-free survival rate was improved by 13% with chemotherapy compared with those treated with radiation therapy. Side effects were more common in the chemotherapy-treated patients.

In an effort to build on improvements noted with the first-line chemotherapy into the management of patients with advanced endometrial cancer, the GOG performed a randomized trial (GOG 184) comparing volume-directed radiation (pelvic radiation with or without extended field to cover paraaortic lymph nodes) followed by six cycles of doxorubicin–cisplatin with or without paclitaxel chemotherapy. The results showed no improvement in PFS with the addition of paclitaxel to pelvic radiation plus cisplatin and doxorubicin except in patients with gross residual disease. Although the results of GOG 184 may seem to conflict with the results of GOG 177, several important observations can be made. First, the addition of pelvic radiation therapy may supplant the benefit of adding paclitaxel the two-drug regimen seen in GOG 177. Second, this trial demonstrates the feasibility of combining multiagent cytotoxic chemotherapy with adjuvant radiation. The role of radiation therapy in advanced disease is addressed in GOG0258, which randomized carboplatin and paclitaxel with or without radiation therapy. This study has finished the accrual phase, and results are awaited.

Factors associated with response to chemotherapy have been studied. Behbakht and colleagues evaluated prognostic factors in 137 patients with advanced disease (stage III and stage IV). Multivariate analysis noted age, parametrial involvement, and abdominal metastasis as significant prognostic indicators. An increased frequency of advanced stage was also noted with UPSC histology. Unfortunately, multiple therapies were used, and conclusions concerning treatment cannot be made. Kadar and associates evaluated 58 patients with surgical stage III and stage IV disease. Extrapelvic peritoneal metastasis and positive peritoneal cytologic findings affected survival. If either of these factors was present, the 2-year survival rate was only 25% compared with 83% if they were not present. Postoperative therapy varied, but it did not appear to have any effect on survival.

Adjuvant Therapy: High-Risk Disease

Given the results of GOG 122, new considerations for chemotherapy in a variety of settings have been considered. Today, the role of adjuvant chemotherapy in intermediate- and high-risk early-stage endometrial cancers is increasingly considered. Several trials have assessed the role of chemotherapy in high-risk endometrial cancer. The Japanese GOG group performed a randomized trial of chemotherapy (at least three cycles of cyclophosphamide, doxorubicin, cisplatin [CAP regimen]) versus pelvic radiation in patients with endometrial cancer. Most patients had stage Ic or II disease (75%), but patients with IIIa and IIIc disease were included. For all patients, there was no difference in PFS or OS between the regimens. The study did identify a group of patients with higher risk features (Ic or grade III, stage II or III with depth of invasion >50%) for whom PFS and OS were significantly improved in the chemotherapy arm. Maggi and colleagues performed a similar study comparing five cycles of CAP chemotherapy with pelvic radiation in 340 patients with endometrial cancer. In this trial, 62% of patients had stage IIIa to IIIc disease. The 5-year PFS and OS were not statistically different between the groups. Neither of these studies used paclitaxel, an agent that in phase II and III studies appears to offer improved efficacy.

The role of adjunctive chemotherapy in addition to surgery and radiation therapy has been addressed by the GOG in patients with high-risk stage I and occult stage II endometrial cancers. Morrow et al. reported on 181 patients treated with TAH and BSO, peritoneal cytologic evaluation, and selective pelvic and PALA followed by external irradiation (pelvic with or without extended field) and were then randomly assigned

to receive doxorubicin 60 mg/m^2 every 3 weeks for eight doses. Patients participating in the doxorubicin arm of the protocol had a higher incidence of metastases to pelvic nodes (20% vs. 10%) than did those in the no doxorubicin arm; otherwise, the risk factors were equal between the two groups. There were recurrences in 22 of 92 (23%) in the doxorubicin arm versus recurrences in 23 of 89 (26%) in the nondoxorubicin arm. Of patients with recurrences, those who received doxorubicin had a greater chance of metastasis to the abdomen than did those not receiving it (40% vs. 17%). However, distant metastases occurred more frequently without the use of doxorubicin than with it (56% vs. 18%). The small sample size (and reduced power), the heterogeneous population, and the use of single-agent doxorubicin (as opposed to combination therapy) are weaknesses of the study. The Radiation Oncology Group (RTOG) and the EORTC have both published data on patients with high-risk early-stage endometrial cancers treated with adjuvant radiation therapy with or without adjuvant platinum-based chemotherapy. Both trials suggest that adjuvant radiation combined with adjuvant chemotherapy in high-risk early-stage endometrial cancers is feasible and may result in better OS.

Based on the experience with current studies, two important trials assessing the role of chemotherapy have been developed. The PORTEC-3 trial is an ongoing randomized phase III trial comparing concurrent chemoradiation followed by adjuvant paclitaxel–carboplatin chemotherapy versus pelvic radiation alone. The GOG completed a randomized phase III trial (GOG 249) comparing vaginal brachytherapy plus adjuvant carboplatin and paclitaxel versus pelvic radiation. Neither the PORTEC-3 trial nor GOG 249 required lymph node dissection as part of the inclusion criteria. However, full surgical staging was encouraged in the GOG trial. The results of these trials will elucidate the role of adjuvant chemotherapy combined with adjuvant radiation in high-risk early-stage endometrial cancer.

Hormones

Progestins have been used for more than 30 years, and the objective responsiveness of recurrent carcinoma of the endometrium to these hormones has been substantiated (Fig. 5.15). Historically, approximately one-third of all patients with recurrent carcinoma of the endometrium are said to respond to the hormone, although patients with well-differentiated tumors have a response rate much higher than that of patients with moderately or poorly differentiated lesions. The GOG described 420 patients with advanced or recurrent endometrial carcinoma treated with medroxyprogesterone acetate (MPA) 50 mg three times a day. Of the 219 patients with objective measurable disease, there were only 17 complete responders (8%) and 13 partial responders (6%). More than half of the patients remained stable, and one-third progressed. The median survival time was 10.5 months. Grade I lesions responded more frequently than poorly differentiated carcinomas did. The GOG evaluated, in a randomized phase III trial (#81), MPA at 1000 mg/day compared with 200 mg/day. In almost 300 patients, there was no difference in response rate or survival between the two groups. Lentz reported another GOG trial, #121, of high-dose megestrol acetate (800 mg/day) in patients with advanced or recurrent endometrial carcinoma. Of 58 patients, 13 (24%) responded; six (11%) had a partial response. Four of the responses lasted more than 18 months and were primarily between the grade I and grade II lesions.

More recently, considerable interest has been shown in the presence of specific estrogen and progesterone receptors in neoplastic human uterine tissue. These receptors are definitely present and vary from tumor to tumor. It has been shown that there is a greater number of both estrogen and progesterone receptors in well-differentiated lesions than in poorly differentiated ones (Table 5.19). In a small group of patients, it was noted that about one-third of those with recurrent cancer had a positive receptor site analysis to both estrogen and progesterone. The receptor data may therefore correlate with clinical findings of responsiveness to progesterones in patients with recurrent cancer. Preliminary data suggest an excellent correlation (Table 5.20). Obviously, considerable additional data are needed to verify these findings; however, the prospects are excellent. If

TABLE 5.20 Response to Progestin Therapy in Regard to Receptor Content

Receptor Content	Progestin Response (%)
Positive	44/55 (80)
Negative	4/76 (5)

Based on papers by Ehrlich et al., Benraad et al., Creasman et al., Kauppila, Pollow et al., and Quinn et al.

direct correlation can be substantiated, the receptor site analysis can guide the type of progestin therapy or chemotherapy given for recurrent endometrial cancer. If receptor site analysis is positive for both estrogen and progesterone, a patient's chances of responding to progestins are extremely good, even if she has a poorly differentiated lesion. However, if the receptor site analysis is negative, the data suggest that the patient's response to progestins may be extremely low, making it more advisable to go directly to cytotoxic agents without wasting time on progestin therapy. Kauppila noted from five studies in the literature that 89% of progesterone receptor–positive tumors were hormonally responsive compared with only 17% of progesterone receptor–negative tumors. The GOG noted that 4 of 10 (40%) estrogen receptor–positive, progesterone receptor–positive tumors responded to progestins compared with 5 of 41 (12%) progesterone receptor–negative tumors.

Progestin therapy may be administered in several different ways; MPA (Depo-Provera), 400 mg intramuscularly at weekly intervals, oral MPA (Provera) in the range of 150 mg/day, and megestrol acetate (Megace) 160 mg/day are recommended progestins. Progestins are continued indefinitely if an objective response is obtained. If progression of disease is noted, progestins should be discontinued, and chemotherapy should be considered.

Progestins have been evaluated as adjunctive therapy in the hope of preventing recurrences. Lewis and coworkers, in a randomized study, treated endometrial cancer patients postoperatively with MPA or placebo. The 4-year survival rate was similar in the two groups. Kauppila, in describing more than 1100 patients who received adjunctive progestin therapy for 2 years after surgery and radiation therapy, found that even in stage I low-grade tumors, recurrences did appear; it was their belief that prophylactic progestins were not of benefit to these patients. In a prospective study of 363 patients with stage I disease who received adjuvant MPA for 12 months, DePalo and colleagues compared survival with that of 383 patients with stage I disease who did not receive MPA postoperatively; there was no difference in survival between the two groups. In a British study in which 429 patients with stage I or stage II cancers were randomized between postoperative MPA and observation, no difference in survival was seen after 5 years. A Cochrane Database review concluded that current evidence did not support the use of adjuvant progestin therapy in the primary treatment of endometrial cancer.

With only modest response to progestins, other hormonal agents have been evaluated. Tamoxifen has been shown to bind estrogen receptors and thereby block access of the estrogen into the nucleus. It has also been suggested that tamoxifen can increase the number of progesterone receptors in vivo. Combined results of several small studies noted a response rate of 22% (complete response rate of 8%) in 257 patients. These studies suggest that grade I lesions are more responsive than other grades of tumors. Progestins plus tamoxifen have been evaluated in combination in recurrent carcinoma of the endometrium. Tamoxifen, 40 mg/day, with intermittent Provera, 200 mg/day on alternate weeks, had a 33% response rate with a median PFS of 3 months and median survival of 13 months (GOG 0119). A phase II trial of megestrol acetate, 160 mg orally for 3 weeks, alternating with tamoxifen, 40 mg/day for 3 weeks, until disease progression showed an overall response rate of 27% with a median PFS of 2.7 months and median OS of 14 months (GOG 0153). The response rate was 38% in patients with histologic grade I tumors, 24% in those with grade II, and 22% among patients with grade III. Although tamoxifen is theoretically attractive (it causes an increase in progesterone receptors for better progestin effect), studies of small groups of patients have not produced favorable results. The use of tamoxifen is interesting in view of the reports of endometrial cancer in patients taking tamoxifen. This is in contrast to in vitro data suggesting that tamoxifen does not stimulate and in fact may inhibit established endometrial cell line growth.

Gonadotropin-releasing hormone (GnRH) analogues have been evaluated in the treatment of endometrial cancer in a small number of patients. These analogues suppress gonadotropins with a reduction in estrogen but not cortisol levels. Gallagher and associates treated 17 patients with recurrent endometrial cancer who had received previous progesterone therapy; six (35%) had a response that continued for a median of 20 months. Further study is needed, but it appears that GnRH analogues may have a direct inhibitory effect on cancer cells.

Special Circumstances

Multiple Malignant Neoplasms

Simultaneous or subsequent primary cancers involving the breast, ovary, and large intestines occur more frequently in patients with endometrial cancer than might be expected. The reverse also appears to be true, in that women with breast or ovarian cancer have a higher than expected risk for development of subsequent primary cancers of the endometrium. As a result, the recommendation in a patient with one of these malignant neoplasms is to evaluate the other organ sites at the time of diagnosis or during follow-up visits. Appropriate screening, such as mammography, should be emphasized.

Simultaneous malignant neoplasms of the ovary and endometrium are noted in about 8% of patients with carcinoma of the uterus, and twice that rate is noted in patients with ovarian carcinoma. Ovarian involvement in cases in which endometrial cancer is present has been reported to be as high as 40% of autopsy specimens and 15% of specimens obtained at the time of hysterectomy and bilateral salpingo-oophorectomy. In approximately one-third of cases of endometrioid carcinoma of the ovary, endometrial carcinoma has also been noted. When the occurrence is simultaneous, the question arises whether these are simultaneous multiple malignant neoplasms or one

is metastatic from the other. It appears that if metastasis is present, it is more common for it to go from the endometrium to the ovary than from the ovary to the endometrium. Metastasis to the ovary is suspected if the endometrial carcinoma involves significant myometrium, particularly with lymphatic or vascular channel invasion, or if the tumor is on the ovarian surface. If, however, the corpus carcinoma is small and limited to the endometrium or superficial myometrium, with associated atypical hyperplasia, and the ovarian tumor is centrally located, the tumors are probably independent of each other. Most common tumors are the endometrioid type, but they can occasionally be of different histologic types in the two organs. Most studies suggest that most of the synchronous ovarian and corpus carcinomas are independent primary tumors. The survival of patients with what is believed to be multiple primaries mimics the excellent prognosis of the individual cancer, suggesting that the two tumors are probably each stage I and not stage III. This has certainly been true when the simultaneous endometrial and ovarian carcinomas are of the endometrioid type. In one study, the survival was 100% of the 16 patients described. It appears that when such a situation is encountered (ie, when there is no evidence of direct extension of either tumor), myometrial invasion is usually absent or superficial, there is no lymphatic or blood vessel invasion, there is atypical hyperplasia of the endometrium frequently associated with the cancer, both tumors are usually confined to the primary sites and have minimal spread, and tumor is predominantly within the ovary or the endometrium. Whether the histologic type is uniform or dissimilar, therapy should be appropriate for stage I disease, which in many instances may be treated adequately with surgery only (hysterectomy and bilateral salpingo-oophorectomy with appropriate surgical staging).

Uterine Papillary Serous Carcinoma

Much debate has surrounded the biology and clinical behavior of UPSC tumors. There is a common perception that UPSC tumors behave differently than similarly staged patients with endometrioid tumors. Given the relative rarity of UPSC tumors, most series reported in the literature have been small, retrospective series covering a long time period using variable levels of surgical staging and a variety of postoperative therapies. Older studies that did not include comprehensive surgical staging suggest that nearly 50% of "early staged" cases of UPSC recurred. One explanation for this finding is that for UPSC tumors, extrauterine disease spread is common at diagnosis, even in clinically stage I disease. One of the larger series by Goff and associates identified 50 patients with UPSC, 33 pure UPSC and 17 admixed with other histologic types. Unlike endometrioid tumors, UPSC tumors have a greater frequency of disease spread at presentation. In the Goff series, 72% had extrauterine disease; lymph node metastasis was found in 36% with no myometrial invasion, 50% with less than half invasion, and 40% with outer half invasion. **Of particular significance was the fact that 14 patients (28%) had disease limited to the endometrium, yet 36% had lymph node metastasis, 43% had intraperitoneal disease, and 50% had positive peritoneal cytologic findings, essentially equal to the findings in patients with outer-half myometrial invasion.** In this study, the only significant predictor of extrauterine disease was LVSI. The propensity for extrauterine spread even in the absence of invasion is not an unusual feature in UPSC tumors. Chan evaluated 100 patients with UPSC tumors and identified 12 without myometrial invasion who had complete staging. Of these patients, six were found to have extrauterine disease spread. A pooled analysis of several studies (Table 5.21) showed that **approximately 50% of cases will be upstaged with comprehensive staging.** It is not surprising that if patients with UPSC tumors do not undergo surgical staging, unrecognized disease spread will be a common occurrence, and survival for "early-stage" patients will be poorer.

Some suggest that in appropriately staged patients, outcomes of UPSC/CC tumors are comparable to patients with high-risk endometrioid tumors. Creasman and colleagues using the FIGO Annual Report database compared patients with surgically staged I UPSC and CC carcinomas with those with endometrioid G3 cancers. Of 3996 surgically stage I cancers, there were 148 UPSC, 59 CC (5% of all stage I), and 325 G3 (8%) cancers. These were more IA cancers (no myometrial invasion) with UPSC and CC than G3. **Five-year survival rates for UPSC and CC were 72% and 81% respectively, compared with 76% for G3 lesions.** Postoperative radiation therapy improved survival somewhat (6%–8%), but the difference was not significant. The role of chemotherapy was not defined in this study because few patients had this treatment. Huh et al. reported on 60 patients with comprehensively staged stage I UPSC cases and showed that 5-year OS for patients treated by surgery alone was 66%, and it was 59% by radiation alone. Of interest, there was no recurrences in a small group ($n = 7$) treated with chemotherapy. Nickels Fader evaluated data from a pooled multi-institutional dataset of 206 surgically staged, stage I to II UPSC patients. A variety of postoperative therapies were used, including observation after surgery, chemotherapy, radiation, and combinations of chemotherapy and radiation.

Of all patients 21% recurred, including 11% of patients with no myometrial invasion.

The peritoneal cavity and distant sites (lung, liver) are common sites of failure in UPSC tumors. In an effort to improve peritoneal coverage whole-abdominal radiation has been studied extensively in this disease. In a small phase II study of whole-abdominal radiation, Sutton reported 5-year PFS of only 38% in stage I or II disease. In GOG 122 (whole-abdominal radiation vs. chemotherapy), chemotherapy was superior for all patients, including the subset with UPSC/CC tumors. Given the histologic similarity and propensity for intraperitoneal disease spread like ovarian cancer, several investigators have advocated use of systemic chemotherapies active in ovarian cancer for UPSC tumors. Levenback and colleagues from MD Anderson treated 20 patients with UPSC using cisplatin, doxorubicin, and cyclophosphamide. This included patients with measurable disease (advanced and recurrent disease) and adjuvant therapy. Only two of 11 patients with measurable disease had an objective response. The 5-year survival rate for all patients was 23%. Paclitaxel and carboplatin have been increasingly used, and several series suggest improvements in outcomes with this regimen. For example, Huh et al. demonstrated no recurrences in 12 patients with stage I disease treated with platinum-based therapy, and Kelly showed that 0 of 15 patients had a recurrence with IB UPSC tumors treated with platinum chemotherapy compared with 10 of 13 who did not receive chemotherapy. In a review of the GOG phase III experience of advanced or recurrent endometrial cancers by McMeekin et al., there was no difference noted in response rate to chemotherapy based on histologic type (endometrioid vs. UPSC/CC).

The optimal therapy for UPSC/CC tumors remains to be determined. Chemotherapy alone or in combination with radiation is being investigated. Given unique molecular findings in UPSC and CC tumors, it is also hoped that targeted therapies may offer a unique option in this disease.

Carcinosarcoma

Clinical profile. Most patients with uterine carcinosarcoma present with postmenopausal bleeding. As in other cases of postmenopausal bleeding, histologic evaluation by endometrial biopsy or curettage is mandatory and will establish the diagnosis. Not infrequently, a large polypoid mass may extend from the endometrial cavity protruding through the cervical os, which can be easily biopsied (Fig. 5.16). Carcinosarcomas have both malignant epithelial and mesenchymal elements, but on small biopsies, the epithelial component may be the only one recognized preoperatively (Figs. 5.17 and 5.18). Some patients may present without bleeding but with an enlarging pelvic mass as a result of tumor and hematometrium. Patients with advanced-stage disease may present similarly to patients with ovarian cancer with pleural effusions, ascites, adnexal masses, and evidence of intraperitoneal disease spread.

Preoperative assessment with imaging studies is controversial. At a minimum, chest radiography is recommended given the potential for distant disease spread. For common endometrial cancers, routine preoperative CT scans have not been shown to alter clinical management, but data are limited for patients with carcinosarcoma. Consultation with a gynecologic oncologist should strongly be considered in cases with a preoperative diagnosis of carcinosarcoma.

Surgical management. The surgical management for patients with uterine carcinosarcoma should include collection of cytologic washings, hysterectomy with bilateral salpingo-oophorectomy, and pelvic and paraaortic lymph node dissection. Patients with carcinosarcoma of the uterus should be staged according to the 2009 FIGO staging system for endometrial cancer. Extrauterine disease spread in carcinosarcoma is not uncommon. In one analysis of the SEER data from 1988 to 2004, 40% of cases were classified as having stage III or IV disease. When gross extrauterine disease is encountered, many advocate a debulking surgery akin to what is used to manage ovarian cancer.

The GOG prospectively evaluated disease distribution in 530 patients with clinical stage I or II uterine sarcomas. All patients underwent collection of pelvic washings, hysterectomy, and pelvic and paraaortic lymph node dissection. In the subgroup of 301 patients with carcinosarcoma, extrauterine disease was found commonly; 21% were identified with positive cytologic washing, 37% had myometrial invasion into the outer half of the myometrium, 12% had adnexal metastases, and 17% had

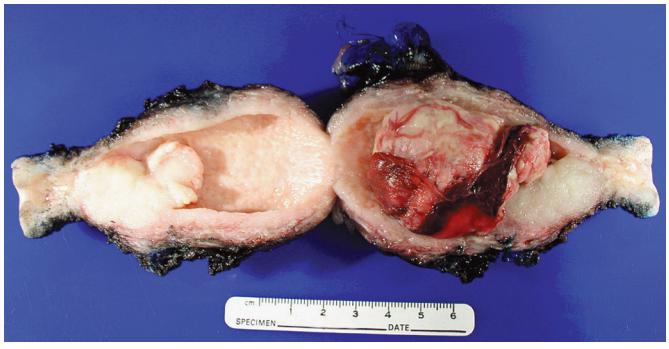

FIGURE 5.16 Uterine carcinosarcoma with a polypoid mass filling the uterine cavity and with deep myometrial invasion. (Courtesy of Dr. Pablo Souza, University of Oklahoma.)

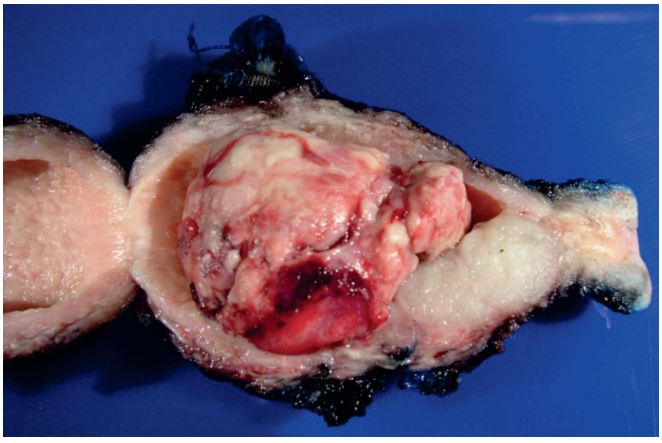

FIGURE 5.17 Close-up view of specimen in Fig. 5.16 showing carcinosarcoma with tumor filling the endometrial cavity. (Courtesy of Dr. Pablo Souza, University of Oklahoma.)

nodal involvement. Compared with a similar surgical staging study conducted by the GOG evaluating endometrial cancer patients, positive cytology was found in only 12%, deep myometrial invasion in 22%, adnexal involvement in 5%, and nodal metastases in 9% of cases (Table 5.22). For carcinosarcoma, after surgical staging, 59% were stage I, 21% were stage II, 9% were stage III, and 11% were stage IV. In almost every case, when extrauterine metastases are encountered, only the epithelial component of the tumor was present.

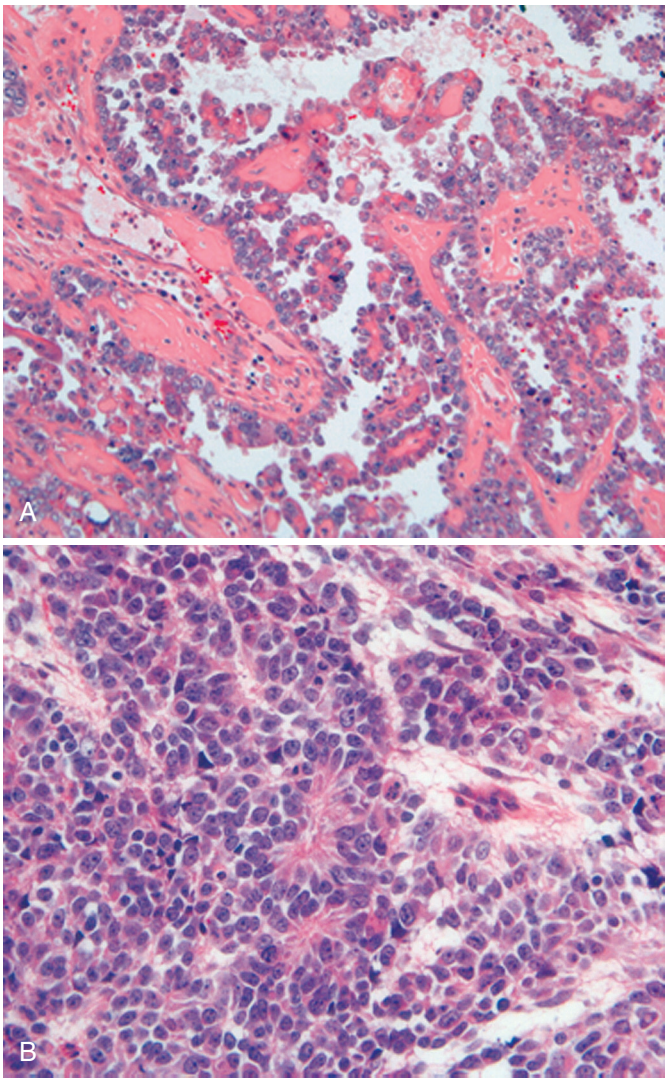

FIGURE 5.18 Photomicrograph of carcinosarcoma of the uterus. Within the tumor are two discrete malignant populations: a high-grade epithelial component (**A**) and a stromal component (**B**). (Courtesy of Dr. Pablo Souza, University of Oklahoma.)

Carcinosarcomas frequently carry a poor prognosis. In some cases managed without complete surgical staging, unrecognized disease spread may account for poorer outcomes. For example, in the 1988 to 2004 SEER database, of 3962 cases of carcinosarcoma, only 53% underwent lymph node dissection. For patients with apparent uterine confined disease, 5-year cancer-specific survival was 59% for stage Ia (no myometrial invasion), 54% for stage IB, and 38% for stage Ic. Even in series with uniform use of staging recurrences are common, indicating that unrecognized disease spread occurs frequently. In the GOG series, 53% of all patients with carcinosarcoma and 40% with stage I disease had a recurrence within 3 years of diagnosis. As in endometrial cancer, survival was related to the presence of nodal metastases, to the depth of myometrial invasion, and to whether the lower uterine segment or cervix was involved. Patients with adnexal involvement also had a poor prognosis. Ferguson reported a series of 42 patients in stage I who all underwent pelvic nodal dissection and found 3-year disease-free survival and OS were 42% and 62%, respectively, even though nearly all patients received some form of postoperative adjuvant therapy.

Although many believe carcinosarcoma to actually represent a metaplastic high-grade or undifferentiated endometrial cancer (and not a true sarcoma), some data indicate a different clinical behavior between uterine carcinosarcoma and high-grade (grade III, serous, or clear cell) endometrial cancers. Amant and colleagues compared 104 patients with grade III, UPSC, or clear cell endometrial cancers with 33 patients with carcinosarcoma. Among patients with stage I or II disease, patients with carcinosarcoma had a poorer survival rate and a higher incidence of pulmonary metastases. Carcinosarcoma was also an independent predictor of survival with an HR of 3.2 for recurrence compared with the other histologies. In a population-based comparison between carcinosarcoma and grade III endometrioid cancers, patients with carcinosarcoma had poorer survival compared with endometrioid cancers when compared stage by stage. For example, the 5-year survival rate was 38% versus 68% for patients with stage IC disease. Some have argued that based on the differences in clinical behavior, carcinosarcoma should be studied separately from high-risk endometrial cancers.

TABLE 5.22 Frequency and Distribution of Disease Spread in Patients With Uterine Malignancies

	Carcinosarcoma (%) (n = 301)	Leiomyosarcoma (%) (n = 59)	Endometrial Adenocarcinoma (%) (n = 621)
Deep myometrial invasion	37	—	22
Positive peritoneal cytology	21	5	12
Adnexal involvement	12	3	5
Nodal metastases	17	3.5	9

From Major FJ, Blessing JA, Silverberg SG, et al. Prognostic factors in early-stage uterine sarcoma: a Gynecologic Oncology Group study. *Cancer* 1993;71:1702; Creasman WT, Morrow CP, Bundy BN, et al. Surgical pathologic spread patterns of endometrial cancer: a Gynecologic Oncology Group study. *Cancer* 1987;60:2035.

Patterns of failure after surgery alone or after adjuvant therapies can help to inform how to best direct therapies for patients with cancers. For example, local therapies such as pelvic radiation may reduce local (vaginal or pelvic) failures but have no or minimal effect on the frequency that cancers recur at distant sites (lung, liver, abdominal cavity). In the GOG study (#20), 40% of patients received postoperative pelvic radiation therapy, with 17% of these patients having a recurrence in the pelvis, 16% at an extrapelvic location, and 19% in the lung (Table 5.23). In the 60% of patients who received no radiation, 24% had a pelvic recurrence, 24% had an extrapelvic recurrence, and 10% recurred in the lung. In the GOG trial, therapy was not randomized but was selected by the physician. Pelvic recurrences usually develop within the first 12 to 18 months after diagnosis and surgery. In a series of 23 carcinosarcoma patients with surgically staged, stage I disease who received no postoperative therapy, 11 patients were noted to have recurrence. The median time to recurrence in these patients was 13 months, and patterns of failure showed that three patients had an isolated pelvic recurrence, three had an isolated distant recurrence, and five had both local and distant failures.

TABLE 5.23 Patterns of Failure in Uterine Sarcomas

	Carcinosarcoma ($n = 301$)		Leiomyosarcoma ($n = 59$)	
Site of First Failure	No Radiation ($n = 182$)	Radiation ($n = 119$)	No Radiation ($n = 46$)	Radiation ($n = 13$)
Pelvis	24%	17%	17%	0
Extrapelvic	24%	16%	29%	8%
Lung	10%	19%	37%	54%
Other	11%	7%	4%	15%

Adjuvant Therapy

Postoperative radiation therapy or chemotherapy has been used to reduce the risk of recurrence in patients with uterine sarcoma. In older studies, all types of uterine sarcomas were commonly grouped together so that the effect of therapy on a particular histologic type of sarcoma was largely unknown. Historically, radiation therapy has been most commonly used in an effort to reduce pelvic failures. When radiation therapy is given, 4500 to 6000 cGy to the pelvis has been advocated, with some also recommending intravaginal brachytherapy to deliver a boost to the vaginal cuff or entire vagina. Preoperative radiation is infrequently used and typically reserved for cases with bulky cervical involvement or parametrial extension.

Several series have shown improved rates of local control with the use of radiation without necessarily improving survival rates compared with patients managed without radiation. In a prospective GOG study (#20) that included patients with stage I or II uterine sarcomas of all types, 156 patients were randomly assigned to postoperative treatment with doxorubicin or not. Pelvic radiation was permitted at the physician's discretion. In this study, which included 93 patients with carcinosarcoma, 47% of patients' disease recurred with or without the use of pelvic radiation therapy (Table 5.24). Pelvic radiation did appear to reduce local recurrences. Similarly, there was not a statistically significant difference in recurrence rates, PFS, or survival in patients who did or did not receive doxorubicin. More recently, EORTC enrolled 224 patients with stage I or II uterine sarcomas (including 91 with carcinosarcoma) and randomly assigned patients to observation vs. pelvic radiation therapy after surgery. For the group as a whole, there was no difference in disease-free survival or OS between the two treatment groups. For patients with carcinosarcoma, improved local control was noted with pelvic radiation therapy. The study found that after observation, 47% of patients with carcinosarcoma developed a local recurrence versus 24% after pelvic radiation. Distant sites of failure remained a significant problem regardless of treatment (35% after radiation; 29% with observation).

TABLE 5.24 Gynecologic Oncology Group Randomized Trial of Doxorubicin Versus No Further Therapy in Completely Resected Stage I and Stage II Uterine Sarcoma: Rates of Recurrence

	Adjuvant Doxorubicin ($n = 75$)	No Chemotherapy ($n = 53$)
CS ($n = 90$)	39%	51%
LMS ($n = 52$)	44%	61%

	Adjuvant Doxorubicin ($n = 75$)		No Chemotherapy ($n = 53$)	
	Radiation ($n = 31$)	No Radiation ($n = 44$)	Radiation ($n = 28$)	No Radiation ($n = 53$)
All sarcoma types ($n = 156$)	39%	43%	57%	51%

	Radiation ± Chemotherapy ($n = 59$)	No Radiation ± Chemotherapy ($n = 97$)
All sarcoma types ($n = 156$)	47%	47%

CS, Carcinosarcoma; *LMS,* leiomyosarcoma.
Modified from Omura GA, Blessing JA, Majors F, et al. A randomized clinical trial of adjuvant Adriamycin in uterine sarcoma: a Gynecologic Oncology Group study. *J Clin Oncol* 1985;3:1240.

Because a common site of failure is at a distant site from the pelvis, the use of adjuvant local irradiation, although improving local control, may ultimately have no effect in increasing the OS rate. Systemic therapy using chemotherapy with or without radiation has been evaluated in adjuvant settings. The selection of drugs or regimens likely to be beneficial is based on information from studies performed with patient populations with advanced or recurrent disease. To date, ifosfamide, cisplatin, and paclitaxel have shown the most promise for development for carcinosarcomas. Kanjeekal and colleagues reviewed the literature on the chemotherapy for uterine sarcomas and noted that for carcinosarcoma, the most promising regimens would likely include platinum-based combinations. Drawing on experience from patients with advanced and recurrent carcinosarcoma, which found that the combination regimen of ifosfamide and cisplatin produced nearly a doubling in response rate and a modestly prolonged PFS compared with ifosfamide alone (GOG0107), the GOG initiated a randomized trial comparing three cycles of ifosfamide and cisplatin with whole-abdominal radiation therapy (WART) (GOG0150). Eligible patients could have had stage I to IV disease provided no residual disease greater than 1 cm remained after surgery. For the group as a whole, stage was one of the most important prognostic factors, with 37% of patients with stage I disease versus 80% with stage IV disease having a recurrence by 5 years. The crude 5-year rate of recurrence rate was 58% for patients treated by WART versus 52% for chemotherapy. After adjusting for stage and age, the recurrence rate was 29% lower for chemotherapy; however, the results did not achieve statistical significance (relative hazard, 0.789; CI 0.48–1.04; $P = 0.245$). Despite this, the authors concluded the results supported further evaluation of combination chemotherapy in future research trials. A retrospective review by Makker and colleagues of 49 patients with stage I to IV disease treated by radiation alone versus chemotherapy ± radiation suggested that the inclusion of chemotherapy into an adjuvant regimen improved PFS and OS compared with chemotherapy alone.

Management of Recurrent Disease

Not unlike with surgical development, the development of chemotherapy in uterine sarcomas began with studies combining all uterine sarcoma types. This strategy appeared justified because, regardless of tumor type, about half the patients with early-stage uterine sarcoma developed a recurrence. Given its importance in patients with soft tissue sarcomas, doxorubicin has been used extensively in patients with uterine sarcomas. The GOG performed a randomized trial comparing doxorubicin with or without DTIC (dimethyl triazenoimidazole carboxamide) in 226 patients with stage III, stage IV, and recurrent sarcomas of the uterus. There was no difference in response rate, PFS, or survival between doxorubicin and doxorubicin plus DTIC-treated groups. Response rate for leiomyosarcoma was 25% versus 15% for carcinosarcoma, and survival time of patients with leiomyosarcoma was significantly longer than that of patients with other cell types. This study was important because it suggested that there was a difference between sarcomas types and response to different agents. With the recognition that there are differences in prognosis and response between the histologic types, carcinosarcoma and leiomyosarcoma are now studied in separate chemotherapy trials.

The first GOG trial to evaluate carcinosarcomas as a separate group was reported by Thigpen and coworkers (#26-C). This phase II study evaluated cisplatin in 28 patients with advanced or recurrent disease who had received prior chemotherapy and had measurable disease. The response rate was 18%, with two patients obtaining a complete response. A subsequent phase II study used cisplatin in a similar group of 63 patients who had not received prior chemotherapy and noted a response rate of 19% (8% complete response).

As a result of activity seen in soft tissue sarcomas, ifosfamide was selected for evaluation in uterine sarcomas. Using ifosfamide with the uroprotective agent mesna (2-mercaptoethane sodium sulfate), Sutton reported for the GOG on 28 patients with advanced or recurrent carcinosarcoma who had not received prior chemotherapy (#87-B). He described a 32% response rate, including 18% of patients with a complete response. Given these promising results, interest in studying combination regimens in this disease resurfaced. The GOG evaluated ifosfamide and mesna with and without cisplatin in patients with advanced, persistent, or recurrent carcinosarcomas in a phase III study (#108). The study evaluated 194 patients and found that response rate for ifosfamide alone was 36% compared to 54% for the combination. Patients treated with cisplatin had a modest improvement in median PFS (6 months vs. 4 months), but there was no statistically significant improvement in survival (ifosfamide, 9 months vs. ifosfamide plus cisplatin, 10 months, median survival). The combination regimen produced greater incidences of neutropenia, anemia, and peripheral neuropathy.

Paclitaxel has been evaluated in 44 patients with advanced or recurrent disease who all had received one prior chemotherapy regimen. Curtin et al. for the GOG reported an 18% response rate with acceptable toxicity. The GOG has subsequently conducted a phase III trial comparing ifosfamide with and without paclitaxel (#161). This trial enrolled 179 eligible patients with stage III, IV, or recurrent carcinosarcoma who had not received prior chemotherapy. The combination regimen produced higher response rates (45% vs. 29%), longer PFS (median, 5.8 months vs. 3.6 months), and longer survival times (median, 13.5 months vs. 8.4 months). There was a 31% decrease in the HR of death (0.69; 95% CI 0.49–0.97; $P = 0.03$). The combination regimen produced more neuropathy and thrombocytopenia and required 3 days for infusion. Because there is interest in improving convenience and cost and reducing toxicity, other regimens have been evaluated in patients with carcinosarcoma. Powell reported on a phase II study, GOG0232-B, evaluating the combination of paclitaxel with carboplatin in 46 patients with advanced or recurrent carcinosarcoma. The response rate was 54% (13% complete response), and 59% of patients completed six or more cycles of therapy. The GOG has completed but not yet reported a phase III trial (#261) comparing ifosfamide–paclitaxel with paclitaxel–carboplatin in untreated patients.

Follow-Up

After surgery, with or without adjuvant therapy, patients with endometrial cancer should enter a routine surveillance program. We advocate for patients to be seen every 3 to 4 months for the first 2 years and then yearly. Most recurrences manifest within 2 years, making closer surveillance during this time reasonable. Surveillance visits should include a focused review of systems (questions related to pelvic, leg, or back pain; vaginal bleeding urinary changes; changes in bowel habits) and physical examination, including pelvic examination. Routine Pap smear collection of the vaginal cuff is controversial. We tend to perform Pap smears as a sampling of the vaginal cuff in an effort to afford early detection of vaginal cuff recurrences. Some have suggested that routine Pap smears are not cost-effective and that most recurrences are clinically palpable or associated with patient symptoms. In addition, after radiation (vaginal or pelvic), vaginal cuff recurrences are uncommon, and radiation may produce cytologic changes occasionally difficult to classify. Most low- and intermediate-risk patients do not require routine, scheduled imaging studies to evaluate for recurrence. Patients with new complaints or worsening of abdominal and pelvic complaints may be considered for additional studies (CT scans, colonoscopy). It has been suggested by some that CA-125 can be used to monitor therapy in patients with advanced or recurrent adenocarcinoma of the endometrium, much as is done in ovarian cancer. Niloff and colleagues and others have noted that CA-125 is elevated in as many as three-fourths of these patients. Data are limited in regard to monitoring. Fanning and Piver did note in 21 women that clinical response, in addition to subsequent relapse, correlated with CA-125 levels of patients with advanced or recurrent disease. Monitoring with CA-125 is helpful, primarily in patients with high risk for recurrent disease, as in patients with recurrent disease receiving therapy who have a proven elevation of their serum value.

Even though the most patients with endometrial carcinoma do not experience recurrence or die of disease, the number of endometrial cancer deaths has risen over the past several years. Patients identified with recurrence are assessed for treatment options. Long-term disease control of recurrent disease is a function of site of recurrence. Patients with recurrence at a distant site or with multiple sites of recurrence are best treated with hormonal or chemotherapy, as discussed earlier, in a palliative setting. Isolated vaginal cuff recurrences may occur, particularly in patients in whom postoperative radiation was not used. Provided no other disease spread is noted, 60% to 80% of patients with vaginal cuff recurrences can achieve long-term disease control with the use of surgery, radiation therapy, or both. Patients with pelvic sidewall or isolated paraaortic recurrences may have long-term disease control, but overall prognosis is poorer than with vaginal recurrence. Rarely, patients with vaginal or pelvic recurrence after radiation therapy may be offered pelvic exenteration with the hopes of cure.

Sarcoma of the Uterus

D. Scott McMeekin, MD, William T. Creasman, MD

OUTLINE

Classification
Incidence and Epidemiology
Leiomyosarcoma
- Clinical Profile
- Surgical Management
- Adjuvant Therapy
- Management of Recurrent Disease

Endometrial Stromal Sarcoma
- Clinical Profile
- Surgical Management
- Adjuvant Therapy
- Management of Recurrent Disease

Other Sarcomas

KEY POINTS

1. Uterine sarcomas are uncommon tumors. The most common tumors are leiomyosarcomas (LMSs) (59%) and endometrial stromal sarcomas (ESSs) (33%). Other sarcomas comprise less than 8% of the remaining.
2. The standard treatment for any sarcoma is removal of the uterus tubes and ovaries if possible.
3. The prognosis of LMSs is poor; even at an early stage, adjuvant therapy has not been shown to affect survival.
4. ESSs are often hormonally responsive.

CLASSIFICATION

Sarcomas are uncommon tumors arising from mesenchymal elements and are distinguished from carcinomas that arise from epithelial elements. Uterine sarcomas are thought to arise primarily from two tissues: endometrial stroma and the uterine muscle itself. When endometrial mesenchymal tissue undergoes malignant transformation, it may be accompanied by a malignant epithelial component (carcinosarcoma [CS], formerly referred to as malignant mixed Müllerian tumor), it may be associated with a benign-appearing epithelial component (adenosarcoma), or it may have no recognizable epithelial component (endometrial stromal sarcoma [ESS]). Tumors arising from malignant transformation of uterine smooth muscle are known as uterine leiomyosarcomas (LMSs). Other sarcomas, such as angiosarcoma and fibrosarcoma, arise in supporting tissues and are rare.

INCIDENCE AND EPIDEMIOLOGY

The Surveillance, Epidemiology, and End Results (SEER) database notes that LMSs account for 59% of 8365 cases reported. ESSs are represented by 33%, and other sarcomas account for 8%. The peak age for all sarcomas was 45 to 54 years with the peak age for LMS being slightly older than 55 years.

In previous editions, classification of sarcomas included CS, LMS, and ESS as the three most common uterine sarcomas with CS being the most common. **Convincing evidence now suggest that CSs are not true sarcomas but are derived from epithelial cells and therefore are now included as a type 2 endometrial cancer category. Although there are minor other types of uterine sarcoma, their occurrence is such that they will not be included in this chapter.**

Sarcomas arising within the uterus are relatively rare and account for 3% to 8% of uterine cancers. According to the SEER, the age-adjusted incidences for all sarcomas (per 100,000 women age 35 years and older) in US women were 2.68 for Native American, Asian, and Hispanic; 3.58 for white; and 7.02 for black women. By comparison, the incidence for epithelial uterine cancers, per 100,000 women, is roughly nine for black women and 20 for white women. Uterine sarcomas represented 8% of primary uterine malignancies in the most recent analysis of the SEER database. Harlow and coworkers had previously reported from SEER databases covering 1973 to 1981 that suggested an annual incidence of only 1.7 cases per 100,000 women. Sarcomas have been traditionally thought to represent only 3% to 5% of all uterine tumors. The increasing incidence of uterine sarcomas noted in the SEER studies may reflect better diagnosis and perhaps a true increase in an aging population.

The type and frequency of uterine sarcomas are related to both age and race. LMS can occur at an early age, has an incidence plateau in middle age, and declines thereafter. In a large prospective surgical-pathologic study conducted by the Gynecologic Oncology Group (GOG) evaluating patients with all types of sarcomas, the median age of patients with LMS was 55 years compared with 65 years for those with CS. Brooks and coworkers suggested that white women were older at the time of diagnosis of their sarcomas compared with black women.

Using SEER data (1992–1998), Sherman and Devesa reported on racial differences in uterine malignancies. They found that for all histopathologic categories, the age-adjusted incidence of uterine cancers (per 100,000 women) was 23 for non-Hispanic white, 14 for white Hispanic, and 15 for black women. In contrast, LMSs are more common in black women. For LMSs, ESSs, and adenosarcomas combined, the incidence was 1.24 for black versus 0.79 for non-Hispanic white women. Harlow and associates found the same trend reporting on an earlier SEER data set. It has also been suggested that blacks present with stage I disease less commonly than whites. Given that uterine sarcomas are rare and form a heterogeneous group, little is known about other risk factors favoring development of these tumors.

LEIOMYOSARCOMA

Clinical Profile

Many of these patients experience perimenopausal bleeding, are found to have a pelvic mass on examination, and will be thought to have uterine leiomyomas. Giuntoli and coworkers, reporting on the Mayo Clinic experience of 208 patients with uterine LMS collected over a 23-year period, found that vaginal bleeding was the most common symptom (56%) followed by a palpable pelvic mass (54%) and pelvic pain (22%). **A commonly described "clinical pearl" has been the relationship of a rapidly enlarging uterus to LMS. The data to support such an observation are mixed, however**. Parker and associates evaluated 1332 patients who underwent surgery for presumed leiomyoma. In the group of 371 patients who had rapid uterine growth, only one case (0.2%) of LMS was identified. Similarly, in a subgroup of 198 patients who had carefully documented rapid uterine growth, no cases of LMS were found. Leibsohn and coworkers reported on 1432 patients undergoing hysterectomy for bleeding related to uterine leiomyomas and identified 7 (0.49%) patients with LMS.

Because LMS arises within the uterine smooth muscle, biopsy of the malignant tissue is difficult, and many lesions are found only at final pathology. In Leibsohn et al.'s series none of the seven patients with LMS were identified on preoperative biopsy and in only three cases was there an intraoperative suspicion of sarcoma. Various authors have reported that LMS may be present in the submucosa of the uterus in 30% to 50% of patients, but even at that, biopsy diagnosis is not easily accomplished. Schwartz and coworkers described the tumors to be both broad based and pedunculated and that in 19 of 20 cases, the LMS was confined to one mass.

Because of the difficulty in establishing a preoperative diagnosis and the high frequency of uterine leiomyoma in the population, it is not unexpected that several case reports have detailed the finding of LMSs in patients who have undergone conservative management of symptomatic leiomyomas by myomectomy, after Lupron treatment before myomectomy, and after vascular embolization of presumed leiomyomas. These cases speak to the importance of pretreatment counseling of patients who undergo such therapies.

There is considerable discussion about the histologic criteria necessary for the diagnosis of LMS (Fig. 6.1). LMSs must be distinguished from a variety of benign smooth muscle tumors (Table 6.1). The predominant differentiating features between benign and malignant tumors include mitotic activity (as gauged by the number of mitotic figures per 10 high-power fields [hpf]), cellular atypia, and necrosis. Leiomyoma, cellular leiomyoma, and bizarre leiomyoma (also called atypical or symplastic leiomyoma) are considered to be benign. These entities are distinguished from LMS mainly by the mitotic count of the tumor. Although cellular leiomyomas and bizarre leiomyomas may appear at first sight to be malignant, they contain fewer than 5 mitoses/10 hpf on histologic evaluation, and the prognosis is excellent with surgery only. Smooth muscle tumors of uncertain malignant potential (STUMP) include a group of smooth muscle tumors with 5 to 9 mitoses/10 hpf that can exhibit a variable behavior.

Intravenous leiomyomatosis is a rare smooth muscle tumor characterized by nodular masses of histologically benign smooth muscle cells growing within venous channels that are lined by epithelium; arteries are not involved. Treatment involves surgical removal, and the prognosis is good.

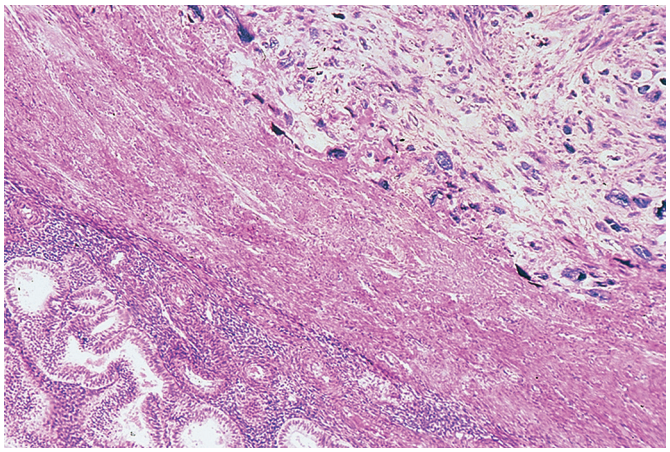

FIGURE 6.1 Photomicrograph of uterine leiomyosarcoma demonstrating the malignant lesion at the top right, normal endometrium at the bottom left, and normal myometrium between them.

TABLE 6.1 Metastatic Potential of Smooth Muscle Tumors of the Uterus

Mitotic Figures/10 hpf	Atypia*	Diagnosis	Metastatic Potential
1–4	Any degree	Leiomyoma	Very low
5–9	None	Leiomyoma with high mitotic activity	Very low
5–9	Grade 1	Smooth muscle tumor of uncertain malignant potential	Low
5–9	Grade 2 or 3	Leiomyosarcoma	Moderate
≥10	Grade 1	Leiomyosarcoma	High
≥10	Grade 2 or 3	Leiomyosarcoma	Very high

*Grade based on a scale of 1 to 3.
From O'Connor DM, Norris HJ. Mitotically active leiomyomas of the uterus. *Hum Pathol* 1990;21:223.

Recurrences are unusual and are usually managed successfully with further surgical excision.

Benign metastasizing leiomyoma is another rare condition in which smooth muscle tumor deposits are found in the lung, lymph nodes, or abdomen and appear histologically like a benign leiomyoma. Most women have a history of pelvic surgery for benign leiomyomas years before these metastatic sites are recognized. Surgical excision has been the primary treatment.

Norris and Taylor believed that mitotic count was extremely important in that if fewer than 10 mitoses/10 hpf were identified, the lesion was benign regardless of the degree of cellular atypia; if more than 10 mitoses/10 hpf were present, the prognosis was grave. More recently, Norris and Taylor stated that tumors with fewer than 5 mitoses/10 hpf can rarely metastasize. In a follow-up study from the Armed Forces Institute of Pathology, O'Connor and Norris evaluated 73 smooth muscle tumors of the uterus with 5 to 9 mitotic figures/10 hpf but lacking cytologic atypia. They concluded that the metastatic rate was too low to consider these as being sarcoma. Several of their patients were treated only with myomectomies with excellent results. Lissoni and colleagues have suggested extending this philosophy to additional patients.

Kempson and Bari believe that the mitotic count is important but state that prognosis is poor if more than 5 mitoses/10 hpf are identified. Their experience with tumors containing 5 to 9 mitoses/10 hpf indicates that the tumors usually behave aggressively and will metastasize. These authors believe that the degree of cellular atypia is of limited value by itself in determining the malignancy of smooth muscle tumors. In tumors with higher mitotic counts, there were usually a greater number of very atypical cells. This atypia was also seen in tumors with 5 to 9 mitoses/10 hpf. Tumors with fewer than 5 mitoses/10 hpf were thought to be benign regardless of the atypia of the cells. None of Kempson and Bari's patients with fewer than 5 mitoses/10 hpf had disease outside the uterus, but distant disease was a common finding if more than 5 mitoses/10 hpf were noted. The presence of coagulative necrosis, especially with diffuse significant atypia, suggests strongly that the lesion is a LMS regardless of the mitotic count.

However, Silverberg believes that the mitotic count alone cannot be used as a strict histologic criterion because he had patients with fewer than 10 mitoses/10 hpf who succumbed to their disease. He emphasized that the grade of the tumor, which reflects the cytologic atypia, is a better criterion than mitotic count alone. Toledo and Oliva point out that mitotic rate alone is not sufficient to predict prognosis. Although mitotic rate and nuclear atypia are important features, tumor cell necrosis is a unique feature of LMS. Most uterine LMS with necrosis will show high mitotic rate and atypia. Essentially all investigators note the gravity of the situation if intravascular invasion or disease outside the uterus is found. Silverberg believes that the single most important prognostic indicator is the menopausal status of the patient. Women who are premenopausal when the diagnosis is made tend to have a much better prognosis than that of women who are postmenopausal, even when criteria such as blood vessel invasion, growth pattern, grade, and mitotic counts are considered. LMSs occur in young patients and tend to be more localized when they are first diagnosed, and they probably exhibit a slower growth pattern than CSs or ESSs do.

Surgical Management

Planning the surgical management of LMS is difficult because many cases go unrecognized preoperatively. Patients commonly undergo myomectomy or hysterectomy for presumptive leiomyomas, which are subsequently identified as a sarcoma. When a preoperative diagnosis is known, hysterectomy should be performed. Retention of the ovaries in premenopausal patients has not shown to worsen outcome in several retrospective series and may be considered. Surgical staging with lymph node dissection is controversial, but most authorities tend to recommend biopsy of suspicious nodes only. When LMS is recognized postoperatively, reexploration for the purposes of completing surgical staging is not recommended. After diagnosis, evaluation of the chest with chest radiography or computed tomography is reasonable given the propensity of spread to the lungs. Goff and colleagues found that 10% of patients with LMS had lung metastases at presentation.

Data on patterns of spread for LMS are limited by the rarity of the tumor. Goff and coworkers found that 16 of 21 patients had stage I disease at surgery, and only patients with disseminated intraabdominal disease had nodal involvement. Giuntoli and coworkers reported that only 34 of 208 patients in the Mayo Clinic series had pelvic nodal dissections performed, and of the four with positive nodes, extrauterine disease was reported in three. The GOG sarcoma study on patterns of spread found that in 59 surgically staged patients, 5% had positive extrauterine spread to peritoneal cytology, 3% had adnexal involvement, and 3.5% had nodal metastases (Table 6.2). After surgical staging, 83% were stage I, and only 13% of patients were upstaged based on biopsies. In 2009, the Federation of International Gynecologists and Obstetricians (FIGO) introduced a new staging system for LMS, ESS, and adenosarcoma. For LMS, stage reflects tumor size and extrauterine spread (see Table 6.2).

Leiomyosarcomas most commonly spread hematogenously. Corscaden and Singh reported the results of autopsies of 15 patients who died of LMS of the uterus. Of these patients, 100% had intraabdominal visceral involvement, 80% had lung or pleural metastases, 40% had paraaortic nodal involvement, 33% had renal metastases, and 20% had liver metastases. In the GOG study, the most common first site of recurrence was the lung (41%), and only 13% had a pelvic failure (Table 6.3).

The prognosis for LMS is poor, even for early-stage disease. Vardi found that of the total group of 32 patients, 44% died of disease within the first 3 years after diagnosis. There was a 63.6% 5-year survival rate in women in whom diagnosis was made while they were premenopausal compared with a 5.5% 5-year survival in postmenopausal women. The GOG found that only 31% of patients remained disease free at 3 years. Gadducci and coworkers found that 39% of patients with stage I or II disease had a recurrence, with a median time to recurrence of 18 months. Berchuck and coworkers reported that only 29% of patients with stage I or II disease remained free of disease, with a median follow-up period of 7.5 years. Although almost all deaths and recurrences are during the 4 years after

diagnosis, Gallup and coworkers reported a recurrence 25 years after initial therapy. Contrary to an older perception, these data indicate that LMSs have a poorer prognosis than CSs.

Predictors of outcome have been assessed by several groups. The GOG found that patients with greater numbers of mitoses were associated with an increased risk of recurrence such that 79% of patients with more than 20 mitoses/hpf recurred compared with 61% with 10 to 20 mitoses/hpf. Patients who present with extrauterine disease also have a very poor prognosis. Berchuck and coworkers found no survivors beyond 2 years in this group of patients. Gadducci and coworkers assessed 126 patients collected from a multi-institutional study and identified stage, mitotic count, and age as independent prognostic factors predicting recurrence. Giuntoli and coworkers found that high grade, advanced stage, and having had ovaries removed at surgery were independent predictors of poorer survival.

TABLE 6.2 Federation of International Gynecologists and Obstetricians 2009 Staging Classification for Uterine Sarcomas

Stage I (tumor limited to uterus)*
- IA: <5 cm tumor size
- IB: ≥5 cm tumor size

For Leiomyosarcoma
- IA: tumor limited to endometrium or endocervix without myometrial invasion
- IB: tumor invades <50% myometrium
- IC: tumor invades ≥50% myometrium

For Endometrial Stromal Sarcoma and Adenosarcoma

Stage II (tumor extension into the pelvis)
- IIA: adnexal involvement
- IIB: other extrauterine pelvic disease

Stage III (tumor invades abdominal tissues)
- IIIA: one site of involvement
- IIIB: >1 site of involvement
- IIIC: metastasis to pelvic and/or paraaortic lymph nodes

Stage IV (tumor invades bladder and/or rectum, and/or distant metastasis)
- IVA: involvement of bladder and/or rectum
- IVB: distant metastasis

*For stage I disease, two substages are used based on tumor type. Modified from Mutch DG. Meeting Report—the new FIGO staging system for cancers of the vulva, cervix, endometrium and sarcomas. *Gynecol Oncol* 2009;115:325-328 and FIGO Committee. FIGO staging for uterine sarcomas. *Int J Gynecol Obstet* 2009;104:179.

Adjuvant Therapy

For patients with LMS, no adjuvant therapy has been shown to be effective in prolonging survival. As with other high-risk uterine cancers, LMSs have been managed postoperatively by radiation therapy or chemotherapy. Berchuck and coworkers found that among patients receiving any form of adjuvant therapy, 83% recurred compared with 68% who underwent surgery alone. Given the propensity for hematogenous spread, radiation does not adequately address the high frequency of distant sites of failure (lung, liver, abdominal cavity). Supporters of radiation note that pelvic control may be obtained, which can prevent bulky pelvic recurrences and improve patient comfort and quality of life. The GOG reported that only three of 13 patients who received radiation remained without recurrence, but no pelvic failures were seen. Giuntoli and coworkers performed a subset analysis within their large series of patients, identifying 31 patients who received adjuvant radiation therapy. In a comparison with 31 well-matched patients who did not receive radiation, there was not a statistically significant difference in survival between the groups, although the 5-year survival rate for those receiving radiation was 60% compared with 40% without radiation therapy. In the only prospective randomized trial, the European Organization for Research and Treatment of Cancer (EORTC) showed in the subgroup of 103 patients with LMS, there was no improvement of local control with radiation (local recurrence; 20% after radiation vs. 24% after surgery alone). Of note, most patients developed distant sites of failure.

Given the importance of distant failures in this disease, chemotherapy has been used to manage early-stage LMSs. In the GOG adjuvant trial evaluating the role of doxorubicin with or without radiation, 61% of patients with LMS treated without doxorubicin compared with 44% who received chemotherapy had a recurrence. This study **was too small to specifically evaluate the importance that histology played in response to therapy. With the identification of an active combination regimen of docetaxel plus gemcitabine for patients with advanced or recurrent disease, early data suggest that this regimen may hold promise in an adjuvant setting**. In one series of 18 patients with stage I or II LMS, 59% remain progression free at 3 years.

Hensley et al. reported results of a phase II study of 23 patients completely resected LMS treated with four cycles of gemcitabine and docetaxel. In patients with uterus-limited disease, the 2-year progression-free survival (PFS) rate was

TABLE 6.3 Frequency and Distribution of Disease Spread in Patients With Uterine Malignancies

	Carcinosarcoma (%) (n = 301)	Leiomyosarcoma (%) (n = 59)	Endometrial Adenocarcinoma (%) (n = 621)
Deep myometrial invasion	37	—	22
Positive peritoneal cytology	21	5	12
Adnexal involvement	12	3	5
Nodal metastases	17	3.5	9

59%. GOG 277 evaluated 47 women with uterine-limited disease with four cycles of doxorubicin followed by four courses of gemcitabine and docetaxel. At a median follow-up period of 27.4 months, a 78% 2 year PFS was noted with a median PFS of 39.3 months.

Hensley and coworkers more recently enrolled 46 with resected uterus-limited high-grade uterine LMS who received four cycles of gemcitabine and docetaxel. If confirmed disease free after four cycles, they then received four cycles of doxorubicin. At 2 years, PFS was 78% of patients; it was 57% at 3 years. Bevacizumab was added to the gemcitabine–docetaxel regimen in 25 women with combined complete and partial response of 44%. GOG 250 enrolled patients with LMS in a phase III placebo-controlled study to evaluate the addition of bevacizumab to gemcitabine and docetaxel. The addition of bevacizumab failed to improve PFS, overall survival, or OR. Currently, there is a randomized trial of adjuvant chemotherapy versus observation in women with LMS limited to the uterus (GOG 277).

Multiple single agents have been tried and have been unsuccessful. Recently, there has been an increased interest in the study of biologic targets, including mTOR (mammalian target of rapamycin) inhibitors, with modest results. Multikinase inhibitors that affect the vascular endothelial growth factor pathway to date have been unsuccessful.

Management of Recurrent Disease

Data from randomized phase III trials conducted by the GOG, which included advanced and recurrent uterine sarcomas of all types, helped to identify the differential sensitivity of LMSs compared with CSs to different agents. In the trial comparing doxorubicin with and without dacarbazine (DTIC), patients with LMSs were found to have longer survival times compared with patients with other types when treated with a doxorubicin-containing regimen. In a subsequent study using doxorubicin with or without cyclophosphamide, histologic type was not found to be a prognostic indicator. Given that 80% of all patients died of disease within 2 years, the GOG adopted a strategy of performing phase II trials with the hope of identifying active agents that could later be tested in randomized studies. The rarity of LMSs, however, has made randomized study of this tumor more difficult.

Historically, doxorubicin and ifosfamide have demonstrated the most activity in patients with recurrent disease with responses ranging from 25% to 33% for doxorubicin and 18% for ifosfamide when used as single agents. Sutton et al. and the GOG published the results of a phase II study combining ifosfamide and mesna and doxorubicin, showing an overall response rate of 30%. The duration response was 4 months, and the regimen produced substantial toxicity. Paclitaxel has been studied in LMSs, with an 8% response seen in patients who had received prior chemotherapy and a 9% response in those who were chemotherapy naïve. A novel combination of gemcitabine with docetaxel has shown a 53% response rate in a small phase II trial of patients that included 29 patients with uterine LMS. This regimen was subsequently evaluated in two phase II trials. In one trial of 39 patients with advanced or recurrent LMS who had received no prior chemotherapy, the regimen produced a 36% response rate and a median PFS of 4.4 months. In a similar population of 48 patients who had received one prior chemotherapy regimen, a 27% response rate was noted. In both studies, myelosuppression was the most common toxicity.

Targeted biologic agents are also being explored, although no agent has yet to demonstrate activity in this tumor type. A randomized trial comparing the docetaxel plus gemcitabine regimen with or without the antivascular endothelial growth factor antibody bevacizumab is currently ongoing. Patients with late recurrences of LMS in the form of isolated pulmonary metastases are candidates for thoracotomy and sequential resection of the lesions. Five-year survival rates of 30% to 50% have been reported after such therapy.

Recently, several reports have appeared in the medical as well as lay literature in which women with a preoperative diagnosis of leiomyoma were treated with minimally invasive surgery including morcellation, and the final pathology noted a uterine malignancy. Most of these cancers were LMS. Because preoperative diagnosis of LMS is very imprecise compared with other uterine malignancies and occur in peri- or early menopause, a benign preoperative diagnosis could be easily made. These cases have resulted in disseminated disease with poor prognosis. As a result, several studies have evaluated the incidence of malignancy associated with a hysterectomy or myomectomy done for presumed benign disease. In reported studies of women undergoing hysterectomy or myomectomy for a myometrial mass, the prevalence of sarcoma is about 1 in 500 (0.2%) in most studies and reviews. Most sarcomas were LMS. The largest study of unexplained malignancy in women undergoing morcellation was from the US insurance database including 232,882 women undergoing minimally invasive hysterectomy noted morcellation was performed in 36,470 (15.7%). Among those in which morcellation was performed, 99 cases (0.34%) of uterine cancer were found. The prevalence of cancer in this series for women younger than the age of 40 years was 1 in 1500 and 1 in 1100 for women 40 to 44 years of age. Unfortunately, histology of uterine cancer cases was not reported. Data from a national US hospital database of 41,777 women undergoing myomectomy included 3220 who underwent power morcellation, and 0.09% had uterine cancer. Occult uterine cancer was 1 in 2337 in women younger than 40 years, 1 in 702 in those age 40 to 49 years, 1 in 154 in those age 50 to 59 years, and 1 in 31 in women age 60 years or older. Studies have noted morcellation is associated with the worst prognosis with uterine sarcoma. A meta-analysis of four observational studies in women with uterine sarcoma found morcellation compared with no morcellation was associated with higher recurrence rate (61% vs. 39%) and mortality rate (48% vs. 29%). **These data support the US Food and Drug Administration guideline that power morcellation should not be used in peri- and postmenopausal women (November 2014).**

More recent data by Wright et al. using a Markov model suggest that morcellation may be beneficial in women younger than the age of 40 years and not beneficial in older women. Contained morcellation in a containment bag is a potential emerging technique that may put this controversy to rest.

ENDOMETRIAL STROMAL SARCOMA

Clinical Profile

Endometrial stromal tumors are rare mesenchymal tumors composed of cells that resemble endometrial stromal cells of the proliferative endometrium. The most common symptom of ESS is irregular vaginal bleeding. Asymptomatic uterine enlargement, pelvic pain, or a palpable mass are also common symptoms. The tumors are generally soft, fleshy, smooth, polypoid masses that may protrude into the endometrial cavity. The multiple-polyp form of the neoplasm has also been described, as has the characteristic yellow color of many of these lesions. On occasion, the uterine wall is diffusely enlarged by tumor without the presence of an obvious tumor mass. Preoperative diagnosis remains challenging because endometrial biopsy may not identify the lesion in many cases.

In the past, endometrial stromal tumors were largely grouped as either endolymphatic stromal myosis or ESS. Endolymphatic stromal myosis was distinguished from stromal sarcomas by the minimal extent of tumor infiltration into the myometrium, the lack of metastases, and an indolent clinical behavior. There was significant histologic overlap between the two entities that made diagnosis difficult, however. Currently, endometrial stromal tumors are classified into two groups based on their metastatic potential. Stromal nodules are benign proliferations with the appearance indistinguishable from endometrial stroma of proliferative endometrium. They tend to be well-circumscribed lesions smaller than 15 cm and do not demonstrate infiltrating margins or vascular space invasion. They behave like benign lesions without reported recurrences or metastases. Stromal sarcomas represent the second type of stromal neoplasm. Stromal sarcomas demonstrate local invasiveness or vascular and lymphatic space involvement and infiltrate and separate the muscle fibers of the uterus. Stromal sarcomas have traditionally been divided into low- and high-grade ESSs, largely based on the mitotic activity. Today there is a greater recognition that most high-grade tumors should be classified as undifferentiated endometrial sarcomas.

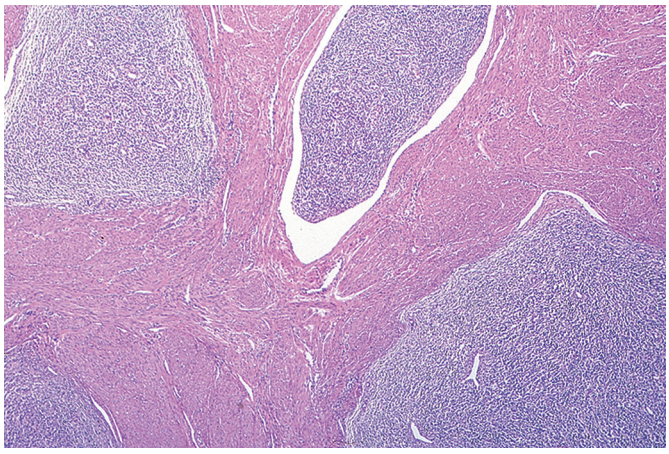

FIGURE 6.2 Low-power photomicrograph of a low-grade endometrial stromal sarcoma with invasion into the myometrium.

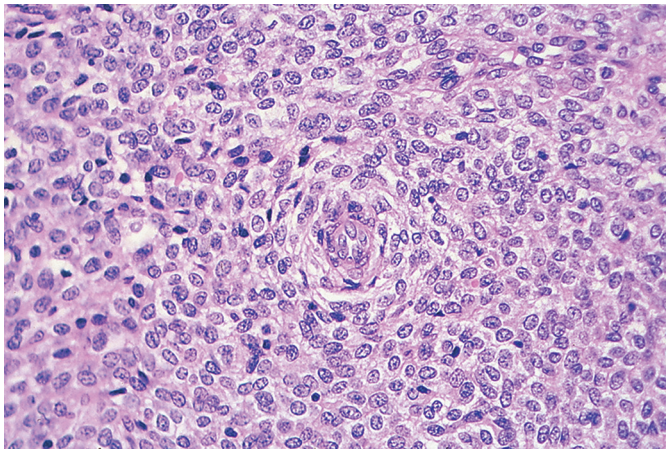

FIGURE 6.3 High-power view of low-grade endometrial stromal sarcoma shown in Fig. 6.2.

Low-grade endometrial stromal sarcoma (LGESS), previously described as endolymphatic stromal myosis, can have an infiltrating growth pattern that on gross examination can project out in a wormlike fashion into the myometrium or into pelvic blood vessels. On microscopic examination, there is little or no cellular atypia, and there are few if any mitoses (Figs. 6.2 and 6.3). Although metastasis can occur, the clinical course is usually indolent, and surgery only is usually adequate treatment. Low-grade sarcomas may recur, but their clinical course is marked by late recurrences, typically more than 5 years from diagnosis, with recurrences up to 25 years having been reported. In a review of 72 cases of LGESS, 88% of patients remained alive at 80 months.

High-grade ESS traditionally has been distinguished from LGESS by having 10 or greater mitoses per 10 hpf based on work by Norris and Taylor. From a review of 17 stromal sarcomas, Kempson and Bari noted that 10 tumors contained more than 20 mitoses/10 hpf, and 9 of 10 patients died of disease. Seven patients had tumors that contained 5 mitoses or fewer/10 hpf, and none have developed a recurrence. Kempson and colleagues subsequently reviewed 109 cases of ESS and found that stage was the predominant predictor of behavior, even more so than the number of mitoses. For example, disease in 45% of stage I patients with rare mitosis and minimal atypia recurred. In this series, as long as the stromal cells appeared bland (similar to normal proliferative endometrial stromal cells), the 10 mitoses/10 hpf cutoff was not predictive of recurrence or survival. Leath and colleagues demonstrated that the clinical behavior of high-grade endometrial stromal sarcoma (HGESS) is frequently aggressive, with more patients presenting with advanced stage (extrauterine disease, 61% vs. 32%) and poorer survival compared with LGESS. Today there is a belief that many HGESS tumors are in fact undifferentiated endometrial sarcomas. These tumors show myometrial invasion and nuclear pleomorphism and have a high mitotic rate and extensive necrosis but lack smooth muscle or endometrial stromal differentiation.

Surgical Management

The standard management for patients with stromal sarcoma is hysterectomy and bilateral salpingo-oophorectomy. The role of nodal dissections is unresolved, largely because there are a scarcity of data when complete surgical staging has been performed. Goff and associates found no nodal disease, but only seven patients were evaluated. In the GOG surgical staging series, 52 stromal sarcomas were included, but the frequency of nodal disease was not reported. Data suggest that bilateral salpingo-oophorectomy should be performed. Several investigators have suggested that recurrences were higher in patients who had ovaries preserved. In 2009, the FIGO introduced a new staging classification for ESSs (see Table 6.3).

Patients with LGESS tend to present with disease confined to the uterus, with stage I or II disease being reported in approximately 70% of series. In contrast, patients with HGESS had stage I or II disease in 40% to 50% of cases. In a retrospective review of 52 cases of LGESS by Piver and colleagues, 47% of stage I patients developed recurrence after surgery. Despite this, the 5-year survival rates were 88% for stage I and 100% for stage II patients. Gadducci and coworkers evaluated 66 patients with stromal sarcomas, including 26 with LGESS and 40 with HGESS. For 20 patients with stage I or II low-grade tumors, 25% recurred (median follow-up period, 86 months), all in the pelvis. The median time to recurrence was 36 months, with a range of 4 to 108 months. For LGESS, 5-year survival rates have ranged from 80% to 100 even though 20% to 40% of patients eventually have a recurrence. Piver and coworkers reported on patterns of failure in stage I patients whose disease recurred, with 12 of 19 recurrences being in the pelvis, 3 of 19 being at distant sites, and 4 of 19 with combined pelvic and distant failures.

The prognosis for HGESS is comparable to LMSs. Gadducci and coworkers reported 5-year disease-free survival (DFS) rate of only about 20% for this group of patients. The median time to recurrence is shorter than with LGESS, with a median time of 7 months. Mitotic count was an independent predictor of survival with patients with 10 to 20 mitoses/10 hpf having a 2-year DFS of approximately 60% compared with approximately 10% if there were 20 mitoses or more/10 hpf. Other investigators have suggested 5-year survival rate between 20% and 55% for HGESS. Recurrences in the pelvis, abdomen, and lung are commonly seen, with the majority including at least some distant site of failure. A study of 24 patients with HGESS from the Mayo Clinic found that prognosis was related to the extent of disease, size of primary tumor, and grade. Mitotic count was not a prognostic factor, nor was DNA pattern.

Adjuvant Therapy

As with other uterine sarcomas, adjuvant therapy has been evaluated to reduce recurrences. Gadducci and coworkers had no recurrences in five patients with low-grade disease who received adjuvant therapy versus 5 of 15 (33%) who did not. In the Piver et al. study, five patients with low-grade disease received postoperative pelvic radiation, and no recurrences were seen. Piver et al., noting the sensitivity of advanced or recurrent disease to progestins, suggested that adjuvant progestin therapy may be an effective strategy. In the large multi-institutional series by Leath and coworkers, 30 of 72 patients received adjuvant hormonal therapy and survival curves suggested a possible benefit associated with its use.

Berchuck and coworkers reported recurrence rates of 57% with adjuvant chemotherapy or radiation therapy versus 56% who did not receive adjuvant therapy in 25 patients with stage I ESS (high and low grade). Gadducci and coworkers noted no benefit to adjuvant therapy in stage I or II high-grade tumors. Given the rarity of ESS, no prospective study has been performed to identify active agents to be used in adjuvant treatment. As with other sarcoma types, radiation therapy may have a role in reducing pelvic recurrences but with an unknown effect on survival.

Management of Recurrent Disease

Although initial studies did allow for patients with ESS, the small numbers of such patients included does not allow for interpretation of results. Low-grade endometrial sarcomas have a high frequency of progestin receptors, making progestational agents reasonable. Piver and associates found that progestins produced a 46% response rate in a small number of patients with LGESS treated at recurrence. Responses lasted from 2 to 104 months. Recurrences of LGESS should be considered for local resection when they develop in the pelvis. For HGESS, limited success has been reported with drugs commonly used for uterine sarcomas including ifosfamide and doxorubicin.

OTHER SARCOMAS

Clement and Scully described 100 cases of adenosarcoma of the uterus. This is an unusual tumor with low malignant potential. Similar to other endometrial lesions, adenosarcoma usually presents with abnormal vaginal bleeding. On gross evaluation, the tumor is usually a polypoid mass that can fill the endometrial cavity. Involvement of the cervix and myometrium is less commonly seen. In 2009, the FIGO introduced a new staging classification for adenosarcomas (see Table 6.3). Histologic evaluation notes benign or atypical neoplastic glands with a sarcomatous stroma. In 78% of patients, the sarcomatous stroma was homologous. The stromal mitotic rate was 1 to 40/10 hpf. Extensive stromal fibrosis was common. Myometrial invasion was present in only 15, and it was deeply invasive in only four. Recurrence became apparent in 23 patients and in one-third appeared 5 years after diagnosis. Recurrence was confined to the vagina, pelvis, or abdomen, with two exceptions. Of those with recurrence, only 11 died with tumor. Only the presence of myometrial invasion was associated with an increased risk of recurrence. A variant of adenocarcinoma is a pattern that has been called adenosarcoma with sarcomatous overgrowth. This is characterized by overgrowth of the neoplasm by a pure sarcomatous component occupying at least 25% of the lesion. It is an ominous feature with reported recurrence rates exceeding 50% compared with the usual adenosarcoma.

Pure heterologous uterine sarcomas are rare. Of these, rhabdomyosarcoma is the most common followed by chondrosarcoma and osteosarcoma. Rhabdomyosarcoma is derived from primitive myogenic precursors and is the most common soft tissue tumor in children and adolescents; 21% occur in genitourinary sites, and 20% of these in the uterus. Therapy has evolved from radical surgery and radiation therapy to more reliance on chemotherapy. Some authors have reported successful preservation of reproductive functions.

Other Considerations
- Future Childbearing
- Coexistence of Normal Pregnancy and Gestational Trophoblastic Neoplasia
- Transplacental Fetal Metastases
- Survivorship Issues After Successful Treatment of Gestational Trophoblastic Neoplasia

KEY POINTS

1. Gestational trophoblastic disease (GTD) describes a spectrum of neoplastic conditions derived from the placenta, including hydatidiform moles, postmolar gestational trophoblastic neoplasia (GTN), gestational choriocarcinoma, placental site trophoblastic tumor (PSTT), and epithelioid trophoblastic tumor (ETT).
2. GTN is the most curable gynecologic malignancy.
3. Complete hydatidiform moles are completely derived from the paternal genome and most frequently have a diploid 46XX karyotype.
4. Partial moles are composed of both paternal and maternal genomes, resulting in triploidy, and most frequently have the 69XXX karyotype. Partial moles have evidence of fetal development, which differentiates them from complete moles.
5. Malignant GTN is more common after a complete molar pregnancy than a partial molar pregnancy.
6. Human chorionic gonadotropin (hCG) values should be followed for 6 months after molar pregnancy evacuation to detect postmolar GTN.
7. GTN is defined by a plateaued, rising, or prolonged persistence of elevated hCG values after molar evacuation; histologic diagnosis of choriocarcinoma, invasive mole, PSTT, or ETT; or identification of metastatic disease after molar evacuation.
8. GTN is staged based on the World Health Organization prognostic score as either low risk (≤6) or high risk (≥7).
9. Low-risk GTN is treated with actinomycin D or methotrexate. Cure rates approach 100%.
10. High risk GTN is treated with EMA/CO (etoposide, methotrexate, actinomycin D, cyclophosphamide, and vincristine) chemotherapy. Cure rates are greater than 90%.

Gestational trophoblastic disease (GTD) comprises a spectrum of neoplastic conditions derived from the placenta. Whereas hydatidiform moles, gestational choriocarcinoma, and placental site trophoblastic tumor (PSTT) are histologic diagnoses, postmolar GTN is defined by clinical and laboratory criteria. The disease entities included in GTD have a wide variation in behavior, but GTN specifically refers to those with the potential for tissue invasion and metastases.

Gestational trophoblastic disease has been recognized since antiquity. Individual hydropic molar villi (Fig. 7.1) were sometimes identified as separate fetuses. In the early 19th century, Velpeau and Boivin recognized hydatidiform mole as a

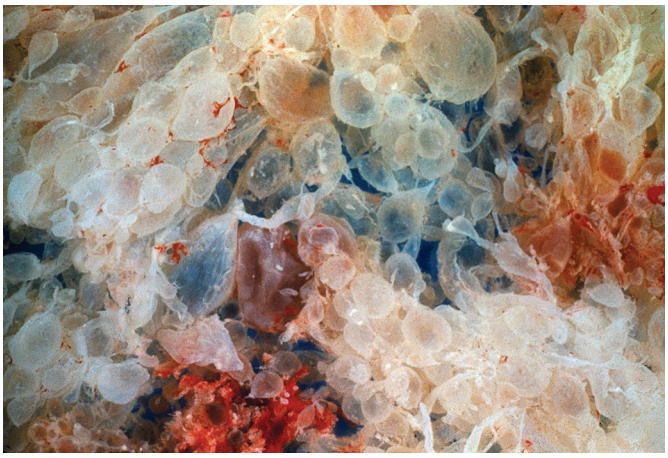

FIGURE 7.1 Complete hydatidiform mole, gross specimen. Note the diffuse hydropic placental villi, which make up almost the entire specimen. (Courtesy of David Mutch, MD.)

TABLE 7.1 Features of Partial and Complete Hydatidiform Moles

Feature	Partial Mole	Complete Mole
Karyotype	Most commonly 69,XXX or –,XXY	Most commonly 46,XX or –,XY
Pathology		
Fetus	Often present	Absent
Amnion, fetal RBC	Usually present	Absent
Villous edema	Variable, focal	Diffuse
Trophoblastic proliferation	Focal, slight to moderate	Diffuse, slight to severe
CLINICAL PRESENTATION		
Diagnosis	Missed abortion	Molar gestation
Uterine size	Small for dates	50% large for dates
Theca-lutein cysts	Rare	25%–30%
Medical complications	Rare	10%–25%
Postmolar GTN	2.5%–7.5%	6.8%–20%

GTN, Gestational trophoblastic neoplasia; *RBC,* red blood cell.

cystic dilation of the chorionic villi. In 1895, Marchand demonstrated that hydatidiform mole and less frequently normal pregnancy preceded the development of choriocarcinoma. In the early 20th century, Fels identified elevated chorionic gonadotropic hormones in the urine of women with hydatidiform moles.

Before the mid-1950s, the prognosis for women with GTN was dismal, and there were no effective treatments. In the 1940s, Hertz demonstrated that fetal tissues required large amounts of folic acid and that their growth could be inhibited by methotrexate. However, it was not until 1956 that Li reported the first sustained remission in a patient with choriocarcinoma treated with methotrexate.

Since that report, GTN has been recognized as the most curable gynecologic malignancy. Reasons for this include (1) identification and development of quantitative assays for human chorionic gonadotropin (hCG) in serum and urine allowed hCG to become the prototype for tumor markers; (2) sensitivity of GTN to various chemotherapeutic agents; and (3) identification of risk factors allowing individualization of treatment, often using multimodality treatment with chemotherapy combined with surgery or radiation therapy (or both) in selected cases.

In general, GTD represents a derangement in the development of the conceptus, associated with unregulated trophoblastic proliferation and invasion, with the propensity for hematogenous metastasis in GTN. The diseases are characterized by paraneoplastic disorders from secretion of gestational hormones, most notably hCG. GTD is the only group of female reproductive neoplasms derived from paternal genetic material (androgenic origin).

Although largely unclear, the etiology of GTD likely involves genetic abnormalities involved in fertilization. Abnormalities in differentiation and pronuclear cleavage, decidual implantation, myometrial invasion, and host immunologic tolerance are also involved. Several candidate tumor suppressor genes (eg, DOC-2/hDab2), chromosomal loci (e.g., 7qp12-7q11,23 and 9q13,3-13,4), and oncogenes (eg, CD9) have been implicated in the pathogenesis of GTD.

HYDATIDIFORM MOLE

Two distinct forms of molar pregnancies, complete (CM) and partial (PM) moles, are currently recognized (Table 7.1). Cytogenetic studies have conclusively demonstrated that they are completely separate but related entities. Despite the cytogenetic, pathologic, and clinical differences outlined in Table 7.1, the clinical management of patients with CMs and PMs is similar.

Epidemiology

The incidence of molar pregnancies in the United States is approximately 1 in 1500 pregnancies. Race or ethnicity, age, socioeconomic status, diet, and prior reproductive history all influence the risk. The most reliable studies suggest that the incidence of hydatidiform mole is slightly less than 1 in 1000 pregnancies in most of the world, 1.2 in 1000 in South Africa, as high as 2 in 1000 in Japan, 7 in 1000 deliveries in Malaysia and the Philippines, and possibly higher in Saudi Arabia. The reported incidence of molar pregnancies among various ethnicities and races may be biased as a result of dependence on hospital records, particularly from tertiary referral centers, rather than population-based studies. Historically, GTD was thought to occur more frequently in the Asian population; however, recent population-based studies in Japan have shown a decreasing incidence of GTD in Japan, even with a relatively homogeneous population.

Extremes of reproductive age are associated with increased risk of molar pregnancy. Based on an analysis of 2202 patients with hydatidiform moles compared with a contemporary control group including all types of pregnancy events, a Duke

study found a significantly higher incidence of molar pregnancy in women younger than 15 years and older than 40 years of age.

Other studies have confirmed the peak incidence of molar pregnancies at the extremes of maternal reproductive age. Some of these studies noted an increased risk associated with increasing paternal reproductive age for CM but not for PM.

Dietary factors associated with an increased risk of hydatidiform mole may include a low-protein diet and vitamin A deficiency, although these factors are difficult to separate from effects of lower socioeconomic class alone. Berkowitz and colleagues have suggested that a deficiency of animal fat and fat-soluble vitamin carotene is associated with increased risk of molar pregnancies. Populations with a high prevalence of vitamin A deficiency have been noted to have higher incidences of hydatidiform mole. Although carotene-rich vegetables are available in these countries, the lack of dietary fat needed for carotene absorption may result in an overall carotene-deficient condition.

Prior molar pregnancy also increases the risk of recurrent molar pregnancy. Women with a single previous molar pregnancy have more than 10 times the risk of having another molar pregnancy compared with those who have never had one. Based on data by Bagshawe and colleagues, after having had one molar pregnancy, the risk for a second was 1 in 76; after two molar pregnancies, the risk for a third was 1 in 6.5. Sand reported that the risk of a third molar pregnancy was 28%. Goldstein and colleagues noted that 9 of 1339 patients (1 in 150) had at least two consecutive molar pregnancies. Other centers have reported that the incidence of a second molar pregnancy is as high as 1 in 50 women with one prior molar pregnancy.

With recurrent molar pregnancies, there is also an increased risk of developing malignant GTN, although patients with consecutive molar pregnancies may have subsequent normal pregnancies. Berkowitz and colleagues noted that four of their patients with consecutive molar pregnancies later had full-term pregnancies. Lurain noted that five of eight patients with consecutive molar pregnancies later had normal full-term pregnancies.

In a case-controlled study from Baltimore, factors found to be associated with GTN included professional occupation, history of prior spontaneous abortions, and the mean number of months from antecedent pregnancy to the index pregnancy. Contraceptive history, irradiation, ABO blood groups, and smoking factors of the male partner were not associated with development of GTN. Among PMs, no clinical factor such as gravidity, parity, age, uterine size, gestational age at diagnosis, or hCG levels at presentation were associated with development of GTN.

Cytogenetics and Pathology

Molar pregnancies consist of CMs and PMs. In most series, CM and PM comprise approximately 70% and 30% of molar pregnancies, respectively.

Complete hydatidiform moles are completely derived from the paternal genome (see Table 7.1). Most frequently, CMs have a diploid 46, XX genome with exclusively androgenetic markers on the chromosomes, implying duplication of a haploid sperm chromosomal complement in the fertilized ovum. Approximately 5% of CMs have a 46,XY androgenetic genome, indicating that dispermic fertilization occurs in some. The mechanism for exclusion of the maternal polar body from the nucleus of the fertilized ovum is unknown. No 46,YY moles have been reported, but aneuploid karyotypes, such as tetraploidy, have been associated with CM. Fetal red blood cells (RBCs) are not observed in microscopic sections of CM, because the fetus never develops a cardiovascular system.

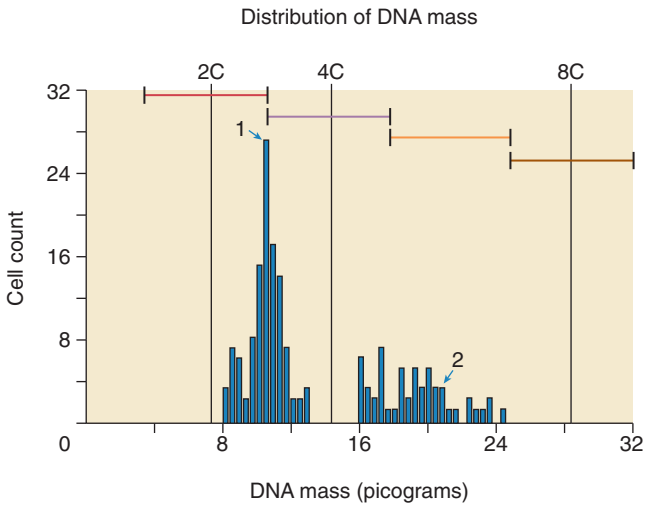

FIGURE 7.2 Flow cytometry of a partial mole. Note the peak at 3C, indicating triploidy. (Courtesy of Dr. Rex Bentley, Duke University Medical Center.)

In contrast, PMs are composed of both paternal and maternal genomes (see Table 7.1). Usually, two paternal haploid sets of chromosomes are combined with one maternal set, resulting in **complete triploidy** (Fig. 7.2). The 69,XXX karyotype is most common, but some PM, have a 69,XXY karyotype, implying dispermic fertilization. Sometimes other aneuploid karyotypes are observed in PM but none with duplication of the Y chromo some. All karyotypes reported for PM feature a maternal haploid set and multiples of the paternal chromosomal complement. Gross or histologic evidence of fetal development such as fetal RBCs is a feature of PM that differentiates it from CM.

Other histopathologic features of CM and PM differ. CMs have diffuse villous edema, often with central cisterna formation (Fig. 7.3). Trophoblastic proliferation is usually diffuse (Fig. 7.4) but may vary in extent. Histologic evidence of a fetus is lacking. Histologic features of PM can be subtle, and many PMs are probably underdiagnosed erroneously as spontaneous abortions. A PM exhibits focal, varying degrees of hydropic villi with scalloping and trophoblastic inclusions within the villi (Fig. 7.5). Focal trophoblastic proliferation is usually subtle compared with CM. Fetal RBCs are observed within vessels of the villi (Fig. 7.6), and sometimes a fetus can be grossly identified. The fetus is usually nonviable and rarely survives beyond 20 weeks of gestation. The difference in the amount of trophoblastic proliferation between CM and PM is related to their different clinical presentations. Malignant GTN occurs in 2.5% to 7.5% of patients with PM compared with approximately

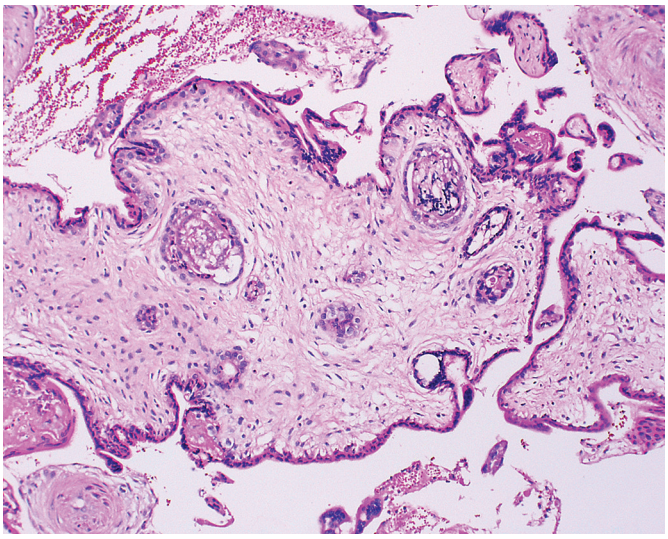

FIGURE 7.3 Low-power photomicrograph of a complete mole illustrating diffuse hydropic change of the villi, which have marked paucity of stroma in the central zone of each villus (cisternae formation). Sheets of trophoblast cell are adjacent to the villi. (Courtesy of Dr. Rex Bentley, Duke University Medical Center.)

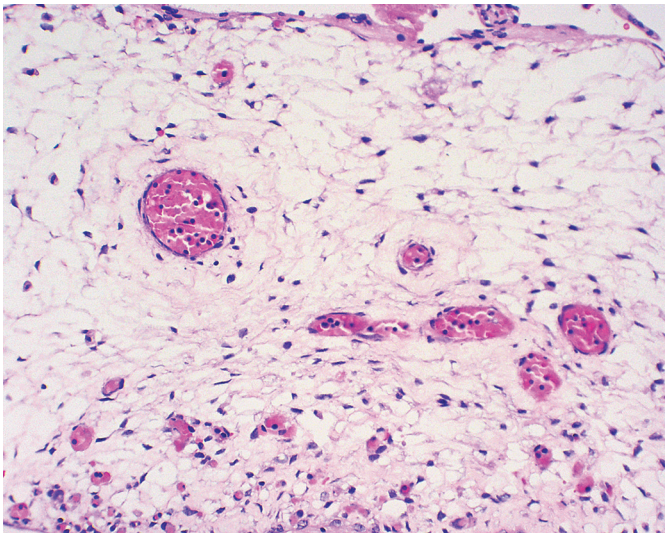

FIGURE 7.4 High-power photomicrograph of a complete mole. The villus (upper left) is associated with sheets of trophoblast cells, containing the multinucleated syncytiotrophoblasts and the small, polygonal cytotrophoblast cells. Production of human chorionic gonadotropin occurs mainly in the syncytiotrophoblast cells. (Courtesy of Dr. Rex Bentley, Duke University Medical Center.)

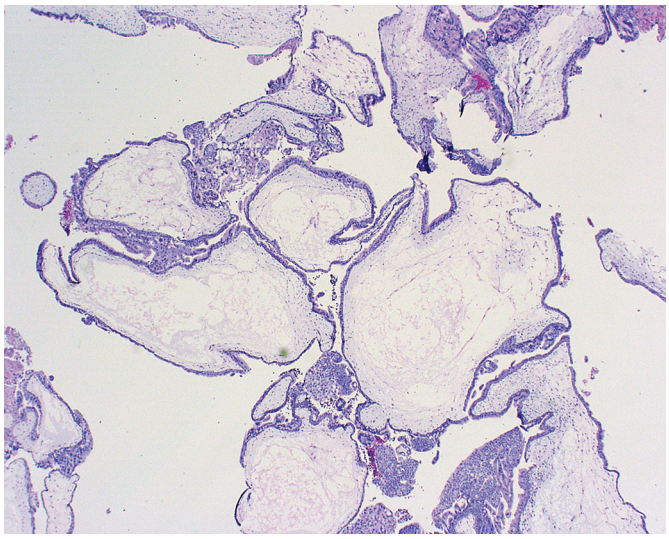

FIGURE 7.5 This low-power photomicrograph of a partial hydatidiform mole contains enlarged placental villi with stromal edema, scalloping at the edge of the villi, and trophoblastic inclusions within the stroma of the villi. Minimal trophoblastic proliferation is present. (Courtesy of Dr. Rex Bentley, Duke University Medical Center.)

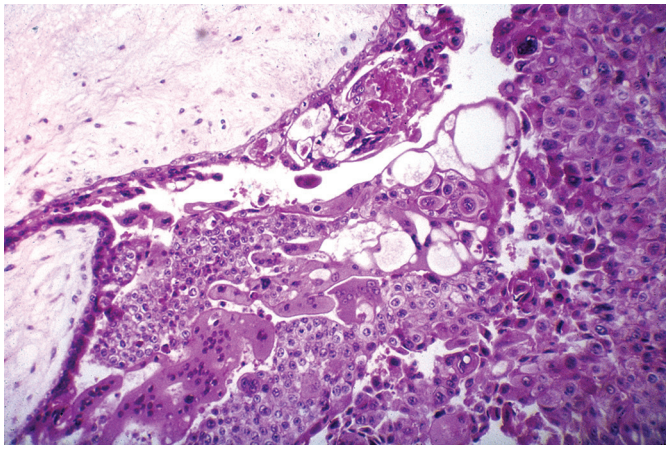

FIGURE 7.6 In this high-power photomicrograph of a villus from a partial mole, small vessels within the stroma are seen containing nucleated fetal red blood cells. (Courtesy of Dr. Rex Bentley, Duke University Medical Center.)

6.8% to more than 20% after evacuation of a CM mole (see Table 7.1).

Other techniques have been developed to differentiate CM from PM. These include karyotyping, flow cytometry, fluorescence in situ hybridization, and amplification of short tandem repeat loci. Additionally, p57 immunohistochemistry is absent in CM but present in PM because it is paternally imprinted but maternally expressed. Although most cases of molar pregnancy can be classified as CM or PM using histopathology alone, histologic differences may not be apparent if the diagnosis is made early in gestation. In this scenario, molecular genetic techniques may be critical for accurate diagnosis.

Presentation and Symptoms

Irregular bleeding is the hallmark symptom of hydatidiform moles. Nearly all patients with moles have delayed or irregular menses for varying time periods. Vaginal bleeding usually occurs during the first trimester. The bleeding may vary from spotting to hemorrhage requiring blood transfusion. In earlier series, bleeding occurred in 73% to 100% of molar pregnancies

including CM and PM. Expulsion of recognizable molar vesicles may accompany vaginal bleeding when the gestation approaches the second trimester.

There is increasing information that the presentation of moles may be changing as a result of earlier and improved diagnostic tests, including early ultrasound and hCG serum assays. The New England Trophoblastic Disease Center (NETDC) group compared symptoms in CM treated at their institution from 1994 to 2013 to those treated from 1988 to 1993. Patients in the more recent cohort were less likely to present with vaginal bleeding, 46% versus 84% in the earlier cohort. Patients in the recent cohort were also more likely to be diagnosed with a molar pregnancy at less than 11 weeks (56% vs. 41%). However, earlier diagnosis did not result in decreased rates of GTN.

Other symptoms include nausea and vomiting caused by the high levels of hCG. Nausea and vomiting were reported in almost one-third of patients with hydatidiform mole in older studies. However, in the most recent series from the NETDC, 14% of 180 patients presented with hyperemesis from 1994 to 2013. Curry and colleagues also reported hyperemesis in 14% of patients.

Preeclampsia-like symptoms in the first trimester of pregnancy are nearly pathognomonic of a hydatidiform mole. Symptoms of headache with hypertension, hyperreflexia, and proteinuria define preeclampsia. Preeclampsia was present in 1% of patients in the NETDC cohort and in 12% of the patients in the study by Curry and colleagues. Fortunately, eclampsia in the setting of hydatidiform mole is rare.

Molar pregnancy is also associated with other medical comorbidities such as tachycardia and hypertension from hyperthyroidism or shortness of breath and chest pain from acute respiratory distress syndrome. Hyperthyroidism occurs rarely but can be very severe. Laboratory evidence of hyperthyroidism can occur in as many as 10% of patients; however, clinical manifestations are less frequent. Hyperthyroidism is caused by the production of elevated levels of normal hCG by molar tissue. hCG has structural homology with the thyroid-stimulating hormone (TSH) molecule and binds to TSH receptors, which results in thyroid hyperfunction. Furthermore, Yoshimura and colleagues demonstrated that the isoforms of hCG produced by molar pregnancies have higher thyrotrophic activity compared with the hCG produced by normal pregnancies. Clinical manifestations of hyperthyroidism disappear after the molar pregnancy is evacuated. Antithyroid therapy may be indicated for a short period to control hyperthyroidism during molar evacuation. Specifically, the use of beta-blockers to prevent tachycardia may be indicated.

Acute respiratory distress caused by trophoblastic pulmonary embolization can also occur. It is very rare, occurring in only 2% of patients in the NETDC cohort. These patients often have coexisting pathology that may alter cardiac or pulmonary function such as preeclampsia, hyperthyroidism, and anemia, and this combination can contribute to acute cardiopulmonary decompensation. Respiratory distress is most often associated with a large volume of molar tissue and uterine enlargement greater than 16 weeks' gestational size.

Theca-lutein cysts are caused by hyperstimulation of the ovaries by excessive hCG production. Traditionally, approximately 15% to 25% of patients with unevacuated molar pregnancies present with theca-lutein cysts larger than 6 cm. More recent series have shown rates of theca-lutein cysts at presentation of 6% to 9%. Although theca-lutein cysts will resolve after molar evacuation, there may be considerable lag behind the decline of hCG levels. Surgical intervention is rarely required for acute torsion or bleeding. Patients who develop theca-lutein cysts have a higher incidence of postmolar GTN. Furthermore, patients with the combination of enlarged ovaries with a large for gestational age uterus results are at a high risk for malignant GTN. Up to 57% of patients with this combination require subsequent therapy for postmolar GTN.

Classically, a patient with a hydatidiform mole was said to have a uterine size excessive for gestational age. Historically, this was found in more than 50% of patients with CM; however, approximately one-third of patients have uteri smaller than expected for gestational age. In the NETDC cohort from 1994 to 2013, uterine size was excessive for dates in only 24%.

Similar to the comparative study performed by NETDC, Mangili and colleagues from Italy compared clinical features of molar pregnancies between two historical cohorts, 1970 to 1982 versus 1992 to 2004. The later cohort had significantly less vaginal bleeding on presentation (51% vs. 74%, $P < 0.0001$), fewer with increased uterine volume (29% vs. 51%, $P < 0.0001$), and fewer with theca-lutein cysts (13% vs. 21%, $P = 0.03$). There was no difference in rates of hyperemesis or preeclampsia. Because molar pregnancies are diagnosed at an increasingly early gestational age, clinical symptoms are less frequent. As a result, there is increasing reliance on histopathologic analysis to identify cases of molar pregnancies.

The previously outlined conditions are seen mainly in patients with CM. Patients with PM usually do not exhibit excessive uterine size, theca-lutein cysts, preeclampsia, hyperthyroidism, or respiratory problems. In most patients with PM, the clinical and ultrasound diagnosis is usually a missed or incomplete abortion. PMs are often underdiagnosed because of the lack of clinical suspicion and the often subtle or focal nature of the pathologic changes in the placental tissues. Therefore, products of conception from missed or incomplete abortions should be thoroughly examined by pathologists to prevent a missed diagnosis of PM. Cytogenetic testing may be required to accurately diagnose GTD.

Diagnosis

Patients with CM are often clinically diagnosed by characteristic ultrasound features and a markedly elevated hCG. In contrast, the majority of patients with PM and an increasing proportion of patients with CM are clinically misdiagnosed as missed abortion. A quantitative hCG of greater than 100,000 IU/L, an enlarged uterus with absent fetal heart sounds, and vaginal bleeding suggest a diagnosis of hydatidiform mole. However, a single hCG determination is not diagnostic. A single high hCG value may be seen with a normal single or multiple pregnancy, especially if there has been bleeding or disruption of the placenta. Therefore, an isolated hCG value alone should not be

FIGURE 7.7 Transabdominal ultrasound image of an unevacuated complete mole, illustrating the characteristic mixed echogenic pattern in the uterus. (Courtesy of John Soper, MD.)

FIGURE 7.8 Gross specimen in a patient treated for complete hydatidiform mole with primary hysterectomy. (Courtesy of John Soper, MD.)

used as the sole determining factor in diagnosing hydatidiform mole. Conversely, a "normal" hCG level for an anticipated gestational age does not exclude the possibility of a molar pregnancy.

Ultrasonography has replaced all other radiographic means (eg, amniography or uterine angiography) for diagnosis of hydatidiform mole. Molar tissue typically is identified as a diffuse mixed echogenic and vesicular pattern replacing the placenta (Fig. 7.7), traditionally labeled a "snowstorm appearance." Recently, with increasing use of early ultrasonography, classic features may be subtle or lacking in cases of early CM or PM. In a recent series based on histopathologic identification of molar pregnancies, 52% of patients were diagnosed based on ultrasound examination before evacuation of the uterus. In another series, the abundant vesicular pattern and "snowstorm appearance" were absent in 10% of CM pregnancies and only subtly present in 63% of CM based on ultrasonography performed at mean gestational age of 7 weeks and 6 days.

The largest study to date, from Charing Cross Hospital in the United Kingdom, assessed more than 1000 cases of GTD from 2002 to 2005 and found an overall 44% detection rate by ultrasonography of molar pregnancies before evacuation. The overall detection rate was 35% to 40% before 14 weeks of gestation and 60% after 14 weeks. The sensitivity was 44%, and the specificity was 74%. The positive predictive value was 88%, and the negative predictive value was 23% for detecting molar pregnancy of any type. Detection rates were higher for CM versus PM and for later gestations. Nonetheless, fewer than 50% of molar pregnancies were diagnosed by ultrasonography in first-trimester scans.

In a smaller series from St. George's in London, the sensitivity of ultrasonography for the diagnosis of a CM was 95% and 20% for PM. Another series evaluated the use of both ultrasound and hCG values to diagnose hydatidiform mole. When ultrasonography was used alone, 42% of patients with molar pregnancies did not have a definite diagnosis on first examination. When the hCG value was above a threshold of 82,350 mIU/mL and was used with the initial ultrasound findings, 89% of hydatidiform moles were correctly identified (Fig. 7.8). A combined algorithm using hCG, clinical history, examination, and imaging is required to make the diagnosis of hydatidiform mole.

Several reports have been made of a hydatidiform mole arising in ectopic sites, such as the fallopian tube. These patients present with classic symptoms and signs of ectopic pregnancy, including occasionally with tubal rupture and hemorrhagic shock. Tubal GTD was diagnosed in 16 (0.8%) of 2100 women with GTD who were managed at the NETDC. Various authors have warned that the current trend of treating ectopic pregnancies with conservative surgery or single-dose methotrexate necessitates close monitoring of serum hCG levels to avoid missing the diagnosis of ectopic GTD.

Evacuation

Given the subtle presentation of GTD in the modern era, the diagnosis of molar pregnancy will increasingly be made only after histologic evaluation of uterine curettings. Curettage is

TABLE 7.2 Management of Hydatidiform Mole

Evacuation: suction D&E (or hysterectomy in selected patients)
Postevacuation quantitative hCG level and chest radiography
Monitor quantitative hCG levels every 1–2 weeks until three normal values or criteria for GTN
After hCG level is normal for three values, then monitor hCG levels every 1–3 months for 6 months
Initiate chemotherapy for GTN using indications listed in Table 7.4:
1. Plateaued or rising hCG values
2. Histologic diagnosis of choriocarcinoma, invasive mole, or placental site trophoblastic tumor
3. Persistent hCG >6 months after evacuation
4. Metastatic disease

D&E, Suction dilation and evacuation; *GTN,* gestational trophoblastic neoplasia; *hCG,* human chorionic gonadotropin.

often performed for a suspected incomplete spontaneous abortion. When GTD is diagnosed, patients should be monitored with serial hCG measurements. Baseline postevacuation chest radiography should be considered. For patients in whom hydatidiform mole is suspected before evacuation, the following laboratory evaluation is recommended (Table 7.2): complete blood count with platelet determination, clotting function studies, renal and liver function studies, blood type with antibody screen, and hCG level. A pre-evacuation chest radiograph should also be obtained.

Evacuation of molar pregnancies should be performed expeditiously. Medical complications are observed in approximately 25% of patients with molar pregnancy and uterine enlargement of greater than 14 to 16 weeks' gestational size. The molar pregnancy should be evacuated as soon as possible after stabilization of any medical complications. The choice of facilities for molar evacuation should be based on the expertise of the physician, uterine size, and ability of the facility to manage existing medical complications. In most patients, the preferred method of evacuation is suction dilation and evacuation (D&E) (see Table 7.2).

Medical induction of labor with oxytocin or prostaglandin and hysterotomy are not recommended for evacuation because they increase blood loss and may increase the risk for malignant sequelae compared with suction D&E. The Charing Cross group reported a significant trend toward more frequent evacuation by suction curettage compared with sharp curettage or medical induction for molar evacuation over their study interval. Postmolar GTN developed in 5.9%, 3.8%, and 9.1% of their patients evacuated with suction curettage, sharp curettage, and medical induction, respectively (P <0.05 for increased postmolar GTN in the medical induction group). Furthermore, many patients require D&E to complete the evacuation of the mole after medical induction of labor.

Evacuation is usually performed under general anesthesia, but local or regional anesthesia may be used for a cooperative patient with a small uterus. After serial dilatation of the cervix, uterine evacuation is accomplished with the largest cannula that can be introduced through the cervix. Most providers begin

FIGURE 7.9 Ultrasound image demonstrating a large theca-lutein ovarian cyst associated with a complete hydatidiform mole. These usually contain multiple thin septations and have an appearance similar to iatrogenic ovarian hyperstimulation during ovulation induction. Theca-lutein cysts regress spontaneously after evacuation of the molar pregnancy, but regression often lags behind human chorionic gonadotropin level decline. (Courtesy of John Soper, MD.)

curettage in the lower uterine segment, allowing the uterus to contract progressively as the pregnancy is evacuated. Evacuation may be accompanied by significant blood loss during evacuation of tissue, particularly with increasing gestational age. Intravenous (IV) oxytocin is begun after the cervix is dilated and continued for serval hours postoperatively to assist with uterine contractility. Other uterotonics such as methylergonovine or misoprostol may be used if needed. After completion of suction D&E, gentle sharp curettage may be performed. Repeat uterine evacuation by D&E has been performed for persistent GTD, defined in the United Kingdom as failure of hCG to normalize within 4 to 6 weeks or an increase in hCG any time after primary D&C. The utility of repeat second D&C is controversial. It may subject patients to surgical complications, when hCG may normalize given more time. Additionally, it does not comply with current International Federation of Gynecology and Obstetrics (FIGO) guidelines for treatment of GTN.

Hysterectomy is an alternative to suction D&E for molar evacuation in selected patients who do not wish to preserve childbearing (Fig. 7.9). The adnexa are routinely preserved, and theca-lutein cysts should be left in situ unless they are torsed or ruptured and actively bleeding. Hysterectomy reduces, but does not eliminate, the risk of malignant postmolar sequelae. The risk of postmolar GTN after hysterectomy remains approximately 3% to 5%; therefore, these patients should be monitored postoperatively with serial hCG levels.

Risk Factors for Postmolar Gestational Trophoblastic Neoplasia

Many of the risk factors for development of postmolar GTN indirectly reflect the amount of trophoblastic proliferation at the time of evacuation. High pre-evacuation hCG levels, uterine size larger than expected by dates, and theca-lutein cysts (see Fig. 7.9) increase the risk. Many of these factors interact. The combination of theca-lutein cysts and uterus larger than expected for dates increases the risk of postmolar GTN to 57%. Other series have used multivariate analysis to identify other risk factors for postmolar GTN and have found that age, parity, initial uterine size, presence of theca-lutein cysts, and initial hCG concentration were not independent prognostic factors.

Multiple risk factors have been incorporated into scoring systems that seek to categorize patients and predict which patients will develop postmolar GTN. However, many of these efforts have not been successful. Parazzini and colleagues found that, although 15% of their patients had risk factors that classified them as "high risk," these patients accounted for a minority of the cases of postmolar GTN. Of note, despite the earlier diagnosis and decreasing symptom burden among patients in the modern era with molar pregnancies, there has not been a decrease in the incidence of postmolar GTN. This implies that other molecular biologic mechanisms may be responsible for the development of postmolar GTN rather than the amount of trophoblastic proliferation at the time of evacuation. Most centers do not treat "high-risk" molar pregnancies with post-evacuation chemotherapy to prevent the development of postmolar GTN; rather, they rely on surveillance with serial hCG levels to diagnose postmolar GTN and then treat it when encountered.

Postmolar Surveillance

After molar evacuation, it is important to monitor all patients to diagnose and treat postmolar GTN promptly. Serial quantitative serum hCG measurements should be performed using one of several commercially available assays capable of detecting hCG to baseline values (<5 mIU/mL). Ideally, serum hCG levels should be obtained every 1 to 2 weeks until three consecutive values are normal. hCG can then be measured at 1- to 3-month intervals until 6 months after the initial normal value (see Table 7.2). Reliable contraception is highly recommended during monitoring of hCG values. Chest radiography is indicated if the hCG level rises. Patients with a histologic diagnosis of malignant GTN (choriocarcinoma, invasive mole, or PSTT), the development of metastatic disease, a rising hCG value, or a plateauing of the hCG values over several weeks' time are diagnosed with postmolar GTN, as discussed later. Whereas approximately 15% to 20% of patients develop postmolar GTN after evacuation of a CM, 1% to 5% of patients develop postmolar GTN after a PM.

Postmolar surveillance by serial hCG monitoring after achieving normal values allows identification of patients who develop late GTN. Although rare instances of long latent periods between molar evacuation and postmolar GTN have been reported, the vast majority of episodes of GTN after hydatidiform moles occur within approximately 6 months of evacuation. The NETDC analyzed 1029 patients followed with hCG assays after CM evacuation at their institution. Postmolar GTN occurred in 153 (15%) patients. Only two women developed postmolar GTN after normalization of hCG levels, and both were followed by an older assay with a sensitivity of 10 mIU/mL.

None of their 82 (95% confidence interval [CI], 0%–4.5%) patients who were followed with an hCG assay with a sensitivity of 5 mIU/mL developed postmolar GTN after their hCG values normalized. However, a substantial number of their patients were excluded from analysis because of incomplete follow-up, including 817 patients lost to follow-up after normalization of hCG and 60 patients lost to follow-up before hCG values normalized. The same group of investigators reported that patients with PM had spontaneous normalization of hCG, with a median time of 46 days, and suggested that surveillance in this group may also be abbreviated.

Kerkmeijer and colleagues from the Netherlands reported that 74.6% patients with molar pregnancies attained spontaneous normalization of hCG after evacuation. Only one case of GTN occurred out of 265 patients who obtained two normal hCG levels. They conclude that hCG surveillance can also be curtailed after normalization of values. Within the same database, they found that no GTN occurred in patients with CM who obtained spontaneous normalization of weekly hCG levels within 2 months after evacuation. Because this total experience is relatively small and plagued by incomplete follow-up, it is prudent to recommend continued surveillance after molar evacuation with hCG monitoring for 6 months after normalization of hCG values. However, it should be noted that the risk of postmolar GTN is quite low after normalization.

Although early pregnancies after molar evacuation are usually normal gestations, an early pregnancy obscures detection of an elevated hCG caused by GTN. Oral contraceptives do not increase the incidence of postmolar GTN or alter the pattern of regression of hCG values. Special consideration should be given to oral contraceptive pills as the contraceptive of choice because they suppress the luteinizing hormone (LH) surge by preventing ovulation. LH shares an alpha subunit with hCG, and thus an LH surge may lead to a false-positive hCG value. In a randomized study conducted by the Gynecologic Oncology Group (GOG), patients treated with oral contraceptives had half as many intercurrent pregnancies during hCG surveillance as those using barrier methods. Furthermore, the incidence of postmolar GTN was lower in patients using oral contraceptives.

After completion of surveillance documenting remission for 6 months, pregnancy can be encouraged and hCG monitoring discontinued. Patients with a history of molar pregnancy remain at an elevated risk of GTN after all future pregnancies. Thus, pathologic examination of all future pregnancies is recommended, including placental examination and examination of the products of conception. Patients should also obtain a serum hCG value at 6 weeks after any pregnancy event (delivery or spontaneous or therapeutic abortion).

Prophylactic Chemotherapy After Molar Evacuation

Two randomized studies have evaluated prophylactic chemotherapy after molar evacuation. Kim and colleagues reported that a single course of methotrexate–folinic acid reduced the incidence of postmolar GTN from 47.4% to 14.3% (P <0.05) in patients with high-risk molar pregnancies, but the incidence was not reduced in patients with low-risk molar pregnancies. Patients who received prophylactic chemotherapy but developed GTN required more chemotherapy than those who had not been exposed to prophylactic chemotherapy. In the study by Limpongsanurak, a single course of actinomycin D was compared with observation in patients after evacuation of high-risk molar pregnancies. Postmolar GTN was 50% in the control group compared with 13.8% in the treatment group (P <0.05). In both studies there were no deaths in the treatment or control groups caused by GTN or treatment toxicity.

However, there are anecdotal cases of fatalities caused by prophylactic chemotherapy, and prophylactic chemotherapy does not eliminate the need for postevacuation follow-up. Furthermore, patients are exposed to drugs most frequently used to treat postmolar GTN, which could lead to relative chemoresistance. Receipt of chemotherapy is also associated with decreased quality of life, cost, and morbidity. In compliant patients, the low morbidity and mortality achieved by monitoring patients and instituting chemotherapy only in patients with postmolar GTN appears to outweigh the potential risk and small benefit of routine prophylactic chemotherapy. Exceptions to this are scenarios in which hCG follow-up is not possible because of patient or system factors; prophylactic chemotherapy may be considered in these cases.

Coexistent Molar Pregnancy With a Normal Fetus

Coexistence of a genetically normal fetus with molar change of the placenta is relatively rare (Fig. 7.10), occurring in 1 in 22,000 to 1 in 100,000 pregnancies. The majority of the literature covering this relatively rare entity consists of case reports and case series. Both CM and PM with a coexistent normal fetus have been reported. A variety of criteria have been used to evaluate these pregnancies. Many of the reports that antedated the histologic and cytogenetic distinction between CM and PM likely included twin gestations with coexistent fetus and molar gestation in addition to singleton PM. Although there might be an increased incidence of coexisting molar pregnancy and fetus related to an increase in multifetal pregnancies caused by ovulation induction for infertility, this may only reflect reporting bias.

Most of these are diagnosed antepartum by ultrasound findings of a complex, cystic placental component distinct from the fetoplacental unit. However, in a few cases, the diagnosis is not suspected until examination of the placenta after delivery. Medical complications of hydatidiform mole appear to be increased, including hyperthyroidism, hemorrhage, and pregnancy-induced hypertension.

Compared with singleton hydatidiform moles, twin pregnancy with a fetus and mole has an increased risk for postmolar GTN and a higher proportion of patients develop high-risk GTN requiring multiagent chemotherapy. In patients with a coexistent mole and fetus who continue pregnancy beyond 12 weeks, the subset that develop early complications leading to termination of the pregnancy before fetal viability has a markedly increased risk of postmolar GTN compared with patients whose pregnancy continues into the third trimester.

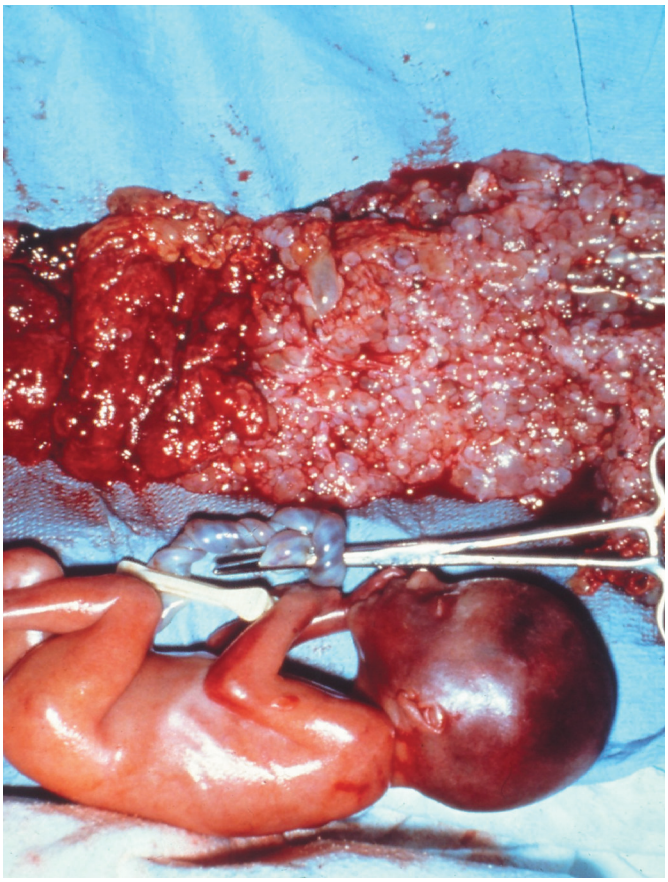

FIGURE 7.10 Gross photo of a fetus and mole.

Among 72 patients collected by a national survey of physicians in Japan, 24 patients underwent first-trimester evacuation with 20.8% subsequently developing postmolar GTN. In comparison, 45.2% of 31 patients who required evacuation during the second trimester and 17.6% of the 17 who delivered in the third trimester developed postmolar GTN (P <0.05). Nine (50%) of the 18 patients with proven androgenic mole in association with a fetus subsequently were treated for postmolar GTN, but this increased risk may have been a result of selection bias. Major congenital abnormalities have not been reported in surviving infants.

For patients with coexistent hydatidiform mole and fetus suspected by ultrasonography, there are no clear guidelines for management. Ultrasonography should be repeated to exclude retroplacental hematoma, other placental abnormalities, and degenerating myoma and to fully evaluate the fetoplacental unit for evidence of a PM or gross fetal malformations. If the diagnosis is still suspected and continuation of pregnancy is desired, fetal karyotype should be obtained, chest radiography should

be performed to screen for metastases, and serial serum hCG values should be followed.

Patients are at an increased risk for medical complications of pregnancy requiring evacuation, including bleeding, premature labor, and pregnancy-induced hypertension. They should be counseled about these risks and the increased risk of postmolar GTN after evacuation or second-trimester delivery. If fetal karyotype is normal, major fetal malformations are excluded by ultrasonography, and there is no evidence of metastatic disease, it is reasonable to allow the pregnancy to continue unless pregnancy-related complications force delivery. After delivery, the placenta should be histologically evaluated, and the patient should be followed closely with serial hCG values, as one would with a singleton hydatidiform mole.

GESTATIONAL TROPHOBLASTIC NEOPLASIA

GTN is defined by a plateaued, rising, or prolonged persistence of elevated hCG values after molar evacuation; histologic diagnosis of choriocarcinoma, invasive mole, PSTT, epithelioid trophoblastic tumor (ETT); or identification of metastatic disease after molar evacuation. Prompt diagnosis of malignant GTN is important because a delay in diagnosis may increase the patient's risk and decrease response to treatment. All patients with malignant GTN should undergo a complete evaluation aimed at identifying metastatic sites (Table 7.3) and other clinically important prognostic factors. Several classification systems have been used to determine prognostic groups and assist in the triage of management for individual patients. The FIGO revised its staging system for patients with malignant GTN in 2000 to reflect prognostic factors other than simple anatomic distribution of disease.

Diagnosis

Between half and two-thirds of cases of GTN that require treatment follow evacuation of CM or PM. Because these patients are treated on the basis of hCG levels rather than hysterectomy, the distribution of histologic lesions is not known.

TABLE 7.3 Distribution of Metastatic Sites From Gestational Trophoblastic Neoplasia

Metastatic Site	Number	(%)	(% Metastatic)
Nonmetastatic	195	54	
Metastatic	136	46

†Rising human chorionic gonadotropin after hysterectomy for hydatidiform mole, no identifiable metastases.
Modified from Soper JT, Clarke-Pearson DL, Hammond CB. Metastatic gestational trophoblastic disease: prognostic factors in previously untreated patients *Obstet Gynecol* 1988;71:338.

Whereas approximately 50% to 70% of patients with postmolar GTN have persistent or invasive moles, 30% to 50% have postmolar gestational choriocarcinoma.

Gestational choriocarcinoma (Fig. 7.11) derived from term pregnancies, spontaneous abortions, and ectopic pregnancies accounts for the vast majority of the other cases of malignant GTN. PSTT (Fig. 7.12) and ETT are rare forms of GTN that can follow any pregnancy event.

Invasive moles are characterized by the presence of edematous chorionic villi with trophoblastic proliferation that invades directly into the myometrium. Metastasis of molar vesicles may occur. Usually invasive moles undergo spontaneous resolution after many months, but they are treated with chemotherapy to prevent morbidity and mortality caused by uterine perforation, hemorrhage, or infection. Gestational choriocarcinoma is a pure epithelial malignancy, comprising both neoplastic syncytiotrophoblast and cytotrophoblast elements without chorionic villi (see Fig. 7.11). Gestational choriocarcinomas are highly malignant, and chemotherapy is indicated.

Placental site trophoblastic tumors are rare. These tumors are characterized by absence of villi with proliferation of intermediate trophoblast cells (see Fig. 7.12). The syncytiotrophoblast population observed in choriocarcinoma is lacking in PSTT, with relatively lower levels of intact hCG secreted by these tumors. In general, PSTTs are not as sensitive to chemotherapy. Fortunately, most patients present with disease confined to the uterus and can be treated with hysterectomy.

Women with postmolar GTN are usually diagnosed early in the course of disease by serial hCG monitoring. In contrast, patients with malignant GTN after nonmolar gestations traditionally presented with predominantly nongynecologic symptoms, including hemoptysis or pulmonary embolism, cerebral hemorrhage, gastrointestinal (GI) or urologic hemorrhage, or metastatic malignancy of an unknown primary site. The index

pregnancy event may have occurred years before presentation or may have been a subclinical spontaneous abortion. In a series from the NETDC, the presentation of choriocarcinoma after term gestation in the modern era (1996–2011) was compared with an earlier period (1964–1996). They found 30% of women in the modern era were asymptomatic and diagnosed by an incidental positive pregnancy test result or placental pathology compared with 2% in the previous time period ($P = 0.001$). The possibility of malignant GTN should be suspected in any woman of reproductive age who presents with metastatic disease from an unknown primary site or cerebral hemorrhage. Under these circumstances, the diagnosis is facilitated by a high index of suspicion that, coupled with serum hCG testing and exclusion of a concurrent pregnancy, confirms the diagnosis without need for tissue biopsy.

Before the development of effective chemotherapy, 10% of patients required hysterectomy after molar evacuation for the treatment of invasive molar pregnancy or choriocarcinoma. Other prechemotherapy reports indicated a mortality rate of more than 20% among patients with invasive mole. Since the development of chemotherapy, between 15% and 36% of patients in the United States are treated after molar evacuation based on inclusive hCG level criteria for initiating chemotherapy in an attempt to limit the morbidity and mortality caused by postmolar GTN. In contrast, Bagshawe and colleagues used very conservative hCG criteria to initiate chemotherapy and reported treating only approximately 8% of their patients after molar evacuation.

The pattern of hCG regression after evacuation of hydatidiform mole is most often used to make a diagnosis of postmolar GTN. After evacuation, most patients have an initial decrease in hCG levels and should be followed with serial hCG values every 1 to 2 weeks. Almost every series has treated patients on the basis of a confirmed hCG rise. In many studies, however, chemotherapy was initiated on the basis of an hCG level plateau of relatively short (<3 weeks) duration. Kohorn noted that 15% of his patients had hCG plateaus after molar evacuation that lasted at least 2 weeks followed by spontaneous regression without intervention. In a trial of actinomycin D, Schlaerth and colleagues observed that 25% of their patients had a substantial spontaneous decrease in hCG levels on the day that chemotherapy was initiated. Based on the correlation between hCG level and tumor burden, Kohorn has suggested an approach using shorter observation periods for patients with high hCG level plateaus but allowing longer periods of observation for those who have hCG plateaus at levels under 1000 mIU/mL.

In some studies, an additional criterion for initiating chemotherapy after molar evacuation has been persistence of hCG for an arbitrary length of time, ranging between 6 weeks and 6 months after evacuation. The initial reports of chemotherapy from the National Institutes of Health (NIH) used persistence of hCG for more than 60 days after molar evacuation as an indication for chemotherapy treatment. Many series have documented that persistence of hCG for more than 60 days after evacuation increases the risk for developing postmolar GTN. However, 60% to 64% of patients with delayed regression of hCG beyond 60 days will ultimately undergo spontaneous hCG regression, with no deaths in those who began therapy more than 60 days from molar evacuation. Furthermore, groups reporting from the United Kingdom, where care for GTD patients is centralized, follow patients with elevated hCG levels for up to 6 months without an increase in morbidity or mortality among those treated after this prolonged follow-up.

Lurain and colleagues from the John I. Brewer Trophoblastic Disease Center reported their experience with 738 patients with complete hydatidiform moles. In their study, 80.7% of patients had spontaneous regression of hCG values to normal, although only 65% had done so by 60 days. An additional 27.9% reached normal values during the next 110 days. Overall, 142 (19%) were treated with chemotherapy because of rising or plateauing hCG levels. Of these, 125 had invasive moles, and 17 had choriocarcinomas. Only 15% of the 142 treated patients, or 3% of the total, developed metastases outside of the uterus. Morrow and Kohorn treated a higher proportion of their patients (36% and 27%, respectively) using hCG criteria derived from regression curves compared with studies that use the individual patient's hCG regression pattern. It appears that use of hCG regression curves may result in treatment of more patients than necessary, and it did not prevent metastatic disease.

In an effort to provide uniformity to the diagnosis of postmolar GTN, the FIGO conducted workshops among members of the Society of Gynecologic Oncologists, International Society for the Study of Trophoblastic Disease, and International Gynecologic Cancer Society to formulate its current recommendations for evaluation and staging this disease. The current FIGO requirements for making a diagnosis of postmolar GTN are as follows (Table 7.4):

1. Four values or more of plateaued hCG (±10%) over at least 3 weeks: days 1, 7, 14, and 21
2. A rise of hCG of 10% or greater for 3 values or more over at least 2 weeks: days 1, 7, and 14

TABLE 7.4 Diagnosis and Evaluation of Gestational Trophoblastic Neoplasia

Diagnosis of GTN

After molar evacuation: four values or more of plateaued hCG (±10%) over at least 3 weeks: days 1, 7, 14, and 21

After molar evacuation: a rise of hCG of 10% or greater for three values or more over at least 2 weeks: days 1, 7, and 14

After molar evacuation: persistence of hCG beyond 6 months

The histologic diagnosis of choriocarcinoma, invasive mole, or PSTT

Metastatic disease without established primary site with elevated hCG (pregnancy has been excluded)

Evaluation of GTN

Complete physical and pelvic examination; baseline hematologic, renal, and hepatic functions

Baseline quantitative hCG level

Chest radiograph or CT scan of chest

Brain MRI

CT or MRI scan of abdomen and pelvis

CT, Computed tomography; *GTN,* gestational trophoblastic neoplasia; *hCG,* human chorionic gonadotropin; *MRI,* magnetic resonance imaging; *PSTT,* placental site trophoblastic tumor.

3. Histologic diagnosis of choriocarcinoma
4. Persistence of hCG beyond 6 months after mole evacuation

The level and duration for observation of the hCG plateau beyond 3 weeks would be determined at the discretion of the treating physician. Observation of hCG level plateau for longer than 3 weeks was permitted because this does not appear to have an adverse effect on survival.

Recently, laboratory assays for hyperglycosylated hCG have been found to be highly sensitive for differentiating active GTN or choriocarcinoma from inactive or "quiescent" GTD in patients with hCG level plateaus. These newer assays, developed by Cole and associates at the US hCG Reference Service at the University of New Mexico, may allow earlier diagnosis of postmolar GTN in the future.

The majority of centers in the United States treat patients if metastases are identified. In contrast, Bagshawe and colleagues in the United Kingdom followed patients with pulmonary nodules conservatively and based treatment decisions on hCG regression patterns. Although the overall results from this policy were excellent, outcome for patients with pulmonary metastases was not detailed. In the United States, where care is decentralized, identification of metastases is included as an indication for initiation of therapy.

"Phantom" Human Chorionic Gonadotropin

Rarely, women present with persistently elevated hCG levels but are subsequently found to have a false-positive hCG assay result, sometimes after receiving chemotherapy or surgery for presumed malignant GTN. Most patients with "phantom" hCG present with low-level hCG elevations, but occasionally values as high as 200 to 300 mIU/mL have been recorded. The false-positive hCG values result from nonspecific heterophile antibodies that interfere with the hCG immunometric sandwich assays. Many of these patients have an undefined previous pregnancy event and do not have radiographic evidence of metastatic disease. Serial hCG values usually do not substantially vary, despite prolonged observation, and do not substantially change with therapeutic interventions such as surgery or chemotherapy.

"Phantom" hCG may also present after evacuation of a hydatidiform mole or after a clearly defined pregnancy event, such as an ectopic pregnancy. It should be suspected if hCG values plateau at low levels and do not respond to therapeutic maneuvers such as methotrexate. Evaluation should include study of serum hCG using a variety of assay techniques at different dilutions of patient serum combined with a urinary hCG level if the serum level is above threshold for the urinary assay. Heterophile antibodies are not excreted in the urine. Therefore, if they are the cause of serum hCG level elevation, urinary hCG values will not be detectable. False-positive hCG assays are also not affected by serial dilution of patient sera and have markedly different values using different assay techniques, with the majority of assays reflecting undetectable hCG. Other techniques are available to inactivate or strip the patient's serum of heterophile antibodies, and many current assays now incorporate these techniques to reduce the incidence of false-positive results. It is important to exclude the possibility of "phantom" hCG before subjecting these patients to hysterectomy or chemotherapy for GTN.

The "Hook Effect"

Instead of being a false-positive test result such as a phantom hCG due to heterophile antibodies, the "hook effect" causes a false-negative hCG value. hCG immunoassays rely on a sandwich assay approach. A sandwich assay approach means that the hCG molecule binds to antibodies attached to a matrix and then additional free-floating "reporter" antibodies bind to the hCG attached to the matrix, and this sandwich of both antibodies on the same molecule is how the hCG level is measured. In the "hook effect," the assay is overwhelmed by very high levels of hCG, generally greater than 1,000,000 mIU/mL. The large number of hCG molecules bind not only to the antibodies on the matrix but to the reporter antibodies as well. Many fewer or no "sandwiches" are created, and the hCG result will either be falsely low or falsely negative. The "hook effect" can be overcome by serial dilution of the serum before using an hCG immunoassay, and this is standard practice in many laboratories; however, if a false-negative hCG is suspected, serial dilution of the patient's serum should be performed.

Pretherapy Evaluation

In contrast to epithelial endometrial cancer, GTN usually spreads by hematogenous dissemination. Venous metastasis can occur in the subvaginal venous plexus, resulting in vaginal metastases (Fig. 7.13), or in the main uterine venous system with metastases to the parametrium and lungs. Although direct shunting into the systemic circulation may occur, the majority of disseminated metastases develop only after pulmonary metastases have become established. The brain, liver, GI tract, and kidneys are the distant organs most often affected, but

FIGURE 7.13 Vaginal metastasis of malignant gestational trophoblastic neoplasia (GTN), presenting as vaginal bleeding with a discolored submucosal mass underlying the urethra. Vaginal metastases of GTN are highly vascular and should not be biopsied. (Courtesy of John Soper, MD.)

metastases to virtually every organ have been reported. Although lymphatic spread can occur, it is relatively uncommon. The hematogenous pattern of metastatic involvement is important when considering the radiographic evaluation of patients with GTN (see Table 7.3).

Pretherapy evaluation of the patient with GTN (see Table 7.4) includes assessment of history for clinical risk factors, examination, laboratory evaluation, and radiographic survey for potential sites of metastatic disease and number of lesions. Clinical risk factors important for assigning staging and treatment include duration of disease interval from antecedent pregnancy, type of antecedent pregnancy, and previous treatment. Because of different clinical characteristics, patients with histologically proven ETT and PSTT are classified separately from patients with gestational choriocarcinoma or postmolar GTN.

The laboratory evaluation should include a pretherapy hCG value. It should be emphasized that the hCG level obtained immediately before instituting treatment for malignant GTN is the one used for staging—not the hCG level obtained at the time of molar evacuation.

Vaginal metastases of GTN are diagnosed by physical examination. These lesions usually involve the mucosa of the anterior vagina and present as dark, often blue, soft nodules (see Fig. 7.13). Ulceration or active bleeding may be present. Because of the highly vascular nature of these lesions, biopsy is not recommended. If the vagina is the only site of metastasis, the majority of these lesions respond to chemotherapy. A few patients require vaginal packing or selective embolization using interventional radiology to control active hemorrhage.

The recommended radiographic staging evaluation for patients with GTN includes evaluation of the abdomen and pelvis with computed tomography (CT) or magnetic resonance imaging (MRI) and contrasted MRI of the brain. Ultrasonography of the pelvis should also be obtained to exclude the possibility of intrauterine pregnancy before instituting chemotherapy. Both ultrasound and MRI studies of the uterus can be used to identify intrauterine tumors and foci of myometrial invasion by GTN, but they are not sensitive or specific enough to replace serum hCG level monitoring for establishing the diagnosis of GTN or for following patients during treatment.

Approximately 45% of patients have metastatic disease when GTN is diagnosed. As indicated by the anatomic sites of metastatic disease encountered among patients initially treated for malignant GTN (see Table 7.3), the lungs are the most frequent site of extrauterine metastasis (Fig. 7.14). Although the majority of patients with high-risk metastatic sites have pulmonary metastases on chest radiograph or symptoms of metastatic involvement, a full metastatic evaluation is recommended for all patients rather than relying on a negative chest radiograph alone to make a determination of nonmetastatic GTN.

Between 29% and 41% of patients treated for nonmetastatic GTN have pulmonary metastases identified on chest CT that are not detected by chest radiography. The prognostic importance of occult pulmonary metastases is debated when they are the only sites of extrauterine metastases. However, many series of patients treated for high-risk metastases include patients who initially presented with normal chest radiographs. It would be a tragedy to miss the diagnosis of a high-risk metastasis in a patient and delay appropriate aggressive initial therapy.

Although operative procedures may be integrated into the treatment of patients with malignant GTN, they are rarely indicated for establishing the diagnosis or staging. Performing a secondary D&C before beginning chemotherapy in a patient with postmolar GTN is controversial. The experience at the University of Southern California indicated that it had an effect on the treatment in only 20% of patients and was complicated by uterine perforation requiring hysterectomy in 8% of patients. In contrast, Pezeshki and associates analyzed 544 women undergoing a second uterine evacuation for presumed postmolar GTN. After a second evacuation, 368 (68%) entered spontaneous remission. Of 251 patients with a histologic diagnosis of persistent GTD, 96 (38%) required chemotherapy compared with 39 (18%) of 219 with negative histology at the second D&C. A GOG study attempted to answer this question definitively. They prospectively enrolled 64 low-risk nonmetastatic GTN patients and performed a second curettage as initial management of GTN. Only preliminary results are currently available. The authors found that 38% underwent a surgical cure and did not need additional treatment, but 55% underwent progression. They observed one uterine perforation and one grade 3 hemorrhage. Four patients underwent transformation to a PSTT, which would have not been discovered without repeat curettage. The results of this study indicate that a surgical cure is possible but less likely than progression of disease and thus will likely not alter current practice patterns regarding repeat curettage. Many clinicians in the United States treat

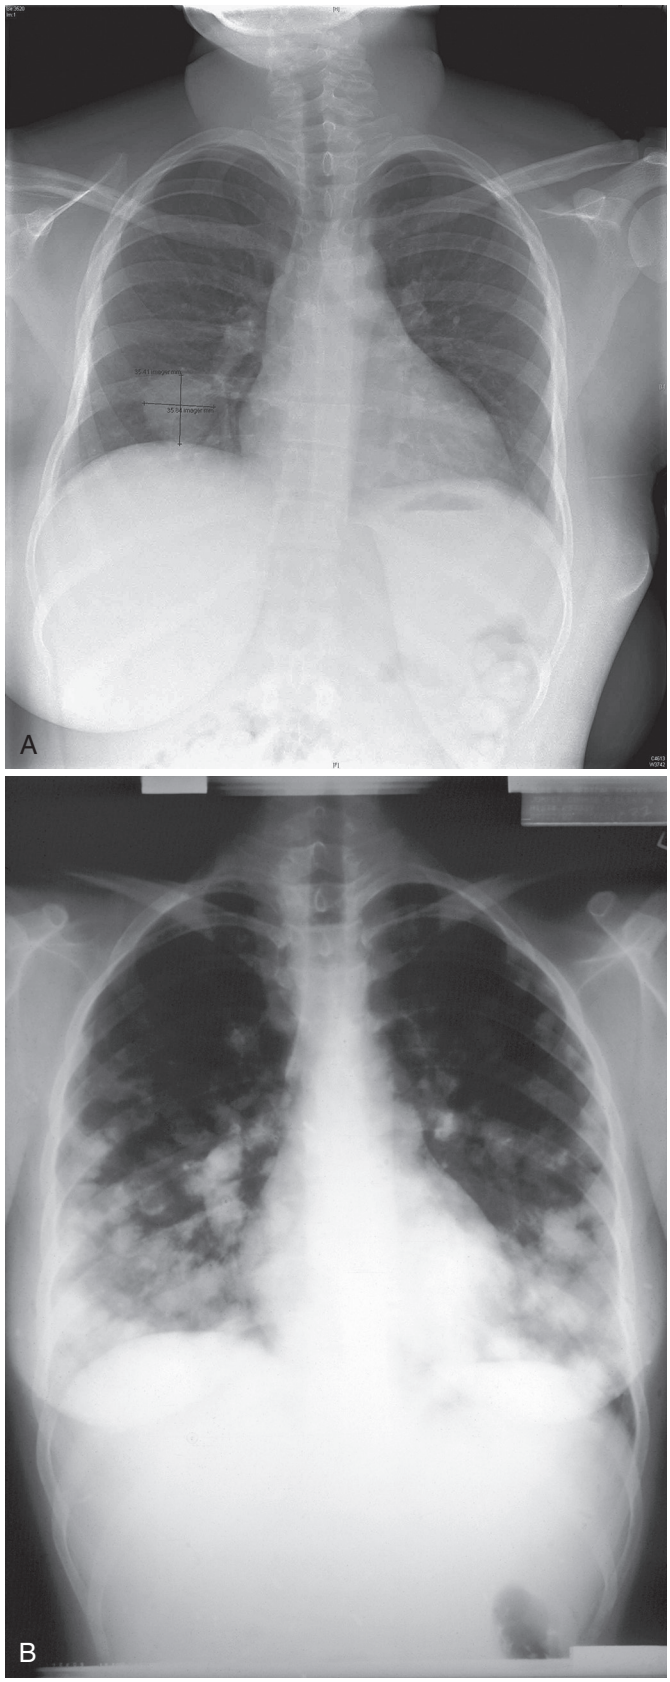

FIGURE 7.14 Pulmonary metastases of gestational trophoblastic neoplasia can present as solitary (**A**) or diffuse (**B**) pulmonary nodules. (Courtesy of John Soper, MD.)

TABLE 7.5 Clinical Classification System for Patients With Malignant Gestational Trophoblastic Neoplasia

Category	Criteria
Nonmetastatic GTN	No evidence of metastases; not assigned to prognostic category
Metastatic GTN	Any extrauterine metastases
Good-prognosis metastatic GTN	Short duration (<4 months) No brain or liver metastases Pretherapy hCG <40,000 mIU/mL No antecedent term pregnancy No prior chemotherapy
Poor-prognosis metastatic GTN	Any one risk factor: Long duration (>4 months) Pretherapy hCG >40,000 mIU/mL Brain or liver metastases Antecedent term pregnancy Prior chemotherapy

GTN, Gestational trophoblastic neoplasia; *hCG,* human chorionic gonadotropin.

patients with postmolar GTN without performing a second D&C because of the concern for preservation of fertility. Other operative procedures such as laparoscopy, thoracotomy, or craniotomy are rarely justifiable to establish the primary diagnosis of GTN.

Classification and Staging

The classification and staging of malignant GTN has evolved over the past 50 years. The Clinical Classification System, based on risk factors, was frequently used in the United States (Table 7.5). In this system, patients with nonmetastatic disease are not assigned into a prognostic group because of uniformly good outcome using simple single-agent chemotherapy. The risk factors used in this system were derived by retrospective analysis of resistance to single-agent methotrexate and actinomycin D regimens among women treated for metastatic GTN at the NIH. Hammond and colleagues subsequently reported essentially 100% survival among women who presented with good-prognosis metastatic GTN treated with single-agent therapy. He noted a survival rate of 70% among patients with metastatic poor prognosis disease initially treated with multiagent chemotherapy compared with only 14% survival for patients in this category who initially received single-agent therapy. Poor tolerance of multiagent therapy was noted in the group of poor-prognosis patients receiving initial single-agent regimens, with toxicity causing death in half of these patients.

A staging system was adopted by the World Health Organization (WHO) in the early 1980s based on the experience at the Charing Cross Hospital in London between 1957 and 1973. Bivariate analysis was used to identify prognostic factors among patients treated with predominantly single-agent chemotherapy regimens. In the original study, patient age, antecedent pregnancy, interval from antecedent pregnancy, hCG level, ABO blood type, size of the largest tumor, sites and number of metastases, and type of prior chemotherapy were each found to

TABLE 7.6 Prognostic Index Score Compared With Clinical Classification System*

Clinical Classification	Low Risk (<5)	Medium Risk (5–7)	High Risk (>8)	Total Clinical Classification
Nonmetastatic GTN	99.5% (217)	100% (10)	—	99.7% (227)
Metastatic GTN				
Good prognosis	100% (86)	100% (5)	—	100% (91)
Poor prognosis	100% (8)	90.5% (21)	68.4% (38)	79.1% (67)
Total WHO	99.8% (311)	94.4% (36)	68.4% (38)	

*Data presented as life table survival percentage (number of patients).

correlate with prognosis. The prognostic index applied a weighted score to each of these factors, which were assumed to act independently. The sum of component scores was then used to determine the individual patient's risk category.

Multivariate analyses have not confirmed that the factors have independent effects on prognosis. Paternal blood-type information is not uniformly available and was omitted in generating WHO score values by many investigators. Others modified the weighted scoring system using a highest risk score of 6 for each prognostic factor while not changing the total score for assigning patients into risk categories. Furthermore, the WHO prognostic index score provided for reassignment of a score among patients who have previously received treatment for GTN, which might obscure the prognostic effects of some of the other clinical factors on primary treatment. Finally, there was no uniformity in assessing size of the largest tumor or assigning number of metastases. Despite these limitations, modifications of the WHO prognostic index score were useful for predicting risk groups of patients with malignant GTN.

In Table 7.6, the Clinical Classification System and WHO prognostic index score are compared among patients who presented for initial treatment of GTN at Duke University Medical Center before 1990. The Clinical Classification System had a greater sensitivity for identifying patients at risk for treatment failure and death (see Table 7.6). Although the WHO prognostic index score was able to provide slightly better discrimination of patients with poor prognosis metastatic disease in low-, intermediate-, and high-risk populations, stratification into three categories was considered less important than identifying patients at risk of failure for initial therapy. Using multivariate analysis, both systems were roughly equivalent for stratifying patients into risk groups.

In the early 1980s, the FIGO proposed an anatomic staging system for malignant GTN (Table 7.7). Although this system recognized the stepwise development of metastatic disease, it did not incorporate any of the other prognostic factors into the FIGO stage. Although stage I patients uniformly had low-risk disease and stage IV patients had uniformly high-risk disease, there was considerable overlap of outcome within stages II and III. Revision of the FIGO staging in 1992 recognized hCG level and time from antecedent pregnancy as risk factors. These factors generated substages within each stage. Although this revised system did correlate with outcome, it resulted in a proliferation of substages, was confusing for clinicians, and is therefore of questionable importance.

TABLE 7.7 Anatomic International Federation of Gynecology and Obstetrics Staging System for Gestational Trophoblastic Neoplasia

Stage	Criteria
I	Disease confined to the uterus
II	Disease outside of uterus but is limited to the genital structures
III	Disease extends to the lungs with or without known genital tract involvement
IV	All other metastatic sites

Modified from Kohorn EI. The new FIGO 2000 staging and risk factor scoring system for gestational trophoblastic disease: description and critical assessment. *Int J Gynecol Cancer* 2000;11:73.

In 2000, the FIGO revised its staging system for GTN again. The original anatomic stages were retained, but the 1992 risk factors were replaced by a risk factor score that used a modification of the WHO prognostic index score (Table 7.8). Patients with histologically diagnosed PSTT and ETT were reported separately, reflecting the distinct tumor biology of these lesions. Changes to the WHO classification included elimination of ABO blood group risk factors and a change in the risk score for liver metastasis from 2 to 4, reflecting the worse prognosis for patients with liver metastasis. Radiographic staging studies were standardized. Finally, the three risk groups of the WHO prognostic index score were consolidated into two groups: low risk with a score of 6 or less and high risk with a score of 7 or greater. Hancock and colleagues retrospectively compared the outcomes of patients according to the risk score categories generated by the modified WHO prognostic index score and the proposed FIGO score. The consolidated risk categories generated by the FIGO score correlated better with outcome than did the modified WHO prognostic index score.

The current FIGO system counts and measures pulmonary metastases only if they are visible on chest radiograph. Other recommended studies include CT scan of the abdomen and pelvis, ultrasonography of the uterus, and MRI or contrasted CT scan of the brain. It is important to realize that the hCG level used to generate the risk score refers to the level recorded at the time GTN is diagnosed *rather than hCG at the time of*

TABLE 7.8 The Revised International Federation of Gynecology and Obstetrics 2000 Scoring System for Gestational Trophoblastic Neoplasia*

FIGO Score	0	1	2	4
Age (years)	<40	≥40		
Antecedent pregnancy	Hydatidiform mole	Abortion	Term pregnancy	
Interval from index pregnancy (months)	<4	4–6	7–12	≥13
Pretreatment hCG (mIU/mL)	<1000	1000–<10,000	10,000–100,000	≥100,000
Largest tumor size including uterus (cm)		3–5	≥5	
Site of metastases	<3	Spleen, kidney	Gastrointestinal	Brain, liver
Number of metastases identified	0	1–4	5–8	>8
Previous failed chemotherapy			Single drug	≥2 drugs

*The total score for a patient is obtained by adding the individual scores for each prognostic factor. Total score 0–6 = low risk; >7 = high risk.
From Kohorn EI. The new FIGO 2000 staging and risk factor scoring system for gestational trophoblastic disease: description and critical assessment. *Int J Gynecol Cancer* 2000;11:73.

molar evacuation. Under the new FIGO system, reporting of patients includes both anatomic stage and FIGO risk score. For example, a 30-year-old patient with nonmetastatic GTN diagnosed 5 months after molar evacuation with an hCG level of 8000 mIU/mL would be recorded as a FIGO stage I: 2. Likewise, a 40-year-old patient with index term pregnancy 7 months previously, hCG of 200,000 mIU/mL, 2 brain metastases, 10 lung lesions, and uterine tumor measuring 6 cm would be FIGO stage IV: 17.

Adoption of the current revision of FIGO staging for GTN will allow uniformity for evaluation and reporting of outcomes. With accumulation of data through FIGO, it is hoped that multivariate analysis can confirm or refute the prognostic importance of individual factors used to generate the risk scores. Although these changes are important on an international scale and are the standard for reporting results of treatment, they are of lesser importance for the practicing general obstetrician/gynecologist initially encountering patients with malignant GTN. For these clinicians, the most important decisions revolve around identification of patients who should be referred out of the community to a specialist for treatment of high-risk disease. Because the clinical classification system (see Table 7.5) is relatively simple, it may be the best system for use by the generalist for the purpose of appropriate referral.

Treatment of Nonmetastatic and Low-Risk Metastatic Gestational Trophoblastic Neoplasia

Primary remission rates of patients treated for nonmetastatic or low-risk GTN are similar using a variety of chemotherapy regimens (Table 7.9). Essentially all patients with low-risk GTN can be cured, usually without the need for hysterectomy. Randomized comparisons of all the regimens detailed in Table 7.9 have not been completed, and comparison of the results may not be valid because of slightly different criteria used to make the diagnosis of nonmetastatic GTN by different investigators. Patients with metastatic GTN who lack any of the clinical high-risk factors or have a total FIGO risk score of 6 or lower have low-risk disease and can be treated successfully with initial single-agent chemotherapy regimens.

Methotrexate 0.4 mg/kg/day given by intramuscular (IM) injection for 5 days, with cycles repeated every 12 to 14 days,

TABLE 7.9 Chemotherapy Regimens for Nonmetastatic and Low-Risk Metastatic Gestational Trophoblastic Neoplasia

Agent and Schedule	Dosage
Methotrexate*	
Weekly	30–50 mg/m^2 IM
5 day/every 2 weeks	0.4 mg/kg IM (maximum, 25 mg/day total dose)
Methotrexate–folinic acid rescue	Methotrexate 1 mg/kg IM, days 1, 3, 5, 7; and Folinic acid 0.1 mg/kg IM, days 2, 4, 6, 8
Every 2 weeks	
Methotrexate infusion–folinic acid	Methotrexate 100 mg/m^2 IV bolus; and Methotrexate 200 mg/m^2 12 hour infusion with 15 mg PO every 6 hours for four doses
Every 2 weeks	
Dactinomycin†	
5 day/every 2 weeks	9–13 mcg/kg/day IV (maximum dose, 500 mcg/day)
Bolus, every 2 weeks	1.25 mg/m^2 IV bolus
Etoposide‡	
5 day/every 2 weeks	200 mg/m^2/day PO

*Dose based on ideal body weight, maximum 2 m^2.
†Potential extravasation injury, gastrointestinal toxicity common.
‡Alopecia, small leukemogenic risk.
IM, Intramuscular; *IV,* intravenous; *PO,* oral.

was the regimen originally used to treat GTN at the NIH. Hammond and colleagues reported the NIH experience treating 58 patients with nonmetastatic GTN. Only four (7%) patients had disease resistant to this regimen, and three of these were salvaged with single-agent actinomycin D. In Lurain's series from the Brewer Trophoblastic Disease Center, all 337 patients with nonmetastatic GTN were cured using this regimen. Only 10.7% of 253 patients initially treated with 5-day IM methotrexate therapy required a second agent, only 1.2% needed multiagent chemotherapy, and only 0.8% required hysterectomy to achieve a complete remission. Factors significantly associated with the development of methotrexate

resistance included pretreatment serum hCG in excess of 50,000 mIU/mL, nonmolar antecedent pregnancy, and histopathologic diagnosis of choriocarcinoma. Others have used 5-day IM methotrexate, reporting similar results. If patients have abnormal liver function, methotrexate should not be used because it is metabolized in the liver. Significant hematologic suppression, cutaneous toxicity, mucositis, alopecia, GI toxicity, and serositis are frequently seen in patients receiving the 5-day methotrexate regimen.

Patients with low-risk GTN and metastasis have higher failure rates. DuBeshter and colleagues used single-agent methotrexate or actinomycin D to treat 48 patients with low-risk metastatic GTN at the NETDC. All patients achieved sustained remission, but 51% required a second drug, 14% needed combination chemotherapy, and 12% required surgery to remove drug-resistant disease. Among 52 patients with low-risk metastatic GTN treated initially with the 5-day methotrexate regimen at Duke University Medical Center, 60% achieved primary remission within a median three cycles of methotrexate chemotherapy. Patients were treated with actinomycin D for documented methotrexate resistance or toxicity with equal frequency. All patients achieved remission, with only 4% requiring multiagent regimens. Likewise, Roberts and Lurain treated 92 patients for low-risk metastatic GTN at the Brewer Trophoblastic Disease Center. Among their 70 patients who were initially treated with chemotherapy alone, 24.6% developed chemoresistant disease, and 9.8% had therapy changed because of toxicity. Overall, 78% achieved remission using the primary regimen with or without hysterectomy. However, all eventually achieved remission, and only one (1.1%) required multiagent chemotherapy.

Bagshawe and Wilde first reported the use of alternating daily doses of IM methotrexate (1 mg/kg) and leucovorin factor or folinic acid (0.1 mg/kg) for four doses of each agent in an attempt to reduce the toxicity of daily methotrexate regimens. Whereas toxicity sparing may be true for high doses of methotrexate, Rotmensch and colleagues evaluated methotrexate levels in patients after daily methotrexate therapy compared with levels in patients receiving alternating daily doses of methotrexate and folinic acid, with a higher daily dose of methotrexate given in the methotrexate–folinic acid regimen. They noted that whereas patients on the methotrexate–folinic acid regimen had higher peak methotrexate levels after treatment with the higher methotrexate dose, trough levels were both subtoxic and subtherapeutic 24 hours after methotrexate administration. This finding alone might explain the therapeutic and toxicity benefit described for the low-dose methotrexate–folinic acid regimen used for treatment in GTN.

At Charing Cross Hospital in London, 347 of 348 (99.7%) low-risk patients treated with methotrexate and folinic acid survived; however, 69 (20%) had to change treatment because of drug resistance, and 23 (6%) patients needed to change because of drug-induced toxicity. An analysis of the data from the Southeastern Trophoblastic Disease Center at Duke University indicated that 8 (27.5%) of 29 patients developed resistance to methotrexate with folinic acid given at 14-day intervals compared with 3 (7.7%) of 39 treated with standard 5-day methotrexate for nonmetastatic disease. Although this difference was statistically significant, a similar proportion of patients was changed to a second agent in each group because a larger number of patients receiving 5-day methotrexate changed therapy because of toxicity. Wong and colleagues also compared 5-day methotrexate with methotrexate with folinic acid, resulting in comparable sustained remission rates. In their series, however, patients who received methotrexate–folinic acid achieved remission earlier but experienced a higher incidence of hepatic toxicity compared with patients receiving the 5-day regimen.

McNeish and associates, reporting from the Charing Cross system, reviewed the results of 485 patients with low-risk GTN (prognostic index score <8, using their modification) treated with cyclical IM methotrexate–folinic acid, and the overall survival rate was 100%. Whereas two-thirds achieved remission with primary chemotherapy, 150 patients were changed to an alternative agent because of chemoresistance. In patients with chemoresistant disease and hCG levels less than 100 mIU/mL, therapy was changed to single-agent actinomycin D, with 89% responding to actinomycin D, and the remaining patients were salvaged with multiagent regimens. If hCG levels were greater than 100 mIU/mL, patients were treated with a multiagent regimen containing etoposide, with 98.9% responding to the first salvage regimen and all patients entering sustained remission.

Berkowitz and colleagues, at the NETDC, used IM methotrexate with folinic acid rescue in 185 patients with GTN. Ninety percent of 163 patients with nonmetastatic disease and 68% of 22 patients with low-risk metastatic disease were placed into complete remission with this regimen. Rather than recycling treatment at fixed intervals, they treated patients based on hCG level response. More than 80% were placed into remission with only one course of chemotherapy. All patients with methotrexate resistance achieved remission with other agents. Other investigators have used higher doses of IV methotrexate (300–500 mg/m^2) followed by oral or IV folinic acid every 6 hours for 24 hours, resulting in primary remission rates of 45% to 86% in patients with nonmetastatic or low-risk metastatic GTN. Overall cure rates in these series were excellent, and toxicity was minimal. A major disadvantage with these regimens is the need for a prolonged (up to 12-hour) IV infusion.

Oral methotrexate is readily absorbed via the GI tract. Barter reported a retrospective analysis of 15 patients treated solely with oral methotrexate 0.4 mg/kg for 5-day cycles that were repeated every 14 days. The primary remission rate was 87% with minimal toxicity. Concerns about patient compliance and the possibility of unpredictable absorption in individual patients have led to infrequent use for this mode of treatment in GTN.

In a prospective phase II trial, the GOG reported an 82% primary remission rate for patients treated with weekly IM methotrexate given at a dose of 30 to 50 mg/m^2. Remission was achieved within a median seven cycles of therapy. There was no apparent benefit for increasing the dose up to 50 mg/m^2. It was concluded that the weekly methotrexate regimen was most cost effective among several alternative methotrexate or actinomycin D schedules when taking efficacy, toxicity, and cost into

consideration. Hoffman and colleagues confirmed the low toxicity and overall remission rates for patients treated with this regimen. In the experience reported by Hoffman and colleagues, weekly methotrexate was compared with methotrexate–folinic acid, producing equivalent primary remission rates. Total doses of methotrexate required to induce remission were lower in the weekly methotrexate group. They also concluded that weekly methotrexate was minimally toxic and equally effective and is their preferred regimen for nonmetastatic GTN.

In contrast to IM methotrexate regimens used for treating ectopic pregnancies, chemotherapy for GTN is given every week until hCG values have achieved normal levels, and then an additional course is administered after the first normal hCG value has been recorded. Hematologic indices must be monitored carefully during chemotherapy, but significant hematologic toxicity is infrequent among patients treated with the weekly methotrexate regimen.

Other investigators have used 5-day courses of IV actinomycin D (9–13 mcg/kg/day) as primary therapy for nonmetastatic or low-risk GTN with equally good results. They believe that toxicity from 5-day actinomycin D is less than that from 5-day methotrexate regimens. However, alopecia, nausea, and significant myelotoxicity can result. Furthermore, extravasation of actinomycin D during administration can result in severe local soft tissue damage.

Treatment of nonmetastatic and low-risk metastatic GTN with actinomycin D (1.25 mg/m^2) given as a single IV bolus dose every 2 weeks, generally referred to as pulse or bolus actinomycin D, had equal remission rates in retrospective series to 5-day courses of IV actinomycin D. The GOG reported a phase II study of this regimen. Of 31 patients who were treated, 29 (94%) achieved remission after an average of 4.4 (range, 2–15) courses of therapy. The two patients who failed to respond to pulse therapy were subsequently cured by alternative treatment. The frequency of toxicity was quite low. The advantages of pulse actinomycin D over other treatment schedules include ease of administration, greater patient convenience, and improved cost effectiveness. Moreover, the single bolus administration appears to reduce the risk of extravasation injuries compared with 5-day IV administration.

Other investigators have alternated courses of 5-day IM methotrexate with 5-day IV actinomycin D in an attempt to limit toxicity and improve primary remission rates. Rose and Piver combined their experience using this approach in nine patients with a literature review of 40 patients treated in this manner. All patients were cured with primary therapy when the two regimens were alternated. However, given the relatively small numbers of patients and selectivity of reporting small series of patients in the literature, one cannot conclude that this strategy is superior to beginning therapy in patients with GTN using a single agent and changing to the alternative only if chemoresistance or toxicity is encountered.

Oral etoposide and 5-fluorouracil (5-FU) are frequently used in Asia for primary treatment of patients with nonmetastatic and low-risk metastatic GTN, but they are not often used in the United States. Among patients treated with a 10-day continuous IV infusion of 5-FU, Sung and colleagues reported a 93% primary remission rate. Acute toxicity included diarrhea, nausea and vomiting, hepatotoxicity, and stomatitis. Wong and colleagues reported a 98% primary remission rate among patients treated with 5-day courses of oral etoposide 100 mg/m^2, recycled at 14-day intervals. Toxicity included frequent alopecia, myelosuppression, and GI toxicity. Furthermore, patients exposed to etoposide have a low but significant risk of developing acute myelogenous leukemia. Based on considerations of convenience, cost, and toxicity, these agents are not usually used as initial therapy for low-risk GTN in the United States.

Few randomized trials have been conducted in patients with low-risk GTN. Lerkhachonsuk and colleagues randomly assigned 49 stage I low-risk patients to the 5-day IV actinomycin D or IM alternating methotrexate–folinic acid. Six women in the methotrexate arm required cross-over to actinomycin D because of rising liver function test (LFT) results. All 20 women in the actinomycin D arm achieved remission versus 14 (73.6%) in the methotrexate–folinic acid arm ($P = 0.02$). Whereas mucositis and alopecia were more frequent in the actinomycin D group, elevations of LFT results were more frequent in the methotrexate–folinic acid group.

Yarand and colleagues randomly assigned 131 women with FIGO low-risk GTN to pulsed weekly IM methotrexate (30 mg/m^2) versus biweekly IV bolus actinomycin D (1.25 mg/m^2). Primary remission rates were 48% versus 90% ($P < 0.01$), respectively. The mean number of treatment cycles needed to achieve remission was lower in the actinomycin D group (4.8 vs. 6.8). Toxicity was reported as low in each of the treatment arms.

A larger GOG phase three trial of weekly methotrexate versus pulsed actinomycin D in 240 women confirmed these results. Biweekly actinomycin bolus was superior to methotrexate in producing a complete response of 70% for the actinomycin arm and 53% for weekly methotrexate ($P = 0.01$). An increased FIGO risk score, increased hCG, and metastatic disease were associated with a higher primary failure rate.

The performance of 5-day methotrexate has also been compared with actinomycin D. A retrospective series by Mousavi reported on 75 women with low-risk GTN who received either actinomycin D or 5-day methotrexate. Complete response rates were 90% for actinomycin D and 68% for methotrexate ($P = 0.018$). However, the mean numbers of chemotherapy courses were 3.1 in the methotrexate group and 5.3 in the actinomycin group ($P = 0.01$). An ongoing GOG trial is examining pulse actinomycin D versus multiday methotrexate regimens to answer this question in a randomized fashion.

Among patients with nonmetastatic and low-risk GTN, early hysterectomy will shorten the duration and amount of chemotherapy required to produce remission. Therefore, each patient's desire for further childbearing should be evaluated at the onset of treatment. Hysterectomy may be performed during the first cycle of chemotherapy (Fig. 7.15). However, further chemotherapy after hysterectomy is mandatory until hCG values are normal.

Treatment for nonmetastatic and low-risk metastatic GTN is outlined in Table 7.10. Most centers in the United States begin

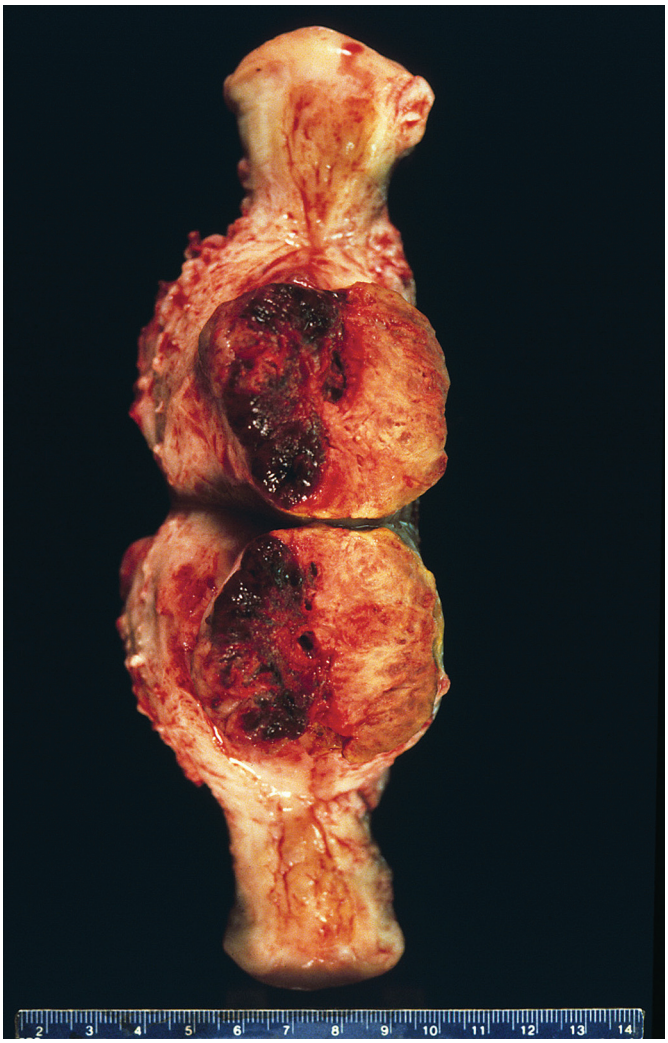

FIGURE 7.15 Hysterectomy specimen in a 39-year-old woman with nonmetastatic gestational trophoblastic neoplasia who underwent surgery during her first course of methotrexate. She entered complete remission 4 weeks after initial therapy. (Courtesy of John Soper, MD.)

TABLE 7.10 Management of Low-Risk Gestational Trophoblastic Neoplasia

Initiate single-agent methotrexate or dactinomycin regimen (see Table 7.9).
Consider hysterectomy if fertility is not desired.
Monitor hematologic, renal, and hepatic indices before each cycle of chemotherapy.
Monitor serum hCG levels weekly during therapy.
Change to alternative single-agent if resistance or severe toxicity to first agent.
If resistance to alternative agent:
1. Repeat metastatic evaluation
2. Consider hysterectomy if no extrauterine metastases
3. Multiagent therapy (MAC or EMA/CO; see text)
Remission: three consecutive weekly hCG values in the normal range
1 or 2 cycles of maintenance or consolidation chemotherapy

EMA/CO, Etoposide, methotrexate, actinomycin D, cyclophosphamide and vincristine; *hCG,* human chorionic gonadotropin; *MAC,* methotrexate, actinomycin D, and cyclophosphamide.

therapy with the bolus actinomycin D regimen or methotrexate. Weekly hCG values should be monitored during treatment, along with hematologic and metabolic studies to monitor for toxicity. Chemotherapy is repeated until hCG levels normalize, and at least one cycle of chemotherapy is given as maintenance chemotherapy to prevent recurrence. Reliable contraception should be used to prevent a new pregnancy during chemotherapy and hCG monitoring after remission. Again, consideration should be given to oral contraceptives given the effect of the LH surge on hCG assay measurement.

Patients for whom hCG levels have plateaued or are rising during therapy should be switched to an alternative single-agent regimen after radiographic restaging. If there are new metastases or failure of the alternative single-agent chemotherapy, the patient should be treated with a multiagent regimen. Hysterectomy should be considered for the treatment of disease that is refractory to chemotherapy and confined to the uterus.

The overall cure rate for patients with nonmetastatic and low-risk GTN approaches 100%. The majority of women who wish to preserve fertility can be cured without hysterectomy. When chemotherapy is given for an additional one to two cycles after the first normal hCG value, recurrence rates are less than 5%.

High-Risk Metastatic Gestational Trophoblastic Neoplasia

Patients with metastatic disease and one or more of the clinical classification system risk factors or a FIGO risk score of 7 or greater have high-risk disease. They require multiagent chemotherapy. It should be emphasized that patients with high-risk metastatic GTN should have their treatment directed by individuals who have experience in treating this relatively rare disease, preferably in a trophoblastic disease center. Survival in modern series is greater than 94%. In contrast to patients with nonmetastatic or low-risk metastatic GTN, early hysterectomy does not appear to improve the outcome in women with high-risk metastatic disease.

Aggressive treatment with multiagent chemotherapy is standard of care for high risk GTN. Triple therapy (Table 7.11) with methotrexate, actinomycin D, and either chlorambucil or cyclophosphamide (MAC) was the standard regimen for many years in the United States, producing sustained remission rates of 63% to 73%. Studies from the Southeastern Regional and the Brewer Trophoblastic Disease Centers in the 1970s documented the importance of initial combination chemotherapy for these patients; whereas single-agent regimens followed by multiagent chemotherapy produced only 14% to 39% remissions, patients with high-risk GTN treated initially with MAC chemotherapy had remission rates of 65% to 70%.

In the late 1970s, the Charing Cross group developed a complex, alternating regimen using cyclophosphamide, hydroxyurea, actinomycin D, methotrexate–folinic acid, vincristine, and doxorubicin (CHAMOCA). Sustained remissions were reported in 56% to 83% of patients with high-risk GTN using modifications of this regimen with an overall impression of reduced toxicity compared to MAC. However, when the GOG performed a randomized trial of MAC versus CHAMOCA, the

TABLE 7.11 Triple-Agent (MAC) Chemotherapy for High-Risk Gestational Trophoblastic Neoplasia

Day	Drug	Dose
1–5	Methotrexate	15 mg IM
	Actinomycin D	500 mcg IV
	Chlorambucil	8–10 mg PO
	OR	
	Cyclophosphamide	3 mg/kg IV
15–22	Begin next cycle

Evaluate for high-risk metastases: brain, liver, kidney.
Stabilize medical status of patient.
Multiagent therapy with EMA/CO (see Table 7.12) or MAC
- Aggressive recycling may require cytokine support.

Management of brain metastases (see text)
- Consider gamma knife radiation if isolated brain lesion.
- CNS-dosed methotrexate

Management of liver metastases (see text)
- Consider selective angiographic embolization.

Monitor hCG weekly during therapy.
- At least three cycles of maintenance chemotherapy after hCG values normalize

CNS, central nervous system; *EMA/CO,* etoposide, methotrexate, actinomycin D, cyclophosphamide and vincristine; *hCG,* human chorionic gonadotropin; *MAC,* methotrexate, actinomycin D, and cyclophosphamide.

primary remission rates were comparable at 73% and 65%, respectively. Of note, five of six patients who failed MAC were salvaged compared with only one of seven patients failing CHAMOCA. Perhaps initial exposure to marginally effective additional agents in CHAMOCA adversely affected the efficacy or tolerance of savage regimens. Furthermore, the CHAMOCA regimen had significantly more acute life-threatening toxicity, with a 45% incidence of grade 4 toxicity compared to only 9% with MAC (P <0.05).

More recent regimens have incorporated etoposide into primary combination chemotherapy for GTN. Alternating weekly chemotherapy (Table 7.12) with etoposide, methotrexate–folinic acid rescue, actinomycin D–cyclophosphamide, and vincristine (EMA/CO) was first developed by the Charing Cross group. Their initial report documented 86% survival rate for patients with high-risk GTN after primary treatment with EMA/CO. In their most recent series published in 2014, Agarwal and colleagues included 196 patients with high-risk GTN treated with EMA/CO between 1995 and 2010. The overall survival rate was 94% with a median follow-up of 4.7 years. Other smaller retrospective series have reported complete response rates of 65% to 94% among patients with high-risk GTN treated initially with EMA/CO. As a result of these reports, EMA/CO has become the most widely used regimen for treatment of patients with high-risk GTN.

Toxicity from EMA/CO includes universal alopecia and rare stomatitis and nausea and vomiting. Myelosuppression is often the acute dose-limiting acute toxicity. Several investigators have used stem cell support with granulocyte colony-stimulating factor to avoid dose reductions or treatment delays during EMA/CO therapy.

Platinum-containing regimens have also been found to be active in treating GTN. Cisplatin combined with etoposide and actinomycin D (PEA) demonstrated complete responses in 57% to 100% of patients with high-risk GTN. A 1-day course of cisplatin and etoposide (EP) was originally substituted for CO and combined with EMA to treat patients with refractory GTN. Surwit and Childers successfully treated four high-risk patients initially with EMA/EP, but concerns about acute toxicity have kept it from becoming widely accepted as primary therapy. It should be emphasized that MAC and EMA/CO are the two regimens that have been most extensively evaluated for the treatment of high-risk GTN (Table 7.13), but these have never been compared in a randomized trial. The majority of the literature for other regimens has been in the form of retrospective analyses of relatively small numbers of patients using slightly different definitions of "high-risk" GTN. Regardless of the regimen selected, aggressive recycling of multiagent therapy is the cornerstone for management of patients with high-risk disease (see Table 7.13).

Management of cerebral metastases is controversial. Radiation therapy has been used concurrently with chemotherapy in an attempt to limit acute hemorrhagic complications from these metastases. Brain irradiation combined with systemic chemotherapy is successful in controlling brain metastases, with

cure rates up to 75% in patients who initially present with brain metastases. However, a similar primary remission rate has also been reported among patients treated with combination regimens that incorporated high-dose systemic methotrexate combined with intrathecal methotrexate infusions without brain irradiation. It should be noted that at Charing Cross Hospital, whole-brain irradiation is not used, and a recent series reports an 85% prolonged remission rate using central nervous system (CNS) dosing of chemotherapy alone. They note that the cognitive complications from whole-brain radiation should be considered, especially in young patients, and recommend against whole-brain radiation given the similar rate of cure compared with whole-brain radiation series that they report in their study. Targeted gamma knife radiation is another tool that clinicians can use to treat brain metastases, although this is a relatively new technology and is not as well studied.

The best treatment for liver or other high-risk sites of metastases has not been established. Even with intense chemotherapy, additional surgery may be necessary to control hemorrhage from metastases, remove chemoresistant disease, or treat other complications to stabilize high-risk patients during therapy.

The Charing Cross group reviewed the role of induction low-dose etoposide-cisplatin in combination with EMA/CO chemotherapy. Patients with high-risk metastatic GTN have a high disease burden, and early deaths (<4 weeks from diagnosis) have been observed in response to initial multiagent chemotherapy. Therefore, Charing Cross instituted a policy of using low-dose induction chemotherapy with cisplatin (20 mg/m^2) and etoposide (100 mg/m^2) to minimize the overwhelming amount of cell death that patients experience upon chemotherapy initiation. They successfully significantly reduced the rates of early death when patients received induction EP to 0.7% versus 7.6% when patients were treated initially with EMA/CO alone.

Treatment of patients with high-risk GTN who have developed chemoresistant disease is extremely challenging and is largely determined by prior chemotherapy exposure and cumulative toxicity from prior treatment. Patients who have not been exposed to etoposide-containing regimens are usually treated with EMA/CO, with remission rates of 71% to 82% reported for this group in several studies. The Charing Cross group used EMA/EP to treat 34 high-risk patients previously exposed to EMA/CO, reporting remission rates of 95% in patients with hCG level plateau during EMA/CO compared to 75% for those with rising hCG levels. Myelosuppression is more severe in patients receiving regimens for salvage than when they are used as primary therapy.

Variations of combination regimens used in the treatment of testicular and ovarian germ cell tumors have been used as salvage therapy in patients with GTN. Etoposide–platinum (± bleomycin ± doxorubicin) and vinblastine–bleomycin–cisplatin have remission rates reported between 50% and 86% in a small series of patients treated with these regimens, but they have long-term survival rates of usually less than 50% and considerable myelosuppression when used in a salvage setting. Ifosfamide-containing chemotherapy produced responses in four of five patients reported by Sutton and colleagues, but only one patient had a sustained remission. Anecdotal case reports and small series of patients also indicate activity of paclitaxel regimens, high-dose chemotherapy with autologous bone marrow or colony-stimulating factor support, and 5-FU/actinomycin D in treating drug-resistant disease.

TABLE 7.14 Surveillance During and After Therapy of Gestational Trophoblastic Neoplasia

Monitor serum quantitative hCG levels every week during chemotherapy:
1. Response: >10% decline in hCG during 1 cycle
2. Plateau: ±10% change in hCG during 1 cycle
3. Resistance: >10% rise in hCG during 1 cycle or plateau for 2 cycles of chemotherapy
   - Evaluate for new metastases.
   - Consider alternative chemotherapy (see text).
   - Consider extirpation of drug-resistant sites of disease.

Remission: three consecutive normal weekly hCG values
1. Maintenance chemotherapy (see text)

Surveillance of remission:
1. hCG values every 2 weeks × 3 months
2. hCG values every month to complete 1 year of follow-up
3. Physical examination every 6–12 months for at least 3–5 years

hCG, Human chorionic gonadotropin.

Chemotherapy is continued until hCG values have normalized, and this is followed by at least three courses of maintenance chemotherapy in the hope of eradicating all viable tumor (Table 7.14). Despite using sensitive hCG assays and maintenance chemotherapy, up to 13% of patients with high-risk disease will develop recurrence after achieving an initial remission.

Surgery

Brewer and associates reported that the survival rates of patients treated with hysterectomy were 40% for women with nonmetastatic choriocarcinoma and only 19% for those with metastatic choriocarcinoma before effective chemotherapy was developed. The majority of their patients died of progressive disease within 2 years of surgery. The emergence of effective chemotherapy has lessened the importance of surgical procedures for primary management of malignant GTN. However, many procedures remain useful adjuncts when integrated into the management of these patients.

Primary or delayed hysterectomy can be integrated into management to remove central disease, and surgical extirpation of metastases may cure highly selected patients with drug-resistant disease. Surgical procedures are often required during therapy of patients with high-risk disease to treat complications of the disease, such as hemorrhage or abscess, and allow stabilization during chemotherapy. Percutaneous angiographic embolization can allow relatively noninvasive control of hemorrhagic complications of pelvic tumors or metastatic lesions.

Most patients with malignant GTN are in their peak reproductive years and do not wish sterilization. Furthermore, the majority can be cured with chemotherapy alone. Hammond and colleagues reported an overall 100% sustained remission

rate among 194 patients treated at Duke University Medical Center for nonmetastatic or low-risk metastatic GTN. Of these, 162 wished to retain fertility, and 89% were able to avoid hysterectomy. All 32 women treated with primary hysterectomy combined with methotrexate or actinomycin D single-agent chemotherapy regimens entered sustained remission.

Compared with similar patients who had low-risk disease and were treated with chemotherapy alone, patients receiving primary hysterectomy had shorter durations of chemotherapy and lower total dosage of chemotherapy, roughly equivalent to one cycle of chemotherapy. Suzuka and associates also analyzed the total dosage of chemotherapy in women treated with etoposide for low-risk GTN. They found that the total dosage of etoposide was decreased in women with nonmetastatic disease treated with adjuvant hysterectomy compared with those who were treated with chemotherapy alone, again roughly equivalent to a single cycle of chemotherapy. In other series, hysterectomy was incorporated into the primary therapy of approximately 25% of patients with low-risk GTN.

Primary adjuvant hysterectomy was not effective in reducing chemotherapy requirements or improving cure rates for women with high-risk GTN. These patients usually present with disseminated disease, and hysterectomy would be expected to contribute much less to reduction of tumor burden compared with patients with low-risk GTN. Therefore, the major role of primary hysterectomy should be as part of primary treatment for women with low-risk nonmetastatic GTN and no desire for future fertility.

Delayed hysterectomy is often considered for patients who fail to respond to primary chemotherapy. In the Duke experience reported by Hammond and colleagues, almost all of the patients with low-risk GTN who were treated with a delayed hysterectomy because of resistance to primary chemotherapy achieved remission without requiring multiagent chemotherapy. Others have reported that salvage hysterectomy is effective in producing remissions in most patients with nonmetastatic or low-risk metastatic disease. Control of extrauterine disease is central in the success of salvage hysterectomy for these patients.

Placental site trophoblastic tumor and ETT are much more rare than invasive mole or gestational choriocarcinoma. In contrast to other forms of GTN, production of hCG is lower, and these tumors are usually resistant to conventional chemotherapy regimens. Papadopoulos and colleagues noted that two-thirds of their patients were cured after surgery alone if PSTT was confined to the uterus. Hysterectomy should be integrated into the primary management of PSTT unless there are widespread metastases.

The majority of women undergoing hysterectomy for malignant GTN have been treated with abdominal hysterectomy, with or without preservation of the adnexa. Ovarian removal is not required because GTN rarely metastasizes to the ovaries, and these tumors are not hormonally influenced. Vaginal hysterectomy may be considered in women with nonmetastatic GTN who have a small uterus and low hCG levels, but it does not allow assessment of the upper abdomen for occult metastases. Laparoscopic-assisted vaginal hysterectomy or total laparoscopic hysterectomy allows surveillance of the upper abdomen and have a shorter acute convalescence than abdominal hysterectomy.

More conservative myometrial resections combined with uterine reconstruction can be considered in highly selected patients with nonmetastatic chemoresistant GTN who wish to avoid hysterectomy. Previous anecdotal reports of local myometrial resections of invasive moles have documented the use of resection and uterine repair for primary therapy of nonmetastatic GTN and PSTT. Because of the high cure rates reported after chemotherapy alone in low-risk GTN patients, it is more rational to consider these as salvage procedures in women with localized chemoresistant disease. Each patient considered for this procedure should be carefully evaluated for systemic metastases, and the uterine lesion should be localized using a combination of color-flow ultrasonography, MRI, and hysteroscopy. Intraoperative frozen sections should be used to assess surgical margins. Small lesions associated with low hCG levels are more likely to be completely excised with a conservative myometrial resection than lesions larger than 2 to 3 cm in diameter.

The most frequently used surgical procedure for removal of extrauterine metastases is thoracotomy with pulmonary wedge resection. Although this can safely be performed in conjunction with chemotherapy, it is not necessary to resect lung metastases in the majority of patients. Radiographic evidence of tumor regression often lags behind hCG response to treatment, and some patients have persistent pulmonary nodules months after completion of therapy. In women with low-risk GTN, the overall risk of recurrence is less than 5%. Even though women with persistent pulmonary nodules may be at an increased risk for recurrence, these patients can be safely followed with serial hCG levels without surgical resection.

Many series of patients with GTN treated with thoracotomy include patients whose disease was not suspected until after resection of a pulmonary nodule. As in the case of brain, liver, or renal metastases, any woman of reproductive age who presents with an apparent metastatic malignancy of unknown primary site should be screened for the possibility of GTN with a serum hCG level. Excisional biopsy is not indicated to histologically confirm the diagnosis of malignant GTN if the patient is not pregnant and has a high hCG value. Given the vascular nature of these lesions, biopsy can have significant morbidity.

Resection of pulmonary nodules in highly selected patients with drug-resistant disease may successfully induce remission. Immediately before performing pulmonary resection, it is important to exclude the possibility of active disease elsewhere by performing a comprehensive metastatic survey. Patients with isolated, unilateral nodules associated with low hCG values are much more likely to benefit from thoracotomy with pulmonary resection than patients with bilateral or multiple unilateral lesions or those with disease in other locations. Tomoda and colleagues reported that 14 (93%) of their 15 patients with isolated nodules and low hCG values survived after pulmonary resection compared with none of four patients with either hCG values greater than 1000 mIU/mL or evidence of active disease elsewhere. Others have reported that hCG level remission within 1 to 2 weeks of surgery portends a favorable outcome.

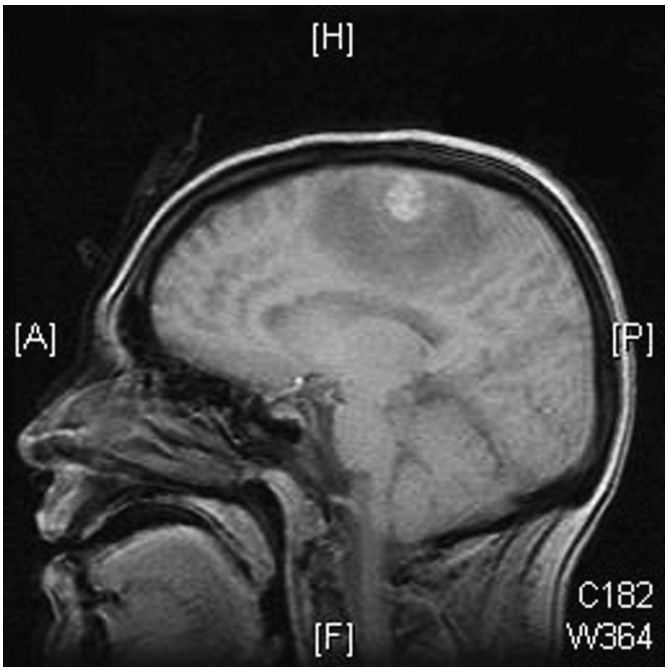

FIGURE 7.16 Brain magnetic resonance image of a patient presenting with high-risk metastatic gestational trophoblastic neoplasia, pulmonary metastases, and seizures associated with a solitary brain metastasis. She is in remission after surgical resection of this brain lesion during her first cycle of chemotherapy followed by multiple cycles of chemotherapy with high-dose methotrexate combinations, platinum–taxane, and hysterectomy. (Courtesy of John Soper, MD.)

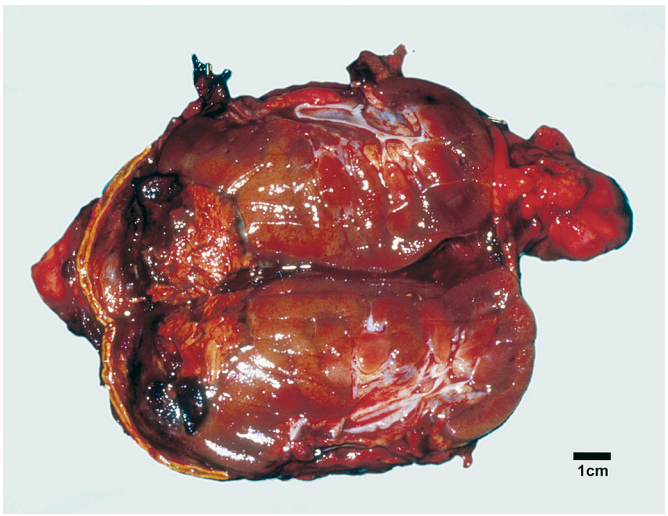

FIGURE 7.17 Nephrectomy specimen with a large hemorrhagic metastasis of choriocarcinoma involving the superior pole. (Courtesy of John Soper, MD.)

Brain metastases (Fig. 7.16) occur in 8% to 15% of patients with metastatic GTN and are associated with a worse prognosis than vaginal or pulmonary metastases. Metastases from GTN tend to be highly vascular and have a tendency for central necrosis and hemorrhage. A significant portion of early deaths is caused by CNS metastases of GTN with acute neurologic deterioration before effective therapy is initiated or very early in the course of treatment. The major goals of treatment include early detection of brain metastases through complete radiologic metastatic survey, stabilization of the patient's neurologic status, and initiation of therapy. Craniotomy solely for the purpose of tissue confirmation is not justified if GTN is clinically diagnosed on the basis of metastatic disease associated with an elevated hCG level.

In series of patients with brain metastases of GTN reported from the United States, brain irradiation has usually been integrated into treatment in an attempt to prevent hemorrhage and neurologic deterioration. However, Rustin and colleagues recommended an approach using early craniotomy with excision of isolated lesions combined with high-dose systemic and intrathecal chemotherapy to treat patients with brain metastases. In their experience, brain irradiation was not used routinely. Both primary radiation therapy combined with chemotherapy and the approach emphasizing early surgical intervention appear to have similar efficacy in previously untreated patients. More recently, a series from Charing Cross reported on their results using high dose methotrexate chemotherapy within EMA/CO and EMA/EP regimens and no brain radiation or initial surgical resection. They reported an 85% overall survival rate for these patients and caution against the long-term cognitive complications from whole-brain radiation and intrathecal methotrexate. In sharp contrast to the outlook for women with brain metastases from other solid tumors, up to 85% of women with brain metastases presenting for primary therapy from malignant GTN will be cured. Craniotomy for resection of drug-resistant brain lesions is only rarely performed. In these patients, it is important to exclude active disease elsewhere before attempting surgical resection. Sometimes craniotomy is required for women who require acute decompression of CNS hemorrhagic lesions to allow stabilization and institution of therapy.

Surgical removal of metastatic disease at other sites is occasionally beneficial for primary or salvage therapy of malignant GTN. Because PSTT and ETT are more often resistant to conventional chemotherapeutic agents, multiple surgical resections of metastatic sites may be required in highly selected patients to produce a cure. In general, resection of distant metastases is unlikely to be successful if there is evidence of disseminated disease resistant to chemotherapy.

Vaginal metastases of malignant GTN are highly vascular, originating via metastasis through the submucosal venous plexus of the vagina. These should not be biopsied or resected unless they represent the only site of drug-resistant disease. Biopsy of a metastatic vaginal lesion often results in massive hemorrhage. Packing or angiographic localization with selective embolization is usually used in an attempt to control bleeding from vaginal metastases during initial therapy.

Renal metastases occur in 1% to 20% of patients treated for metastatic GTN. They are usually associated with other high-risk factors and disseminated disease. All three survivors with renal metastases treated at Duke University Medical Center had nephrectomy incorporated into initial therapy (Fig. 7.17);

however, three of the five fatalities also underwent nephrectomy. Survivors had limited metastatic involvement elsewhere compared with patients with renal metastases who died. The role for nephrectomy appears limited because others have reported patients with high-risk metastatic GTN involving the kidneys who entered remission after treatment with etoposide-containing chemotherapy regimens alone.

Fewer than 5% of patients with metastatic GTN have initial involvement of other intraabdominal organs or the GI tract. Liver metastases are the most common intraabdominal metastases. The overall survival rate for these patients is as high as 55% when they receive EMA/CO chemotherapy. Occasional patients will develop intraabdominal bleeding from metastatic disease that requires resection for stabilization. Selective angiographic embolization techniques should be considered as an option if possible. Only rarely will resection of isolated liver metastases be feasible for treatment of drug-resistant disease because most patients will have other sites of active disease or diffuse involvement of the liver.

With the development of advanced interventional radiology techniques, selective angiographic localization and embolization techniques have been used to conservatively manage hemorrhage from active sites of metastatic GTN and to treat intrauterine arteriovenous malformations (AVMs) that rarely develop after treatment of GTN. Vaginal metastases are the site of active disease most often treated with selective angiographic embolization, when simple packing or suturing techniques have failed to control hemorrhage. Grumbine and colleagues managed a patient with liver metastases with the prophylactic placement of a catheter in the hepatic artery for balloon occlusion or embolization in the event of rupture, and others have successfully used selective embolization to treat hemorrhage from hepatic metastases. Lang used selective catheter placement for chemoembolization in three patients with liver metastases and two with pelvic tumors from GTN. All had chemoresistant GTN and relatively localized persistent tumors. Two of the patients with liver metastases achieved long-term remissions, with minimal hematologic toxicity recorded during treatment.

Angiographic abnormalities in the uterus caused by GTD can persist for many months after evacuation of hydatidiform mole or treatment of malignant GTN. The occurrence of intractable bleeding from intrauterine AVM after successful treatment for GTD is a relatively rare complication. Lim and colleagues reported 14 patients treated over a 20-year interval with selective angiographic embolization for this indication. Hemorrhage was initially controlled with the first procedure in 11 (78%), and six (45%) patients required a second embolization for treatment of recurrent bleeding, but only two (15%) patients required hysterectomy. Successful term pregnancies have been reported after this procedure.

Radiation Therapy

Radiation therapy has a limited role in the management of patients with malignant GTD. Radiation is used most frequently to treat patients with brain or liver metastases in an effort to minimize hemorrhagic complications from disease at these sites.

Brace first reported control of brain metastases using 2000-cGy whole-brain irradiation for patients with GTN treated at the NIH with single-agent regimens. He reported five (24%) survivors among 21 patients treated for brain metastases; three required retreatment for recurrent symptoms of intracranial disease. Whole-brain irradiation has been used in the majority of series of patients with brain metastases reported from the United States. Most series report administration of between 2000 and 4000 cGy in 10 to 20 equal fractions that are given concurrently with combination chemotherapy, with reduced field boosts given in selected patients. Total doses correlate with control of CNS metastases. Schecter and colleagues reported that the 5-year actuarial local control rate for patients given doses less than 2200 cGy was only 24%, significantly worse than 91% local control among patients given 2200 to 6000 cGy.

Survival rates of 50% to 75% are reported in series of patients who initially presented with brain metastases and received combined chemoradiation. Survival of these patients is influenced in part by the extent and subsequent control of extracranial disease in addition to the extent of CNS involvement. Small and colleagues reported that women who were asymptomatic at presentation had a 100% survival rate compared with only 38% survival rate in those who presented with symptoms from brain metastases, a significant difference. Evans and associates reported that patients with new brain metastases diagnosed at the time of recurrence or who developed brain metastases during chemotherapy had survival rates of only 38% and 0%, respectively. These groups had significantly worse survival than the 75% survival rates of their patients who presented with brain metastases for primary therapy.

Chronic central nervous system toxicity such as mental retardation has been reported among long-term survivors of leukemia and other tumors treated with a combination of whole-brain irradiation and concurrent moderate-dose methotrexate regimens. These reports have diminished the enthusiasm for combining whole-brain radiation with chemotherapy regimens that incorporate infusions of 300 to 1000 mg/m^2 of methotrexate used to treat GTN, such as EMA/CO. Stereotactic treatment of individual brain metastases could be considered in these circumstances. A 6- to 12-hour infusions of methotrexate greater than 500 mg/m^2 result in therapeutic cerebrospinal fluid levels of methotrexate, suggesting that doses of methotrexate in these ranges should be used when whole-brain radiation is not used. The group at Charing Cross Hospital reported 85% survival for patients who received primary therapy with this approach.

Hepatic metastases are identified in 2% to 8% of patients presenting for primary therapy of malignant GTN (Fig. 7.18). Involvement of the liver constitutes a poor prognostic factor, as evidenced by survival rates of 40% to 55% for women with primary liver involvement and dismal survival rates for those who develop new liver metastases during therapy. These are highly vascular and tend to produce catastrophic intraabdominal hemorrhage. In an attempt to minimize this risk, patients treated at Duke University Medical Center for liver metastases received approximately 2000-cGy whole-liver irradiation concurrently with MAC chemotherapy. Administration of

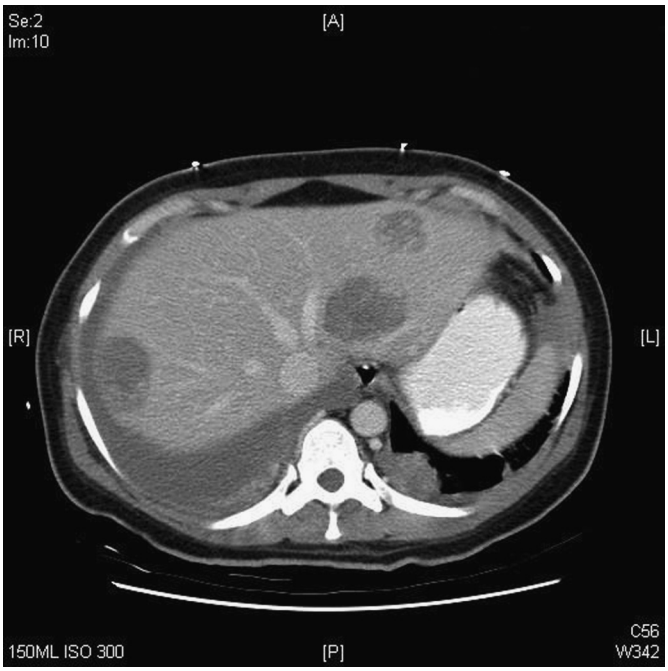

FIGURE 7.18 Multiple liver metastases in a woman presenting less than 4 weeks after term delivery with lung, brain, and liver metastases of gestational trophoblastic neoplasia. Selective hepatic arterial embolization was required to control bleeding from the hepatic metastases; note the fluid density around liver from intraabdominal blood. This patient was treated aggressively with multimodality therapy and placed into remission. (Courtesy of John Soper, MD.)

chemotherapy was limited in only one of 15 patients because of hepatitis, but the survival rate was very poor among these patients, with only two (13%) survivors overall and no survivors among patients who developed liver metastases during therapy. Bakri and colleagues reported survival in none of their patients who were treated with MAC combined with whole-liver radiation compared with survival in five of eight patients who were treated with etoposide-based combination regimens. Modern series have reported survival of approximately 55% among patients treated with etoposide-based regimens without hepatic irradiation. Thus, liver radiation is not used in management of GTN.

Radiation therapy is occasionally administered to other sites of disease in an attempt to treat drug-resistant foci, with anecdotal responses to multimodality therapy. However, the overall efficacy of radiation therapy to sites other than the brain is unclear. Most of the successes probably reflect the summation of an aggressive multimodality approach to individual patients with high-risk metastatic GTN.

It must be emphasized that cure rates of greater than 90% for patients with high-risk metastatic GTN are reported from centers that specialize in the treatment of women with this relatively rare malignancy. Patients with high-risk disease present multiple challenges for management. They often require a highly individualized approach to address the extent of their disease and treatment toxicity. All women with high-risk disease should be treated by physicians experienced in the management of patients with GTN who can coordinate all aspects of therapy.

Placental Site Trophoblastic Tumor

This rare tumor has the potential to metastasize and cause death. Approximately 100 cases have been reported in the literature. It may be diagnosed after abortion, mole, or normal pregnancy. Bleeding, the most common symptom, can appear shortly after termination of pregnancy or years later. Bleeding is often accompanied by uterine enlargement, and the diagnosis of pregnancy is often entertained. The result of a pregnancy test may be positive, but these tumors characteristically produce lower levels of intact hCG than other forms of GTD. Gross uterine findings may vary from a diffuse nodular enlargement of the myometrium, which is usually well circumscribed, to a large polypoid projection into the uterine cavity with involvement of the myometrium. Invasion may extend to the serosa or even with direct extension to the adnexa. Microscopically, it is difficult to differentiate from benign trophoblastic infiltration. PSTT is characterized by mononuclear infiltration of the uterus and its blood vessels with occasional multinucleated giant cells. The predominant cell is an intermediate trophoblast with large polyhedral cells and pleomorphic nuclei. Occasionally, syncytial trophoblast giant cells are present. Mitotic counts have not been a reliable prognostic factor.

Placental site trophoblastic tumors must be distinguished from choriocarcinoma and can occasionally be interpreted as sarcomas. Histochemical stains for human placental lactogen are usually diffusely positive but only focally positive for hCG. The serum hCG, although elevated enough to give a positive pregnancy test result, is often low, even with metastasis; therefore, it is a poor predictor of prognosis. Free beta-chain hCG may have elevated levels, but these are not routinely measured with current hCG assays. Most of these tumors behave in a locally aggressive fashion, although they may metastasize, with at least 20 deaths reported, indicating approximately a 15% to 20% mortality rate. Metastases have been reported at various sites. Some patients may be cured with a D&C only, but a hysterectomy is considered optimal therapy and is usually adequate in most situations. Swisher and Drescher reported a complete response to EMA/CO in a patient with metastasis to lung and vagina. In their review, two of seven patients treated with EMA/CO had a complete response.

In a review by Chang and associates of 88 patients with placental site tumor, 58 of 62 patients with FIGO stage I and II survived and were treated mainly with a hysterectomy with or without chemotherapy. Apparently, 9 of 10 patients survived after a D&C alone. Only 7 of 21 patients with stage III or IV disease survived. All received chemotherapy, and only six received a hysterectomy. Leiserowitz and Webb reported a patient whose tumor was localized with ultrasonography and MRI and treated with local excision and uterine reconstruction. Surgical-free margins were present, and the patient has had three subsequent pregnancies, including two spontaneous abortions and one term delivery.

Epithelioid Trophoblastic Tumor

Epithelioid trophoblastic tumor is a very rare form of GTN. The first report describing this tumor was published in 1998. The

tumor is characterized histologically by a nested, corded, and nodular growth pattern that is normally not deeply invasive and differentiates it from PSTT. ETT is similar to PSTT in that it grows slowly, is resistant to chemotherapy, and produces low levels of hCG. The tumors often present in the lower uterine segment and often have positive staining for p63 and cytokeratin, causing them to be confused with squamous cell carcinoma of the cervix. Surgery in the form of hysterectomy is the mainstay of treatment for ETT, and most patients who present with disease confined to the uterus alone will be cured with hysterectomy alone. The mortality rate from ETT is low with one series reporting a 13% mortality rate with a range of 1 to 39 months of follow-up.

OTHER CONSIDERATIONS

Future Childbearing

After effective treatment for malignant GTN, molar pregnancies occur in only about 1% to 2% of subsequent pregnancies, and many patients have subsequently had normal gestations without difficulty (Table 7.15). Because of the increased risk for the development of a mole in subsequent pregnancies, it is reasonable to evaluate these pregnancies with first-trimester ultrasonography. A particular dilemma has been noted in women undergoing ovulation induction after previous molar gestations. In such cases, patients have occasionally developed repeated hydatidiform moles or malignant GTN subsequent to the implementation of assisted reproductive technologies. In one such patient, in vitro fertilization (IVF) of oocytes retrieved showed a significantly high incidence of abnormal fertilization, resulting in the development of triploid embryos. The authors suggested the possible association of an oocyte defect predisposing to abnormal fertilization resulting in the high incidence of triploid embryos. Investigators have proposed the use of intracytoplasmic sperm injection (ICSI) with preimplantation genetic diagnosis or donor oocyte IVF as therapeutic alternatives in these cases.

It appears that the pregnancy outcomes in women with a history of molar gestations are no different from the outcomes in women who have no such history with respect to term live births, first- and second-trimester abortions, anomalies, stillbirths, prematurity, and primary cesarean section rate (Table 7.15). For women with prior molar gestations, subsequent pregnancy outcome appears similar irrespective of whether the mole is complete or partial.

Treatment of malignant GTN with chemotherapy is compatible with the preservation of fertility and is not associated with an increased risk of congenital malformations. Ayhan and colleagues from Turkey reported on 49 women who had received chemotherapy for GTN and subsequently became pregnant a total of 65 times with 42 (64.7%) term births and three (4.6%) molar pregnancies. No congenital malformations or obstetric complications were observed. Of the 63 patients in the Southeastern Trophoblastic Center study of poor prognosis metastatic GTN, only 19 were able to preserve their reproductive capacity. Only four of these patients had subsequent pregnancies that resulted in one spontaneous abortion and four normal deliveries. In a recent study from the NETDC, an increased risk of still birth in future pregnancies was noted for patients who received chemotherapy for treatment of GTN; however, the overall risk remained low for this group at 1.3%.

In the Charing Cross experience of women treated with EMA/CO, 56% of women who were in remission for at least 2 years and had fertility-conserving therapy achieved pregnancy after completing EMA/CO. At the time of the report, there were 112 live births, including three babies with congenital abnormalities. Woolas and colleagues updated the outcome data of posttreatment reproductive intent and outcome from 1121 GTN survivors. Of 728 women who had tried to become pregnant, 607 reported at least one live birth, 73 conceived but had not registered a live birth, and 48 did not conceive. No differences were apparent among the 392 women who received methotrexate as single-agent chemotherapy and the 336 treated with multiple-agent chemotherapy. Women who had registered a live birth were significantly younger. They concluded that standard chemotherapy protocols in the treatment of malignant GTN have minimal impact on the subsequent ability to reproduce.

TABLE 7.15 Fertility After Treatment for Gestational Trophoblastic Neoplasia

Desired fertility	109/122 (89%) patients	
Reproductive Outcome		
Infertility	62/109 (57%) patients	
Pregnancies	47/109 (43%) patients	57 pregnancies
Normal infants		45*/57 (79%)
Spontaneous abortion		7/57 (12%)
Therapeutic abortion		3/57 (5%)
Mole		2/57 (4%)

*Two sets of twins.

Modified from Hammond CB, Weed JC Jr, Currie JL. The role of operation in the current therapy of gestational trophoblastic disease. *Am J Obstet Gynecol* 1980;136:844-858.

Coexistence of Normal Pregnancy and Gestational Trophoblastic Neoplasia

Rare cases of metastatic GTN coexisting with normal gestations have been reported; some have been treated successfully with delivery and subsequent chemotherapy. In one case, a patient with a normal intrauterine pregnancy of 27 weeks' gestation had a coexisting pulmonary metastatic choriocarcinoma. Treatment with single-agent methotrexate during pregnancy resulted in favorable outcomes for both the mother and the child.

Transplacental Fetal Metastases

Rare cases (only 15 to 20 cases have been reported and only five since 1990) of maternal GTN metastatic to the fetus have been described. The diagnosis of widely metastatic disease in the delivered neonate may occur in the absence of metastatic GTN in the mother (found only in retrospective examination of the term placenta) or precede diagnosis of metastatic GTN in the mother.

Survivorship Issues After Successful Treatment of Gestational Trophoblastic Neoplasia

Survivors of nonmalignant and malignant GTN may be at risk for unique physical and psychosocial problems. This generally relates to the increased risk of developing secondary malignancies after treatment with agents such as etoposide and to issues related to reproductive capacity.

Rustin conducted a population-based study in the United Kingdom analyzing the incidence of secondary malignancies after successful treatment of malignant GTN. Using a sophisticated epidemiologic design, an overall 50% excess of risk (relative risk [RR], 1.5; 95% CI, 1.1–2.1; P <0.011) was observed. The risk was significantly increased for myeloid leukemia (RR, 16.6; 95% CI, 5.4–38.9), colon (RR, 4.6; 95% CI, 1.5–10.7), and breast cancer (RR, 5.8; 95% CI, 1.2–16.9) when the survival exceeded 25 years. The risk was not significantly increased among the 554 women who received single-agent therapy (RR, 1.3; 95% CI, 0.6–2.1). Leukemias only developed in patients who received etoposide plus other cytotoxic drugs.

Savage and coworkers conducted a survey of all patients treated at Charing Cross Hospital between 1958 and 2000 and obtained data for 1903 patients. They found significantly increased risks of leukemia, melanoma, meningioma, and oral cancer among survivors who received EMA/CO but no increased risk of malignancy among patients who received single-agent methotrexate and folinic acid. They also found no difference in rates of early menopause for patients receiving methotrexate but increased rates of early menopause among patients receiving EMA/CO reaching 13% at 40 years old and 36% at 45 years old.

Wenzel and colleagues reported on 76 women with GTN from the New England Trophoblastic Disease Center in regard to chronic psychosocial effects. Across all levels of disease, they found that patients with GTN experience clinically significant levels of anxiety, anger, fatigue, confusion, and sexual problems and are significantly affected by pregnancy concerns for protracted periods.

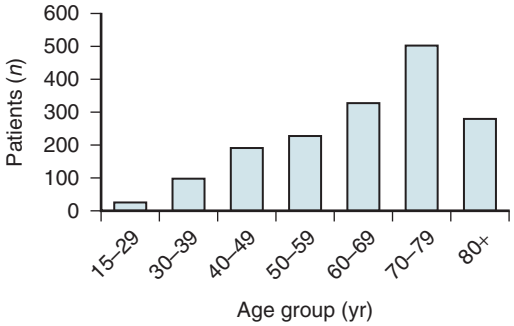
Basal Cell Carcinoma



KEY POINTS

1. Invasive vulvar cancer is a relatively rare tumor, accounting for 4% of all female genital malignant neoplasms.
2. Squamous cell carcinoma of the vulva develops by human papillomavirus- (HPV-) dependent and HPV-independent pathways.
3. Sentinel lymph node biopsy represents the largest innovation in the care of vulvar cancer patients in the past decade.
4. The standard of care is pelvic lymph node irradiation for patients with positive inguinal nodes.
5. Recurrence may be local or distant, and more than 80% will occur in the first 2 years after therapy, demanding initial close follow-up.

Invasive vulvar cancer is a relatively rare tumor, accounting for 4% of all female genital malignant neoplasms with the American Cancer Society reporting just over 5100 cases resulting in 1080 deaths in 2015 in the United States. With the exception of the rare sarcomas, the peak incidence is in women between 65 and 75 years old (Fig. 8.1); in some series, almost half are 70 years of age or older. Although classically a disease of elderly women, the trend in recent years is an increasing prevalence among younger women, which cannot be accounted for by immune suppression alone. Human papillomavirus (HPV) is a key age-dependent risk factor that causes preinvasive disease in the form of vulvar intraepithelial neoplasia (VIN) that is often associated with a history of tobacco use. HPV-related VIN lesions are rarer in older women, and these malignancies may be associated with chronic vulvar dystrophies, such as lichen sclerosis, although a direct association remains unproven. No race or culture is spared, and gravidity and parity appear unrelated in the pathogenesis of this neoplasm. Vulvar cancer is common in poor and elderly women in most parts of the world, and this has led to the hypothesis that inadequate personal hygiene and medical care are contributing factors in disease development.

Younger patients frequently have early stromal invasion associated with diffuse VIN. Choo found 17 patients younger than age 35 years with invasive carcinoma of the vulva. Of these, eight had microinvasion. Al-Ghamdi and coworkers evaluated 21 patients younger than age 40 years with invasive vulvar cancer and found that most, but not all, had associated HPV. Outcomes in these populations were excellent. Lanneau and colleagues have corroborated these results in 56 women younger than age 45 years with squamous cell carcinoma (SCC) of the vulva. They concluded that vulvar cancer in this population is associated with early-stage disease, HPV, VIN, and smoking.

SCC of the vulva develops by HPV-dependent and HPV-independent pathways. The association between HPV and both preinvasive and invasive urogenital lesions has been well described. Susceptibility of the cervical, vaginal, and vulvar epithelium is referred to as the "field effect," which is more pronounced in tobacco users and in patients who are immunocompromised, such as those with HIV/AIDS, or organ transplant recipients. The association of condyloma acuminatum with vulvar carcinoma is well known, but no cause and effect relationship has been confirmed as yet. HPV is suspected in the etiology of squamous neoplasia of the vulva, as it is in lesions

of the cervix. Bloss and colleagues looked at the clinical and histologic features of vulvar carcinomas analyzed for HPV status. Of 21 invasive carcinomas of the vulva analyzed, 10 were found to contain HPV-16 DNA. Others have confirmed this observation, suggesting that HPV DNA associations with malignant changes of the vulva are similar to those observed elsewhere in the genital tract. Although the incidence of vulvar cancer has remained relatively stable over the past several decades, the incidence of VIN has increased, especially that associated with HPV. Hoang and coworkers contrast these multicentric HPV related precursors with VIN of the differentiated type that occurs in postmenopausal women, often in a background of lichen sclerosis or chronic inflammatory dermatoses associated with a high number of somatic mutations, particularly in TP53. In a recent review, Sznurkowski pointed out the need to better understand the relationship between vulvar cancer and HPV for not only causation but also for developing potential therapeutics.

Many previously reported associated features seen in patients with vulvar cancer, such as diabetes, obesity, hypertension, and arteriosclerosis, may just reflect the increased incidence of these diseases associated with aging.

INVASIVE SQUAMOUS CELL CARCINOMA

Histology

The overwhelming majority of all vulvar cancer is squamous in origin. The vulva is covered with skin, and any malignant change that appears elsewhere on the skin can occur in this region. Table 8.1 depicts the incidence of vulvar neoplasia from several collected studies in the literature. The following discussion focuses mainly on SCC because of its preponderance, but as a generalization, the other lesions can be treated similarly, except as noted.

Clinical Presentation and Diagnosis

Squamous cell vulvar cancer usually arises from an area of intraepithelial neoplasia that subsequently develops into a small nodule that may break down and ulcerate (Figs. 8.2 and 8.3). On other occasions, small, warty, or cauliflower-like growths evolve, and these may be confused with condyloma acuminatum. **Long-term pruritus or a lump or mass on the vulva is present in more than 50% of patients with invasive vulvar cancer** (Table 8.2). Biopsy must be done of all suspicious lesions of the vulva, including lumps, ulcers, and pigmented areas, even in the patient not complaining of burning or itching (Table 8.3).

A significant delay in diagnosis and appropriate treatment is common. **Several series of carcinoma of the vulva report delays of 2 to 16 months after onset of symptoms** before

5. Change in sensation: itching or tingling

medical attention is sought. Further delay can occur when medical treatment of vulvar lesions continues without biopsy for definitive diagnosis.

Fortunately, vulvar cancer is commonly indolent, extends slowly, and metastasizes fairly late. Hence, there is an opportunity for preventing the development of advanced stages of this disease through patient and physician education.

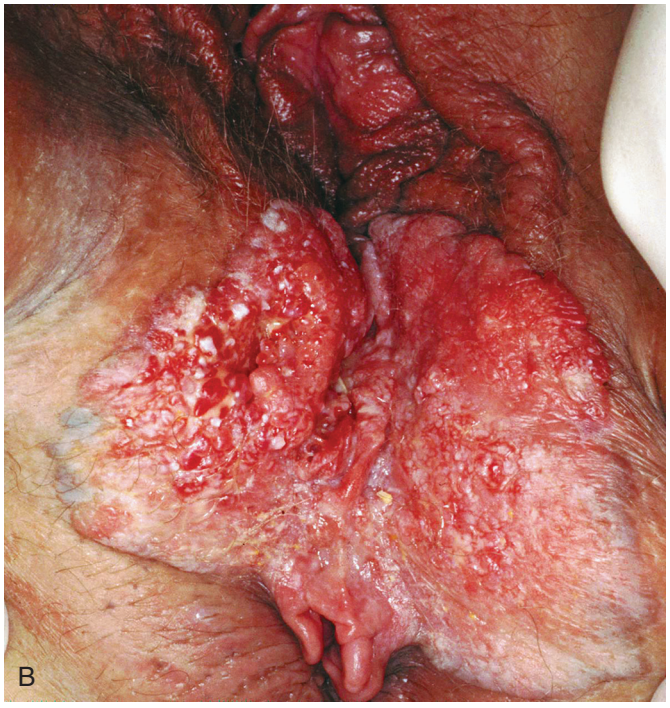

FIGURE 8.4 A, Large ulcerating squamous cell malignancy of the vulva with destruction of the clitoris and the urethra. B, Large exophytic squamous cell carcinoma of the vulva.

Location and Spread Pattern

Primary disease can appear anywhere on the vulva. Approximately 70% arise primarily on the labia. Disease more commonly occurs on the labia majora; however, it may appear on the labia minora, clitoris, or perineum. The disease is usually localized and well demarcated, although it can occasionally be so extensive that the primary location cannot be determined (Fig. 8.4). Multifocal growth pattern in invasive SCC of the vulva is uncommon, except for the so-called "kissing lesions" that can occur.

FIGURE 8.5 Verrucous carcinoma of the vulva.

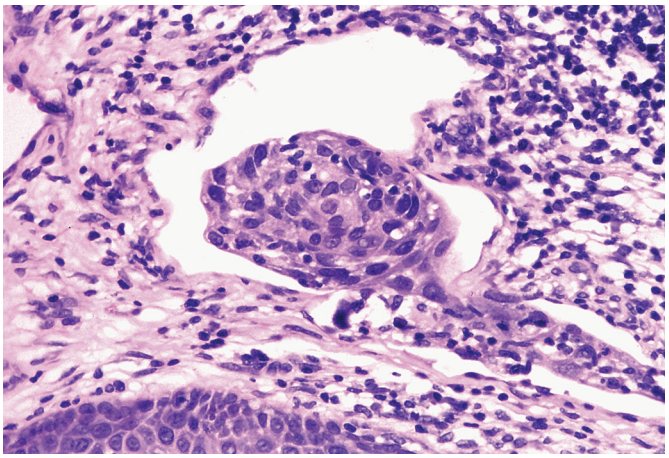

FIGURE 8.6 Photomicrograph of a tumor nodule invading a vulvar lymphatic.

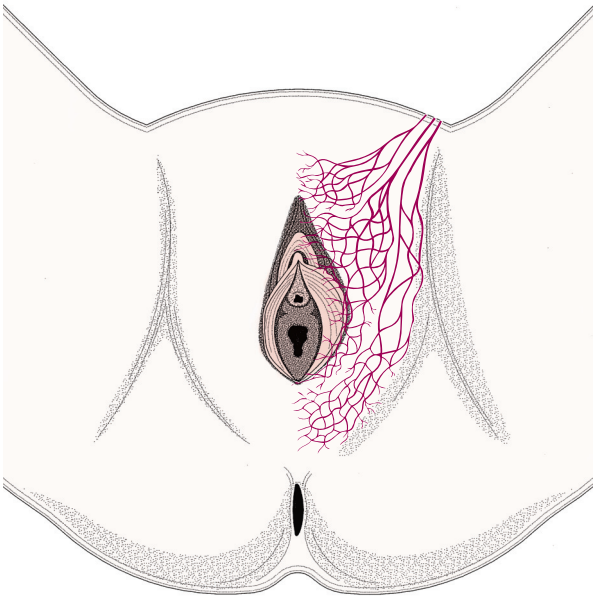

FIGURE 8.7 Lymphatic drainage of the external genitalia.

Verrucous carcinoma of the vulva (Fig. 8.5) is a special and unusual variant of SCC that is locally invasive but nonmetastasizing. The lesion, which may involve the cervix, vagina, and the vulva, presents as a warty, fungating, ulcerated mass with a bulky, elevated appearance reminiscent of a benign HPV lesion. Identification of this variant is important because the biologic behavior of the disease influences therapy. Condyloma may initially be diagnosed on microscopic examination, but distinction from ordinary condylomata is aided by the absence of fibrovascular cores within the proliferating papillary masses of tumor. There is usually a uniform lack of malignant features histologically. Adequate material, including underlying stroma for pathologic evaluation, is necessary to differentiate verrucous carcinoma from condyloma. Tumor may invade deeply into the underlying tissue, often requiring extensive surgery, and has a propensity to recur locally. Woodruff noted a lack of lymph node metastases in 27 patients, including a literature review, who were treated with radical vulvectomy and inguinal lymphadenectomy. As a result, a more conservative approach is advocated with wide local excision and tumor-free margins as the therapeutic aim. Lymphadenectomy is of questionable value except when nodes are obviously involved. Historically, it has been thought that radiotherapy is contraindicated because of its ineffectiveness, and reports have indicated that it can incite more aggressive behavior by this tumor.

Fundamental to the understanding of therapy for invasive cancer of the vulva is thorough knowledge of the lymphatic drainage of this region. **In general, the four histologic types of invasive cancer primarily metastasize via the lymphatic route** (Fig. 8.6). Lymphatic drainage of the external genitalia begins with minute papillae that connect to a multilayered meshwork of fine vessels that extend over the entire labium minus, the prepuce of the clitoris, the fourchette, and the vaginal mucosa up to the level of the hymenal ring (Fig. 8.7). Drainage of these lymphatics extends toward the anterior portion of the labium minus, where they emerge into three or four collecting trunks whose course is toward the mons veneris, bypassing the clitoris. Vessels from the prepuce anastomose with these lymphatics. Similarly, vessels from the labium majus proceed anteriorly to the upper part of the vulva and mons veneris, there joining the vessels of the prepuce and labium minus. These lymphatic vessels abruptly change direction, turning laterally, and terminate in ipsilateral or contralateral femoral nodes. Drainage is usually limited initially to the medial upper quadrant of the femoral node group. The nodes are medial to the great saphenous vein above the cribriform fascia and in turn may drain secondarily to the deep femoral group. The next echelon of nodes is the pelvic/iliac nodes.

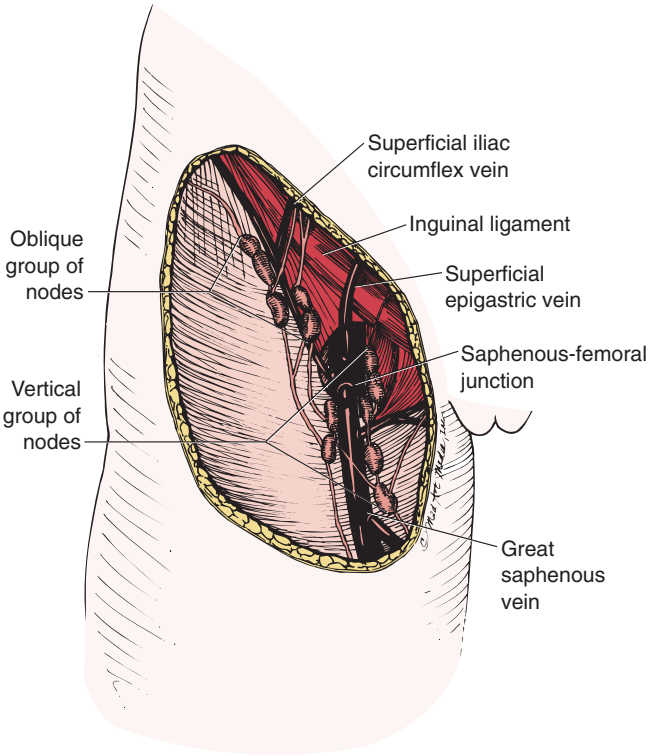

FIGURE 8.8 The superficial inguinal lymph nodes can be divided into the horizontal group and the perpendicular group.

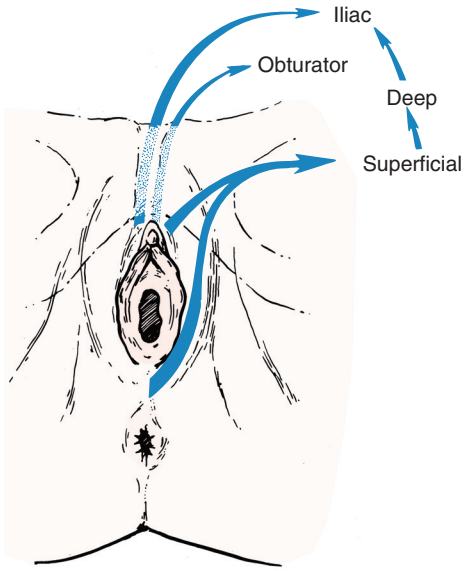

FIGURE 8.9 Lymphatic spread of a vulvar malignancy. See the text for details.

TABLE 8.4 Incidence of Positive Nodes

Series	Cases (*n*)	Positive Groin or Pelvic Nodes (%)	Positive Pelvic Nodes (%)
Morley (1976)	374	37.0	—
Curry et al. (1980)	191	30.0	4.7
Simonsen (1984)	122	50.0	10.0
Sutton et al. (1991)	150	24.0	—
Homesley (1994)	277	29.2	—
Creasman et al. (1997)	1553	31.0	—

The superficial inguinal lymph nodes are located immediately beneath the integument and Camper fascia, with an average of 8 to 10 in number. Most authors agree that these nodes are the primary drainage for the vulva, thereby containing the sentinel lymph node (SLN) (Fig. 8.8). The deep femoral nodes, which are by classic teaching located beneath the cribriform fascia, are the secondary node recipients and are involved before drainage into the deep pelvic nodes. The **Cloquet node**, the last node of the deep femoral group, is located just beneath the Poupart ligament. The multilayered meshwork of lymphatics on the vulva itself is always limited to an area medial to the genitocrural fold (Fig. 8.9). Lymphatic drainage of the vulva occurs via a progressive systematic mechanism, and therapy can be planned according to where in the lymphatic chain tumor is present.

Borgno and colleagues examined 100 inguinal lymphadenectomy specimens at autopsy and demonstrated that the deep femoral nodes are always situated within the openings in the fascia at the fossa ovalis, and no lymph nodes are distal to the lower margin of the fossa ovalis, under the fascia cribrosa. The clinical implication is that a carefully performed deep femoral lymphadenectomy does not require removal of the fascia lata (cribriform fascia) because no lymph nodes are to be found between the femoral vein and artery lateral to the artery or distal to the lower margin of the fossa ovalis beneath the cribriform fascia. They also found that the node of Cloquet or Rosenmüller, which is the uppermost node among the deep femoral lymph nodes, was absent in 54% of dissections. Borgno and colleagues also demonstrated that during surgery, when traction is persistently applied to the lymphovascular fat tissue above the cribriform fascia, all inguinal nodes can be removed. No nodal tissue was found when the cribriform fascia and the fat beneath were submitted separately for pathologic review. Hudson and colleagues confirmed this finding in cadaveric dissections, and Micheletti and coworkers found supporting evidence with embryologic studies.

Although lymphatics draining from the clitoris directly to the deep pelvic lymph nodes are described, their clinical significance appears to be minimal. It is unusual to find a case in which metastasis is present in the pelvic lymph nodes without metastatic disease in the inguinal lymph nodes even when the clitoris is involved. Curry and associates noted clitoral involvement in 58 patients of 191 studied; none had positive deep pelvic nodes without concomitant inguinal node involvement. Similar results were observed in a study of 38 patients, with carcinomas of the clitoris by Ericksson and coworkers, who found also that the deep inguinal or femoral nodes were never positive in the absence of positive superficial inguinal nodes.

The incidence of positive inguinal and pelvic nodes varies considerably, as noted in Table 8.4. Unfortunately, most of

From Homesley HD, Bundy BN, Sedlis A, et al. Prognostic factors for groin node metastasis in squamous cell carcinoma of the vulva (a Gynecologic Oncology Group study). Gynecol Oncol 1993;49:279,.

these studies were unstaged, although, in general, the larger the tumor, the greater the propensity for inguinal and pelvic node metastases. Morley noted a 21% incidence of lymph node involvement if there was a T1 lesion (<2 cm in diameter) versus 45% with a T2 lesion (>2 cm but limited to the vulva). Malfetano and colleagues reported the incidence of inguinal node metastases in patients with stage III and stage IV lesions to be 53% and 90%, respectively. Clinical evaluation of the groin is somewhat more accurate than tumor size. **Homesley found that approximately 24% of patients with clinically nonsuspicious nodes had positive nodes when dissected, and approximately 75% of patients with suspicious (palpable, fixed, or ulcerated) groins had positive nodes.** Table 8.5 demonstrates the association between inguinal lymph node involvement and tumor size, depth of invasion, and clinical examination. Of note, these data did not evaluate laterality or unifocal versus multifocal lesions.

Staging

Many staging systems have been applied to invasive cancer of the vulva. Significant discrepancy exists between clinical and surgical-pathologic evaluation of lymph node status. Iversen demonstrated that overdiagnosis (clinically suspicious but pathologically negative nodes) occurred in 40 of 258 patients (15%). Of the 100 patients with metastasis to the inguinal lymph nodes, lymph node involvement was clinically unsuspected in 36 patients. Patients with "micrometastasis" (lymph node involvement not suspected clinically but positive microscopically) had a significantly better survival rate than did those with gross metastasis. As a result of these repeated findings, it was suggested that staging be based on surgical-pathologic evaluation instead of clinical evaluation alone. Federation of International Gynecologists and Obstetricians (FIGO) staging of vulvar cancer dates back to 1969. In 1988, FIGO replaced the clinical staging system with a surgical-pathologic, or tumor–node–metastasis (TNM), classification system. The most recent 2009 FIGO staging for carcinoma of the vulva (Table 8.6)

TABLE 8.6 Federation of International Gynecologists and Obstetricians Staging of Invasive Cancer of the Vulva

Stage	Description
I	Tumor confined to the vulva
IA	Lesions ≤2 cm in size confined to the vulva or perineum and with stromal invasion ≤1.0 mm*; no nodal metastasis
IB	Lesions >2 cm in size confined to the vulva or perineum with stromal invasion greater than 1.0 mm*; no nodal metastasis
II	Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus); no nodal metastasis
III	Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with positive inguinofemoral lymph nodes
IIIA	(i) With 1 lymph node metastasis (≥5 mm), or (ii) With 1–2 lymph node metastasis(es) (<5 mm)
IIIB	(i) With ≥2 lymph node metastases (≥5 mm), or (ii) With ≥3 lymph node metastases (<5 mm)
IIIC	With positive nodes with extracapsular spread
IV	Tumor invades other regional (2/3 upper urethra, 2/3 upper vagina) or distant structures
IVA	Tumor invades any of the following: (i) Upper urethra or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone, or (ii) Fixed or ulcerated inguinofemoral lymph nodes
IVB	Any distant metastasis, including pelvic lymph nodes

*The depth of invasion is defined as the measurement of the tumor from the epithelial–stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

further characterizes the number and type of lymph node metastases. Previous studies noted decreased survival among individuals with bilateral lymph node metastasis; thus, laterality was incorporated into the staging system. However, recent studies have demonstrated that the number of lymph node metastases and extracapsular spread are predictive of survival regardless of laterality. It is important to consider that many reports in the literature use older staging systems, and thus data must be evaluated within the context of the staging system used.

Donaldson and colleagues demonstrated that lesion size predicted incidence of lymph node metastasis (19% metastasis for lesion <3 cm and 72% for lesion >3 cm). Likewise, tumor grade correlated with node metastasis (one-third of well-differentiated tumors had metastasis compared with 75% for poorly differentiated lesions). Of 38 patients, 11 (29%) had node involvement if invasion of the primary lesion was 5 mm or smaller compared with 17 of 28 (61%) if invasion was larger than 5 mm. If the tumor did not involve lymphatic or vascular spaces, only 2 of 33 (6%) had positive nodes, but 26 of 33 patients (79%) with lymphatic or vascular space involvement had metastasis to the regional lymph nodes. None of 25 patients with lesions invading less than 5 mm and without lymphatic or vascular space involvement had lymph node metastasis.

Tabbaa and associates reported the largest cohort study to evaluate the effect and prognostic performance of the 2009

FIGO staging. They reported FIGO stage I, II, III, and IV 5-year overall survival (OS) rates of 84%, 75%, 48%, and 9%, respectively. The 5-year OS rate was 85% for patients without LN metastasis, and for patients with three or more lymph node metastases, the 5-year OS rate was 30%. They surmised that bilateral nodal disease does not appear to impact cause-specific survival, justifying its omission from the 2009 staging system, and that separating node-positive stage III from node-negative stage II cases appears justified.

Sentinel Lymph Node Biopsy

Sentinel lymph node biopsy (SLNB) represents the largest innovation in the care of patients with vulvar cancer in the past decade. The use of the SLN technique in the evaluation of vulvar cancer was first described in the late 1970s based initially on the experience in penile cancers followed by the successes reported in breast cancer and melanoma. The past 20 years have witnessed a myriad of reports featuring SLN techniques in the management of gynecologic cancers, including vulvar cancer, that have provided experienced clinicians with a standard of care option for surgical lymph node management in appropriately selected patients. The concept of SLNs depends on reliable prediction of a tracer substance identifying the primary nodal drainage of the tumor. The assumption is that if the SLN is negative for malignancy then the other nodes will be negative thus precluding the need for full nodal dissection and thereby significantly reducing the procedural related short-term infection and wound breakdown and long-term edema associated with inguinal femoral lymph node dissection (IFLND).

Only approximately 30% of early stage vulvar cancers have positive nodes with IFLND, which thus exposes a large number of women to ostensibly an unnecessary morbid procedure wherein up to two-thirds of patients experience lymphedema. Therefore, reducing the radicality of groin lymphadenectomy by SLNB merits investigation, validation, and implementation as a reliable alternative to full nodal dissection that requires balancing the slightly higher groin recurrence rates of SLNB versus the significantly greater morbidity of IFLND.

Concerns raised in adopting SLNB as the standard of care include first, the reliability of SLN detection. How feasible is this technique in terms of how often does one detect an SLN, and which technique should be used in terms of injection site and tracer selection? Second, what is the reliability of a negative SLN to predict that all the other inguinal nodes are likewise negative for malignancy? In other words, what is the potential for a false-negative result, whereby a SLNB does not demonstrate metastases but additional groin dissection discovers lymphatic spread? Finally, what is the groin recurrence rate? This question is critical because untreated groin metastases will result in groin recurrences that are most often fatal. It is important to recall that the gold standard for the rate of groin relapse in a node-negative groin is 0.3% based on Homesley et al.'s Gynecologic Oncology Group (GOG) experience. The data for detection rate, sensitivity, or false-negative results can be considered from the perspective of each groin, viewed as a separate entity, or from the patient's perspective whereby the outcomes of SLNB are considered for both groins as a unit.

Another concept to consider is the role of nodal ultrastaging with very fine sectioning and use of immunohistochemistry (IHC) as an adjunct to conventional staining, in which the SLN is subjected to far greater scrutiny in terms of pathologic sectioning than nodes removed via traditional IFLND. Nodal yield from traditional IFLND is much greater in number, and these nodes are not usually subjected to these labor-intensive techniques because of time and resource constraints. Also, a statistical concept known as the false-negative predictive value (FNPV), defined as (1- Negative predictive value), needs to be understood to properly consider the burgeoning SLNB literature in the management of vulvar cancer.

Several small studies were instrumental in validating the feasibility of SLNB, with the original lymphatic mapping data being published by Levenbach and colleagues in 1994. Recent studies have continued to demonstrate improved outcomes for SLNB over time. Initial mapping studies of SLNB in vulvar cancer evaluated 21 patients with isosulfan blue dye only, and an SLN was identified in only 86% of patients and 66% of groins. Addition of lymphoscintigraphy (LSG) with radiolabeled technetium significantly improved the SLN detection rate. A collective review of the literature in 2002 noted a detection rate of 92% with the combined technique. Frumovitz and colleagues reported on 52 women who underwent SLNB 1993 and 1999; 14 had a recurrence. Eight of the recurrences (15.4%) were on the vulva, three (5.8%) in the groin, and three (5.8%) distant. The pattern of recurrence is similar to that seen with standard approaches, although the rate of relapse in the groin appears high.

One of the first large prospective multicenter observational trials to assess SLNB was the GROINSS-V I study reported by Van der Zee and associates that included 403 assessable patients using the combined technique. Eligible patients had T1 or T2 lesions smaller than 4 cm, invasion greater than 1 mm, and clinically nonsuspicious inguinofemoral lymph nodes. SLNB was performed, and if the SLN result was negative, then an IFLN was not performed; only when SLN metastases were identified was an IFLND performed either at time of surgery based on frozen section or subsequently based on final pathologic analysis of the SLN. A total of 623 groins in 403 patients were evaluated. The authors selected 276 selected patients with unifocal vulvar disease and a negative SLN to describe in detail, and the 3-year survival rate was 97%, with a mean follow-up of 35 months. Adjuvant radiotherapy was administered to the groin and pelvis when more than one lymph node demonstrated metastasis or extracapsular nodal tumor growth was identified. Those who underwent SLNB had a FNPV of 2.9% with a false-negative rate of 6%. **The groin recurrence rate for those with negative SLNs was 2.3%.** Patients with unifocal lesions had only a 2% recurrence rate compared with 12% for those with multifocal lesions on the vulva. Lymphedema was noted in 2% for SLNB versus 25% in those with positive SLN who underwent full IFLND. Wound breakdown and recurrent cellulitis occurred in 12% and 0.4% versus 34% and 16% for SLNB versus completion IFLND procedures respectively. Ultrastaging with three sections per mm was performed only on SLNs that were negative on routine histopathologic examination. Ultrastaging

significantly increased detection of nodal metastases. Routine pathologic examination detected 95 (58%) of the 163 groins with metastatic SLNs, and ultrastaging detected the remaining 68 (42%) groins demonstrating metastatic SLNs.

A subset analysis of the GROINSS-V I study conducted by Oonk and colleagues demonstrated that the risk of non-SLN metastases increased with increasing size of SLN metastasis. Also, the risk of non-SLN metastases was higher when the SLN was found to be positive with routine pathology than with ultrastaging. The 5-year disease-specific survival rates were 97% for women with isolated tumor cells in the SLN, 88% for those with SLN metastases smaller than 2 mm, 70% for those with metastases measuring 2 to 5 mm, and 69% for those with metastases larger than 5 mm. No cutoff provided complete assurance that the non-SLNs would be free of metastases thus given the high risk of mortality if such nodes are missed; **additional groin treatment remains the current recommendation for all patients with SLN involvement.**

GOG 173 reported by Levenback and associates included 452 women who underwent SLNB followed by IFLND irrespective of SLNB findings. Eligibility criteria included SCC confined clinically to the vulva with at least 1 mm of invasion and tumor size up to 6 cm in greatest diameter. Patients with groin nodes that were clinically suggestive of cancer were excluded. Every woman underwent intraoperative lymphatic mapping using isosulfan blue dye; however, 2 years into the study, the protocol was amended to require preoperative LSG and intraoperative radiolocalization, which previously had been optional. Nodes were subjected to ultrastaging by serially sectioning them into 3-mm blocks with at least two sections 40 microns apart per block. The use of frozen section was discouraged. If routine hematoxylin and eosin staining was negative for metastatic disease on the first slide, IHC cytokeratin staining was performed on the second slide. A total of 772 groin dissections were performed (320 = bilateral and 132 = unilateral) in 452 women of whom 418 exhibited at least one SLN. Incidence of node positivity among women with at least one SLN identified was 32%. Of the 132 women with positive nodes, 11 had false-negative findings on SLNB (8.3%; 90% confidence interval [CI], 4.7%–13.4%); thus, the sensitivity was 92%. Importantly, this study showed that the false-negative rate for SLNB increased significantly when tumor size was 4 cm or larger (7.4% vs. 2% for tumors <4 cm). They also demonstrated a favorable FNPV of 3.7%, which was the primary statistical endpoint of this trial. This FNPV is comparable to that observed in breast cancer, but salvage rates for that disease are more favorable. This study highlighted the role of pathologic analysis as 23% of the positive nodes were missed on conventional staining and required IHC for detection of cancer. SLN ultrastaging is also important via step sectioning, which significantly increases the chance of finding metastases, according to Puig-Tintore et al.

Coleman et al. published a subset analysis of patients from GOG 173 that examined the importance of the location of the primary tumor relative to the midline and the role of LSG, which was optional in this study. A total of 234 patients were eligible with 64 having lateral lesions (>2 cm from midline) and thereby undergoing only unilateral IFLND after SLNB; the 105 women with midline and 65 with near-midline lesions (<2 cm distance from midline) underwent bilateral completion IFLND. Bilateral groin drainage using LSG was discovered in 22% of lateral, 58% of near-midline, and 70% of midline tumors. At mapping, no SLNs were found in contralateral groins among patients with near-midline and midline tumors who had unilateral-only LSGs, yet groin metastases were found in four of 32 patients with midline tumors undergoing contralateral dissection; none were found in 27 patients with near-midline tumors. They concluded that the likelihood of detectable bilateral drainage using preoperative LSG decreases as a function of distance from midline. Patients with near-midline primary tumors exhibiting unilateral drainage on LSG may safely undergo unilateral SLN. Further validation of this concept is indicated.

A Cochrane review of SLNB in vulvar cancer management was reported by Lawrie et al. that assessed the diagnostic test accuracy of various techniques using traceable agents for SLNB to diagnose groin lymph node metastasis in women with FIGO stage IB or higher vulvar cancer. A total of 34 studies evaluating 1614 women and approximately 2396 groins were included in the analysis. Use of blue dye only provided a sensitivity of 0.94 (68 women; 95% CI 0.69–0.99); for mixed tracers, sensitivity was 0.91 (679 women; 95% CI 0.71–0.98); and for technetium only, it was 0.93 (149 women; 95% CI 0.89–0.96). Sensitivity for combined tests was 0.95 (390 women; 95% CI 0.89–0.97). Negative predictive values (NPVs) for all index tests exceeded 95%. Mean detection rate for blue dye alone was 82%, compared with 95%, 96%, and 98% for mixed tests, technetium only, and combined tests, respectively. It was estimated that for 100 women hypothetically undergoing SLNB assuming groin metastases prevalence of 30% for the combined or technetium only tests, one and two women with groin metastases might be "missed," and for mixed tests, three women with groin metastases would occur as false-negative results. This review concluded that there are only minor differences in diagnostic test accuracy between the technetium and combined tests. Combined testing may reduce the number of false-negative results compared with technetium alone. It must be recognized that there is a learning curve to successful SLNB, and combined tests may further increase detection for less experienced surgeons. Blue dye alone may be associated with more FNs compared with tests that include technetium. They further concluded that SLNB would reduce the need for full IFLND by 70% in patients with early vulvar cancer, but long-term survival data are needed.

A systematic review was presented by Meads et al. to assess the accuracy of SLNB with technetium 99 and/or blue dye–enhanced LSG. A total of 29 studies that included 1779 women were analyzed. Most studies used technetium-99 combined with blue dye. Pooling when appropriate revealed mean SLN detection rates of 94% for technetium, 69% for blue dye alone, and 98% for both. SLNB revealed a pooled sensitivity of 95% (95% CI 92%–98%) with an NPV of 97.9% in studies using technetium with blue dye, ultrastaging, and IHC with inguinal lymphadenectomy as reference. Less morbidity was reported for those undergoing SLNB. The authors concluded that SLNB should be done in carefully selected patients with technetium

and blue dye with ultrastaging and IHC. They further concluded that patients must make an informed choice between the slightly higher groin recurrence rates of SLNB versus the higher morbidity with full lymphadenectomy.

Another systematic review by Hussanzade et al. included 49 studies and reported a false-negative rate by patient and groin perspectives of 8%. Pooled NPVs were 97% for patient- and groin-based analyses. They pointed out that those with palpable groin nodes had lower detection rates and sensitivity with SLNB. They concluded that SLNB with radioactive tracer plus blue dye was accurate in appropriately selected patients with exclusion of those with clinically suspicious inguinal nodes. They also raised the concern of an increased FN rate for midline tumors.

Slomovitz and colleagues performed a review recently that declared SLNB as the standard of care for early stage vulvar cancer secondary to lymphedema rates of 30% to 70% after traditional IFLND combined with the robust prospective data from GOG 173 and the GROINSS-V I studies that confirmed the feasibility and utility of SLNB with similar false-negative rates of 6% for tumors smaller than 4 cm. Important differences between these studies include the fact that GROINSS-V had smaller tumors (T1 or T2 <4 cm) versus GOG 173 in which T1 and T2 tumors measuring 2 to 6 cm were included. Mapping techniques also differed because GROINSS-V required both dye and tracer as well as a minimum threshold of 10 cases for skill verification versus blue dye only was required initially with no skill verification in GOG 173. The authors concluded that the groin relapse rate attributable to a false-negative SLNB for primary vulvar tumors smaller than 4 cm was less than 3%.

Covens and associates convened a working group panel that performed an additional systematic review with meta-analysis whereby they reported a per groin detection rate for SLNB using radiocolloid tracer and blue dye of 87% and a false-negative rate of 6.4%. They recommended SLNB for women with unifocal tumors smaller than 4 cm with clinically nonsuspicious groin nodes, provided that conditions of specific infrastructure and SLN experience and volume are met. The groin recurrence rates are 6.6% for superficial IFLND and 1.4% for complete IFLD versus 3.4% for SLNB. Expert panel recommendations from this paper included using radiocolloid with blue dye and not using blue dye alone secondary to low detection rates. Four quadrant intradermal injections into normal tissue at the margins of the tumor were recommended. Near-infrared tracers (eg, indocyanine green [ICG]) as well as the role of frozen sections require further study. Radiocolloids can be injected 30 min to 24 hours before surgery, depending on the size of the radiocolloid, and manufacturer directions, and blue dye should be injected in the same location as the radiocolloid after induction of anesthesia. A node that has more than five times the background radioactivity should be used to identify an SLN. Pathologically, the panel advocated for SLN ultrastaging by serially sectioning into 3-mm blocks and at least two sections 40 μm apart from each block. If routine hematoxylin and eosin staining is negative for metastatic disease on the first slide, IHC cytokeratin staining should be performed subsequently. Finally, the panel endorsed omission of IFLND in the contralateral side to a positive node when the SLN has been negative in that contralateral side, although they acknowledged that data are limited.

Some issues with SLNB remain less clear, but data are emerging. What is the risk of contralateral non-SLN metastasis in patients with unilaterally positive SLNs? Woelber and colleagues addressed this question in 140 patients, 124 with bilateral and 16 with unilateral SLN dissection. A median number of two SLNs with a range of one to seven per groin were dissected. Of 33 patients with unilaterally positive SLNs, 28 (85%) underwent complete bilateral IFLND despite a contralateral negative SLN, and none demonstrated contralateral non-SLN metastasis. Of the remaining five patients, three received postoperative radiotherapy to the groins. One woman (3.6 %), however, did develop groin recurrence in the initially SLN-negative, fully dissected groin after 19 months. These data support the omission of contralateral IFLND if negative contralateral SLN is found, but clearly further study is needed before altering current guidelines that mostly advocate for bilateral IFLND in these circumstances because these numbers are small and possibly confounded by groin irradiation.

Another unanswered question with SLNB heretofore has been the effect on long-term survival. This issue was recently addressed by te Grootenhuis and associates, who reported the long-term follow-up from the GROINSS-V I study with a median follow-up period of 105 months. The overall local vulvar recurrence rates were 27% at 5 years and 40% at 10 years after primary treatment. These recurrence rates are high considering that these were patients with unifocal tumors smaller than 4 cm. Notably, 89% of patients underwent wide excision versus only 10% who underwent radical vulvectomy for the primary tumor. For SLNB-negative patients, recurrence rates were 25% and 36% at 5 and 10 years, respectively, but SLNB positive patients demonstrated 33% and 46% recurrence rates at 5 and 10 years, respectively. A total of 39 (15%) SLNB-negative patients underwent IFLND secondary to a local recurrence. The isolated groin recurrence rates were 2.5% for SLNB-negative patients and 8% for SLNB-positive patients at 5 years of follow-up. The overall 10-year disease-specific-survival rates were 91% for SLNB-negative patients versus 65% for SLNB-positive patients. For all patients, 10-year disease-specific survival rate decreased from 90% for patients without a local recurrence to 69% for those with a local recurrence.

Additional questions with SLNB remain including optimal imaging techniques such as ultrasonography, computed tomography (CT), magnetic resonance imaging, positron emission tomography/CT, and most recently, single-photon emission computed tomography (SPECT) preoperatively, that would best exclude clinically suspicious nodes that are thought to considerably increase the FN rate for SLNB. Nodes that are totally replaced by tumor may not be identified by mapping because of blockage of lymphatic channels by tumor, thereby resulting in a false-negative result. The role of prior local recurrences as well as prior SLNB also are poorly understood in terms of the accuracy of repeating SLNB. Furthermore, the clinical consequences of micrometastases are unclear. As SLN metastasis size increases, the probability of non-SLN metastases increases, which correlates with decreasing survival. SNLB appears to be

cost effective in separate reports (McCann et al. and Erickson et al.); nonetheless, Sutton and associates performed a model-based economic analysis that clearly showed that IFLND was most cost effective and dominated all other strategies considering 2-year OS, but when morbidity-free outcomes were considered, then SLNB using a combined identification technique with ultrastaging and IHC was superior.

Future directions in optimizing SLNB will include development of novel tracers and dyes such as fluorescent dyes (eg, ICG) for enhanced SNL identification. Additionally, ongoing trials GROINSS-V-II and GOG270 will address the potential role of adjuvant groin irradiation as a substitute for completion IFLND in those with positive SLNB. It is noteworthy that this trial suspended accrual in 2010 because of higher than allowable groin recurrences in the cohort of patients with positive SLNB who received adjuvant radiotherapy. At the time of suspension, 10 groin recurrences were identified in 82 such patients. Extensive analysis of these cases revealed that tumor metastases size (≥2 mm) and extranodal extension were associated with a statistically higher rate of groin recurrence. The trial was reopened for accrual after amending the eligibility criteria. Only those with micrometastases remain eligible for radiation; those with macrometastases are to undergo IFLND.

In summarizing, if an SLN is not identified and in any case in which the mapping procedure appears inadequate, SNLB should be abandoned in favor of complete IFLND. Patient selection is crucial to success. Patients should have a negative metastatic workup. Table 8.7 summarizes factors that affect the success of SNLNB. Ideal candidates have unifocal T_1 or T_2 primary tumors smaller than 4 cm in diameter and clinically nonsuspicious groin nodes. SNLB performance characteristics from select studies are summarized in Table 8.8. The standard has been that if a positive SLN is found on one side, then a complete groin dissection should be done bilaterally; however, emerging evidence supports omission of full contralateral IFLND if the contralateral SLN is negative. Fig. 8.10 proposes a potential management algorithm for SLNB. Clearly, these management schemes require individualization as well as constant vigilance of emerging literature that may alter recommendations.

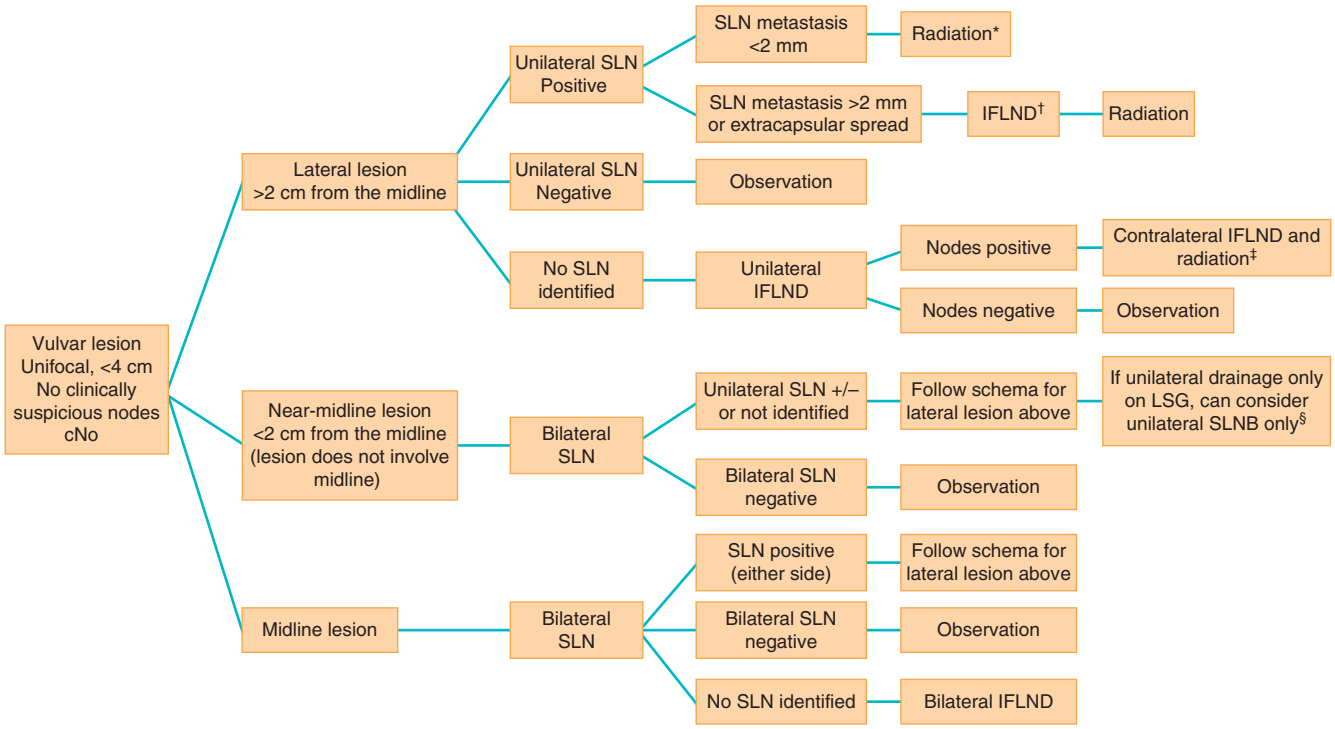
SENTINEL NODES



Management

Overall, management of invasive vulvar cancer has witnessed an evolution from large en bloc resection associated with high morbidity to more conservative approaches, such as radical local resection, separate groin incisions, and now SLNB to minimize complications such as wound breakdown and infection, lymphocele formation, and chronic lymphedema. Way originally reported improved survival in carcinoma of the vulva by use of the en bloc dissection of radical vulvectomy plus inguinal and pelvic lymphadenectomy, which subsequently became the mainstay of treatment in vulvar cancer. The corrected 5-year survival rate for stage I and stage II disease has been reported by many authors to be approximately 90%. This so-called "longhorn" or "butterfly" en bloc resection has evolved into a significantly more tailored approach depending on size and laterality of the lesion, resulting in similar cure rates with lower morbidity. Modified radical vulvectomy is the current approach to resect the primary lesion with a 2-cm margin, sparing a significant amount of normal tissue, especially with smaller lesions. Lymph nodes are resected via separate incisions. Well-lateralized lesions, defined as more than 1 cm from the midline, can be managed with local radical excision or modified radical vulvectomy and ipsilateral inguinofemoral lymph node dissection (LND). Homesley and coworkers presented the GOG experience with such lesions (Table 8.9) and confirmed the low incidence of contralateral node involvement, making ipsilateral inguinal lymphadenectomy a rational approach. However, central lesions must be evaluated with bilateral LND. This is

based on the lymphatic drainage of the vulva confirmed by anatomic studies demonstrating contralateral lymphatic drainage of lesions near the anus and clitoris, thus warranting the evaluation of both groins in central lesions.

Adjuvant therapy is based on surgicopathologic findings after radical vulvectomy and evaluation of appropriate lymph nodes. Historically, if metastasis was noted in the groin nodes, pelvic LND was performed. This practice has been largely abandoned in favor of pelvic radiation therapy to treat the next nodal chain when groin nodes are involved. The pelvic nodes are essentially never involved with metastatic disease when the inguinal nodes are uninvolved. A study by Curry et al. showed that of 191 patients, only nine (5%) had positive pelvic nodes, and all nine patients also had metastatic disease in the groin nodes. The GOG (Homesley et al.) performed a prospective randomized study in patients with vulvar carcinoma who had positive groin nodes; 114 patients with positive inguinal nodes were randomly assigned to receive radiotherapy versus ipsilateral pelvic node dissection. The group treated with radiotherapy had a 68% relative 2-year survival rate, and the group undergoing pelvic node dissection had a 54% relative 2-year survival rate. **Thus the standard of care became pelvic lymph node irradiation** (Fig. 8.11) **for patients with positive inguinal nodes.**

A randomized GOG trial by Stehman and colleagues attempted to evaluate groin irradiation versus groin dissection for patients with N0/N1 nodes. This study was closed prematurely when interim monitoring demonstrated an excess groin failure rate in the radiation arm. Although this study's radiation

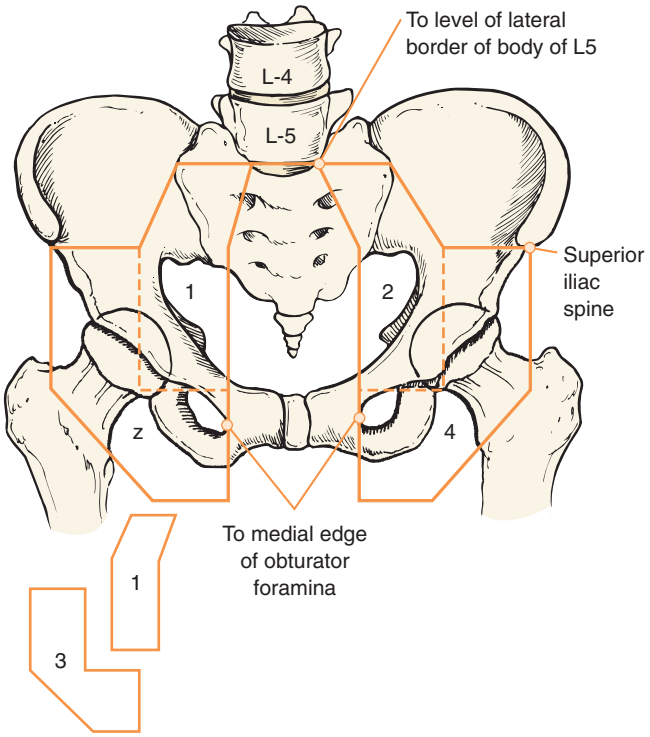

FIGURE 8.11 Radiation ports for inguinal and pelvic treatment. *1, 2,* anteroposterior pelvic and inguinal port; *3, 4,* anterior boost, or "wing." (From Prolog. *Gynecologic Oncology and Surgery*, 2nd ed. 1991, The American College of Obstetricians and Gynecologists, p 51.)

prescription has been criticized, a Cochrane Database Systematic Review (van der Velden and Ansink, 2005) concluded that follow-up studies do not support better disease control with radiation of the intact groin and that LND continues to be the cornerstone of therapy. There may still be some role for radiation therapy, especially in patients who are not surgical candidates, although the risks of groin failure and hip fracture must be considered (Katz et al., 2003).

Boronow also emphasized the possible role of primary radiation therapy in vulvar and vaginal cancers. His report dealt mostly with advanced disease involving vaginal tissues, necessitating an exenterative procedure if a primary surgical approach was used. As an alternative, he recommended surgical extirpation of the lymph nodes with a combination of external and interstitial irradiation for control of the central lesion. In a small, highly individualized series, this approach appeared promising. Similar reports by Fairey and associates and Hacker and colleagues substantiated this. Although neoadjuvant radiation has gained acceptance in this setting, significant challenges remain. Low anterior and posterior fields must be used, resulting in intense exposure of the vulvar skin because the axis of the x-ray beam runs parallel to (and often within) the skin and mucous membrane. Vulvitis may result, and interruption of therapy is often necessary because of the patient's discomfort. Similarly, radiating enlarged, grossly positive inguinal nodes becomes technically difficult. Surgical removal of enlarged nodes with subsequent radiation therapy to the area has been our preference. **Requisite preoperative doses of 45 to 50 Gy to either the groin or vulvar areas significantly complicates any subsequent surgery because wound healing is impaired. Delaying surgical intervention for 4 to 6 weeks after radiation may reduce these risks.**

Neoadjuvant concurrent chemoradiation therapy to provide optimal reduction in the size of the central lesion has also been evaluated. Russell and coworkers described 25 women with locoregionally advanced squamous cancer of the vulva. All patients received external-beam radiation and synchronous radiopotentiating chemotherapy. Complete clinical response was obtained in 16 of 18 previously untreated patients and in four of seven patients with recurrent disease. Concurrent chemoradiation with cisplatin and 5-fluorouracil (5-FU) has been prospectively evaluated by the GOG and found to be highly effective. Moore and colleagues reported on 73 patients with T3 or T4 tumors who would have required ultraradical surgery to clear disease. Resection was accomplished after chemoradiation in 69 of 71, and only three patients required urinary or fecal diversion. Montana and colleagues reported the companion trial for patients with unresectable groin nodes. Many of these poor-prognosis patients experienced progression or intercurrent death during chemoradiation. Still, 38 of 40 who completed treatment had resectable disease, and 15 of 37 had negative lymph nodes.

It has been suggested that in selected stage IV carcinomas of the vulva, ultra-radical surgery may be applicable. Cavanagh and Shepherd, in a review of their data and the literature, identified 53 patients since 1973 who were treated with exenteration and radical vulvectomy. Most of the patients were young, and 47% were alive without recurrence at 5 years. In their series, Cavanagh and Shepherd found all survivors to have negative pelvic lymph nodes.

Technique of Radical Vulvectomy

The goal of radical vulvectomy is to remove the primary lesion to the depth of the perineal fascia with a 2-cm circumferential margin. Ipsilateral or bilateral inguinofemoral lymph nodes are harvested based on the size and laterality of the lesion, as discussed previously. The single-incision technique is described in Fig. 8.12 and can be modified to incorporate one or both groins. Today, most limit the skin incision to the inguinal area, thereby preserving the bridge of skin between the inguinal and vulvar incisions (three-incision technique, Fig. 8.13). All tissue is removed from the inguinal lymph node bundles. An 8-cm incision is made parallel to the inguinal ligament two fingerbreadths (4 cm) beneath the inguinal ligament and two fingerbreadths (4 cm) lateral to the pubic tubercle (Fig. 8.14). The incision is carried down through the Camper fascia, and at this point, skin flaps are bluntly and sharply dissected superiorly and inferiorly, allowing access to the fat pad containing the superficial nodes. The SLNs are located in the fatty layer of tissue beneath the Camper fascia, in part anterior to the cribriform plate and protruding from beneath the fascia lata (Fig. 8.15). The dissection should be carried superiorly to the inguinal ligament and inferiorly to a point approximately 2 cm proximal to the opening of the Hunter canal. The dissection

should be carried laterally to the sartorius muscle and medially to the adductor longus muscle fascia (Fig. 8.16). Blunt dissection facilitates identification of the cribriform fascia, which is most easily identified just below the inguinal ligament or in the area of the saphenous opening. The cribriform fascia unites with the fascia lata, and thus is contiguous with the fascia on the surface of the adductor longus and sartorius muscles; this may facilitate its identification. The portion of the fascia covering the femoral triangle is perforated by the saphenous vein, by lymph nodes of the vertical set, and by numerous blood and lymphatic vessels, hence the name *cribriform fascia*. If the dissection is carried out properly, the adventitia of the femoral vessels should not be clearly seen except through the vessel openings mentioned earlier.

Bell showed that a complete inguinal dissection could be achieved while leaving the fascia intact. He and his co-investigators retrieved a mean of 10 nodes per groin without removing the cribriform fascia. Borgno and colleagues demonstrated that the deep inguinal or femoral nodes are exposed in the fossa ovalis and other openings of the cribriform fascia, allowing access to all inguinal nodes with this technique. The result is that a dissection that uses the boundaries of the femoral triangle and is

carried out to the level of the cribriform fascia with optimal traction on the lymphovascular fat bundle of the inguinal area **will produce a specimen that contains all of the inguinal and femoral nodes.**

Frozen-section analysis can be obtained if the initial plan is to perform an ipsilateral LND and suspicious nodes are encountered during the dissection. If metastatic disease is confirmed, a contralateral LND is performed. Closed-suction drains are then placed in the groin dissection, and the skin incision is closed by means of a running delayed absorbable suture. The LND is typically performed first, and attention is then turned to the vulvectomy.

A complete radical vulvectomy is accomplished by defining the margin of dissection. The mons is incised anteriorly, extending medially to the genitocrural fold and posteriorly midway between the anus and posterior fourchette. A bloodless space can be dissected between vulvar fat and the subcutaneous tissue of the thigh using a finger dissection (see Figs. 8.12, *C* and *D*). The tissue is transected and ligated with 0 or 2-0 delayed absorbable suture at the level of the fascia of the thigh (see Fig. 8.12, *E*). The posterior dissection is performed sharply (see Fig. 8.12, *F*). Special attention is directed to the location of the anus and rectum. It is sometimes helpful for the operator to place a double-gloved finger in the rectum to ascertain its

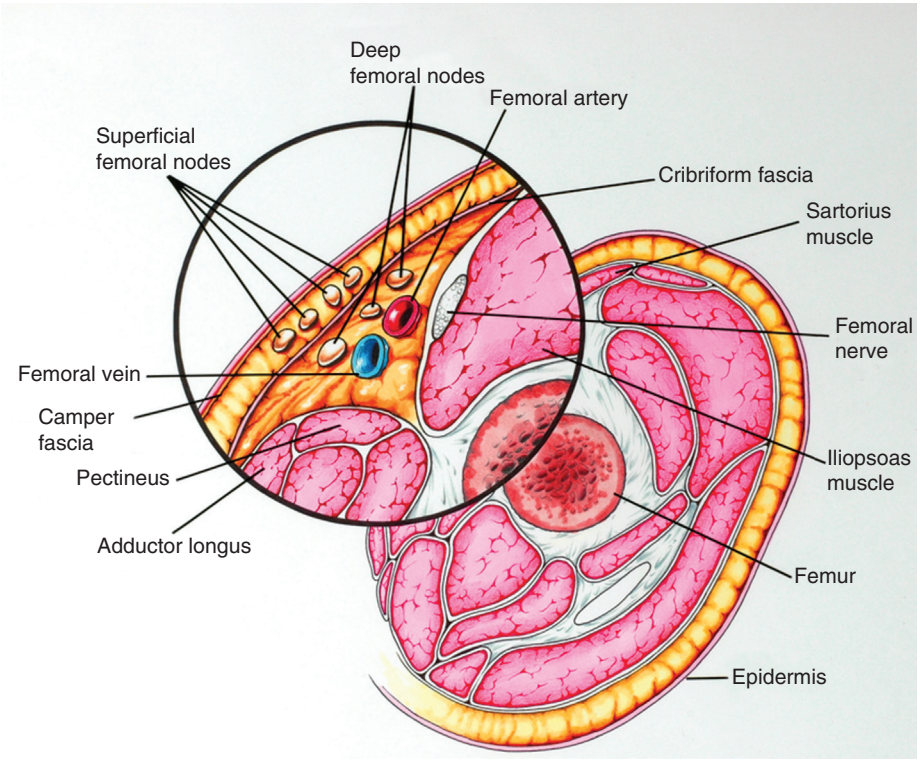

FIGURE 8.15 Many inguinal nodes are located between the Camper fascia and the cribriform fascia, as noted on cross-section through the femoral triangle. Additional nodes are clustered in the foramen ovalis in the part protruding from beneath the plane of the cribriform fascia. (Modified from Cabanas RM. An approach to the treatment of penile carcinoma. *Cancer* 1977;39:456. Copyright © 1977 American Cancer Society. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

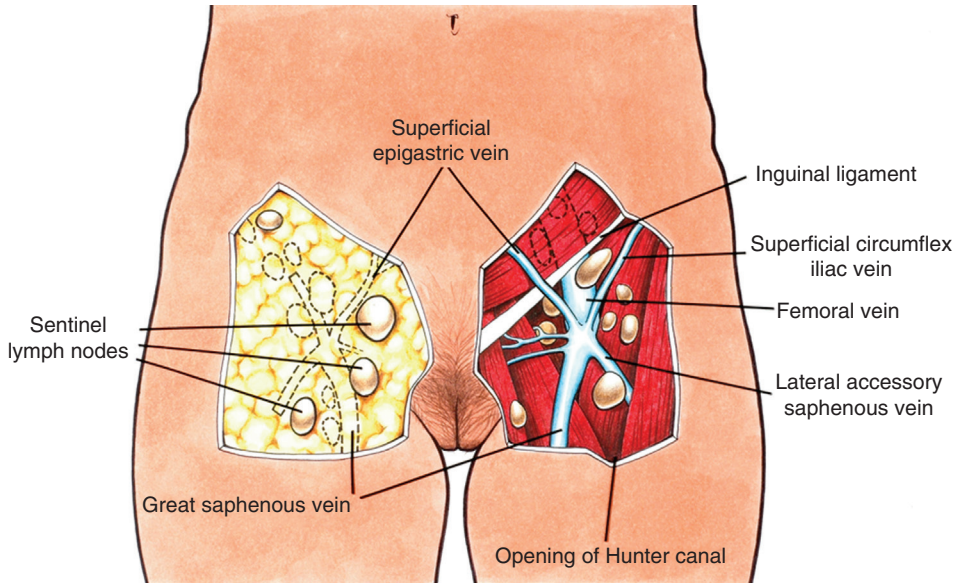

FIGURE 8.16 The *right side* demonstrates the two groups of lymph nodes making up the "sentinel" nodes. The *left side* notes the limits of the dissection with the cribriform fascia removed. The triangle that is dissected in a full inguinal lymphadenectomy is clearly identified on the patient's left side. The inguinal ligament forms the base of the triangle, and the opening of the Hunter canal becomes the apex. The triangle is bound laterally by the sartorius muscle and medially by the adductor muscles and fascia.

location and avoid damage during this part of the procedure. The clitoris is then isolated, and its suspensory ligament is clamped, divided, and suture ligated at its inferior attachment to the pubic bone. It is often helpful at this point to attempt to isolate the ischiocavernosus muscle and divide this structure as laterally as possible (see Fig. 8.12, *G*). The pudendal artery and vein are ligated bilaterally. At this point in the procedure, only the vagina remains attached to the vulva (see Fig. 8.12, *H*). A decision about the amount of vagina to be removed should be made relative to the location and size of cancer and based on knowledge of the lymphatic drainage of the vulva. Every effort should be made to avoid resection of the urethra unless it is close to the cancer. If it is indicated, the distal 1 to 2 cm of this organ can be removed without damage to the functional sphincter. The perineal defect is closed primarily with mattress sutures of 0 or 2-0 delayed absorbable suture. Tension on this closure can be prevented, if necessary, by sharp and blunt mobilization of the vaginal barrel or subcutaneous tissue of the thigh. The most anterior extent of the dissection may be allowed to granulate secondarily for large defects if closure would result in significant tension. This prevents distortion of the urethra and alteration of the urinary stream. If the defect is too large for primary closure, intraposition of a split-thickness skin graft or rhomboid or rotational flaps can be used.

Multiple studies have demonstrated that the classical radical vulvectomy can be safely modified depending on the laterality and extent of the lesion without compromising outcomes if a 1 to 2-cm circumferential margin is maintained. If a unilateral lesion is present, radical local excision or modified radical vulvectomy can be performed. If presurgical clinical examination reveals tumor less than 1.0 cm from structures that will not be surgically removed, then the potential of an inadequate surgical margin is high, and preoperative radiation or concomitant chemotherapy and radiation should be considered.

Morbidity Associated With Treatment of Vulvar Carcinoma

In the early series of Way, the operative mortality rate approached 20%. In the past 2 decades, this has been reduced to 1% to 2%. This procedure is commonly carried out in the ninth and tenth decades of life with surprising safety. However, morbidity remains high and most commonly includes wound breakdown, lower extremity lymphedema, lymphocyst formation, decreased pelvic support, and decreased sexual function.

Wound breakdown occurs in more than 50% of patients in most series. This aspect of morbidity is usually limited to skin loss at the margin of the groin incision. Podratz and colleagues at the Mayo Clinic noted impaired primary wound healing in 148 of 175 patients (85%) who were treated with radical vulvectomy and inguinal lymphadenectomy. Removing lesser amounts of skin and decreasing the undermining of the skin flaps have reduced the incidence of wound breakdown. Routine prophylactic antibiotics and the use of closed-suction drainage aid in wound healing and decrease the incidence of wound cellulitis and wound breakdown. Careful débridement and vigorous care to keep the wounds clean and dry optimize healing. Bed rest for 1 to 3 days after extensive resections may be considered but must be balanced against the increased risks of thromboembolism and pulmonary complications.

Lymphedema of the lower extremities is another potential major problem (see Fig. 8.17). Historically, lymphedema was much more common in patients who underwent inguinal and

FIGURE 8.17 Marked lymphedema of the left leg after inguinal and pelvic lymphadenectomy.

FIGURE 8.18 Severe edema of the vulva after radiation therapy with necrosis at the site of the primary lesion.

pelvic lymphadenectomy. Podratz and colleagues reported that varying degrees of lymphedema of the lower extremities occurred in 69% of their patients. This debilitating long-term complication can be reduced by routine use of custom-made elastic support hose during the first postoperative year while collateral pathways of lymph drainage develop. Streptococcal lymphangitis in the lower extremities is associated with lymphedema; thus, Rutledge and colleagues recommended low-dose prophylactic antibiotic therapy after lymphadenectomy. Zhang and colleagues confirmed Plaxe's observation that sparing of the saphenous vein reduces the incidence of chronic lymphedema and does not compromise the outcome, with similar recurrence rates in patients undergoing complete resection versus preservation of the saphenous vein during inguinal lymphadenectomy.

Boccardo and associates reported performing multiple lymphatic-venous anastomoses after IFLND in 25 patients with vulvar cancer and melanoma of the trunk with blue dye injection into the thigh preoperatively. Afferent lymphatic channels to the blue nodes were anastomosed to a collateral branch of the great saphenous vein. They reported no lymphocele or infectious complications, and only one patient had long-term lower limb lymphedema. Further study is needed of this technique.

Lymphocysts in the groin are infrequent and usually resolve spontaneously. The incidence can be reduced by careful ligation of all the lymph-bearing tissue during the groin dissection and by maintaining closed-suction drains in these spaces postoperatively until drainage is less than 30 cc/day. On occasion, intermittent aseptic aspiration of the fluid facilitates resolution.

Complication rates have been reduced significantly with the use of modified radical excisions and smaller groin incisions as well as use of SLN techniques. Multiple series (Rouzier et al., 2003; Gaarenstroom et al., 2003; Gould et al., 2001) have shown that wound cellulitis occurs in 25% to 39% of patients, wound breakdown in 17% to 31% of patients, and lymphedema in 28% to 39% of patients. SLN techniques have further reduced morbidity significantly.

Morbidity is also associated with radiation therapy. The use of radiation therapy as a priori treatment, especially in patients with fixed inguinal nodes, can result in significant vulvar edema. This is especially true when low fields are used to include vulvar disease. Fig. 8.18 illustrates severe edema in a patient treated primarily with radiation therapy. Necrosis (at 5 o'clock) is a residual from the large lesion-occupying that area before irradiation. Pelvic radiation therapy also increases risk of pelvic fracture, especially in older women. Baxter et al. reported more fractures occurred in patients treated for anal cancer followed by rectal cancer and cervical cancer. Although the risk in vulvar cancer was not specifically evaluated because of small numbers, all women undergoing pelvic radiation had a higher rate of pelvic fracture than women with pelvic malignancies who did not undergo irradiation, and nearly 90% of fractures involved the hip.

Symptoms related to stress incontinence and the development of cystocele or rectocele are sometimes reported by patients undergoing surgery or radiation for the treatment of vulvar cancer. These conditions are secondary to the loss of the support of the lower end of the vagina and subsequent enlargement of the introitus. The findings may also simply

reflect the increased frequency of pelvic visceral prolapse among older women.

Removal of significant vulvar tissue, particularly the clitoris, can result in decreased sexual satisfaction. With small lesions in which the clitoris is not involved, resection with preservation of the clitoris should be performed.

Survival Results

Survival in cancer of the vulva is directly related to the extent of disease. In addition, because this malignant neoplasm is initially diagnosed in elderly women, many patients succumb to intercurrent disease while tumor free. In stage I and stage II disease, the corrected 5-year survival rate should approach 90%. A 75% corrected 5-year survival rate for all stages of vulvar cancer is commonly reported.

Regardless of stage, nodal status is of particular prognostic significance. In many series, if the lymph nodes are negative irrespective of stage, more than 90% of these patients will survive 5 years (corrected survival), but only 40% to 50% will survive if the lymph nodes are positive (Table 8.10). The large National Cancer Data Base (NCDB) study reported a stage I 5-year survival rate of 93% and 87% for stage II. In patients with negative nodes, irrespective of size or primary lesion, the 5-year survival rate was 90%. The survival rate was 55% with one positive node, 59% with two or three positive nodes, and 33% with four positive nodes. In patients with positive nodes, the survival rate was 62% if the primary lesion was 2 cm or smaller and 43% if the primary lesion was larger than 2 cm. OS results by stage are found in Fig. 8.19.

Curry and associates noted that patients with three or fewer involved unilateral groin nodes had a 5-year survival rate of 68% (17 of 25) versus 0% (0 of 5) if more than three nodes had metastases. None of the patients with three or fewer involved nodes had pelvic node metastases. Boyce and associates and Shimm and coworkers reported similar results, with prognosis worsening not only with an increase in the number of positive nodes but also to a lesser extent with bilateral inguinal node involvement. Of the patients with more than four unilateral nodes, 50% had pelvic node metastasis, and if bilateral groin nodes were involved, 26% had positive pelvic nodes. In patients with positive pelvic nodes, the survival rate is poor. Collected series indicate that only one-fifth of patients with pelvic node metastasis survived 5 years (Table 8.11).

Features of nodal metastasis have been noted by some investigators to carry prognostic significance. Raspagliesi and associates evaluated features that included FIGO stage, depth of invasion, grade, lymph node status, lymphovascular space involvement (LVSI), DNA ploidy, and patient age and found that lymph node status and LVSI were both significant independent prognostic factors. Pathologic analysis of metastatic lymph nodes determined that the percentage of nodal replacement and extracapsular spread were both statistically significant also, but the number of positive nodes and laterality were not significant. Similarly, Fons and colleagues confirmed that extracapsular spread was an important prognostic factor. In addition, the significance of bilateral lymph node involvement was lost when the total number of metastatic nodes was taken into account. In other words, the number of metastatic nodes is more important than their location—either unilateral or bilateral. FIGO staging modifications for vulvar cancer included degree of tumor burden within metastatic lymph nodes, number of involved nodes, and presence of extracapsular lymph node spread (Table 8.6). Tumor size is now included in stage I substaging, rather than stage I and stage II, and laterality of lymph node metastasis is no longer included.

Mahner and associates recently presented a large series examining the impact of nodes on outcome that detailed a 10-year experience from the AGO composed of 1249 women who had lymph node assessments. Of the node-positive patients, 39% had one, and 23% had two positive nodes. Three-year progression-free survival (PFS) rate of node-positive patients was 35%, and OS was 56% compared with 75% and 90% in node-negative patients. Those with positive nodes who received postoperative radiation to the groin and other fields demonstrated improved survival (3-year PFS, 40% vs. 26%), but improved treatments such as adding chemotherapy are needed to overcome these poor outcomes.

Tolerance of the Elderly Patients to Therapy

The rate of SCC of the vulva increases with age, often affecting patients in the eighth through tenth decades of life. As the average lifespan of women increases, gynecologic malignant neoplasms in geriatric patients have become more common. The reason for the increase in incidence of cancer in this population has not been clearly established, although multiple factors may be involved, including decreased immunosurveillance, longer duration of environmental carcinogenic exposures, and an accumulation of tumorigenic mutations.

Elderly patients should not be categorically excluded from appropriate aggressive therapies; nonetheless, treatment may require modifications to accommodate comorbidities and functional status. **Surgical therapy such as radical vulvectomy and inguinal lymphadenectomy is generally well tolerated by elderly patients.**

Recurrence

Recurrence may be local or distant, and more than 80% occur in the first 2 years after therapy, demanding initial close follow-up. Oonk et al. noted that 65% of recurrences were found during scheduled follow-up visits and that half of those patients were asymptomatic. Recurrences found during scheduled follow-ups tended to be smaller. Local recurrence is more common with larger tumors and positive capillary-lymphatic space involvement (Table 8.12). More than half of the recurrences are local and near the site of the primary lesion. Recurrence is more common in patients with large primary tumors or metastatic disease in the lymph nodes at initial surgery. The margin of resection has also long been recognized to be a significant prognostic factor. The goal is to achieve a tumor-free margin of 1 cm or more to minimize local recurrence risk. One needs to account for approximately 20% specimen shrinkage with tissue fixation and slide preparation; thus, an 8-mm margin with fixed tissue will correspond to the desired surgical margin of 1 cm. Data from Heaps and colleagues as well as de Hullu et al. and Rouzier et al. established this relationship. The high incidence of local recurrence demands careful attention to adequate margins in the removal of the primary lesion. Some recurrences on the vulva occur at a site remote from the primary excision. Rouzier and colleagues (2001) noted that these patients, who may actually have new primary lesions, had a better prognosis than those who recurred earlier and near the site of the prior excision.

TABLE 8.12 Sites of Recurrence After Modified Radical Operation

Author	Patients (*n*)	Local (%)	Bridge (%)	Groin (%)	Distant (%)
de Hullu et al. (2002)	238	18 (8)	1 (0.4)	2 (0.8)	12 (5)
Gonzalez-Bosquet et al. (2005)	330	64 (19)	—	8 (2.4)	37 (11)

Rouzier et al. (2002)	215	26 (17)	7 (3.3)		

Radical wide local excision and the triple-incision technique may lead to a slightly increased risk for local recurrence (van der Velden et al., 2004). Care must be given to excising the entire lesion with at least a 1- to 2-cm margin. In many instances, local recurrences can be successfully treated by local excision or interstitial irradiation. Patients with recurrent local disease in the lymph node area or distant disease are difficult to treat, and the salvage rate is poor. Simonsen reported a 40% salvage rate with local recurrence and an 8% survival rate at 5 years with regional metastases. Both groups were treated with a combination of surgery and radiation therapy. Prempree and Amornmarn demonstrated similar results using radiation alone. Disease limited to the introitus resulted in the best prognosis: six of six patients survived. As expected, extensive recurrences have the poorest prognosis, especially when bone involvement occurs. Patients with distant recurrences have been treated with platinum-based chemotherapy, and a 30% overall response rate has been achieved. Responses are more likely outside the radiation field.

EARLY VULVAR CARCINOMA

Andreasson and Nyboe constructed three different models of groups at low risk for metastasis in SCC of the vulva region. They concluded that a distinct profile of low-risk patients would require data from large accruals of patients and international collaboration. Based on such studies, the International Society for the Study of Vulvovaginal Disease (ISSVD) proposed the following pathologic definition of microinvasive carcinoma of the vulva: "a squamous carcinoma having a diameter of less than 2 cm, as measured in the fresh state, with a depth of invasion of less than 1 mm, measured from the epithelial-stromal junction of the most superficial adjacent dermal papilla to the deepest point of invasion." LVSI by tumor excludes the lesion from this definition, and groin nodes should be clinically nonsuspicious. The current staging system classifies these lesions as stage Ia. Microinvasive, or stage Ia, lesions are managed with wide local excision and do not require inguinal lymphadenectomy because lymph node metastasis is extremely rare.

Assessing the depth of invasion is obviously critical in assuring microinvasion and, unfortunately, there remains considerable

inconsistency regarding pathologists' measurement methodology. The preferred method measures from the most superficial dermal–epidermal junction of the most superficial adjacent dermal papilla as required in the FIGO staging system. Others have used a method that measures from the surface of the lesion; although this method is simpler, it appears not to be as reflective of true invasion. The importance of LVSI adjacent to the vulvar carcinoma in predicting lymph node metastasis, or prognosis, remains controversial. However, data support the hypothesis that LVSI by tumor at the site of the primary is associated with an increased frequency of lymph node metastasis. There does not appear to be a definitive correlation between tumor differentiation and lymph node metastasis and survival. There may be an association between depth of tumor invasion and tumor differentiation, with deeply invasive tumors being more undifferentiated. More study of this issue is needed.

Podratz and colleagues reported a 5-year survival rate of 90% if the primary lesion was smaller than 1 cm, 89% if the lesion was 1 to 2 cm, and 83% if the lesion was 2 to 3 cm. They found that the 5- and 10-year survival rates of patients with stage I disease were independent of the extent of the surgical procedure, **suggesting that local radical resection with adequate margins is feasible without sacrifice of curability.**

Stehman and colleagues reported the GOG experience with 121 patients with stage I disease and invasion less than 5 mm treated with a modified radical vulvectomy and superficial inguinal lymphadenectomy. There were 19 recurrences, including five groin-only recurrences and seven deaths. Gordiner reported nine groin recurrences in 104 patients treated with superficial dissection. In these nine patients, the median number of nodes removed per groin was seven, but there were four groins with zero to two nodes. In contrast, in Kirby and coworkers' report, only an average of 2.7 nodes was retrieved per groin. The difference among all these reports is likely to be in the extent of the inguinal lymphadenectomy. Our suggestions for management are presented in Figs. 8.20 to 8.22.

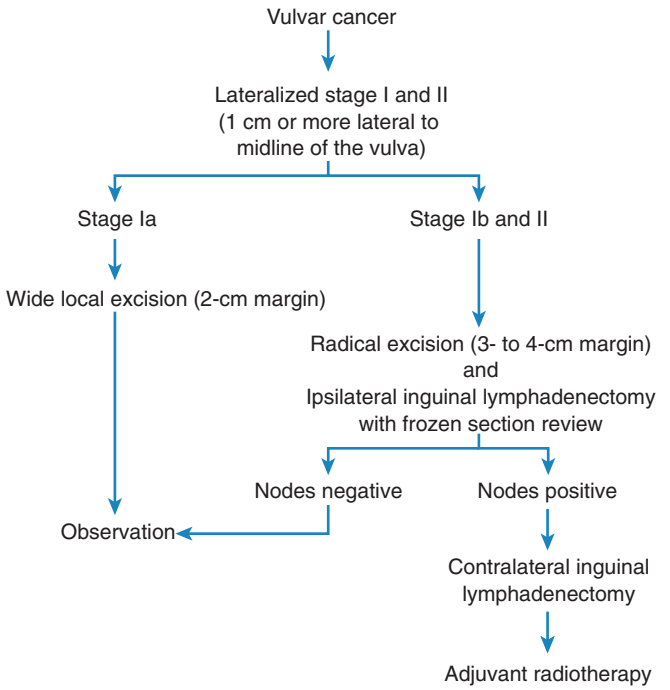

FIGURE 8.20 Algorithm for management of lateralized stage I or II vulvar cancer.

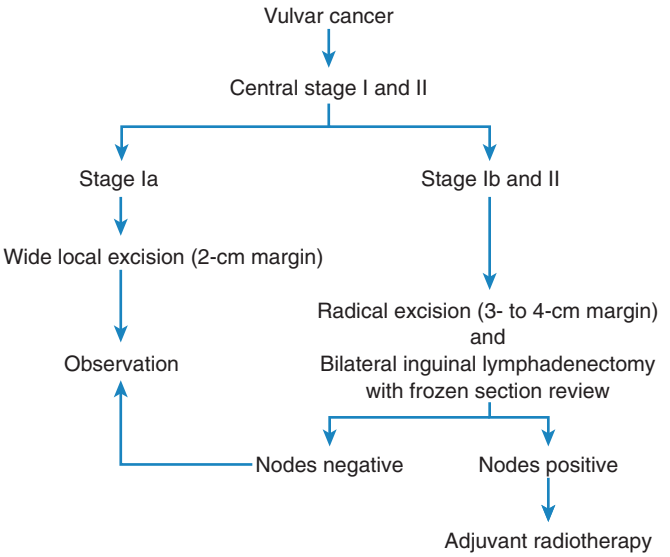

FIGURE 8.21 Algorithm for management of central stage I or II vulvar cancer.

PAGET DISEASE

Paget disease was first described by Sir James Phillips in 1874. Involvement of the vulva is rare. It most often occurs in women in the seventh decade of life but can be seen in young patients. **Pruritus and tenderness are the most common presenting symptoms.** These symptoms may be present for years before the patient seeks medical attention. The vulvar lesion may be localized to one labium or involve the entire vulvar epithelium. It is not unusual for the disease process to extend to the perirectal area, buttocks, inguinal area, or mons. Extension into the vagina has been reported.

Clinical and Histologic Features

On examination, the vulvar lesions are usually hyperemic, sharply demarcated, and thickened, with foci of excoriation and induration. The vulvar skin is often thick and smooth, leading to the impression of leukoplakia. It is not unusual for the hyperemic areas associated with a superficial white coating to give the impression of "cake-icing effect." This finding is classic and, if present, is almost pathognomonic for Paget disease (Fig. 8.23). **Typically, areas of leukoplakia are mixed with patches of redness where excoriation has occurred secondary to intense pruritus.** Vulvar changes are usually superficial, but palpation may indicate thickness or a mass-like effect under the epithelial changes, raising concern of an underlying adenocarcinoma. If clinical findings are suspicious, adequate biopsy of the lesion relative to width and depth of tissue must be obtained to enable adequate histologic evaluation. One

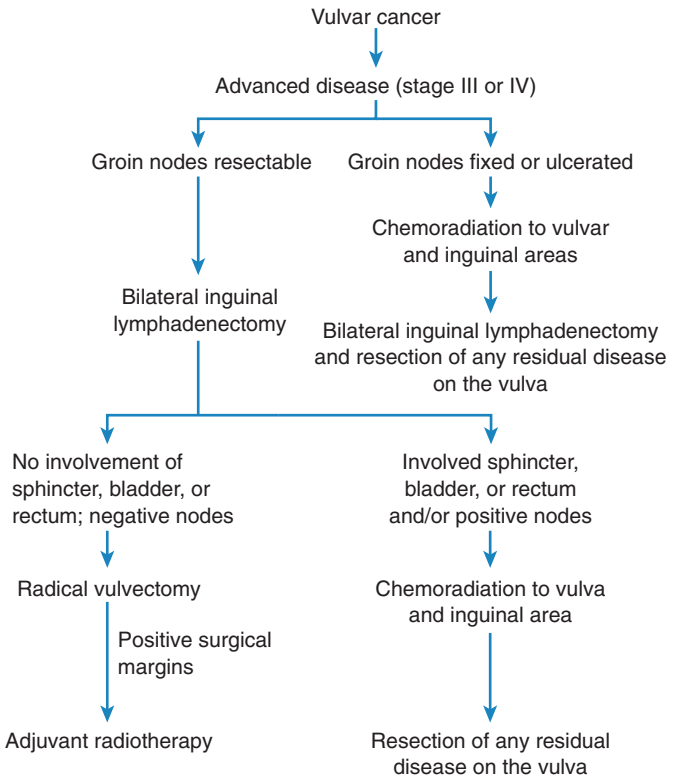

FIGURE 8.22 Algorithm for management of advanced (stage III or IV) vulvar cancer.

FIGURE 8.23 Paget disease of the vulva involving the lower half of the left labium major and labium minor. The white medial portion is characteristic of "cake-icing effect." The red medial aspect is also commonly seen and called "violaceous coloring."

should perform a needle aspiration of any thickness or mass that is palpated beneath the skin involved with Paget disease.

Historically, it appears that there are two separate lesions: intraepithelial extramammary Paget disease and pagetoid changes within the skin associated with an underlying adenocarcinoma. Lopes Filho et al. reported that of all extramammary Paget disease, approximately 65% is observed in the vulva. More recently, invasive Paget disease has been described based on the depth of invasion. Minimally invasive Paget disease is defined by Paget cells that have invaded the basement membrane into the underlying dermis to less than 1 mm. Invasive vulvar Paget disease is a lesion in which the Paget cells invade the basement membrane into the underlying dermis greater than 1 mm. Therapy for these two lesions is considerably different, and a definitive diagnosis is therefore imperative.

A thickened, often acanthotic, epidermis is the typical histologic finding. **Characteristic large cells with clear granular cytoplasm are found within the epidermis** (Fig. 8.24). A single layer of squamous cells often separates the Paget cells from the epidermis, but neoplastic cells may be in immediate contact with the dermis. Intraepidermal formation of glands with true lumens may also be present. The hair follicles may also be involved with Paget cells. These cells contain intracytoplasmic mucin demonstrated by Mayer's mucicarmine or Alcian blue. A mixed inflammatory infiltrate of variable intensity composed usually of lymphocytes and plasma cells is present in the upper dermis. IHC is helpful in distinguishing Paget from Bowen disease and amelanotic superficial spreading melanoma.

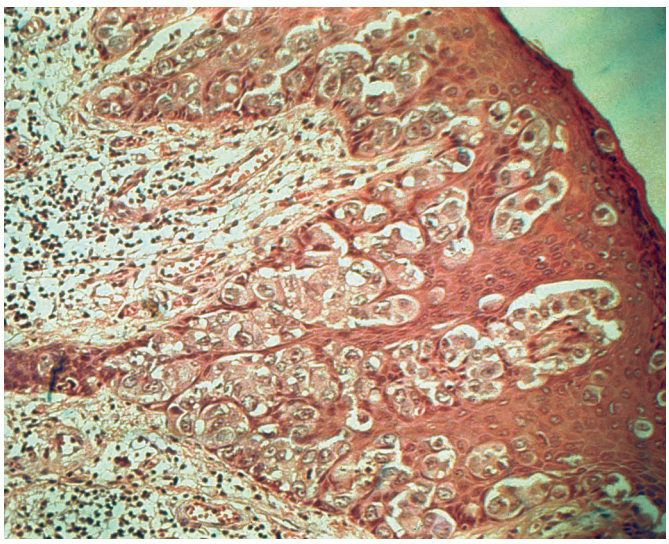

FIGURE 8.24 Histologic picture of Paget disease of the vulva. Large cells with clear cytoplasm are apparent in the epidermis. Note the heavy lymphocytic infiltration in the dermis.

Clinical Course and Management

If only intraepithelial Paget disease is present, the clinical course may be prolonged and indolent, often associated with recurrence of intraepithelial disease. Rarely, the disease can have an invasive component or be associated with an underlying adenocarcinoma of underlying apocrine glands. The latter is not actually Paget disease but rather a secondary infiltration of the vulvar skin with pagetoid cells from the primary adenocarcinoma. Paget

disease with an underlying adenocarcinoma can be aggressive, with metastasis to the regional lymph nodes and distant spread.

The literature has been confusing with regard to the association of invasive carcinoma and concomitant intraepithelial Paget disease. Early reports suggested invasive underlying adenocarcinomas in up to 20% of patients with histologically confirmed pagetoid cells in the vulvar skin. Recent literature suggests a much lower incidence. Similarly, older studies suggest that up to 25% of patients have a concomitant carcinoma at another site, such as the breast, colon, anus, or cervix. Here, too, recent studies have not confirmed such strong associations, with only a rare patient having a simultaneous lesion. In a review of 100 cases from eight institutions, Fanning and colleagues noted 12% of patients with invasive vulvar Paget disease and 4% with an underlying primary vulvar adenocarcinoma. A review of the literature noted an underlying adenocarcinoma in 8% and 10% with invasive Paget disease of the vulva; 20 patients had a total of 26 nonvulvar malignant neoplasms. The authors postulated that the nonvulvar cancers were probably more related to advanced age of the patients and not necessarily to Paget disease. Note that this infrequent association with an underlying cancer is in contradistinction to the more than 90% association observed between mammary Paget and underlying breast cancer.

Because Paget disease without an underlying adenocarcinoma appears to be a true intraepithelial neoplasia, it can be treated as such. Wide local excision to include the entire lesion is usually sufficient. **Even with apparently wide margins, it is not unusual to find Paget disease extending to the edge of the surgical margin, and recurrences are common.** In the Fanning et al. study, 31 of 84 patients with intraepithelial disease developed a recurrence. Radical vulvectomy, hemivulvectomy, and wide local excision were used as treatment. Recurrence rates were similar with all three treatments. Because of the high recurrence rate and challenges in evaluating the margin grossly, intraoperative frozen section of the margins has been recommended in the past (Fig. 8.25). Unfortunately, this approach is time and labor intensive without leading to an improved outcome. Fishman and colleagues evaluated 14 patients with Paget disease who underwent a total of 25 operations. Margin status was determined by frozen section in eight, with an average of 5.5 biopsies per patient to achieve a negative margin. Visual inspection was used to determine the margin in the remaining 17 patients. Frozen section was incorrect in three of eight (37.5%), and visual inspection was wrong in six of 17 (35%). Furthermore, outcome was not significantly different with respect to the margin status. A total of two of five (40%) with a positive margin and three of nine (33%) with a negative margin experienced recurrences.

New lesions can be handled in the same manner as the primary disease—that is, by wide local excision. Studies show that removal of full-thickness skin plus a microscopic amount of subcutaneous fat routinely results in an operative specimen that is 6 mm thick (Fig. 8.26). Because the base of the hair follicles in vulvar skin is at a depth of 4 mm, full-thickness resection should remove cells that may have involved hair shafts.

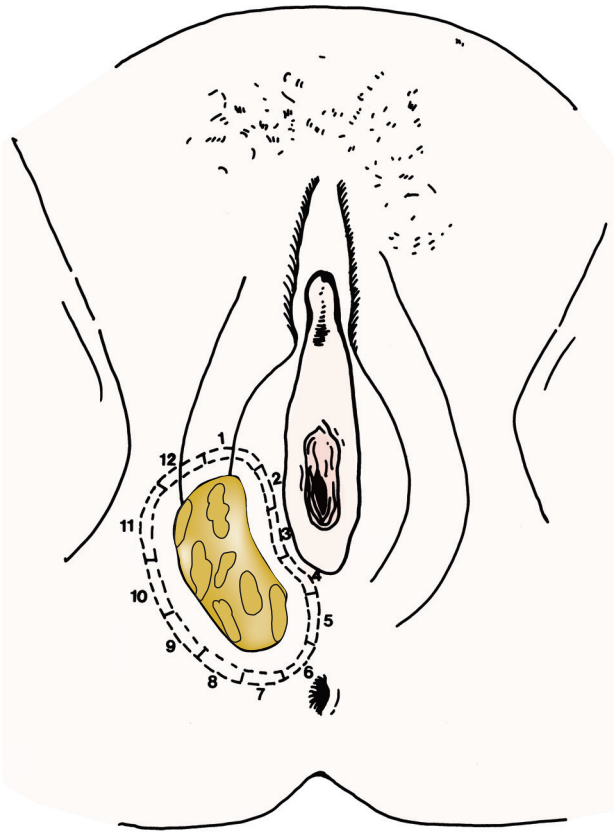

FIGURE 8.25 Diagram of the vulva with an area of Paget disease involving the right labium majus. The two parallel lines lateral to the lesion represent the surgical margin sent intraoperatively for frozen section analysis. The margin is serially cut in a clockwise fashion, labeled, and analyzed. If any segment of the margin reveals Paget disease, the resection is extended in that direction. (From Bergen S, DiSaia PJ, Liao SY, et al. Conservative management of extramammary Paget's disease of the vulva. *Gynecol Oncol* 1989;33:151.)

Lesions can be extensive in both primary and recurrent settings, and treatment should be determined accordingly. A skin graft to cover the removed tissue may be necessary. DiSaia and coworkers described two patients who developed recurrent Paget disease in the middle of a split-thickness skin graft. Retrodissemination of pagetoid cells from peripheral persistent disease was proposed as the likely mechanism of recurrence.

Besa and coworkers reported good results when radiotherapy was used in conjunction with surgery or for patients for whom surgery was not possible. A dose of 50 to 55 Gy appeared adequate. Voigt and colleagues reported a dramatic response of extramammary Paget carcinoma in a man with chemotherapy using carboplatin and 5-FU with folinic acid.

Patients in whom an underlying adenocarcinoma is identified in association with Paget disease of the vulva should be treated in the same manner as patients with other invasive malignant neoplasms of the vulva. This usually includes radical vulvectomy and inguinal lymphadenectomy. If the lymph nodes have no evidence of metastatic disease, the prognosis is good; however, if metastases are present in the lymph nodes, the prognosis is guarded.

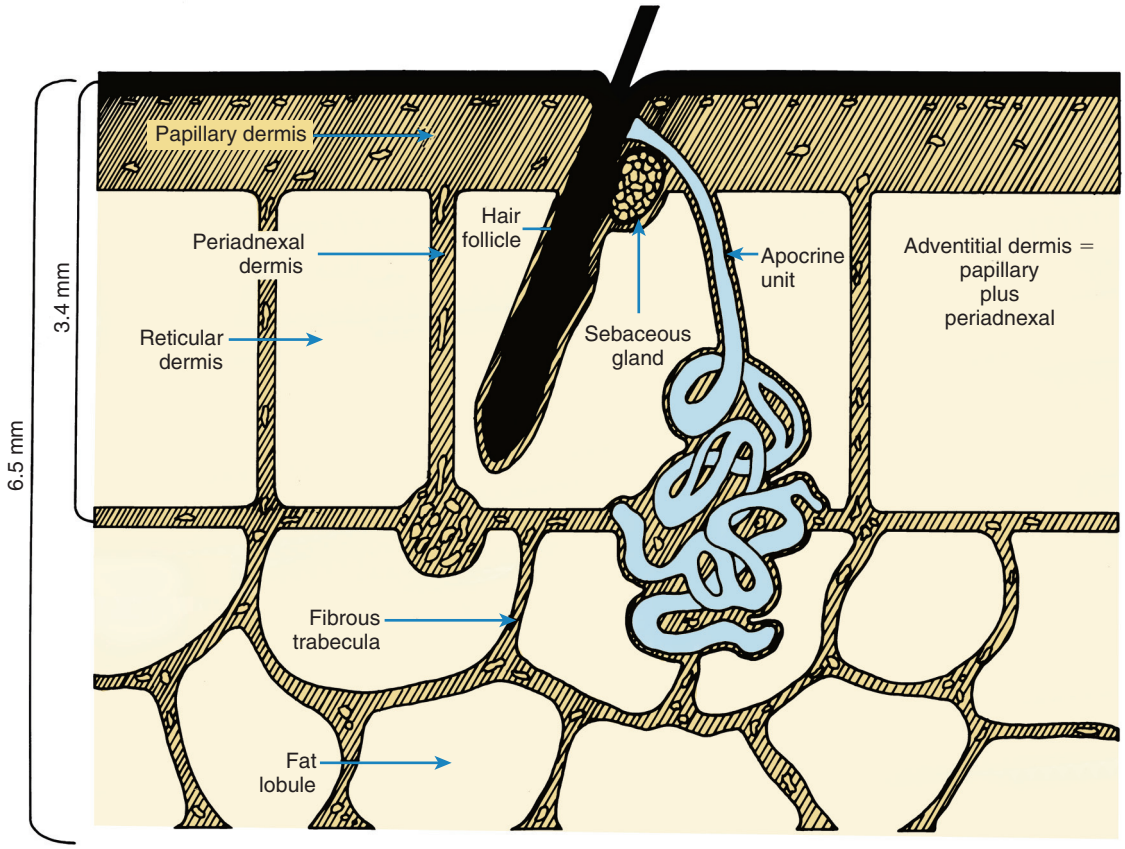

FIGURE 8.26 Schematic of vulvar skin anatomy showing the extension of skin appendages into the subdermal adipose tissue. (From Bergen S, DiSaia PJ, Liao SY, et al. Conservative management of extramammary Paget's disease of the vulva. *Gynecol Oncol* 1989;33:151.)

TABLE 8.13 High-Risk Group for Development of Melanoma

Increased risk with one or more of the following:
- Family history of melanoma
- Poor or no tanning ability, often with a history of sunburn in adolescence

Unusual moles with any of the following characteristics:
- Dark (blue-black) look
- Speckled or splotchy color pattern
- Jagged or fuzzy border
- Recent change in size, shape, or color of a mole
- Any mole larger than a dime

TABLE 8.14 Clark's Staging Classification of Melanoma by Levels

Level	Definition
I	In situ melanoma: All demonstrable tumor is above the basement membrane in the epidermis.
II	Melanoma extends through the basement membrane into the papillary dermis.
III	The tumor fills the papillary dermis and extends to the reticular dermis but does not invade it.
IV	The tumor extends into the reticular dermis.
V	The tumor extends into the subcutaneous fat.

MELANOMA

Melanoma of the vulva is rare but represents the second most common malignant neoplasm of the vulva. This malignant neoplasm probably arises from a lesion containing junctional or compound nevi. Tables 8.13 to 8.15 define the high-risk group and describe the characteristics of pigmented lesions of the vulva or any skin that determine the need for excisional biopsy.

Characteristically, vulvar melanomas are usually pigmented and raised, and they may be ulcerated (Fig. 8.27). In a nationwide study of 198 women from Sweden, vulvar

TABLE 8.15 Lymph Node Metastasis and Clark's Level of Vulvar Melanoma

Clark's Level (*n*)	Nodes Examined (%)	Positive Nodes (%)
I (38)	3 (8)	0 (44)
II (80)	30 (60)	3 (10)
III (70)	38 (54)	6 (16)
IV (90)	55 (61)	13 (23)
V (45)	31 (69)	9 (29)

Modified from Creasman WT, Phillips JL, Mench HR. A survey of hospital management practice for vulvar melanoma. *J Am Coll Surg* 1999;188:670.

melanoma was overrepresented by 2.5 times compared with cutaneous melanoma. **Most vulvar melanomas are on the labia majora or clitoris.** Of all melanomas, 46% of lesions were in glabrous (nonhairy) skin, 12% in hairy skin, and 35% in both areas. The median age of patients with these lesions is 65 years in a series reported by Tasseron and coworkers. In a large NCDB study of melanoma of the vulva, age ranged from 7 to 97 years with a median of 66 years; in this study, 50% were 70 years old or older, and macroscopic amelanotic tumors were present in 27% of patients. Patients may experience pruritus, bleeding, or enlargement of a pigmented area. Melanomas are often misdiagnosed as undifferentiated SCCs, especially when they are histologically amelanotic. The histologic diversity of melanoma can make the diagnosis challenging. In difficult cases, ultrastructural analysis with electron microscopy and immunohistochemistry (especially with S-100 protein and HMB antibody) in conjunction with histologic evaluation can establish the diagnosis.

FIGURE 8.27 Melanoma of the vulva. A typical pigmented neoplasm is present.

Prognosis is related to the size of the lesion, depth of invasion, and margin status. A 50-year experience with vulvar and vaginal melanomas was reported by Seifried and associates in which they found that disease-free survival was dependent on tumor thickness, mitotic rate, ulceration status, and pathologic clearance margin. The Clark classification, which uses histologic levels, is commonly used for melanomas elsewhere on the skin and is of prognostic benefit for the vulva also (Table 8.16). In 1970, Breslow recognized that survival was relative to the greatest thickness of the invasive portion of the melanoma by micrometer measure (Fig. 8.28). The Breslow technique appeals to many because of its simplicity. In 1975, Chung and associates

TABLE 8.16 Correlation of Melanoma Thickness With Survival

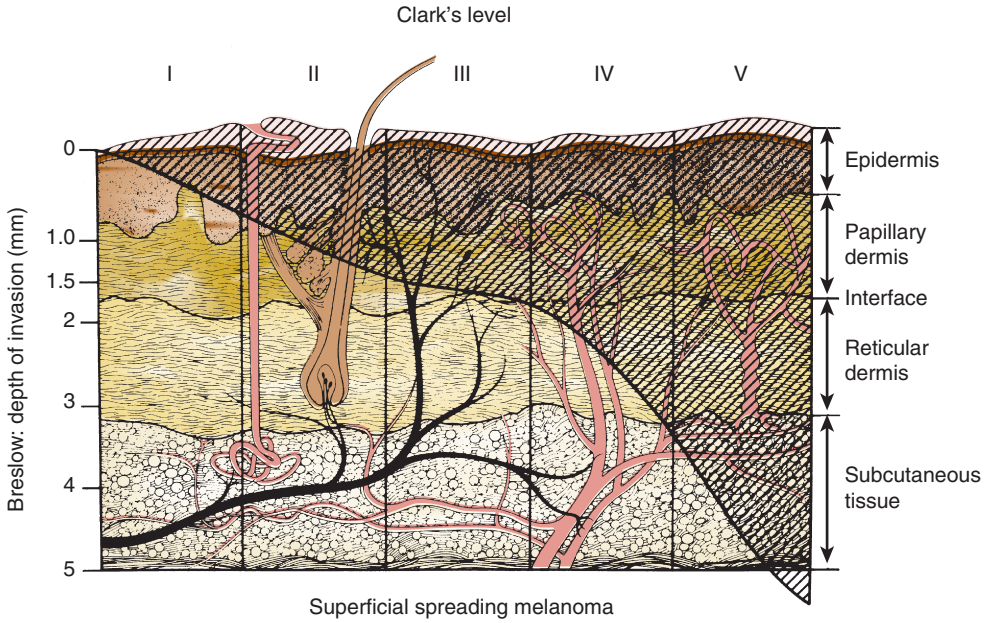

FIGURE 8.28 Comparison of the Clark and Breslow classifications for skin melanomas.

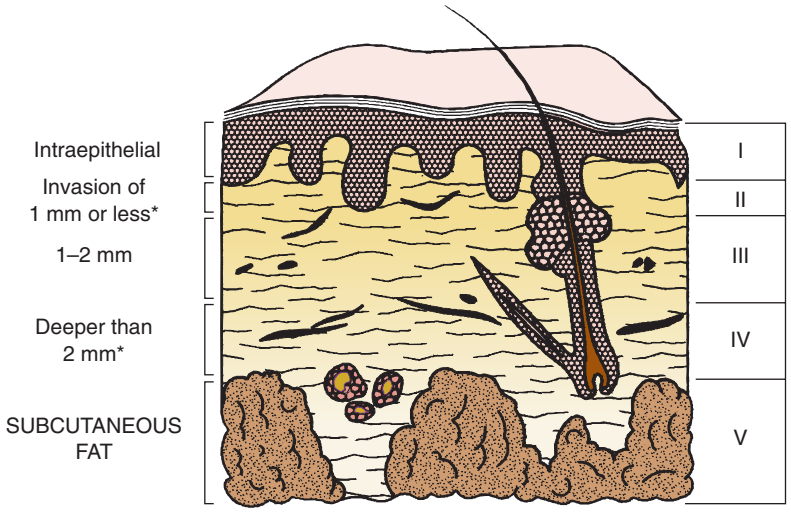

FIGURE 8.29 Chung system of reporting melanoma involvement.

described a third system of reporting level of involvement of vulvar melanoma (Fig. 8.29). Survival rates are influenced by histology as well. Five-year survival rates for superficial spreading and nodular melanomas were 71% and 38%, respectively; 10-year survival rates were 66% and 25%, respectively.

Historically, it had been suggested that all patients with melanoma of the vulva be treated with radical vulvectomy and inguinal and pelvic lymphadenectomy. More conservative approaches are now advocated. In the 596 patients described by the NCDB, surgery was used in more than 90% of patients with stage 0 to stage III disease. Local excision was performed mainly in early stage (stage 0 and stage I) disease. Lymph node evaluation was performed in more than 50% of the patients, with greater frequency for patients with advanced disease. **Radical local excision with a margin of 2 cm for thin lesions (≤7 mm) and 3 to 4 cm for thicker lesions appears to be adequate for most well-circumscribed melanomas.** Because prognosis is directly related to depth of invasion, therapy can be tailored accordingly. If the disease is intraepithelial, the cure rate should approximate 100%. Clark level I or II melanomas may be adequately treated with wide local excision. As the melanoma extends deeper, the chance of lymph node metastasis increases, and the prognosis worsens considerably. Podratz and colleagues reported that 10-year survival rates associated with Clark's level II, III, IV, and V tumors were 100%, 83%, 65%, and 23%, respectively. In the 323 patients described by the NCDB who had a Clark level determination, 157 had lymph nodes evaluated. Most were in level II to level V, and as expected, **metastasis increased as level of invasion increased** (Table 8.17). In the patients with negative nodes, survival of level I to level IV was 88%, 77%, 88%, and 85%, respectively. Interestingly, four of seven patients with positive nodes survived. Using the Breslow method, Jaramillo and coworkers and Day and coworkers reported nearly 100% survival rate in patients with lesions smaller than 1.5 mm in thickness, 65% to 70% survival rate in patients with lesions 1.5 to 4 mm, and 25% to 35% survival rate in patients with lesions larger than 4 mm (Table 8.18). Trimble and colleagues described 80 patients with a median follow-up time of 193 months. The 10-year survival rates for Chung level I to V were 100%, 81%, 87%, 11%, and 33%, respectively.

Verschraegen and colleagues reported that 32 of 51 patients ultimately had a recurrence of their melanoma. Both Clark's and Breslow's assessments were predictive. The type of operation performed did not impact the recurrence rate. The role of lymphadenectomy in this disease is probably more prognostic than therapeutic, and strong consideration can be given for SLN

TABLE 8.17 Lymph Node Metastasis and Clark's Level of Vulvar Melanoma

Clark's Level	Nodes Examined	Positive Nodes
I (n = 38)	3 (8%)	0 (44%)
II (n =80)	30 (60%)	3 (10%)
III (n = 70)	38 (54%)	6 (16%)
IV (n =90)	55 (61%)	13 (23%)
V (n =45)	31 (69%)	9 (29%)

TABLE 8.18 Correlation of Melanoma Thickness With Survival of Patients

Thickness (mm)	8-Year Survival Rate (%)
<0.85	100
0.85–1.5	99
1.5-4	66
>4	25–35

From Jaramillo BA, Ganjei P, Averette HE, et al. Malignant melanoma of the vulva. *Obstet Gynecol* 1985;66:398; Day CL, Lew RA, Mihm MC Jr, et al. The natural break points for primary tumor thickness in clinical stage I melanoma. *N Engl J Med* 1981;305:1155.

dissection as used for melanoma arising from other parts of the body. If disease is limited to the vulva, regardless of its extent, and the lymph nodes are negative, the survival rate is good. Most patients with positive inguinal or pelvic nodes eventually succumb to the disease.

Standard management of primary disease includes surgical resection, but there is a lack of consensus in the published literature regarding additional treatment options. Radiation, chemotherapy, biologic agents and, most recently, an array of immunologic therapies have been implemented in high-risk and recurrent settings. Recommendations can be extrapolated from the experience in nongenital cutaneous melanomas. Therapy should be tailored to the individual patient.

Rouzbahman and colleagues characterized the molecular features of 33 vulvar and 11 vaginal melanomas and found BRAF mutations in 8%, C-KIT mutations in 28%, NRAS mutations in 28%, and TP53 mutation in only 7.6% of the vulvar cases. Thus, the mutational analysis differed in distribution from other primary melanomas, and such analyses may lead to novel molecularly based therapeutics.

SARCOMA

Sarcoma of the vulva is rare, and the experience is limited even in large referral institutions. The source of these tumors can be any of the supporting mesenchymal structures of the vulva. Symptoms and findings can be similar to those noted with SCC, or patients can present with a well-circumscribed mass. In a review of 12 patients, DiSaia and colleagues noted that vulvar sarcoma occurred more often in younger patients (mean age, 38 years) than other vulvar malignant neoplasms. A variety of histologic subtypes have been reported, all exceedingly rare, including leiomyosarcoma; rhabdomyosarcoma; malignant fibrous histiocytoma; epithelioid sarcoma; dermatofibrosarcoma protuberans; and, even more rare, Kaposi sarcoma. The clinical course of these tumors tends to be similar to sarcomas occurring in other anatomic locations. The histologic grade appears to be the most important factor in prognosis. Whereas undifferentiated tumors often grow rapidly and metastasize early, well-differentiated tumors may be cured with local resection or follow an indolent course. Primary therapy consists of radical excision with adequate margins and bilateral inguinal lymphadenectomy except in the low-grade lesions, in which node involvement is rare. Patients undergoing wide local excision are at risk for local recurrence and should be observed closely. Recurrences can be managed with re-resection, chemotherapy, radiation, or combined modalities tailored to the individual patient.

BARTHOLIN GLAND CARCINOMA

Adenocarcinoma of the Bartholin gland is a rare lesion occurring in only about 1% of all vulvar malignant neoplasms (Fig. 8.30). Peak incidence is in women in their mid-60s, although it has been reported in a teenager. Because of its location, the tumor can be of considerable size before the patient is aware of symptoms. Dyspareunia may be one of the first symptoms,

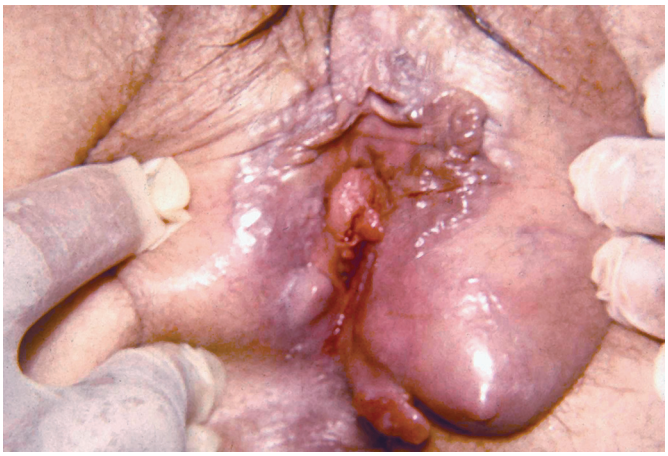

FIGURE 8.30 Adenocarcinoma of the Bartholin gland with local skin metastasis.

although the finding of a mass or ulcerative lesion may be the first indication. **An enlargement in the Bartholin gland area in a postmenopausal woman should be considered a malignant neoplasm until proved otherwise.** The lesion can spread into the ischiorectal fossa and to the inguinal nodes by the usual lymphatic spread pattern for vulvar cancer and via posterior spread to the pelvic nodes directly. Almost half of all carcinomas of Bartholin gland origin are SCCs. Every attempt should be made to differentiate between a true Bartholin gland cancer and a primary SCC of the vulva arising in proximity to the Bartholin gland. The prognosis is good if lymph node metastasis is not present.

Therapy includes radical resection with a large, wide, extensive dissection around the gland and inguinal lymphadenectomy. To have adequate margins, there may be a need to remove a considerable amount of vagina and, on occasion, part of the rectum. Pelvic lymphadenectomy is not indicated. A more conservative approach in selected patients with early disease may be appropriate. The largest series reported by Copeland and associates included 36 patients of whom 27 had squamous histology whose 5-year survival rate was 84%. Of 30 patients with LNDs, 14 (47%) had nodal metastasis, and 11 remain free of disease. Disease recurred in nine patients (six local recurrences, two distant, one local and distant), and four were treated successfully. Less impressive results were reported by Wheelock et al. in a series of 10 patients of whom nine underwent radical vulvectomy with bilateral inguinal lymphadenectomy. A total of five of the nine patients had positive lymph nodes of whom four died of disease. Recently, Bhalwal and colleagues reported on 33 women accessioned over 18 years with Bartholin gland carcinoma of whom 88% had squamous histology and 12% exhibited adenocarcinomas. Compared with those with primary vulvar cancers, those with Bartholin gland carcinoma were younger, had later stages of disease at diagnosis, and were more likely to receive radiation. Nonetheless, despite diagnoses at more advanced stages, patients with Bartholin gland cancers seem to have similar oncologic outcomes and survival rates to patients with vulvar carcinomas not related to the Bartholin gland.

Adenoid cystic carcinoma of the Bartholin gland is rare and manifested by frequent local painful recurrences and slowly progressive disease, including pulmonary metastasis, sometimes many years after initial therapy. The characteristic perineural and lymphatic invasion seen in these tumors are likely responsible for the pain and high recurrence rate. Recommended primary treatment ranges from wide local excision to radical vulvectomy and inguinal lymphadenectomy followed by careful monitoring. Local recurrences are best treated by surgery. As with some other rare tumors, radiation and chemotherapy can be considered individually, especially in refractory cases and in those with distant metastasis.

BASAL CELL CARCINOMA

Basal cell carcinoma usually presents in the eighth decade of life, comprising approximately 1.4% of all vulvar cancers. Clinical presentation often includes itching, irritation, or soreness and a lesion that bleeds and then seems to heal. The process repeats itself as the lesion slowly increases in size. No specific etiology or risk factors have been identified. Most lesions are small, and the most common location is the anterior hair-bearing aspect of the labia majora. A typical lesion has a rolled, pearly border showing fine telangiectatic vessels on the surface with central ulceration (Fig. 8.31). These lesions typically behave like they do elsewhere on the body, with local invasion being the rule. Stromal infiltration is usually circumscribed and orderly with a slow and indolent growth rate. Lymphatics are rarely involved, and metastases are rare.

FIGURE 8.31 Basal cell carcinoma.

Primary treatment consists of wide local excision and primary closure without the need to surgically evaluate regional lymph nodes. Close follow-up is important. In resecting large lesions, skin grafting may be required. In the rare cases of very large lesions or clinically involved lymph nodes, successful response to preoperative radiation has been reported. Basal cell carcinoma must be differentiated pathologically from basosquamous cell carcinoma, which must be treated as one would treat a SCC of the vulva.

Invasive Cancer of the Vagina

Marilyn Huang, MD, Brian M. Slomovitz, MD, MS, FACOG, Robert L. Coleman, MD

OUTLINE

Squamous Cell Carcinoma of the Vagina
- Epidemiology
- Screening
- Signs and Symptoms
- Diagnostic Considerations
- Staging
- Patterns of Spread
- Prognostic Features
- Management
- Survival and Recurrence

Rare Histologies
- Adenocarcinoma and Clear Cell Adenocarcinoma
- Recurrent Adenocarcinoma
- Malignant Melanoma
- Sarcoma
- Endodermal Sinus Tumor
- Special Considerations

KEY POINTS

1. Primary carcinoma of the vagina comprises 3% of gynecologic malignancies.
2. Metastatic disease to the vagina develops more commonly than primary disease.
3. Most disease is treated with radiation therapy and in a similar fashion to cervical cancer.

The vagina, in sharp contrast to the uterine cervix and other gynecologic organs, rarely undergoes malignant transformation. **Primary cancer of the vagina is uncommon, accounting for only 3% of gynecologic malignancies** (Table 9-1). Vaginal cancers in the United States occur in about 4000 women and account for 900 deaths each year.

When primary vaginal cancer occurs, it is usually in the upper third of the vagina (Table 9-2) and is most commonly an epithelial carcinoma. The mean age of diagnosis is approximately 65 years old with an incidence **between 35 and 90 years and more than 50% of the cases occurring between the seventh and ninth decades of life** (Fig. 9.1). By convention, any primary malignant neoplasm involving both the cervix and vagina is classified as cervical cancer.

Squamous cell carcinoma (SCC) is the most frequent histologic subtype (78%). Adenocarcinoma (6%), melanoma (3%), and sarcoma (3%) have all been described as primary vaginal cancers (Table 9-3). The relationship of diethylstilbestrol (DES) intrauterine exposure to clear cell adenocarcinoma of the vagina has resulted in the reporting of significant numbers of cases of vaginal adenocarcinoma in both exposed and unexposed individuals. A personal history of radiation therapy contributes to the development of vaginal sarcomas.

The principal focus of this chapter is squamous cancers. Rare histologies are discussed later in the chapter. However, the clinical evaluation and staging for vaginal tumors are the same for all types of vaginal cancers.

SQUAMOUS CELL CARCINOMA OF THE VAGINA

Epidemiology

Similar to cervical cancer, epidemiologic evidence suggests that vaginal cancer has a strong relationship with human papilloma virus (HPV) infection. **HPV subtype 16 presence has been associated with up to two-thirds of all new cases of vaginal cancer.** Approximately one-third of women who develop vaginal cancer will have a history of cervical dysplasia or cervical cancer more than 5 years earlier. A study from the University of South Carolina found that the median interval between cervical disease and development of vaginal cancer was 14 years, and 16% of patients had a history of prior radiation. Proposed mechanisms for developing vaginal cancer with a remote history of cervical cancer include occult residual disease, radiation-induced tumorigenesis, and a new primary cancer in a high-risk individual. A large retrospective cohort of more than 130,000 women with cervical intraepithelial neoplasia 3 (CIN3) demonstrated a significantly increased risk of vaginal cancer compared with women within the same population and time period (incidence ratio, 6.8). Similarly, of the 153 women treated for vaginal cancer, 34 had a prior history of cervical cancer. In general, a new vaginal lesion 5 years or more after treatment of cervical cancer constitutes a new primary vaginal cancer.

The natural course of vaginal intraepithelial neoplasia (VAIN) is not well understood because most patients are treated

TABLE 9.1 Incidence of Vaginal Cancer

Series	Malignant Genital Neoplasms (*n*)	Vaginal Cancer (%)
Smith (1955)	8199	1.5

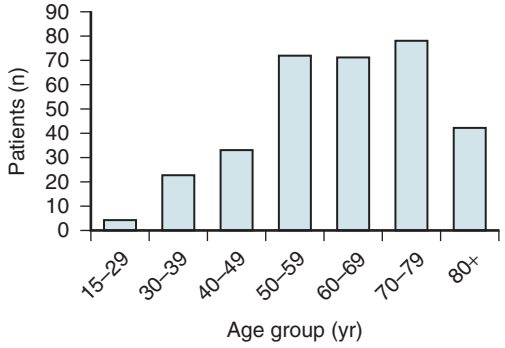
Miscellaneous	3



after they are diagnosed. Up to 99% of VAIN 1 and 93% of VAIN 2/3 result from HPV, with HPV-16 subtype being the most common. Thus, risk factors for vaginal cancer are similar to those for cervical neoplasia: multiple lifetime sexual partners, early age at first intercourse, and smoking. Between 3% and 7% of cases of VAIN progress to invasive carcinoma despite treatment. Chronic vaginal irritation has been suggested to contribute to the etiology of vaginal cancer; however, the mechanism by which this promotes carcinogenesis is not well understood and has not been extensively studied.

Screening

The diagnosis of vaginal cancer may often be missed in women who have had a prior hysterectomy. It is particularly important that the lateral "horns" of the upper vaginal vault be thoroughly examined. For some patients, this may require use of an endocervical speculum to ensure a complete evaluation of the vaginal apices.

The Papanicolaou (Pap) test is effective in detecting vaginal cancer in asymptomatic women. The American Cancer Society recommends that Pap screening for cervical cancer may be discontinued in women who have had a hysterectomy for conditions other than cervical dysplasia or cancer. However, women with a history of cervical dysplasia or cervical cancer are at increased risk, and Pap testing should be continued whether or not they may have had a hysterectomy.

For a screening test to be effective, the incidence of the disease must be sufficient to justify the cost. Because the incidence of vaginal cancer is so low, routine screening is not cost effective. **However, development of vaginal cancer is possible even in women with a history of hysterectomy for benign disease.** Bell and colleagues described 87 patients with primary cancer of the vagina, 31 of whom had undergone total hysterectomy for benign disease. Benedet and colleagues found that 19 of their 97 patients (20%) with vaginal cancer had surgery for benign diseases. Peters et al. reported that 38% (25 of 68) of the patients in their series had undergone prior hysterectomies for benign disease. Guidelines aside, these observations underscore the need to individualize vaginal cancer cytologic screening by careful consideration of estimated risks and benefits of such clinical activity.

Age group (yr)	Patients (*n*)	Patients (%)
15–29	4	1.2
30–39	23	7.1
40–49	33	10.2
50–59	72	22.2
60–69	71	21.9
70–79	78	24.1
80+	43	13.3
Total	324	100.0

FIGURE 9.1 Carcinoma of the vagina: patients treated from 1999 to 2001. Number of cases by age group. (From IJGO (International Journal of Gynecology and Obstetrics): vol 95, suppl 1, Nov 2006, pages S29–S42.)

Signs and Symptoms

The signs and symptoms of invasive vaginal cancer (Fig. 9.2) are similar to those of cervical cancer. Many women may be asymptomatic. **Painless vaginal discharge, often bloody, is the most frequent symptom in most series.** Postcoital or postmenopausal vaginal bleeding is the initial symptom in many patients with invasive lesions, and a gross lesion is obvious on speculum examination. Patients may also present with watery, blood-tinged, or malodorous vaginal discharge. Urinary symptoms (pain and frequency) are more common than with cervical cancer because neoplasms that are lower in the vagina are close to the vesicle neck, with resulting compression of the bladder at an earlier stage of the disease. Tenesmus is commonly associated with posterior vaginal lesions. Approximately 5% to 10% of women are asymptomatic, with disease diagnosed on suspected physical examination and confirmed by biopsy.

Diagnostic Considerations

All patients presenting with a vaginal cancer need a full workup to rule out metastatic disease. Medical history should emphasize history of cancer, radiotherapy, and surgery. Physical examination, including an adequate pelvic examination (under anesthesia if necessary), should be performed. The diagnosis is often missed on first examination, especially if the lesion is small and covered by the blades of the speculum. Definitive diagnosis is made by histologic confirmation on biopsy.

In patients with an abnormal Pap test result and no gross abnormality, careful vaginal colposcopy is necessary. To differentiate between an early vaginal cancer and VAIN III, it is often necessary to perform a partial upper vaginectomy as reapproximated vaginal tissue at the time of hysterectomy may bury the lesion.

Hoffman and associates reported on 32 patients with VAIN III who underwent an upper vaginectomy; 28% had invasive carcinoma.

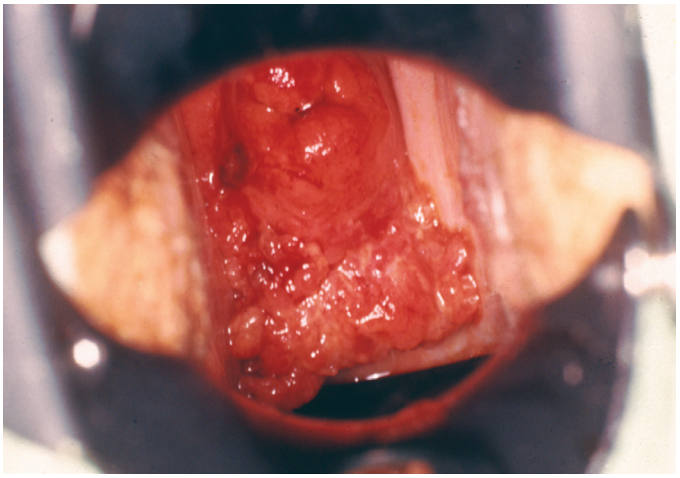


FIGURE 9.2 Lesion of the posterior fornix in squamous cell carcinoma.

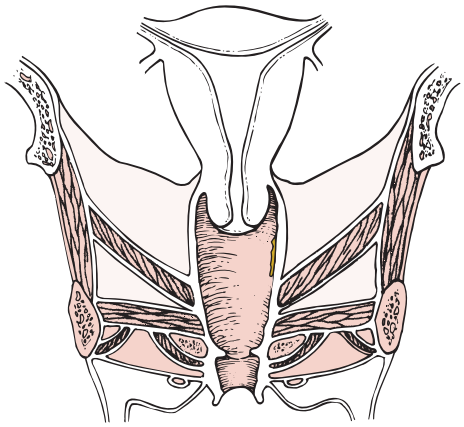
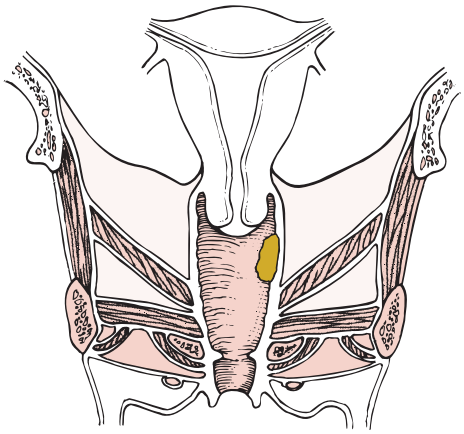
Metastatic carcinoma to the vagina occurs more often than primary disease because more than 80% of malignant vaginal lesions are metastasis from other sites. In 269 patients with metastatic vaginal cancer, Mazur et al. found that 84% were from genital sites, and the remaining 16% were most commonly metastatic from the gastrointestinal tract or breast. The cervix (32%) and endometrium (18%) are the most common primary sites of cancer. Whereas endometrial carcinomas and choriocarcinomas often metastasize to the vagina, rectal and bladder cancers directly invade the vagina.

When the primary site of growth is in the vagina and does not involve surrounding organs (eg, vulva or cervix), the tumor is considered a primary vaginal cancer. Special consideration needs to be made for patients with a remote (>5 years) or questionable history of a gynecologic malignancy (especially cervical cancer) who present with a vaginal lesion. Patients with a history of endometrial cancer and a vaginal lesion with a histologic diagnosis of adenocarcinoma consistent with recurrence are diagnosed with recurrent endometrial cancer.



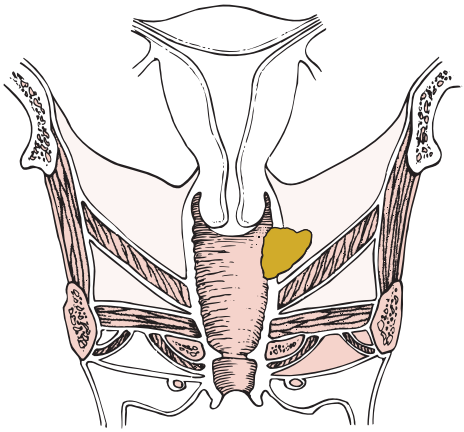
After being diagnosed with vagina cancer, patients should be examined for evidence of local or distant spread in a manner analogous to that of cervical cancer. All patients should have at least the following diagnostic studies in addition to a thorough history and physical examination: chest radiography, intravenous pyelography, cystoscopy, and proctosigmoidoscopy, the last two depending on the location of disease. A computed tomography (CT) scan or magnetic resonance imaging (MRI) can replace the pyelography, cystoscopy, and proctosigmoidoscopy. If bone pain is present, further radiographs are warranted. Although staging is clinical, not surgical, an imaging evaluation should be performed to evaluate lymph node metastasis, distant metastasis, and the genitourinary system.

Staging

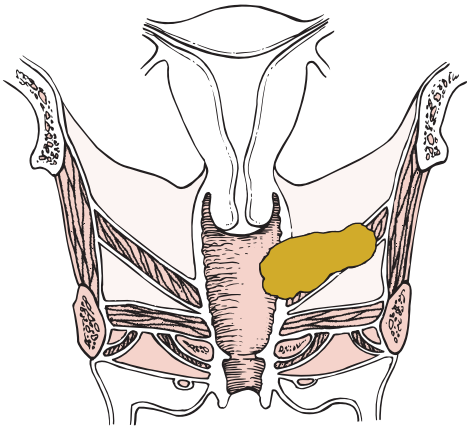


Most vaginal cancers are staged using the International Federation of Gynecology and Obstetrics (FIGO) combined with the American Joint Committee on Cancer (AJCC) TNM system (Fig. 9.3); a summary of the staging classification last updated January 2010 follows:

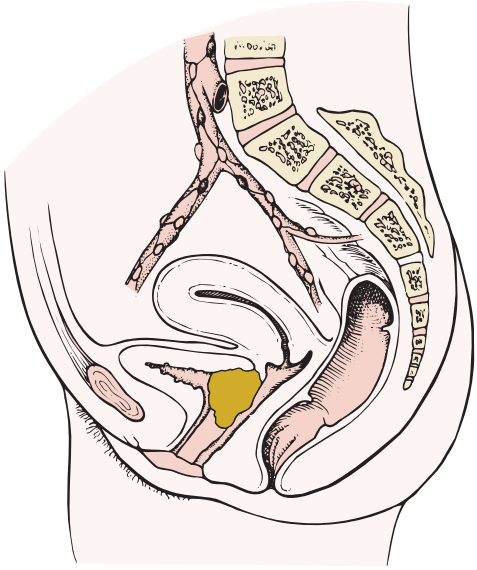
Stage 0	Carcinoma in situ, intraepithelial carcinoma
Stage I	Carcinoma is limited to the vaginal wall
Stage II	Carcinoma has involved the subvaginal tissue but has not extended onto the pelvic wall
Stage III	Carcinoma has extended onto the pelvic wall
Stage IV	Carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum; bullous edema or tumor bulge into the bladder or rectum is not acceptable evidence of invasion of these organs
Stage IVa	Spread of the growth to adjacent organs or direct extension beyond the true pelvis
Stage IVb	Spread to distant organs



Vaginal cancer is staged clinically. By the FIGO system, tumors that involve the cervix or vulva are not considered



Stage 0



Stage I

Stage II

Stage III

Stage IV

FIGURE 9.3 Staging diagrams for vaginal cancer.

primary vaginal cancers and are classified as either cervical or vulvar primaries. Although FIGO does not specify the stage of patients with inguinal lymph node involvement, the AJCC assigns patients with T1 to T3 tumors with positive inguinal lymph nodes to stage III. Involvement of the pubic symphysis is also classified as stage III. Similar to cervical cancer staging, FIGO does encourage the use of advanced imaging modalities to guide therapy.

Patterns of Spread

Vaginal cancer metastasizes by direct extension, lymphatic dissemination, and hematogenous spread. The pelvic soft tissues, pelvic bones, bladder, and rectum are commonly involved via direct extension in patients with locally advanced disease. The lymphatic vasculature of the vagina begins as an extremely fine capillary meshwork in the mucosa and submucosa (Fig. 9.4). In the deep layers of the submucosa and muscularis, there is a similar parallel but coarser network. Irregular anastomoses have been demonstrated between the two. Both systems drain into small trunks that coalesce at the lateral aspect of the vagina and form a number of collecting trunks. It is at this point that the efferent lymph drainage channels of the organ originate. The lymphatic trunks of the upper vagina drain into the iliac and eventually the paraaortic lymph nodes. A lymphatic network that anastomoses with the regional lymph nodes of the femoral triangle principally drains the lower vagina. All lymph nodes in the pelvis may at one time or another serve as primary sites or regional drainage nodes for vaginal lymph and its contents.

Because most patients with vaginal cancer are treated with radiation, the incidence of lymph node involvement is not well recorded. However, retrospective studies demonstrate that 30% to 35% of patients with vaginal cancer have lymph node metastasis. Paraaortic spread is almost exclusively seen in patients with concomitant pelvic node metastases.

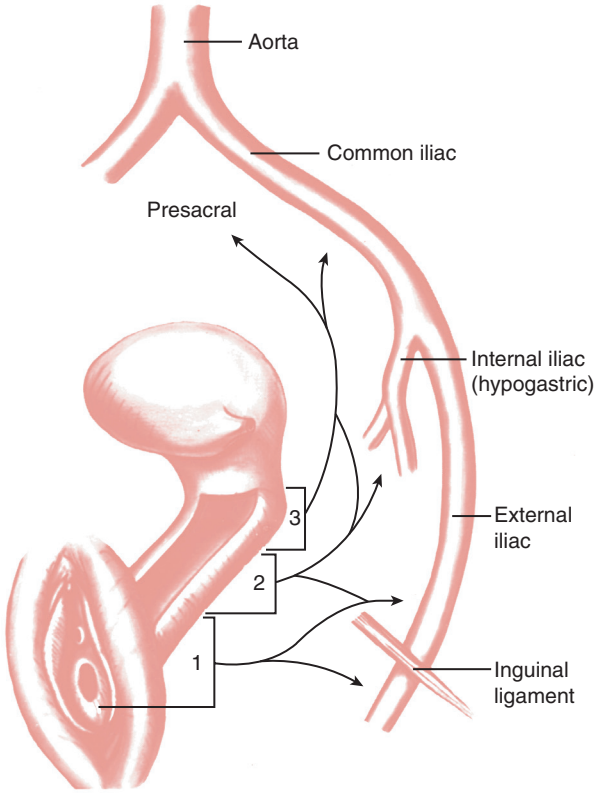


FIGURE 9.4 Lymphatic drainage of the vagina: channels from the lower third drain into the femoral and external iliac nodes (*1*); the channels from the middle third drain into the hypogastric nodes (*2*); channels from the upper third drain into the common iliac, presacral, and hypogastric nodes (*3*). (Modified from Plentl AA, Friedman EA. *Lymphatic System of the Female Genitalia.* Philadelphia, 1971, WB Saunders.)

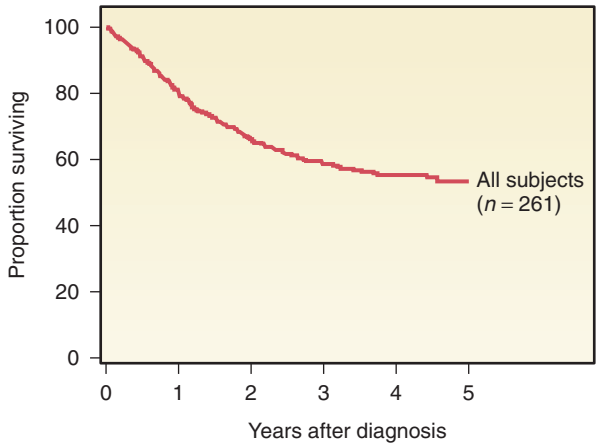
Imaging and Vaginal Cancer



Imaging such as CT, MRI, and positron emission tomography (PET) are often used to guide therapy. MRI is particularly useful in delineating tumor size and extent of spread to the paravaginal or parametrial involvement given its superior soft tissue resolution. PET imaging has become a standard diagnostic tool in the initial staging of cervical cancer and for posttreatment surveillance and has similar applicability for vaginal cancer. Metabolic imaging with PET has been shown to be more sensitive than CT and MRI, specifically for cancer of the head and neck, lung, esophagus, and cervix. In a study from Washington University, Lamoreaux and associates found that PET imaging detected primary and metastatic lesions more often than CT scans. In vaginal cancers, PET is more sensitive for detecting primary vaginal tumors and involved inguinal or pelvic lymph nodes. We recommend that all patients with vaginal cancer have imaging, and PET/CT with or without pelvic MRI is a reasonable option for these patients.

Sentinel Lymph Node Dissection

Patients with vaginal cancer rarely undergo lymph node dissection. Sentinel lymph node evaluation is a technique to determine if there is microscopic nodal metastasis. Frumovitz and colleagues evaluated the utility of radiocolloid and blue dye injection in 14 women with newly diagnosed vaginal cancer. The authors found that lymphatic drainage from the primary tumor does not always follow the predicted lymphatic channels. Pretreatment lymphoscintigraphy did improve treatment planning in this small study. However, because of the lack of data, incorporation of sentinel lymph node dissection into the treatment plan should be limited to research protocols.

Prognostic Features

Our understanding of vaginal cancer and improved radiation techniques have increased survival rates (Fig. 9.5 and Table 9-4). **Several investigators believe that age at time of diagnosis is one of the most important prognostic factors.** Reflecting intolerance of aggressive multimodality therapy and attendant comorbidities, age acts as a surrogate of clinical outcome. Although not well described, performance status likely reflects a factor with greater precision in determining the impact of chronologic age. Tumor histology may also have prognostic relevance. Vaginal melanomas and sarcomas have the poorest

*5-year survival rate.

prognosis compared with SCC and adenocarcinomas. However, survival differences among the different histologies have not been well documented due to rarity of cases.

Stage, tumor location, and tumor size also appear to affect prognosis. In a review of 843 patients with vaginal cancer, patients with stage I disease had a 64% to 90% 5-year survival rate; rates were 31% to 80% for stage II, 0% to 79% for stage III, and 0% to 62% for stage IV. In this study, lesions of the distal vagina had a poorer prognosis than those originating in the proximal vagina. In a review of 104 patients, Smith (1964) found 6.8% survivors among 29 patients with cancer of the lower third of the vagina, 25% of 48 patients with tumors of the middle third, and 37% of 27 patients with lesions of the upper third. In 1958, Merrill and Bender reported a 29% survival rate in 14 patients with upper third lesions and an 11% rate in nine patients with distal third involvement. More recently, Tewari and colleagues (2001) reported better survival for patients with lesions smaller than 3 cm compared with those larger than 3 cm. Chyle et al. found that tumor size larger than 5 cm was associated with a higher local recurrence rate compared with smaller tumors.

In 2005, Frank and colleagues at MD Anderson Cancer Center reported their 30-year experience treating patients with vaginal cancer. In this series of 193 patients, disease-specific survival and pelvic disease control rates were correlated with stage (I, II, or III/IV) and tumor size (<4 cm or >4 cm).

Intuitively, lymph node status at the time of diagnosis would portend a worse prognosis; however, this has not been well evaluated. In one study by Pingley et al., the 5-year survival rate for patients without lymph node involvement was 56% compared with 33% for patients with lymph node involvement. Furthermore, as in radiation therapy trials of cervical cancer patients, time to treatment initiation and total treatment time also affect vaginal cancer survival. Lee and associates found that the pelvic control rate was 97% if the treatment was completed within 63 days compared with 54% if treatment lasted longer than this time.

In a review of the Surveillance, Epidemiology, and End Result (SEER) population-based cancer registry, 2149 women with vaginal cancer between 1990 and 2004 were identified. Advanced stage, tumor size larger than 4 cm, aggressive histologies (eg, melanoma), and combined treatment modality (vs. surgery alone) were associated with a worse prognosis.

Management

Until the 1930s, vaginal cancers were considered incurable. With advances in radiation therapy, cure rates for even advanced cancers approach those for cervical cancer. Early stage vaginal cancers (stages I and II) treatment approaches include surgical resection or definitive radiotherapy. Bilateral pelvic lymphadenectomy is required given the high risk of occult nodal spread. Surgical series have reported rates of pathologic nodal involvement for stage I of 6% to 14% with stage II of 26% to 32%. Advanced-stage vaginal cancers are mainly managed with definitive radiation therapy. The use of neoadjuvant chemotherapy for locally advanced vaginal cancers has only been reported as case reports and small series with most patients relapsing and dying of disease. Consideration for up front exenteration may also be considered in carefully selected patients with resectable advanced-stage disease.

Prevention

Although the potential effect of HPV vaccines may not be as high for vaginal cancer as it may be for cervical cancer, vaccinating young women against HPV, specifically types 16 and 18,

should help to reduce the incidence of HPV-related vaginal disease.

Stage 0 and I

Vaginal intraepithelial neoplasia usually occurs at the vaginal apex, is multifocal, and is common in patients with a history of cervical dysplasia. Treatment options for patients with VAIN include surgery (wide local excision or vaginectomy), 5% fluorouracil cream, local ablation (eg, laser, cryotherapy, electrodiathermy), and intracavitary radiation (Table 9-5).

Creasman and associates reported the results of the National Cancer Data Base (NCDB), a large central registry of hospital data, for 10 years (1984–1994). There were 4885 cases, with 1242 carcinomas in situ (CIS) representing 26% of all vaginal lesions. CIS was almost exclusively treated with surgery; only 5% were treated with radiotherapy. Brown and colleagues reported no new cases of in situ or invasive carcinoma of the vagina developing after radiation therapy for CIS or early invasive carcinoma. Their report discouraged overly aggressive therapy for early-stage tumors because of the good prognosis for these lesions and the adverse effects of high-dose irradiation on the pliability of the vagina and on sexual function. Lee and Symmonds reported the results of 66 patients treated previously with wide local excision or partial vaginectomy and seven patients with multicentric disease treated with total vaginectomy. Only one patient developed recurrence; recurrence was vaginal carcinoma, which resulted in the patient dying of disease. In young, sexually active patients with diffuse involvement of the vaginal epithelium, total or subtotal vaginectomy with split-thickness skin graft reconstruction of the vagina often allows for excellent long-term results. When radiation therapy is chosen, patients who have CIS and superficial stage I tumors can be treated with intracavitary insertion alone.

Surgical management is an option for lesions 0.5 cm or less in patients with invasive carcinoma. For early lesions, particularly in the upper vagina (see Fig. 9.2), surgery may be preferred in many patients. Peters et al. have described superficially invasive SCC of the vagina as a lesion that invades less than 2.5 mm from the surface, lacking involvement of lymphovascular spaces, and occurring in a background of CIS. Their experience with six patients suggests that local therapy was sufficient, and no attempt was made to treat pelvic nodes either surgically or with irradiation. This conservative approach might allow preservation of optimal sexual function in young patients who have these early invasive SCC and adenocarcinoma lesions.

There are no randomized trials defining treatment exclusively for vaginal cancer because of its rarity. Treatment approaches have been largely extrapolated from cervical and anal cancers. For invasive carcinoma thicker than 0.5 cm, total vaginectomy and lymphadenectomy have been performed in the past. If the patient did not have a prior hysterectomy, a radical hysterectomy and upper vaginectomy would need to be performed. However, pelvic external-beam radiotherapy and interstitial implants may be appropriate for some patients, especially those with tumors larger than 2 cm and those involving the mid to lower portion of the vagina. Patients with small stage I cancers (<2 cm) who are not good surgical candidates can adequately be treated with brachytherapy alone. For large vaginal tumors (>2 cm), options for radiating the primary lesion are tailored by physician preference and extent of disease. **Bulky stage I cancers (>2 cm) of the upper portion of the vagina in patients with intact uteri are treated with techniques similar to those used for carcinoma of the cervix.** External irradiation in a dose of 4500 to 5000 cGy is generally recommended with another 2500 cGy given as intracavitary or interstitial brachytherapy in bulky stage I and stage II cancers (see Table 9-5). For young patients who require radiation therapy, pretreatment laparotomy or laparoscopy with ovarian transposition and surgical staging is a rational approach.

Stage II to IVa

For patients who have stage II to IV vaginal cancer, treatment is tailored to the extent of the disease, and the radiation therapy plan should reflect consideration of the depth of invasion of the lesion. Proper planning of radiation therapy and individualization of treatment plans are essential to minimize the more serious complications of acute and long-term radiation sequelae in these organs. The difficulty in applying radiation systems to vaginal cancer led some, such as Wertheim and Brunschwig, to advocate for radical exenteration surgery as primary therapy. However, the complications associated with this radical procedure, especially in older patients, have become a serious limiting factor to surgical approach.

Patients with advanced-stage disease should be treated with external irradiation and brachytherapy. External irradiation to the pelvis is usually sufficient, and paraaortic extension is not routinely administered. Groin radiation is often considered if the tumor involves the lower third of the vagina or in the presence of metastatic groin disease. Perez and associates evaluated 149 patients with vaginal carcinoma and clinically negative lymph nodes who were not treated with groin radiation. In the group of patients with tumors confined to the upper

TABLE 9.5 Radiotherapy for Vaginal Cancer

Stage	External Irradiation	Vaginal Therapy
0	Surgical excision preferred for localized disease	7000-cGy surface dose
I		
1- to 2-cm lesion		Brachytherapy irradiation, 6000–7000 cGy*
Larger lesions	4000–5000 cGy of the whole pelvis	Brachytherapy delivering 3000–4000 cGy
II	4000–5000 cGy of the whole pelvis	Same as for stage I
III	5000 cGy of the whole pelvis (optional 1000–2000 cGy through reduced fields)	Brachytherapy implant, 2000–3000 cGy (if tumor regression is satisfactory)
IV (pelvis only)	Same as for stage III	Same as for stage III

*Surgical excision for selected sites on 1- to 2-cm lesions may be used instead of brachytherapy.

vagina, there were no recurrences compared with an 8% recurrence rate in those patients whose tumor involved the lower third of the vagina.

If the uterus is intact and the lesion is in the upper vagina, an intrauterine tandem and ovoids would be appropriate. If the patient has had a hysterectomy, interstitial radiation alone or in combination with intracavitary therapy optimizes dose distribution.

For patients who can be treated with brachytherapy only, a minimum of 6000 to 7000 cGy is delivered to the neoplasm in 5 to 7 days. Pelvic and groin radiation consists of a total of 45 to 50.4 Gy given in 1.8-Gy fractions daily. Use of concomitant sensitizing chemotherapy is discussed in the following section.

If there is metastatic lymph node involvement to the pelvic or groin lymph nodes, external radiation is given to a dose of 60 to 66 Gy. In addition, adenopathy greater than 2 cm may be best controlled with excision. The deep nodes must be included in the treatment fields because large tumors have a high incidence of regional lymphatic metastasis. After receiving 5000 cGy, the patient with a large lesion should be reevaluated for an additional 1000 to 2000 cGy of external radiation to reduced field. Higher radiation doses, however, are associated with greater vaginal toxicity. **Newer treatment planning protocols using intensity-modulated radiation therapy may yield higher tumor control with less local normal tissue effects.** Long-term morbidity outcomes with this technology are awaited.

Radiation therapy alone for locally advanced vaginal cancers generate relatively poor outcomes because of predominantly local failures. Chemoradiation is standard of care for patients with locally advanced carcinoma of the cervix. Because the natural history, histology, and risk factors are similar for vaginal cancer, chemosensitization with weekly cisplatin has been recommended in patients receiving radiation for advanced-stage disease. Prospective studies will likely not be performed given the rarity of this disease. There are several small retrospective series that demonstrated high locoregional control rates after chemoradiation therapy with no increase in radiation-related long-term side effects compared to radiation alone. A single institution series of 71 patients treated with definitive radiation therapy with ($n = 20$) or without ($n = 51$) concurrent chemotherapy, the addition of chemosensitization resulted in improvement in 3-year disease-free survival (43 vs. 73%) and 3-year overall survival (56 vs. 79%). However, given the lack of high-quality data, radiation therapy alone is reasonable if the patient is not a candidate for cisplatin-based chemotherapy. A phase III clinical trial of ribonucleotide reductase inhibitor triapine is currently being conducted by the NRG-GOG (Gynecologic Oncology Group) in women with stage IB2, II, or IIIB-IVA or stage II-IVA vaginal cancer (NCT02466971). Women with advanced-stage vaginal cancer are eligible.

Chemotherapy

Studies are limited regarding the experience with chemotherapy for patients with vaginal cancer. In a phase II GOG study, 26 patients with progressive or recurrent vaginal carcinoma were treated with cisplatin (50 mg/m^2 every 3 weeks). There was minimal, insignificant activity, particularly in the patients with SCC. Other agents that have been used for the treatment of vaginal cancer include 5-fluorouracil (5-FU), mitomycin-C, epirubicin, or combinations of two of these agents.

A small series of patients with stage II vaginal carcinoma treated with neoadjuvant chemotherapy followed by radical surgery has been reported by Panici and colleagues. Eleven patients were treated with paclitaxel 175 mg/m^2 and cisplatin 75 mg/m^2 for three courses followed by surgery. There were a 27% complete response rate and a 64% partial response rate. At a median follow-up of 75 months, two (18%) patients had a recurrence, and one died of disease.

Special Considerations

Although one is often dealing with a radiosensitive neoplasm in a relatively radioresistant bed (the vagina), serious limitations exist. The proximity of relatively radiosensitive normal tissues, such as the bladder and rectum, provides a challenge to the therapist, especially in the treatment of tumors in the lower third of the vagina. Therapy must be individualized, and radical surgery should be reserved for treatment failures (Fig. 9.6).

The incidence of complications after radiation therapy or surgery for vaginal cancer can be substantial. Serious complications consist primarily of rectal stenosis, rectovaginal fistulas, and severe rectal bleeding often requiring diversion. As many as 35% of patients experience cystitis or proctitis during or shortly after therapy, but symptoms usually resolve spontaneously. A few patients have extensive vaginal necrosis that usually resolves with prolonged conservative management.

Frank and associates found that the incidence of major complications associated with radiation were associated with FIGO stage. Four percent of stage I patients, 9% of stage II patients, and 21% of stage III/IVa patients had major complications. Patients who are sexually active should be encouraged to continue regular intercourse. For others, vaginal dilators should be used to maintain vaginal patency during and after therapy.

Survival and Recurrence

A study by Rutledge in 1967 reported 3- and 5-year survival rates of 42% and 44%, respectively, for patients treated primarily with radiotherapy. Comparable survival results at 5 years were reported by Prempree and colleagues, who used radiotherapy for stage I (83%), stage II (63%), stage III (40%), and stage IV (0%) lesions; their absolute 5-year cure rate for all stages was 55.5%.

In 1982, Perez and Camel reported their long-term follow-up of patients treated with radiation therapy for invasive carcinoma of the vagina. The actuarial disease-free 5-year survival rates for stage I (39 patients) were 90%; stage IIa (39 patients), 58%; stage IIb (21 patients), 32%; stage III (12 patients), 40%; and stage IV (8 patients), 0%. Of 39 patients with stage I carcinoma, 37 (95%) showed no evidence of vaginal or pelvic recurrence. Most of them received interstitial or intracavitary therapy or both; the addition of external-beam irradiation did not significantly increase survival or tumor control. In stage IIa (paravaginal extension), tumor was controlled in 22 of 34 patients (64.7%) with a combination of brachytherapy and external-beam irradiation; only two of five (40%) treated with

brachytherapy alone exhibited tumor control in the pelvis. The incidence of complications was 9.7% for all stages.

In 1991, Eddy and coworkers published similar results for stage I and stage II lesions of the vagina treated with curative radiotherapy and reported 5-year survival rates of 78% for patients assigned to stage I and 71% for patients assigned to stage II. In addition, Stock and colleagues (1995) reported local control rates of 72% for stage I and 62% for stage II disease (Table 9-6). In the large database (NCDB) reported in 1998, the 5-year relative survival rates were 96% for stage 0, 73% for stage I, 58% for stage II, and 36% for stage III and IV. Women with stage I disease who were treated with surgery had a 5-year survival rate of 90% compared with 63% for patients treated with radiotherapy and 79% for patients treated with surgery and radiotherapy.

In the study from MD Anderson, the 5-year disease-specific survival rate was 85% for patients with stage I disease, 78% for stage II, and 58% for stage III/IVa. In this study, external-beam radiation fields and dose were determined by evaluating distribution of gross disease and possible sites of microscopic paravaginal and nodal disease.

Sinha and colleagues from Indiana University reviewed their experience with treating vaginal cancers. Overall survival rates were similar to the MD Anderson study (stage I, 92%; stage II, 82%; and stages III and IVA, 20%; $P = 0.0005$). Because of the poor prognosis associated with advanced stage disease, these investigators suggested routine use of combined chemotherapy and radiation as a treatment strategy for these patients.

Vaginal cancers appear to behave similar to cervical or vulvar cancer by first recurring locally. More than 80% of patients with recurrent disease have pelvic recurrence noted clinically, and most recurrences appear within 2 years of primary therapy. Distant sites of involvement occur later and much less frequently. Effective treatment for previously irradiated but locally recurrent or persistent vaginal cancer patients requires radical surgery (ie, pelvic exenteration). However, for those with extrapelvic recurrence, the long-term prognosis is poor. Chyle and colleagues reported a 12% 5-year survival rate after first recurrence. Rubin and associates reported on 33 patients with recurrent vaginal cancer. Eighteen had recurrent disease in the pelvis; 15 were extrapelvic recurrences. At the time of the report, 30 patients had died of disease. The average length of survival from recurrence was 8 months. In the past, chemotherapy for recurrent SCC of the vagina has been relatively ineffective. In the only GOG study of recurrent vaginal cancer, Thigpen and coworkers described 16 patients with SCC of the vagina treated in a phase II study of cisplatin 50 mg/m^2 intravenously every 3 weeks. The results were disappointing. There was only one responder, and this was a complete responder who had extrapelvic disease and who had received no prior therapy. Most of the patients with recurrence in previously irradiated fields showed no response; five of the remaining 15 patients had stable disease.

In the SEER study, an apparent survival advantage was seen with the incorporation of chemoradiation (patients treated since 2000) compared with radiation alone (patients treated between 1990 and 1994).

RARE HISTOLOGIES

Adenocarcinoma and Clear Cell Adenocarcinoma

Approximately 6% of vaginal cancers are adenocarcinomas. Before 1965, clear cell adenocarcinoma of the cervix in women younger than age 30 years was reported only rarely, and vaginal clear cell adenocarcinoma was unknown. In April 1970, Herbst and Scully reported seven cases of primary vaginal adenocarcinoma in patients between the ages of 15 and 22 years. These seven cases exceeded the number of cases in the world literature in adolescent girls born before 1945. Because of this case clustering, an epidemiologic study of the patients and their families was initiated to identify associative factors. With the addition of another patient to the study, it was discovered that the mothers of seven of the eight patients with vaginal adenocarcinoma had been treated with DES, a nonsteroidal synthetic estrogen, in the first trimester of the relevant pregnancy. Since that time, additional cases of vaginal and cervical adenocarcinoma have been reported in patients whose mothers ingested nonsteroidal estrogen during pregnancy. DES and related drugs were used to support high-risk pregnancies and reduce fetal wastage in the mid-1940s and 1950s, but their use then declined. The incidence of DES-induced clear cell carcinoma peaked in the mid-1970s.

As of 1992, 594 cases of vaginal and cervical (≈40% involve the cervix) adenocarcinoma have been accessioned by the registry established by Herbst and colleagues. Among the cases in which a maternal history was obtainable, the proportion that was positive for medication with DES or chemically related estrogens was approximately two-thirds. Progestins had been administered in six of the cases, and a steroidal estrogen had been administered in another three cases. The risk for development of these carcinomas in DES-exposed female patients through the age of 24 years has been estimated to be 0.14 to 1.4 per 1000. Of the cases, 90% have occurred in patients 14 years of age or older. About 68% of the individuals with clear cell adenocarcinoma of the cervix and 86% of those with primary vaginal tumors had a history of hormone exposure. In addition, there was a lower risk for cancer among women whose mothers began DES after the 12th week of pregnancy. It is not known how many exposed women are in the United States, but estimates place this population at 0.5 million to 2 million.

Patients 15 years of age and younger appeared to have more aggressive carcinomas than those of patients 19 years of age and older. Abnormal bleeding was the initial symptom in most of the patients, but 20% were asymptomatic, and carcinomas were discovered on routine pelvic examinations. Cytologic testing has proved useful, but a false-negative rate of up to 20% has been reported, probably because of the heavy polymorphonuclear infiltration seen with these lesions. The carcinomas may occur anywhere on the vagina or cervix, but most have been in the upper part of the vagina, particularly on the anterior wall (Fig. 9.7). **Adenosis (the presence of glandular epithelium or its mucinous products in the vagina) has been found accompanying vaginal clear cell adenocarcinoma in virtually all cases.** Adenosis is benign tissue, but it may be the nonneoplastic precursor of the clear cell adenocarcinoma in some cases, although direct transitions from adenosis to cancer have not been identified. The same observations apply to cervical eversion (ectropion, "congenital erosion") and clear cell adenocarcinoma of the cervix.

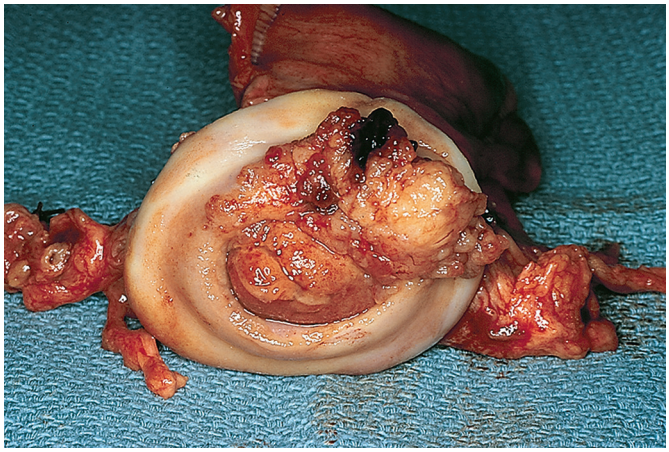

FIGURE 9.7 Clear cell adenocarcinoma (radical hysterectomy and upper vaginectomy specimen). Note the involvement of the cervix and the anterior wall of the upper vagina.

Both surgery and radiation have been effective in treating these tumors (Table 9-7), although follow-up for many of these patients is limited. Incidence of lymph node metastases is fairly high, with approximately 16% in stage I and 30% or more in stage II. The clear cell adenocarcinomas tend to remain superficial, suggesting the possibility that this disease can be treated locally, especially if the lesion is small.

The Registry for Research on Hormonal Transplacental Carcinogenesis has reported a study examining the effectiveness of various forms of therapy for early-stage vaginal clear cell adenocarcinomas. Of 219 patients with stage I vaginal clear cell adenocarcinomas, 20% received local therapy, and 80% underwent conventional therapy. Actuarial survival rates at 5 and 10 years for patients treated with local therapy and conventional therapy were equivalent (92% and 88%, respectively). This study indicated that for certain early cancers, local therapy, which can conserve reproductive function, is an effective mode. Another study showed that pregnancy does not appear to affect the prognosis or behavior of clear cell adenocarcinoma. However, one instance of pelvic node metastasis has been reported in a patient with invasion of less than 3 mm.

If the cancer is confined to the cervix, upper vagina, or both, radical hysterectomy with upper vaginectomy and pelvic lymphadenectomy with retention of the ovaries is the recommended therapy. In young patients, avoidance of pelvic irradiation is desirable in view of the increased risks of long-term morbidity (radiation-induced carcinogenesis and progressive vasculitis) in patients surviving many decades after full-dose pelvic irradiation and the possible decrease of optimal vaginal function.

More extensive tumors and lesions involving the lower two-thirds of the vagina, including the pelvic nodes and parametrial tissues, are more suitable for radiation. Although some

TABLE 9.7 Suggested Management of Clear Cell Adenocarcinoma of the Cervix and Vagina

Stage	Surgery	Radiation
	CERVIX	
Ib	Radical hysterectomy with clear vaginal margins and bilateral pelvic lymphadenectomy	5000 cGy of the whole pelvis in patients with positive pelvic nodes
IIa	Radical hysterectomy with bilateral pelvic lymphadenectomy and upper vaginectomy	5000 cGy of the whole pelvis in patients with positive pelvic nodes
IIb	Consider exenteration for radiation failures	5000 cGy of the whole pelvis, tandem, and ovoids

From Herbst AL. Neoplastic diseases of the vagina. In Mishell DR Jr, Stenchever MA, Droegemuller W, et al. eds. *Comprehensive Gynecology*, 3rd ed. St. Louis, 1997, Mosby Year Book.

experienced surgeons have used radical hysterectomy with total vaginectomy and split-thickness skin graft vaginal reconstruction in this group of patients, it is difficult to get negative surgical margins (especially on the bladder). Herbst and coworkers reported a discouraging 37% recurrence rate among 22 patients treated by conventional irradiation, but 21 of these 22 patients had large vaginal adenocarcinomas and probably would not have been good surgical candidates for vaginectomy. Pelvic exenterations are reserved for radiation failures in patients with central persistence of the neoplasm and involvement of the lower two-thirds of the vagina.

Transvaginal local excision of stage I vaginal adenocarcinoma, which is associated with higher recurrence rates than transabdominal approaches, appears to be an inferior treatment. Some institutions have attempted radiation treatment with transvaginal cone or implant, especially for small vaginal tumors after local excision. The identification of the risk for pelvic lymph node spread, even in cases of small stage I tumors, led to the recommendation that retroperitoneal node dissection be carried out before the local treatment. Follow-up of many of the cases is limited. Therefore, comparing the efficacy of various modes of therapy is difficult.

Survival percentages are highly correlated with tumor stage. The following percentages were found for patients at these stages:

Stage I	91%
Stage II vaginal	82%
Stage IIa cervical	80%
Stage IIb cervical	56%
Stage III	37%

The overall survival rate of 80% is somewhat better than the 65% crude survival rate reported for SCC of the cervix and much higher than the 35% to 45% overall survival rate reported for SCC of the vagina. The better prognosis might be the result of early detection because it occurs mainly in young patients exposed to DES (Table 9-8).

Recurrent Adenocarcinoma

A higher proportion of clear cell adenocarcinomas metastasize to the lungs and supraclavicular area compared with squamous cancers. In the study by Herbst and colleagues, 346 patients were analyzed for frequency, site, and treatment of recurrent disease. Of the 346 patients, 20 were never free of disease after initial therapy, and 19 had died at the time of the report. Recurrence developed in 58 patients, and diagnosis was made in most of these within 3 years after primary tumor treatment: 60% had recurrence in the pelvis, almost half of these being in the vagina; 36% (21 patients) had recurrence in the lungs; and 20% (12 patients) had recurrence in the supraclavicular lymph nodes. Surgery and radiation have been effective in the control of pelvic recurrences in some cases.

The results of chemotherapy are disappointing. Objective responses (>50% reduction of tumor size for longer than 3 months) were observed in 8 of 34 cases in which chemotherapy regimens were analyzed. Two patients who received doxorubicin (Adriamycin) had objective remissions, but an alkylating agent was also given in one of these. Two patients who received combination chemotherapy (5-FU, methotrexate, vincristine, cyclophosphamide, and prednisolone; and 5-FU, dactinomycin, and cyclophosphamide) also had objective remissions. No total

remissions were observed. There were no responses in nine cases in which a progestational agent alone was used.

In a 1981 report by Herbst, follow-up data of 409 patients for periods up to 15 years were published. In this study, 55 patients had an initial recurrence in the pelvis (60% of the total group with recurrence) up to 7 years after initial therapy. This emphasizes the importance of prolonged follow-up. Of the 58 patients with recurrences, 12 survived 3 years or longer after treatment of their first recurrence. A second recurrence was observed in 17 of the patients, and 12 of them died within 1 year of the diagnosis. However, three patients had survived longer than 2 years after treatment of their second recurrence.

Primary adenocarcinoma of the vagina can occur unrelated to intrauterine DES exposure. Some cases that were thought to have arisen in association with vaginal adenosis or from foci of endometriosis generally resembled endocervical or endometrial carcinomas. Because of their content of clear cells, others were considered to be of mesonephric origin. A few exceptional cases may have arisen from Gartner duct remnants and thus may have truly been mesonephric in origin. Therapy for these adenocarcinomas is presently analogous to that for their squamous counterpart.

Vaginal metastases from adenocarcinoma of other pelvic and abdominal organs are more common than primary vaginal cancers. Lesions of cervical and endometrial origin are most common. Ovary, tube, colon, rectum, and renal cell neoplasms can also be present with vaginal metastasis.

Malignant Melanoma

Malignant melanoma of the vagina is rare and represents fewer than 0.5% of all vaginal malignant neoplasms and 0.4% to 0.8% of all malignant melanomas in women. The main presenting symptoms is vaginal bleeding, but vaginal discharge, and a blue-black or black-brown mass, plaque, or ulceration may also occur. The tumors are predominantly located in the lower third of the vagina, commonly on the anterior wall. These malignancies typically occur at a mean age of 60 years (range, 22–84 years), and almost all reported cases have been in white women. Lesions may be single or multiple, pigmented or nonpigmented, and arising from melanocytes present in the epithelium of the vagina (Fig. 9.8).

Multiple therapies have been attempted during the past several decades, and surgery remains the treatment of choice. The surgical approach must be tailored to the location of the lesions. The NCDB report noted 192 patients with vaginal melanoma; 95 (49%) were 70 years of age or older. Surgery was used as the first course of treatment in 66%, and 40% received radiotherapy. External radiation was more frequently used to treat advanced melanoma cases. Neoplasms that involve the lower third of the vagina are usually treated similarly to vulvar melanoma, with radical vulvectomy, partial vaginectomy, and inguinal and deep node dissection. Neoplasms that involve the upper two-thirds of the vagina require some form of exenteration for optimal results. Radiation therapy in general has not proved effective, and the results of chemotherapy have been equally disappointing; thus, the radical surgical approach remains the primary therapy when it is applicable.

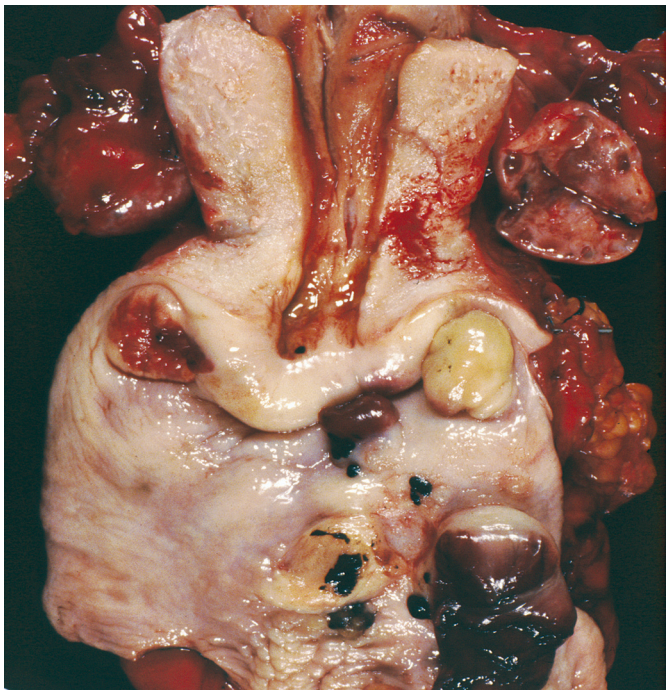

FIGURE 9.8 An exenteration specimen showing an open uterus, tubes, and ovaries with multifocal melanotic lesions of the vagina in a patient who underwent vaginectomy with her exenteration.

Survival figures for this group of lesions are difficult to determine because of the infrequent occurrence of this disease. Patients with negative nodes who have disease involving the upper two-thirds of the vagina and who are treated by exenteration have about a 50% probability of surviving 5 years or longer. The overall survival rate for vaginal melanoma is about 15%. Lymph node metastases portend a poorer prognosis. Many patients have advanced disease at the time of diagnosis.

Treatment must be based on the extent of the disease, location, tolerance of the patient, and depth of invasion. Increasing emphasis is placed on the depth of invasion. Superficial lesions (Clark's level I and level II) can be managed with less than exenterative-type surgery, but more deeply invasive tumors must be managed with extended radical surgery with some expectation of a favorable outcome, as reported by Van Nostrand and associates. Survival appears to be more favorable with depths of invasion of less than 2 mm. In the NCDB report, the 5-year survival rate for 76 patients whose diagnosis was made between 1985 and 1989 was 14%. The number of diagnoses with Clark's level information was small (51 patients). The 3-year relative survival rate by Clark's level without regard to node status or presence of metastasis was as follows:

Level II	45% (11 patients)
Level III	36% (5 patients)
Level IV	27% (4 patients)
Level V	14% (9 patients)

No level I was reported.

The dissection of lymph nodes that are clinically negative for melanoma of the vagina, urethra, and vulva continues to

be controversial. For level I and level II lesions, there appears to be little value in lymphadenectomy if nodes are clinically negative. Whether or not there is a role for selective sampling via lymphatic mapping and sentinel node localization is not known. However, in the few vulvovaginal primary lesions mapped, groin sentinel nodes have been isolated. Such dissections may provide prognostic information without extensive morbidity seen with inguinofemoral lymphadenectomy. Patients with level IV and level V lesions with positive nodes rarely survive, but local control may be achieved with lymphadenectomy. Recurrences develop primarily in the pelvis and lung. The interval to recurrence varies, but it is usually less than 1 year. Survival from point of recurrence averages 8 months. Recent advances in immunotherapy for the treatment of melanoma may lead to improved prognosis and survival in this cohort.

Sarcoma

Spindle cell sarcomas of the vagina, such as leiomyosarcoma and fibrosarcoma, occur rarely. Tavassoli and Norris reported 60 smooth muscle tumors of the vagina. Only five neoplasms recurred, and these were all larger than 3 cm, with more than five mitotic figures per 10 high-power fields (hpf). Local excision was the treatment of choice when the tumor was well differentiated and well circumscribed and the margins were not infiltrated. In general, these lesions behave like their corresponding cell types on the vulva in that the well-differentiated lesions have a much better prognosis than the pleomorphic types, which tend to have a poor prognosis regardless of therapy. The vagina, similar to the vulva, has a rich lymphatic and vascular network, possibly contributing to the early dissemination of these neoplasms (especially the pleomorphic types). In general, hematogenous dissemination occurs surprisingly late in the course of the disease, so that the importance of local therapy is underlined. However, after local excision of a circumscribed lesion and postoperative local radiation therapy, the value of pelvic radiation therapy is unclear. In most instances when it has been successfully applied, the lesions were well differentiated and well circumscribed, suggesting that surgery itself was curative.

An unusual and tragic lesion that predominantly affects children is sarcoma botryoides (Fig. 9.9). These lesions are usually multicentric and tend to arise in the anterior wall at the apex of the vagina. There is a tendency for this tumor to originate higher in the genital tract in older patients. In all patients, the tumor may be multifocal, but this is rare and should not be taken as a basis for extensive surgery.

Whereas these lesions were formerly treated by exenterative procedures, equal success has been obtained in recent years with less radical surgery and adjuvant chemotherapy, with or without radiotherapy. There were 30 sarcomas reported in children from the NCDB, 32 patients were between the ages of 20 and 49 years, 36 patients were between 50 and 69 years, and 37 patients were 70 years or older. The diagnosis was embryonal rhabdomyosarcoma in 70% of the children (n = 21), infantile embryonal carcinoma in 20% (n = 4), and rhabdomyosarcoma in 10% (n = 3). More than three-quarters of the children received

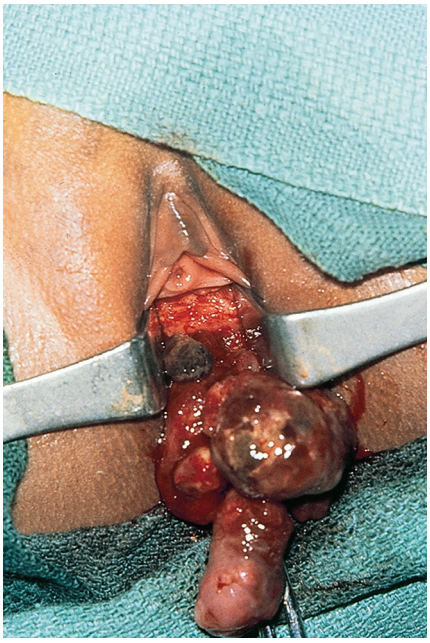

FIGURE 9.9 Sarcoma botryoides (rhabdomyosarcoma) in a 3-year-old child.

chemotherapy, including four-fifths who were treated surgically. The 12 children whose diagnosis was made between 1985 and 1989 were younger than 5 years, and their 5-year survival rate was 90%.

A combination of vincristine, dactinomycin, and cyclophosphamide appears to be effective in this disease and results in a marked reduction in tumor size when the drug combination is used as initial therapy, permitting more conservative surgery. Although there is continued use of external radiation therapy in many centers, its role in managing sarcoma botryoides of the female genital tract remains unclear. Small lesions appear to be adequately treated with chemotherapy and surgery. A combination of chemotherapy and radiation therapy without surgery has been reported by Flamant and colleagues to be curative of localized vaginal lesions.

The tendency for genitourinary rhabdomyosarcoma to spread to regional lymph nodes is well established. The Intergroup Rhabdomyosarcoma Study reported a 26% incidence of known lymph node metastasis. The pelvis is the most common site for primary recurrences.

Leiomyosarcoma was the most frequent type of sarcoma for adults, accounting for 50% of the cases in patients aged 20 to 49 years and for 35% in those aged 70 years or older. Adjuvant chemotherapy was used less with increasing age, but radiotherapy was used most frequently for older patients. Survival rates decreased with increasing age. The relative 5-year survival rates were 84% for those aged 20 to 49 years and 48% for those 50 to 69 years. Those older than 70 years had a 2-year relative survival rate of only 30%.

Endodermal Sinus Tumor

This rare carcinoma occurring in the vaginas of infants is most likely of germ cell origin. Norris and coworkers use the term

mesonephroma or *mesonephric carcinoma* because of an alternative theory of the origin of this carcinoma. The disease usually occurs in infants younger than 2 years, and survival rates have been poor, with fewer than 25% of patients alive at 2 years. Lesions most often occur on the posterior vaginal wall or fornices. Combination therapy (surgery and chemotherapy) appears appropriate. **Patients who have vaginal endodermal sinus tumors are usually seen because of vaginal bleeding or discharge and have polypoid or sessile tumors.** In the majority of cases, the differential diagnosis of endodermal sinus tumor is that of embryonal rhabdomyosarcoma (sarcoma botryoides). This is the most common vaginal tumor of children and almost always develops in patients younger than 5 years; the average age at the time of diagnosis is 3 years. The characteristic grapelike appearance of sarcoma botryoides differs from the usual endodermal sinus tumor. In addition, the edematous and cellular areas that are composed of immature skeletal muscle cells characteristic of embryonal rhabdomyosarcoma bear no resemblance to the histologic appearance of endodermal sinus tumor.

Young and Scully described 32 patients with endodermal sinus tumors. At the time of the report, 18 had died of their disease despite radical surgical therapy. Six patients were treated by surgery and then received vincristine, dactinomycin, and cyclophosphamide. Of these six patients, two also received radiation therapy. All were alive and free of disease 2 to 9 years after surgery. Copeland and associates have reported similar results with the same combination. Thus, chemotherapy after conservative surgical excision can be effective in controlling this neoplasm.

Special Considerations

Pride and Buchler suggested that **vaginal carcinoma might occur more frequently in patients who received pelvic irradiation 10 years or longer before the appearance of the new lesion.** Of patients previously treated for cervical cancer, those who had received radiation therapy (>5 years previously) were more likely to develop vaginal cancer than were those whose cervical cancers had been treated surgically, according to Murad and colleagues. Abnormal vaginal cytologic findings are common after radiation, and many have ignored these dysplastic lesions as if they were routine results of irradiation therapy. However, a study from MD Anderson suggested that 30% of these "dysplastic" or "intraepithelial" lesions will progress to invasive cancer if they are left untreated. In this report, 28 patients with dysplasia or carcinoma in situ of the vagina after previous pelvic radiation therapy were observed for progression, and nine developed invasive carcinoma. The median length of time from diagnosis of the intraepithelial lesion to invasion was 34 months. Therefore, treatment of these intraepithelial lesions by local excision is warranted. Laser vaporization or topical chemotherapy with 5-FU should be seriously considered.

Adnexal Masses

Camille C. Gunderson, MD, Robert S. Mannel, MD, Philip J. Di Saia, MD

OUTLINE

Adnexal Masses
- Evaluative Approach
- Classifying the Mass
- Differential Diagnosis

Extraovarian Adnexal Masses
- Uterine Masses
- Tubal Masses
- Adnexal Masses of Nongynecologic Origin

Ovarian Masses
- Functional Cysts
- Endometriotic Cysts
- Benign Ovarian Neoplasms
- Serous Cystadenoma
- Mucinous Cystadenoma
- Dermoid Cyst (Benign Cystic Teratoma)
- Fibroma
- Brenner Tumor

Management of Adnexal Masses
- Observation versus Surgery
- Minimally Invasive Surgery for Adnexal Masses

Special Circumstances
- Adnexal Mass in Childhood
- Postmenopausal Ovary
- Borderline Malignant Epithelial Ovarian Neoplasms
- Fertility Preservation
- Cyst Rupture or Spill of Tumor
- Prophylactic versus Risk-Reducing Oophorectomy

KEY POINTS

1. Adnexal masses are common, and careful evaluation is required before a therapeutic intervention is planned.
2. Masses are classified based on the workup for risk of malignant potential. Of all the variables, age is probably the most predictive of cancer.
3. There are many markers that help in determining how likely the mass represents a cancer, and these should be considered preoperatively.
4. It is important to be prepared for the possibility that any mass is malignant.
5. Arrangements should always be made for this possibility if the patient goes to the operating room.

ADNEXAL MASSES

The adnexae consist of the fallopian tubes, broad ligament, ovaries, and structures within the broad ligament that are formed from embryologic rests. Detection of pelvic abnormalities is more frequent in women of reproductive age because these patients have serial examinations as part of periodic screening for cancer (ie, Pap testing) and contraceptive counseling. Management of an adnexal mass is complex because of the scope of the disorders it encompasses and the numerous therapies that may be appropriate (Table 10.1). The risk of malignancy and the fundamental concept that early diagnosis and treatment in cancer are related to reduced mortality and morbidity propel the system. An adnexal mass often involves ovarian substance because of the propensity of the ovary for neoplasia. Fewer neoplasms occur in the fallopian tube, although that structure may commonly be involved in an inflammatory process that manifests as an adnexal mass. It is estimated that 5% to 10% of women in the United States will undergo a surgical procedure for a suspected ovarian neoplasm during their lifetime, and 13% to 21% of these women will be found to have an ovarian malignant neoplasm. The overwhelming majority of adnexal masses are benign, and it is important to determine preoperatively whether a patient is at high risk for ovarian malignant disease to minimize the number of operative procedures performed for self-limited processes.

Evaluative Approach

Patients may present with an adnexal mass in a variety of clinical settings. Some may be symptomatic (pelvic pain or pressure) as a result of the mass, others may have a mass identified as part of a workup for another condition (computed tomography [CT] scan performed for back pain), and some have a mass incidentally identified as part of a normal well-woman examination. In addition, masses are occasionally identified during pregnancy as a result of the number of prenatal ultrasounds

TABLE 10.1 Differential Diagnosis of Adnexal Mass

Organ	Cystic	Solid
Ovary	Functional cyst	Neoplasm
	Neoplastic cyst	Benign
	Benign	Malignant
	Malignant	
	Endometriosis	
Fallopian tube	Tubo-ovarian abscess	Tubo-ovarian abscess
	Hydrosalpinx	Ectopic pregnancy
	Paraovarian cyst	Neoplasm
Uterus	Intrauterine pregnancy in a bicornuate uterus	Pedunculated or interligamentous myoma
Bowel	Sigmoid or cecum distended with gas or feces	Diverticulitis
		Ileitis
		Appendicitis
		Colonic cancer
Miscellaneous	Distended bladder	Abdominal wall hematoma or abscess
	Pelvic kidney	Retroperitoneal neoplasm
	Urachal cyst	

TABLE 10.2 Pelvic Findings in Benign and Malignant Ovarian Tumors

Clinical Findings	Benign	Malignant
Unilateral	+++	+++
Bilateral	+++	+++
Cystic	+++	+++
Solid	+++	+++
Mobile	+++	+++
Fixed	+++	+++
Irregular	+++	+++
Smooth	+++	+++
Ascites	+++	+++
Cul-de-sac nodules	−++	+++
Rapid growth rate	−++	+++

that are performed. A patient with a mass is approached differently depending on the clinical scenario. The approach of what to do in the setting of adnexal mass can be broken down into two fundamental questions: (1) What is the suspicion that the mass is malignant? and (2) Is the patient symptomatic? Understanding these two issues helps focus treatment planning into a decision for surgery versus observation.

To determine the appropriate intervention for an adnexal mass, a thorough evaluation, including a complete history and physical examination, liberal use of transvaginal ultrasonography, and judicious use of serum tumor markers, should be performed. Pelvic examination should always be performed under optimal circumstances. The patient's bladder should be empty. It is not unheard of for a patient with 10-cm midline mass to have the mass disappear with catheterization of the bladder. The rare pelvic kidney should always be kept in mind as a possible cause of a pelvic mass. Tragic reports of excision of such a mass in a patient with one kidney are found in the literature. Whenever possible, the rectum and rectosigmoid should also be empty when a pelvic examination is done. This avoids the misdiagnosis of fecal material as an adnexal mass. Detection of an adnexal mass is greatly facilitated by a rectovaginal examination (see Fig. 3.13), which allows more complete access to the cul-de-sac and to the more superficial areas of the pelvic basin. Knowledge of the size, shape, contour, and general location of the mass within the pelvis helps the physician arrive at the most likely diagnosis. Benign tumors are commonly smooth walled, cystic, mobile, unilateral, and smaller than 8 cm (7 cm is the exact diameter of a new tennis ball). Malignant tumors are usually solid or semisolid, bilateral, irregular, fixed, and associated with nodules in the cul-de-sac. Ascites usually is found with malignant neoplasms (Table 10.2). Koonings and coworkers showed that the risk of malignant disease was 2.6-fold greater for women with bilateral neoplasms than for women with unilateral neoplasms.

The patient's symptoms may derive from the physical nature of the mass by producing pressure against the bladder or rectum and increasing abdominal distention. Pain may be acute or chronic in nature. It may be a result of rapid size change and can be caused by torsion, hemorrhage into the mass, or rupture. Pain may also be a result of associated inflammatory processes from tubo-ovarian abscess or diverticular abscess. The nature and severity of the pain and other associated symptoms frequently lead to operative intervention, irrespective of the risk for malignancy.

Classifying the Mass

The complete evaluation of a patient with an adnexal mass requires that the physician assemble and analyze all of the available information from the history, examination, imaging studies, and tumor markers. One goal is to characterize the mass based on its malignant potential. Management then depends on a combination of many factors, including age and menopausal status of the patient, morphologic characteristics of the mass by ultrasonography, clinical findings, and patient desires. Classically, features associated most commonly with benign masses include young age, absence of symptoms (nausea, vomiting, weight loss, changes in urinary frequency, pain), unilateral and unilocular cystic masses, and normal cancer antigen 125 (CA-125) level. Despite these factors, it is clear that no single characteristic guarantees that a mass will be benign. Increasingly, models taking into account all available information have shown the best ability to predict benign versus malignant masses.

Of all variables, however, age is probably the most important factor for predicting the potential for malignancy. For example, Moore and colleagues showed in one large prospective series of 531 patients with adnexal masses for whom surgery was to be performed that 7% of premenopausal versus 39% of postmenopausal patients had a diagnosis of an epithelial ovarian

malignancy on final pathology. The differential diagnosis of an adnexal mass varies with the age of the patient. In premenarchal girls and postmenopausal women, an adnexal mass should be considered highly abnormal and must be immediately investigated. In premenarchal patients, most neoplasms are germ cell in origin and require immediate surgical exploration. Stromal, germ cell, and epithelial tumors are seen in postmenopausal women. It was once dogma that a postmenopausal patient with any enlargement of the ovary be considered to have "cancer until proven otherwise." In an era before pelvic ultrasonography, examining a patient with a "palpable postmenopausal ovary" was thought pathognomonic for ovarian cancer. Today, with common use of imaging studies, it has been shown that adnexal masses in postmenopausal women are more frequent than previously recognized, and many of these are benign. Greenlee and colleagues demonstrated in a prevalence study of more than 15,000 women older than 55 years of age who underwent pelvic ultrasonography that 14% had an adnexal cyst at initial screening. As with patients in all age groups, a complete evaluation can better characterize the risk of malignancy. (See section on postmenopausal ovary.)

One of the most common modalities used for characterizing an adnexal mass is pelvic ultrasonography. Pelvic ultrasonography may be performed transabdominally (better for larger masses extending out of the pelvis) or transvaginally (best for masses in the cul-de-sac or pelvis) to characterize masses. Many adnexal masses have characteristic appearances that define them as benign or suspicious for malignancy. The ultrasonography shows size, mass morphology, unilateral or bilateral involvement, and associated findings such as ascites. Ultrasonography is the most valuable initial tool and should be considered the first choice in assessing an adnexal mass by imaging. In some cases, CT or magnetic resonance imaging (MRI) may augment information on the mass and provide additional relevant anatomic information (eg, description of upper abdominal findings and information on adenopathy and ureteral patency). Masses may be described as purely cystic (so-called simple cyst), solid, or mixed solid–cystic (so-called complex cyst). The risk of malignancy increases with increasing complexity. Large series have shown that simple cysts have a very low risk of malignancy. Cysts with septations and no solid component also have been shown to have a low risk of malignancy. Malignancy is more commonly associated when a cyst wall or septation is thickened or has nodularity or the cyst contains solid components.

Much research has been devoted to developing accurate biomarkers that can detect malignancy and better characterize adnexal masses. To date, no single marker has been shown to be accurate in distinguishing a mass as benign or malignant. Information from tumor markers may be useful in characterizing the potential risk of malignancy so appropriate therapy may be offered (eg, surgery vs. observation), and patients may be appropriately triaged to specialists who are trained to perform complete surgical staging and debulking as needed.

One of the most widely used serum biomarkers for ovarian cancer is CA-125. CA-125 is used to monitor response of therapy and to assess for possible recurrence in patients with a known diagnosis of ovarian cancer. It is elevated in approximately 80% of patients with nonmucinous, epithelial ovarian cancers. It is elevated in only approximately 50% of stage I ovarian cancers, however. In combination with examination and serial pelvic ultrasonography, CA-125 has been evaluated in several large screening studies including asymptomatic women at risk for ovarian cancer to identify those with unrecognized disease. These studies show that CA-125 may augment the information from ultrasonography alone. CA-125 testing has limited sensitivity and specificity, making routine CA-125 testing problematic. Conditions associated with peritoneal or serosal inflammation or irritation of any etiology may be associated with CA-125 level elevations. In addition to ovarian cancer, CA-125 levels may be elevated by a number of other malignancies and benign conditions, including endometriosis, uterine leiomyomata, benign adnexal masses, tubal inflammation or infection, liver disease or hepatitis, congestive heart failure, menses, and pregnancy. Because most of these conditions are seen in younger women, CA-125 testing in premenopausal women is particularly difficult to interpret. A higher sensitivity has been reported in postmenopausal women, in whom CA-125 levels greater than 50 mL have been associated with a high risk of ovarian malignancy. In a prospective study comparing ultrasonography with CA-125 levels to characterize patients with persistent adnexal masses ($n = 1066$), Van Calster reported ultrasound pattern classification correctly classified 93% of tumors as benign or malignant compared with 83% by CA-125 testing. Histologic diagnoses most commonly misclassified by CA-125 testing were fibromas, endometriosis, abscess, and borderline tumors. CA-125 information in the setting of an adnexal mass may provide information in conjunction with patient symptoms, examination, and imaging studies as to whether to offer observation or perform surgery, make referral to specialists, or perform additional testing.

The CA-125 to carcinoembryonic antigen (CEA) ratio is now being considered helpful in deciphering the site of neoplastic origin. CEA is generally a marker for gastrointestinal (GI) malignancy but is also a marker for the rare entity of mucinous ovarian cancer. A ratio greater than 25 is generally consistent with ovarian origin.

OVA1 Test

The OVA1 test is a biomarker panel that measures five proteins (CA-125, β_2-microglobulin, apolipoprotein A1, prealbumin, and transferrin); it was approved by the Food and Drug Administration in 2009 to better classify adnexal masses to assist physicians with making referral to gynecologic cancer specialists. The concept is that an abnormal test result should prompt referral to specialists trained in staging and debulking of ovarian cancer. The OVA1 test produces a score from 0 to 10, with a cutoff of 5 for premenopausal and 4.4 for postmenopausal women. In a pivotal trial of 516 patients, OVA1 testing augmented information from radiologic imaging and laboratory testing. The Society of Gynecologic Oncologists (SGO) in September 2009 noted support for testing that resulted in appropriate referral of patients but also noted that OVA1 testing has not been validated as a screening tool and should not be used in this manner.

HE4

Human epididymis protein 4 (HE4) is a novel tumor marker for recurrence that is indicated for women with known ovarian cancer who have been treated. HE4 is a glycoprotein produced in normal glandular epithelium of the reproductive tract, renal tubules, and respiratory epithelium. HE4 levels appear to be less susceptible to peritoneal irritation, perhaps reducing false-positive findings. For example, in one study, HE4 levels were not increased in patients with endometriosis. HE4 testing has been investigated in combination with CA-125 levels to increase sensitivity and specificity of biomarker testing. In combination with patient menopausal status and CA-125 and HE4 testing, Moore and coworkers reported a sensitivity of 94% for all patients.

Multimodality Approach

Because no single test or finding in a vacuum is accurately predictive of a benign or malignant status of an adnexal mass, combining all information is our best option. Jacobs and associates introduced the concept of the Risk of Malignancy Index (ROMI) in 1990 combining demographic, sonographic, and tumor marker data into the assessment of a patient with an adnexal mass. It was a simple, reproducible system that has been modified and studied in several large trials. In a systematic review of the literature of ROMI, Geomini et al. suggested that all models have acceptable sensitivity and specificity, but the best predictors accounted for data from ultrasound findings, menopausal status, and CA-125 level. One modification proposed by Tingulstad and coworkers created a formula of U × M × CA-125 level, where U = ultrasound score (higher-risk morphology = 3, low-risk morphology = 1), M = menopausal status (postmenopausal = 3, premenopausal = 1), and CA-125 level is the actual testing value. van den Akker and coworkers reported a prospective observational study of 548 women with adnexal masses using this modified ROMI with a threshold value of 200 and achieved a sensitivity of 81% and specificity of 85%. They found that using the ROMI, they could accurately refer 80% of ovarian cancers to specialists using a threshold value of 200. In 2015, the United Kingdom Collaborative Trial published its risk of ovarian cancer algorithm (ROCA), in which they evaluated CA-125 velocity for ovarian cancer detection in contrast to a single-threshold rule. They found that emphasis of biomarker velocity within the algorithm led to 85.8% sensitivity and 99.8% specificity, leading to a doubling in the number of screen-detected cancers in comparison to use of a fixed CA-125 cutoff value.

Differential Diagnosis

The differentiation between benign (Table 10.3) and malignant ovarian enlargements is often the exclusive decision of the pathologist, but a short discussion of these lesions is pertinent even in a textbook of oncology. Although functional ovarian cysts are usually asymptomatic, they can on occasion be accompanied by a minor degree of lower abdominal discomfort, pelvic pain, or dyspareunia. In addition, rupture of one of these fluid-filled structures can result in additional peritoneal irritation and possibly an accompanying hemoperitoneum; however, this is rarely serious. More intense lower abdominal discomfort results when these ovarian tumors undergo torsion or infarction. Similar to functional cysts of the ovary, benign ovarian neoplasms do not produce any symptoms that readily differentiate them from malignant tumors or from various other pelvic diseases. Although these tumors are more likely to twist, resulting in infarction, malignant neoplasms may have the same fate. Indeed, one of the most unfortunate features of benign ovarian neoplasms is that they are indistinguishable clinically from their malignant counterparts. Although it is not known whether malignant ovarian tumors arise de novo or develop from benign tumors, there is strong inferential evidence that at least some benign tumors will become malignant. All too often, the first symptom of cancer in an ovarian tumor is increasing abdominal distention, although benign ovarian neoplasms may become apparent because of increasing abdominal girth, and indeed the "giant tumors" of the ovary are often benign mucinous cystadenomas. Benign mucinous cystadenomas weighing up to 300 lb have been reported.

TABLE 10.3 Benign Ovarian Tumors

- Nonneoplastic tumors
- Germinal inclusion cyst
- Pregnancy luteoma
- Endometrioma
- Neoplastic tumors derived from coelomic epithelium
- Cystic tumors
- Serous cystoma
- Mucinous cystoma
- Mixed forms
- Fibroma, adenofibroma
- Brenner tumor
- Tumors derived from germ cells
- Dermoid (benign cystic teratoma)

EXTRAOVARIAN ADNEXAL MASSES

Given the proximity in the pelvis, a variety of nonovarian structures may be responsible for the appearance of an "adnexal mass." This category includes disorders of the uterus, fallopian tubes, intestines, and adjacent structures. The process that creates the mass can be congenital, functional, neoplastic, or inflammatory. It is important to keep a broad differential diagnosis of the adnexal mass and to use all of the information available based on the history, physical examination, and imaging studies. On occasion, extragenital lesions, which are often large and cystic, are found on pelvic examination; exploratory laparotomy is indicated because of the size alone. These extragenital lesions include peritoneal cysts, omental cysts, retroperitoneal lesions, and diseases of the GI tract (cecum, appendix, sigmoid, and even small bowel, any of which can fall into the pelvis and become adherent). Retroperitoneal disorders may also be palpated on pelvic examination. Retroperitoneal sarcomas, lymphomas, and teratomas of the sacrococcygeal areas are commonly noted on rectovaginal examination and misdiagnosed as an adnexal mass.

Uterine Masses

Pregnancy should always be kept in mind as a cause of uterine enlargement. Most physicians are familiar with the unreliability of a menstrual history, and any patient of reproductive age with a pelvic mass should first have pregnancy ruled out by any of a variety of pregnancy tests or by detection of a fetus with ultrasound examination.

Myomas of the uterus are the most common uterine neoplasms (Fig. 10.1). They are usually discrete, relatively round tumors that are firm to palpation and may be single or multiple. Myomas may be located within the myometrium (intramural), just beneath the endometrial lining (submucosal), or on the surface of the uterus (serosal). A myoma may frequently be found in the broad ligament attached to the lower uterine segment by a thin pedicle. This will often confuse the examiner and suggest that the mass originates in the ovary or tube. In the United States, myomas are found in at least 10% of white women and 30% to 40% of black women older than age 35 years. In the postmenopausal group, it is said that the incidence increases to 30% in white women and 50% in black women. Fortunately, these neoplasms usually shrink after menopause, especially in patients not receiving high doses of exogenous estrogen stimulation. It appears that most of these benign neoplasms are somewhat estrogen dependent. Growth is commonly seen during pregnancy, probably secondary to elevated hormone levels. Degeneration, infarction, and infection can occur in these lesions, and these complications are associated with considerable lower abdominal pain. Sarcomatous elements, associated with myomas less than 0.1% of the time, are most often recognized postoperatively. Symptoms of associated sarcomatous elements may include a rapidly enlarging pelvic mass, often accompanied by pain and tenderness. The mean age at diagnosis of these lesions is 50 to 55 years, with a range of 25 to 85 years.

A recent enlargement of the uterus in a postmenopausal patient is rarely caused by fibroids, particularly if the enlargement develops in a short time ("rapid" growth). The use of hormone replacement therapy in and of itself is not an explanation for such an enlargement. The most probable diagnosis is a malignant neoplasm, and physicians must prepare to do an appropriate surgical procedure even if the result of dilatation and curettage (D&C) is negative.

Other conditions that can cause enlargement of the uterus are adenomyosis and endometrial carcinoma or sarcoma. Endometrial carcinoma can enlarge the uterus to as much as four times normal size. Most patients with endometrial cancer describe abnormal vaginal bleeding, and the diagnosis can be made appropriate endometrial sampling (office biopsy or D&C).

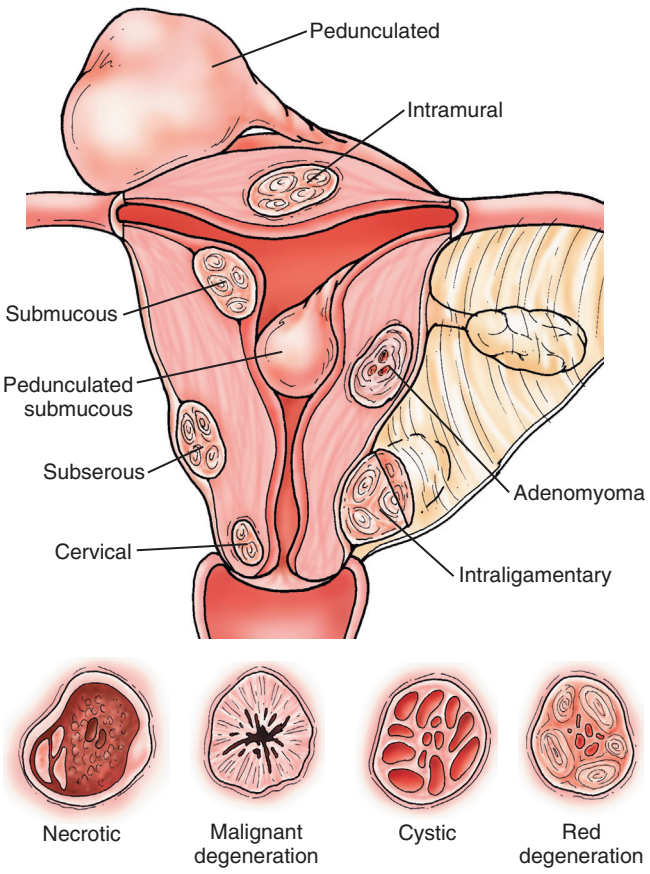

FIGURE 10.1 Myomas can be seen initially in multiple sizes and states of growth, disease, and degeneration. (Courtesy of Erle Henriksen, MD, Los Angeles, CA.)

Tubal Masses

Neoplasms arising from the fallopian tube are rare. More commonly, adnexal masses secondary to tubal disease are inflammatory or represent an ectopic pregnancy. Distinction between tubal and ovarian masses on the basis of examination alone is often difficult. In the acute phase of salpingitis, the fallopian tube is distended by grossly purulent material. This infection may be secondary to gonorrhea or other organisms, including anaerobes. As the salpingitis process progresses, the adjacent ovary may become involved, creating a so-called tubo-ovarian abscess. Although this acute process may resolve, the patient is often subject to reinfection. As a result of repeated chronic infectious processes, the tubal ostia may close or firmly adhere to the adjacent ovary, and the fallopian tube fills with a clear fluid. As the structure distends, it creates a mass that can easily be mistaken for an ovarian cyst. Although the symptoms of acute pelvic inflammatory disease are distinct (pelvic pain, fever, increased vaginal discharge, and abnormal uterine bleeding), the symptoms of chronic pelvic infection may be subtle. Even the traditional elevation of the erythrocyte sedimentation rate or leukocyte count may be absent in as many as 30% of patients with chronic pelvic inflammatory disease and adnexal masses.

A cystic mass in the adnexal region may be neither ovarian nor tubal in origin but caused instead by remnants of embryologic structures. The parovarium, located within the portion of the broad ligament containing the fallopian tube, consists of vestigial remnants of the Wolffian duct. Paraovarian cysts are found as distal remnants of the Wolffian duct system. They are characteristically located between the fallopian tube and the ovary; when large, they are often found with the fallopian tube

stretched over the top of the cyst. These paraovarian cysts are most commonly unilocular and filled with clear yellow fluid. They often persist into the postmenopausal period and can appear as cystic structures in the adnexa on imaging studies done for other complaints.

Approximately 98% of ectopic pregnancies are tubal. Unfortunately, a pelvic mass can be found on examination in fewer than half the cases of tubal pregnancy. Rupture usually occurs when the distended fallopian tube reaches a diameter of 4 cm. Tubal pregnancy must be distinguished from pelvic inflammatory disease, torsion of the adnexa, and bleeding corpus luteum cysts because all produce pain or abnormal bleeding.

Carcinoma limited to the fallopian tube is rare and accounts for fewer than 0.5% of all female genital tract malignant neoplasms. Historically, most of these neoplasms were discovered by serendipity, with a preoperative diagnosis of ovarian neoplasm being most common. On gross evaluation, the fallopian tube is usually enlarged, smooth walled, and sausage shaped. On occasion, patients present with the symptom of several weeks of profuse watery vaginal discharge, the so-called hydrops tubae profluens. However, it is now known that the fallopian tube and, more specifically, the fimbriae is the origin of most high-grade serous carcinomas of the ovary. This has become apparent over recent years as women with hereditary risk underwent risk-reducing surgery and represents a shift away from incessant ovulation as the leading hypothesis of epithelial ovarian carcinogenesis.

Adnexal Masses of Nongynecologic Origin

Bowel

By far the most common entity of the GI tract that initially appears to be an adnexal mass is fecal material in the sigmoid colon or cecum, which may on initial pelvic examination be palpated as a soft, mobile, tubular mass. Patients should be reexamined after appropriate cleansing enemas to confirm or rule out this possibility.

Inflammatory disorders of the large and small intestine can also be detected on pelvic examination. Diarrhea, nausea and vomiting, anorexia, or passage of blood or mucus per rectum should suggest these GI tract disorders. Patients with diverticulitis, even with abscess formation, sometimes exhibit remarkably minor symptoms initially. Careful questioning to detect subtle changes in GI symptoms is often rewarding. Periappendiceal abscesses may be formed as a result of rupture of the appendix and present as pelvic masses. Unfortunately, they vary in location, although they are generally found on the right side of the pelvis and are usually fixed, firm, and tender to palpation. Diverticulitis is a more common disorder with increasing age. Although it is usually located in the sigmoid colon, the mass may be midline or right sided. Inflammation of the ileum (regional ileitis) may occasionally present as a right-sided adnexal mass as the loops of thickened and inflamed ileum become fixed in the pelvis.

Gastrointestinal malignant disease is suggested by the presence of blood in the stool, anemia, and alterations in bowel habits. Neoplasms of the large intestine are particularly common with increasing age, and 60% to 70% occur on the left side within the reach of a palpating finger or flexible sigmoidoscope. However, carcinoma of the cecum often presents as a right-sided adnexal mass, and on examination, induration and irregularity may be found in the involved area. An elevated serum CEA level should raise suspicion for GI malignancy, particularly when the CA-125 to CEA ratio is less than 25. If one suspects GI origin of the mass, appropriate endoscopic or radiographic studies usually help in the definitive diagnosis.

OVARIAN MASSES

Functional Cysts

The cyclic ovarian function of a reproductive-age women continually produces follicular growth and resorption. Among the most frequently found "masses" involving the adnexa are the nonneoplastic cysts related to the process of ovulation that are sometimes referred to as functional cysts. They are by far the most common clinically detectable enlargements of the ovary occurring during the reproductive years. If ovulation does not occur, a clear fluid-filled follicular cyst (Fig. 10.2) lined by granulosa cells may result that can reach a size as large as 10 cm in diameter. These cysts usually resolve spontaneously within a few days to 2 weeks but can persist longer. When ovulation occurs, a corpus luteum is formed that may become abnormally enlarged through internal hemorrhage or cyst formation. The masses are of great significance because young women will have cysts on their ovaries at essentially all times (in varying sizes, numbers) during the reproductive years, and occasionally the cysts can produce pain and discomfort, and a mass will be noted on examination or ultrasonography. Clinical sequelae of these benign physiologic processes can also bring patients to the physician's attention because the masses may undergo torsion; acutely hemorrhage into the mass; or grow to sufficient size to produce pain, pressure, or bloating symptoms. The clinical challenge is that these functional cysts cannot be readily distinguished from true neoplasms on clinical grounds alone. Ultrasound evaluation typically shows a thin-walled, simple-appearing, anechoic cyst without solid component or septations. A hemorrhagic cyst may also show more complexity on ultrasonography given the presence of blood and fibrin stranding.

In addition, such cysts are often associated with variable delays in the onset of menses and confusion regarding the possibility of pregnancy. Theca-lutein cysts result from overstimulation of the ovary by hCG and on histologic examination are characterized by extensive luteinization of the stroma surrounding the follicle. Although theca-lutein cysts do not commonly occur in a normal pregnancy, they are often associated with hydatidiform moles and choriocarcinoma. Gross examination of the ovary containing theca-lutein cysts shows a structure almost completely replaced by lobulated thin-walled cysts that vary in size and are smooth and yellow.

Corpus luteum, follicular, and theca-lutein cysts are benign and represent an exaggerated physiologic response of the ovary. In most instances, they involute over time, but they do need to be included in the differential diagnosis. Luteomas of pregnancy are often large and solid but are not neoplastic

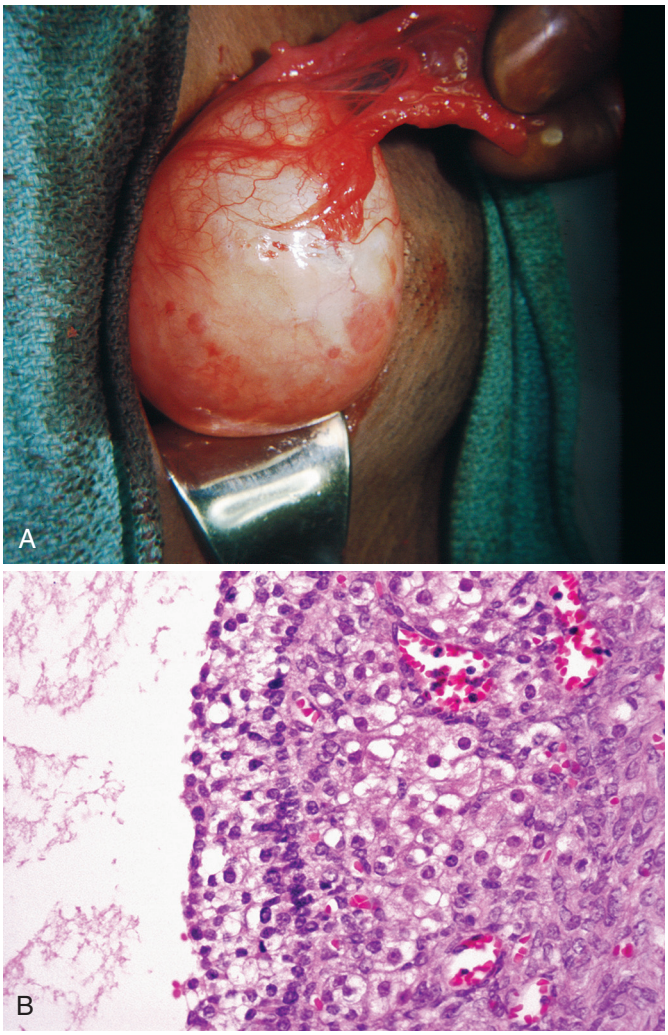

FIGURE 10.2 A, Follicular cyst (8 cm) with fimbria. B, Microscopic view of a follicular cyst as seen in A. (Courtesy of Ibrahim Ramzy, MD, University of California, Irvine, CA.)

masses originating in the ovary during pregnancy. Most cases are discovered at cesarean section in the last 2 months of pregnancy. The exact origin of luteomas have not been established. It is probably a hCG-dependent nonneoplastic hyperplasia and usually regresses after delivery. Therefore, surgical excision of these lesions at the time of cesarean section is not necessary.

Polycystic (sclerocystic) ovaries contain multiple follicle cysts with hyperplasia and luteinization of theca interna surrounding the cysts and atretic follicles. The ovaries are two to five times normal size with a thickened capsule. The condition is found most frequently in association with the Stein–Leventhal or polycystic ovarian syndrome.

Endometriotic Cysts

Endometriosis is a condition in which implants of normal-appearing endometrial glands and stroma are found outside their normal location in the uterine cavity. Presumptive evidence of endometriosis is also supported by significant scarring in the pelvis and the presence of hemosiderin-laden macrophages in the cyst wall or peritoneum. The most common sites for endometriosis are the ovaries, the supporting ligaments of the uterus, and the peritoneum of the cul-de-sac and bladder. Endometriosis is most common in women 35 to 45 years of age and is more common in white and nulliparous women. Endometriotic cysts sometimes may be distinguished from ovarian neoplasms by patient history (history of endometriosis or symptoms suggestive of endometriosis, including dysmenorrhea, pelvic pain, or infertility) and examination findings (nodularity of the uterosacral ligaments). Pelvic pain is by far the most usual symptom of endometriosis. Although physical activity and sexual intercourse usually increase the discomfort, the amount of endometriosis present does not seem to correlate with the intensity of the symptoms. For some, pain produced from small peritoneal implants appears to be incapacitating. Ultrasonography may show a homogenous echo, sometimes referred to as having a "ground-glass appearance," and on occasion may be misinterpreted as a solid mass. Septations and wall nodularity are also seen commonly. Of note, CA-125 levels are frequently elevated in patients with endometriosis. The morphologic complexity on ultrasonography coupled with CA-125 level elevations make endometriotic cysts among the most common masses incorrectly thought to be suspicious for malignancy on workup. During surgery, the ovary may be enlarged and cystic. The lumen contains blood of varying color, depending on the amount and age of the hemorrhage. In most instances, it is dark brown (chocolate cyst). In at least 50% of cases, both ovaries are involved. These cysts rarely exceed a diameter of 12 cm. They are frequently adherent to surrounding structures.

Benign Ovarian Neoplasms

The ovary is composed of tissue derived from coelomic epithelium, germ cells, and mesenchyme, and any one of these components may undergo neoplastic change (benign or malignant). Morphologically, neoplasms can be divided into solid and cystic types based on ultrasonography and gross appearances. The most common benign cystic neoplasms of the ovary are serous and mucinous cystadenomas and cystic teratomas (dermoids). Benign cystadenomas may vary in size from 5 to 50 cm and are thin walled, ovoid, and frequently unilocular. Benign neoplasms do not spontaneously regress, nor do they have the potential to disseminate or metastasize. Whether some begin neoplasms are premalignant is a source of controversy. Intraepithelial neoplasia has been reported in otherwise benign serous cystadenomas; in early stage invasive epithelial cancer, several authors have described the presence of transitional changes from normal epithelium to intraepithelial neoplasia to invasive cancer.

Serous Cystadenoma

Serous cystadenomas are more common than the mucinous type of tumor, but as a rule, they do not attain the large size characteristic of their mucinous counterparts. On gross evaluation, the cyst fluid is usually thin, watery, and yellow tinged. The surface of the cyst is usually smooth and frequently

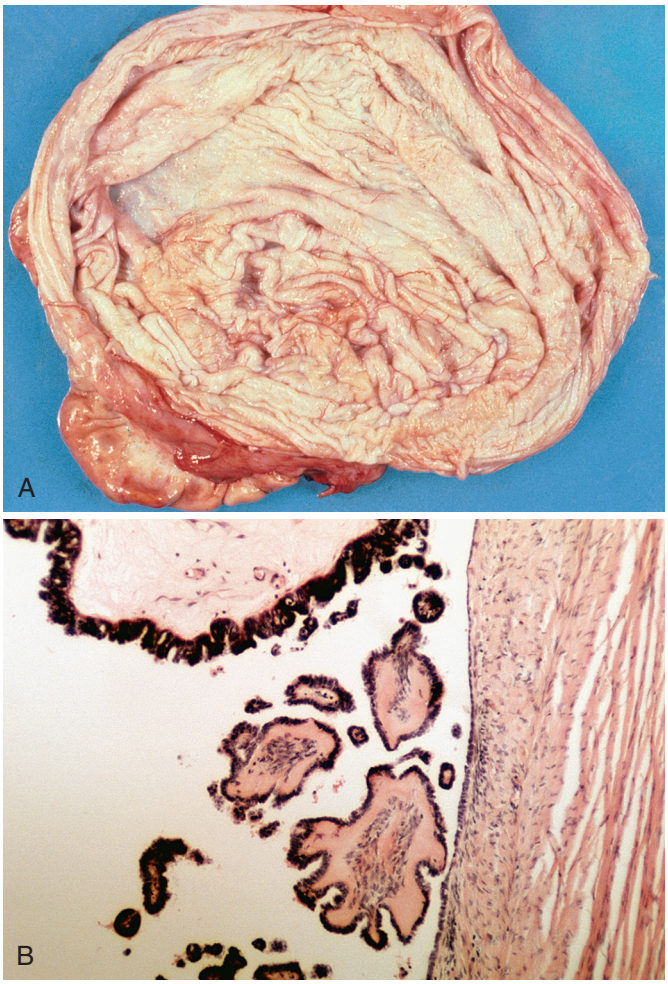

FIGURE 10.3 A, Gross photograph of an opened serous cyst adenoma that contained 500 mL of clear straw-colored fluid. Note the papillary projections on the inner surface, especially on the right. B, Microscopic view of a serous cystadenoma with a few papillary projections from the surface.

unilocular (Fig. 10.3). Septations dividing the cyst can be seen, however. Some serous tumors may have small papillary projections on the surface of the cyst wall, which at times are so numerous that a cauliflower pattern is produced. Large, frond-like solid projections or nodules or areas of necrosis should raise the concern for malignancy. On microscopic examination, the epithelium is usually of the low columnar type with cilia. Particularly characteristic of this type of cyst are small calcific granules, the so-called psammoma bodies, which are an end product of degeneration of the papillary implants. Associated fibrosis may lead to the so-called cystadenofibroma.

Many serous cystadenomas of the ovary are asymptomatic and are discovered as an incidental finding during routine pelvic examination or through imaging studies performed for another reason. Symptoms may develop because of the size of the mass (pain, pressure on the bladder or rectum) or as a result of rupture or torsion. Ultrasound appearance is frequently similar to a large functional cyst, unilocular and simple.

FIGURE 10.4 Barium enema film of a patient with a large mucinous cystadenoma of the right ovary filling the pelvis and lower abdomen.

Mucinous Cystadenoma

Mucinous cystadenomas (Fig. 10.4) may become huge, with some (Fig. 10.5) reported to weigh more than 300 lb. On gross evaluation, the masses are round or ovoid with smooth capsules that are usually translucent or bluish to whitish gray. The interior is divided by a number of discrete septa into loculi containing in general a clear, viscid fluid. Papillae are rarely noted. However, on microscopic examination, the lining of the epithelium is of a tall, pale-staining secretory type with nuclei at the basal pole; the presence of goblet cells is common. The cells are found to be rich in mucin if suitable stains are obtained. It is believed that this type of cyst usually arises from simple metaplasia of the germinal epithelium. It may occasionally arise from a teratoma in which all the other elements have been lost. It rarely occurs from a Brenner tumor in which there has been mucinous transformation of the epithelium.

Bilaterality may be found in as many as 10% of patients with serous cystadenomas, in contrast with mucinous cystadenomas, for which there is essentially no significant incidence of bilaterality. This information is helpful when the surgeon needs to make a judgment about surgical inspection of the opposite ovary in a young woman desirous of further childbearing. If the other ovary is of normal size, shape, and configuration, surgical evaluation is not needed.

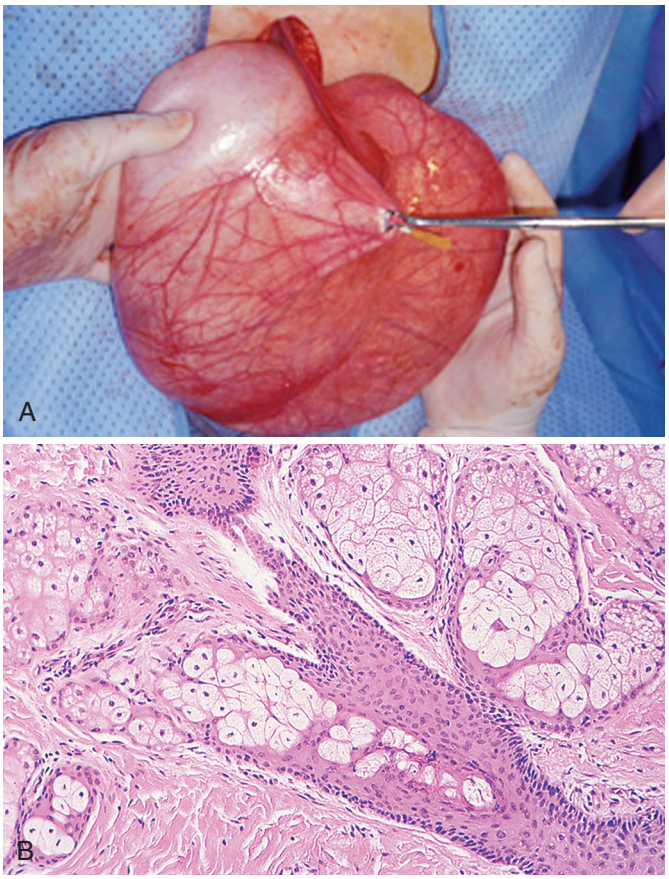

FIGURE 10.6 **A,** Ruptured dermoid cyst with sebaceous material seen. **B,** Photomicrograph of a mature teratoma (dermoid) of the ovary.

Dermoid Cyst (Benign Cystic Teratoma)

Dermoid cysts are rarely large (typically <10 cm), are often bilateral (15%–25%), and occur with disproportionate frequency in younger patients. On gross evaluation, there is a thick, opaque, whitish wall; on opening of the cyst, one frequently finds hair, bone, cartilage, and a large amount of greasy fluid, which rapidly becomes sebaceous on cooling. On microscopic examination, various amounts of mature ectoderm, mesoderm, and endoderm may be present. Stratified squamous epithelium, hair follicles, sebaceous and sudoriferous glands, cartilage, neural and respiratory elements, and indeed all elements normally seen in fetal life may be present. Sequelae include growth of the mass, rupture (Fig. 10.6), and malignant degeneration. Malignant degeneration occurs in benign cystic teratomas in 1% to 3% of these tumors, and it is usually of a squamous type. These neoplasms are thought to arise from early ova that have been triggered by some type of parthenogenetic process. Imaging evaluation of teratomas can be useful. For example, abdominal radiographs may demonstrate calcifications (teeth, bone), and CT imaging is excellent at showing fat densities commonly seen with dermoids. Ultrasound appearance is variable, and complex morphology with hyperechoic areas is common.

Removal of the ovary or cyst is recommended, and given the young age of many patients with mature teratoma, cystectomy (open or laparoscopically) in a patient desirous of further childbearing is standard. In most instances, a significant portion of normal ovary can be preserved and reconstituted. Care must be taken to remove the entire capsule of the neoplasm to avoid recurrence. In our experience, bilaterality is relatively rare when the opposite ovary is normal in appearance and is usually identified by preoperative ultrasonography. We do not recommend bivalving or opening a normal-appearing contralateral ovary in these circumstances. Care should be taken to prevent spillage of the contents of the dermoid cyst because this material can cause a chemical peritonitis. Because many of the masses are found in pregnant patients undergoing routine prenatal ultrasonography, conservative management until delivery is reasonable. Caspi reported on 49 women with ultrasonographically diagnosed ovarian cystic teratoma smaller than 6 cm in pregnancy who were followed for change in size. A total

of 68 pregnancies resulted. None of the classic complications of dermoid cysts such as torsion, dystocia, or rupture occurred. The authors concluded that such small lesions are safe to just follow, especially in pregnancy.

Fibroma

Benign solid tumors of the ovary are usually of connective tissue origin (fibromas, thecomas, or Brenner tumors). They vary in size from small nodules found on the surface of the ovary to large neoplasms weighing several thousand grams. On physical examination, these neoplasms are usually firm, slightly irregular in contour, and mobile. The occurrence of fibromas (Fig. 10.7) is not at all infrequent. Sometimes they are first noted as small nodules on the ovarian cortex. In other instances, they can be extremely large, filling the entire pelvis and lower abdomen. The tumors are characterized by their firmness and resemblance to myomas, and they are frequently misdiagnosed as such. The cut surface has a homogeneous grayish-white and firm appearance, although areas of cystic degeneration are common in larger tumors. On microscopic examination, one finds stellate or spindle-shaped cells arranged in fusiform fashion. The cells are uniformly well differentiated with nothing to suggest malignancy. Hyalinization is frequent, particularly in the larger tumors, and if fat stains are done, admixtures of theca cells may be seen. Meigs syndrome is characterized by ascites, hydrothorax, and an ovarian tumor that was originally believed to be specifically a fibroma; however, many other types of ovarian tumors are now known to be associated with this syndrome, such as Brenner tumors and Krukenberg tumors. The cause of Meigs syndrome is not completely understood, but it seems that the hydrothorax occurs by certain lymphatics through the diaphragm. After removal of the ovarian neoplasm, there is a prompt resolution of both abdominal and pleural fluid.

Brenner Tumor

Brenner tumor (Fig. 10.8), an uncommon type of ovarian neoplasm, is grossly identical to a fibroma. Frequently, the tumor is an incidental finding in an otherwise unremarkable ovary. On microscopic examination, one finds a markedly

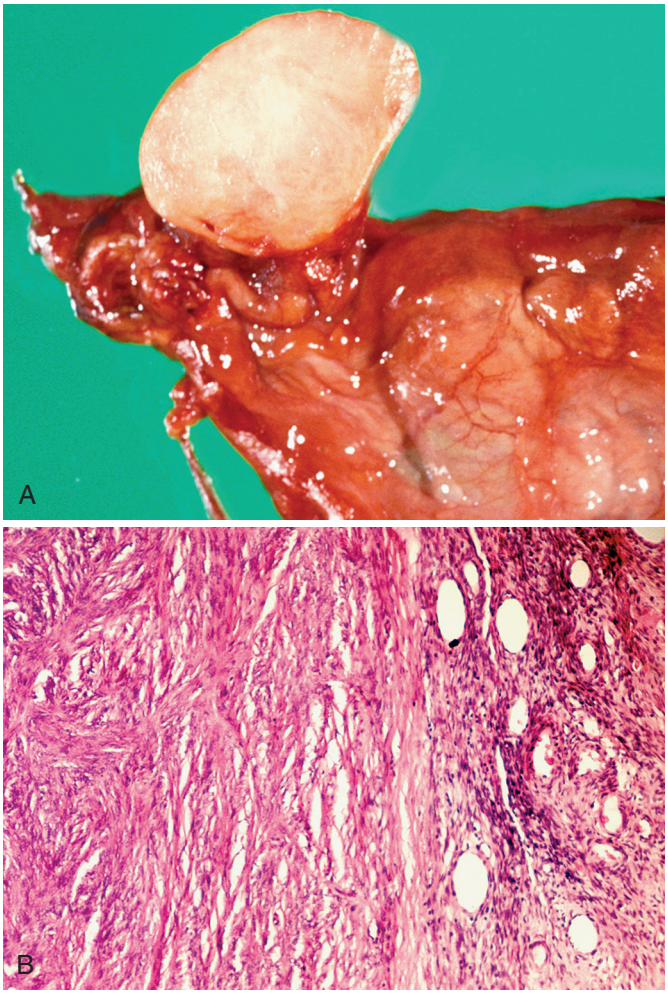

FIGURE 10.7 Ovarian fibroma. **A,** Gross appearance: solid white lesion with a firm cut surface and fallopian tube. **B,** Histologic section: whorls of fibromatous matrix. (Courtesy of Ibrahim Ramzy, MD, University of California, Irvine, CA.)

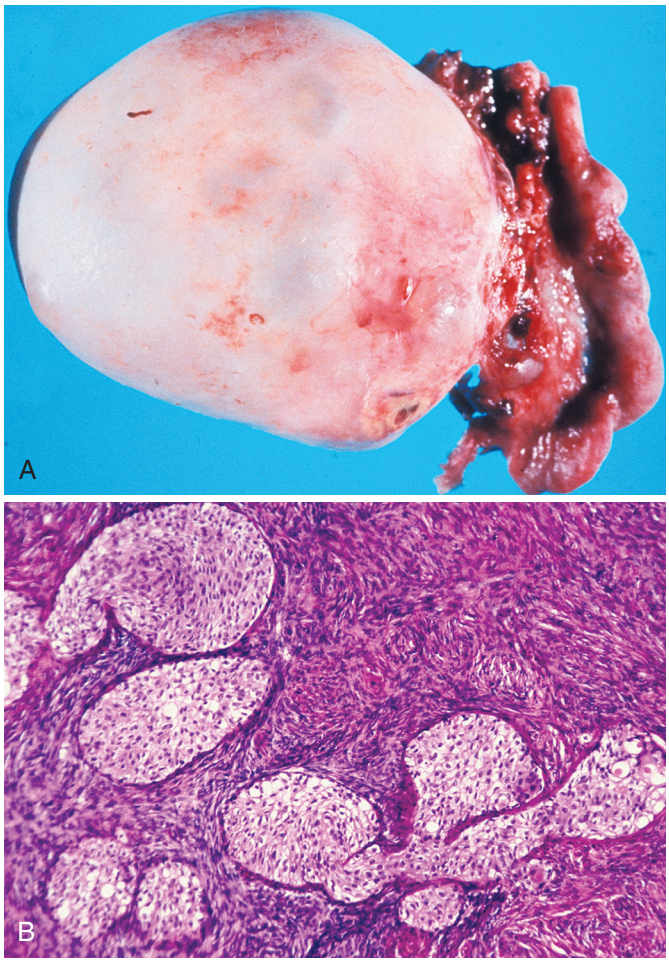

FIGURE 10.8 Brenner tumor. **A,** Gross appearance: solid, firm, white cut surface. **B,** Histologic section: hyperplastic fibromatous matrix interspersed with nests of epithelioid cells. (Courtesy of Ibrahim Ramzy, MD, University of California, Irvine, CA.)

hyperplastic fibromatous matrix interspersed with nests of epithelioid cells. The epithelioid cells under high magnification show a "coffee bean" pattern caused by the longitudinal grooving of the nuclei. The cell nests show a frequent tendency toward central cystic degeneration, producing a superficial resemblance to a follicle. Although it was originally believed that Brenner tumors arise from simple Walthard cell rests, it has been conclusively demonstrated that Brenner tumors can arise from diverse sources, including the surface epithelium, rete ovarii, and ovarian stroma itself. It was originally stressed that Brenner tumors were uniformly benign, but there have been scattered reports in the past several decades of a number of malignant Brenner tumors. Brenner tumors are generally thought to be hormonally inert, but several cases in recent years have been associated with postmenopausal endometrial hyperplasia, and a frequent estrogen effect has been attributed to this neoplasm. These lesions are managed by simple excision.

MANAGEMENT OF ADNEXAL MASSES

Observation versus Surgery

Optimal management for patients with adnexal masses can be achieved by combining all available information from the history, examination, and diagnostic studies to create an accurate differential diagnosis. The presence and severity of symptoms are other important considerations. For example, a patient with a 6-cm unilocular cyst may be initially observed expectantly, but a similar patient with severe pain may need urgent surgery. In addition, consultation with additional specialists (gynecologic oncologist, urologist, general surgeon) may be required based on suspicion of malignancy or the differential diagnosis being considered.

Decisions that must be considered are as follows:

1. Does the patient require surgical evaluation (vs. observation)?
2. After a decision for surgery has been made, is a specialist referral or consultation required, and what type of surgical procedure is planned (open vs. minimally invasive)?
3. If observation has been elected, at what intervals and with what thresholds for changing course would be considered?

Deciding which patients need surgical exploration can best be done by considering the characteristics of the adnexal mass. In reproductive-age women, 95% of ovarian cysts smaller than 5 cm in diameter are nonneoplastic. In addition, functional cysts are seldom larger than 7 cm in diameter and are usually unilateral and freely mobile. A physician can presume that during the reproductive years, an adnexal mass as described earlier is a functional or hyperplastic change of the ovary rather than a true neoplasm. The transitory existence of functional cysts is of prime importance in distinguishing them from true neoplasms. Tradition and clinical experience have shown that functional cysts usually persist for only a few days to a few weeks, and reexamination during a later phase of the menstrual cycle has been a reliable procedure in confirming this diagnosis. Many gynecologists prescribe oral contraceptives to accelerate the involution of the functional cyst on the presumption that these cysts are gonadotropin dependent. The unconfirmed theory is that the inhibitory effect of the contraceptive steroids on the release of pituitary gonadotropins shortens the lifespan of these cysts, hastening their identification as functional or nonneoplastic lesions. In an era before the use of ultrasonography, Spanos conducted a careful study of 286 patients who had adnexal cysts. Combination oral contraceptives were prescribed, and the women were reexamined in 6 weeks. In 72% of the women, the masses disappeared during the observation period. Of the 81 patients whose masses persisted, none were found to have a functional cyst at laparotomy. The fact that five of the removed tumors were malignant underscores the importance of avoiding an unnecessary delay in the operative investigation of these patients. In general, masses larger than 10 cm in diameter should be surgically explored regardless of concerns for malignancy because these masses are not likely to be functional and seldom resolve spontaneously. Our practice is to reassess young women with suspected functional cysts with a repeat examination and ultrasonography in 6 to 8 weeks. If the cyst resolves, no further therapy is indicated. If the cyst persists, the patient is counseled regarding surgical evaluation (Fig. 10.9).

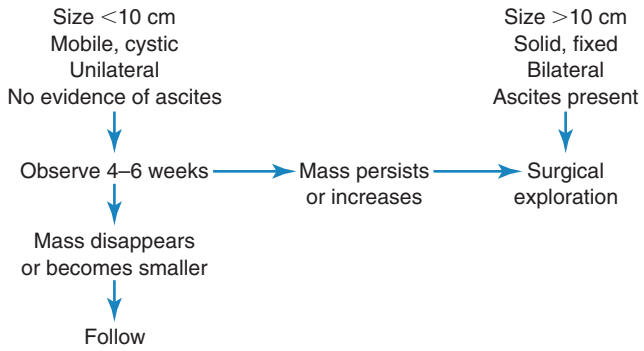

FIGURE 10.9 Management of a premenopausal woman with an adnexal mass.

Data also have accumulated showing that some patients with nonfunctional cyst adnexal masses may be conservatively followed with serial observation and not undergo surgery. For example, postmenopausal women with unilocular cysts smaller than 5 cm and normal CA-125 levels may be considered for observation because the risk for malignancy is very low. In addition, many of the masses will resolve spontaneously. In some older patients with concurrent medical comorbidities, avoiding surgery may be a safer strategy. Patients undergo serial repeat pelvic ultrasonography every 3 to 6 months with CA-125 testing. Surgical intervention is recommended if the morphology becomes complex, the size increases, or the CA-125 level increases outside of normal range. Saunders and colleagues at the University of Kentucky evaluated a series of 1319 patients (25% premenopausal, 75% postmenopausal) with 2870 septated ovarian cysts without solid or papillary projections. On serial follow-up, 39% of cysts resolved (mean duration to resolution, 12 months). Of 1756 cysts that persisted, 128 surgeries were performed, and no case of ovarian cancer was identified. The most common histopathologies were serous cystadenoma, mucinous cystadenoma, and endometrioma. The authors suggested that patients with septated cysts without solid components are at low risk for ovarian cancer and may be followed.

TABLE 10.4 Adnexal Mass: Indications for Surgery

- Ovarian cystic structure >5 cm that has been observed 6–8 weeks without regression
- Any solid ovarian lesion
- Any ovarian lesion with papillary vegetation on the cyst wall
- Any adnexal mass >10 cm in diameter
- Ascites
- Palpable adnexal mass in a premenarchal or postmenopausal patient
- Torsion or rupture suspected

TABLE 10.5 Society of Gynecologic Oncologists and American College of Obstetricians and Gynecologists Referral Guidelines for Women With a Newly Diagnosed Pelvic Mass

Premenopausal Patients (<50 Years Old)

CA-125 >200 units/mL
Presence of ascites
Evidence of intraperitoneal or distant metastasis (based on examination or imaging studies)
Family history (first-degree relative) of breast or ovarian cancer

Postmenopausal Patients (>50 Years)

1. Elevated CA-125 level
2. Ascites
3. Evidence of intraperitoneal or distant metastasis (based on examination or imaging studies)
4. Family history (first degree relative) of breast or ovarian cancer

Adapted from ACOG Practice Bulletin. Management of adnexal mass. *Obstet Gynecol* 2007;110:207.

Masses that raise a suspicion for malignancy require surgical intervention (Table 10.4). In addition, consultation with a specialist trained in the management of ovarian cancer should be considered. Patients with associated hallmarks of ovarian cancer, including peritoneal or omental implants, ovarian caking, and markedly elevated CA-125 levels, frequently have advanced ovarian cancer and require care from physicians specialized in surgical debulking techniques. In other tumors with the potential for malignancy, surgical evaluation should be considered, and consultation is advised. Conditions raising the concern of possible malignancy include the following:

1. Bilateral adnexal masses
2. Complex masses, especially including solid components, thick septations, or mural nodules
3. Premenopausal patients with complex masses that persist or grow after period of observation
4. Postmenopausal patients with simple masses larger than 5 cm or complex masses of any size
5. Masses associated with elevated tumor markers
6. Symptomatic masses

In a joint publication, the American College of Obstetrics and Gynecology (ACOG) and the SGO suggested referral guidelines to triage patients with adnexal masses to specialists in the care of ovarian cancer. The guidelines are shown in Table 10.5. The SGO performed a multisite, retrospective validation trial assessing the guidelines in 1035 women undergoing surgery for an adnexal mass. The prevalence of ovarian cancer was 31%. When using the referral guidelines, the positive predictive values were 34% for premenopausal and 60% for postmenopausal women. The negative predictive value was approximately 92% for each group. Others have criticized the guidelines for largely detecting cases of advanced cancers and missing many cases of early stage cancers (when appropriate staging would be desired).

Minimally Invasive Surgery for Adnexal Masses

Minimally invasive surgery (MIS), either laparoscopic or robotic, is the preferred approach for a presumptively benign adnexal mass. With the use of specific ultrasound criteria, benign masses can be predicted with a high degree of certainty, especially in premenopausal women. Careful selection of patients is critical for the appropriate use of MIS for removal of adnexal masses. The patient's age, the clinical examination, tumor markers, and the ultrasound findings provide important information that helps determine the appropriate operative approach. MIS should be used cautiously in the presence of any mass with clinical or ultrasonographic characteristics suggestive of malignancy, especially an adnexal mass in a postmenopausal woman associated with an elevated serum CA-125 value.

All patients scheduled for MIS with an adnexal mass should also consent to possible laparotomy. If the preoperative risk for finding malignancy is high enough, referral to a surgeon prepared to proceed with staging or surgical debulking if malignant disease is uncovered is warranted. Cell washings are obtained from the pelvis and upper abdomen and saved for proper staging if a malignant neoplasm is found. Any lesions or suspicious areas are sampled and sent for frozen section analysis. If an unexpected malignancy is found, appropriate biopsies and photo documentation can be taken, and referral can be made to a cancer specialist. The main reasons for conversion from laparoscopy to laparotomy are extensive adhesions or intraoperative complications.

Nezhat and colleagues reported their experience with 1209 patients with adnexal masses who were managed laparoscopically. Of 1011 cases with surgical management, ovarian cancer was discovered intraoperatively in four. The management of a cystic mass included aspiration of fluid, which was sent for cytologic examination, followed by opening of the cyst and inspection of the wall for any irregular thickening. Frozen section biopsy specimens were obtained if the surgeon thought any surfaces were suspicious. An ovarian cystectomy–oophorectomy was then performed, and tissue was sent for permanent histologic examination. The Nezhat et al. study suggests that experienced surgeons using intraoperative histologic sampling may safely evaluate adnexal masses laparoscopically.

Hasson reported another series of 102 women with ovarian cysts who were managed laparoscopically. In 83 of the women, laparoscopic fenestration and biopsy were done, with or without coagulation or removal of the cyst lining. Only 1 of 56

functional, simple, or paraovarian cysts recurred during the study. Two of the 18 ovarian endometriomas treated with fenestration and coagulation or removal of the lining recurred, and eight of nine such lesions recurred with treatment by fenestration alone. There were no surgical complications.

Canis et al. reported on their group's experience with 247 adnexal masses suspicious at ultrasound examination; 17 patients were evaluated by laparotomy and 230 by laparoscopy. Of the 230 women triaged to laparoscopy, the procedure was completed laparoscopically in 204 women. Women who were treated by laparoscopy included 7 of 37 malignant tumors and 191 of 210 benign masses. One case of tumor dissemination occurred after a laparoscopic adnexectomy and morcellation of a grade 1 immature teratoma. This study demonstrated the feasibility of laparoscopy for management of a suspicious adnexal mass, thus sparing the patient the known morbidity of a laparotomy. Some surgeons prefer to manage cystic ovarian masses with a mini laparotomy. A small incision (3–5 cm) is made over the mass, and the cyst fluid is aspirated with a long needle, trocar, or suction cannula after draping the field with dry laparotomy pads (Fig. 10.10, *A*). The collapsed mass can then be removed through the small incision (Fig. 10.10, *B*) and submitted to pathology. Spill is minimal with this approach, but thorough irrigation of the surgical field is recommended before closure. Our preferred approach is to place the mass into a bag inserted laparoscopically to enable aspiration and extraction of the mass without intraperitoneal spill and with use of a truly minimally invasive approach.

SPECIAL CIRCUMSTANCES

Adnexal Masses in Childhood

The differential diagnosis of an adnexal mass in children and adolescents also includes benign and malignant processes. Table 10.6 outlines the frequencies of adnexal masses in young women and children. Fig. 10.11 outlines the process of differentiating between benign and malignant masses in childhood. Whenever possible, conservative or MIS is preferred to preserve endocrine and reproductive functions. Dermoid cysts are among the most common ovarian masses in both pediatric and adolescent patients. These tumors are bilateral in 15% to 25% of cases. Two percent of dermoids (teratomas) have malignant components; these are usually found in adolescent patients but can also be found in childhood. A complete workup of a pelvic mass in this age group should include imaging and determination of serum levels of tumor markers such as CA-125, α-fetoprotein, lactate dehydrogenase, and β-hCG. The differential diagnosis should consider acute appendicitis, intussusception, gastroenteritis, chronic constipation, genitourinary problems, and pelvic infection.

In a study by Ehren and colleagues, 63 children and adolescents with benign or malignant ovarian tumors were described. Abdominal pain was the most common complaint; 22% had torsion. The most common sign on initial examination was a palpable abdominal mass (45 of 54 patients). Benign teratoma was the final diagnosis in 41 of the patients (65%), and 29 had

calcification apparent on abdominal radiography. All patients younger than 12 years with ovarian neoplasms had germ cell lesions, although an epithelial tumor has been reported in a 4-year-old patient. Two patients experienced precocious puberty, and of note, both had embryonal carcinoma. In this 63-patient study, appendicitis was the most usual misdiagnosis. Twenty-one percent had malignant tumors. Breen and Maxson noted that 35% of ovarian tumors in children were malignant.

Van Winter and associates reported on 521 adnexal masses in infancy, childhood, and adolescence; 92% were benign, including 335 nonneoplastic and 144 of 186 (77%) neoplastic lesions. The frequency of ovarian malignant neoplasms correlated inversely with the patient's age. Germ cell, stromal, and epithelial malignant neoplasms accounted for 40%, 21%, and 33%, respectively, of the 42 cancers. Nonconformance between preoperative and postoperative diagnoses was noted in 94 cases. The most common preoperative diagnosis necessitating reassignment was acute appendicitis. During the last decade of this study, ultrasonography and CT did not miss a single malignant neoplasm. The majority of these patients presented with a pain or a mass (Table 10.7).

It is important to note that when adnexal torsion is identified in a pediatric patient, the first step should be untwisting of the adnexa rather than immediate resection. The surgeon should then carefully inspect the adnexa for 10 to 15 minutes to assess viability. Often, the adnexa will revascularize and immediately demonstrate improved perfusion, and thus the standard of care is now considered to be ovarian preservation. Celik et al. prospectively followed 14 girls who underwent conservative management of torsion; they found that 13 of 14 girls had resumption of normal ovarian size and folliculogenesis. No recurrence of torsion was noted.

Postmenopausal Ovary

During the postmenopausal years, when the ovaries become smaller and quiescent after cessation of menses, the presence of a palpable ovary must alert the physician to the possibility of an underlying malignant neoplasm. Physiologic enlargement and functional cysts should not be present in late postmenopausal ovaries. The postmenopausal gonad atrophies to a size of 1.5 × 1 × 0.5 cm on average (Fig. 10.12), and at that size, it should not be palpable on pelvic examination. The possibility of malignant disease must therefore be carefully assessed when

an ovary is palpable in a postmenopausal woman. Goswamy and colleagues studied ovaries from 2221 postmenopausal women with regard to ovarian volumes (Fig. 10.13). They noted that there were three ranges of volume and that volume appeared to be increased in obese and multiparous women.

Adnexal masses are usually evaluated by ultrasonography, and suspicious masses should be surgically evaluated (Fig. 10.14). When surgery is performed, the approach should be made with the assumption that the patient may have an early ovarian carcinoma. Cytologic washings should be obtained, and careful exploration of the abdomen should be done, as in any patient being staged for ovarian cancer. If laparotomy is chosen, a vertical abdominal incision is recommended, which allows

for careful assessment of the upper abdomen. Small simple cysts are not uncommon in the adnexae of postmenopausal asymptomatic women who undergo pelvic imaging. Wolf and colleagues identified unilocular cysts ranging in size up to 5 cm in 22 of 149 (14.8%) asymptomatic postmenopausal women. Conway and colleagues performed transvaginal sonography on 1769 similar asymptomatic women and found 116 (6.6%) simple cysts up to 5 cm in diameter. Others have had a similar outcome (Table 10.8).

Castillo et al. evaluated 8794 asymptomatic postmenopausal women with ultrasonography and identified 215 women with simple adnexal cysts (2.5%). Of 104 women who underwent conservative observation, 44% had spontaneous resolution of the cysts during follow-up, and of women with cysts that did not resolve, 70% of the cysts remained the same size, 17% increased, and 17% decreased. Of 45 women who underwent surgery, one was identified with an ovarian cancer. The authors suggested that the risk of malignancy in simple cysts is low and that conservative management is reasonable.

Lerner and colleagues accurately predicted a benign outcome in 247 of 248 patients studied. They used color-flow Doppler analysis to improve the accuracy of ultrasonic characterization of ovarian masses. However, this technique has not been as accurate when used by others. Shalev and coworkers described 55 postmenopausal women who underwent operative laparoscopy for an adnexal cyst that was not complex and when the serum CA-125 level was normal. All of the 55 cysts were benign. During the same period, 75 women underwent exploratory laparotomy for complex cysts or an elevated serum CA-125 level. Of the 75 women, 23 had malignant lesions. Size is an important determinant of malignant potential. Cysts smaller than 5 cm in diameter are rarely malignant, but cysts larger than 5 cm in diameter have a high probability of malignancy in postmenopausal patients.

A diagnosis of ovarian cancer should be considered when a postmenopausal woman presents with a pelvic mass. The presence of ascites, which can be detected clinically or by ultrasound examination, markedly increases the probability of a diagnosis of malignancy. In addition, CA-125, although nonspecific in the population of premenopausal patients, is sensitive in postmenopausal patients when it is used in combination with a

clinical impression and an abnormal ultrasound finding. Early surgical intervention is a key component in the treatment of these patients, and extensive diagnostic testing should be discouraged.

Borderline Malignant Epithelial Ovarian Neoplasms

In the past 4 decades, clear evidence has been presented that there is a group of epithelial ovarian tumors with histologic and biologic features intermediate between those of clearly benign and those of frankly malignant ovarian neoplasms. These borderline malignant neoplasms account for approximately 15% of all epithelial ovarian cancers. In the younger population, these lesions tend to occur more frequently than the obviously malignant epithelial ovarian carcinomas, which are seen more frequently in older patients (Fig. 10.15). There is a 10-year survival rate of more than 95% for stage I lesions in these borderline neoplasms. However, symptomatic recurrence and death may occur as many as 20 years after therapy in a few patients.

Borderline serous epithelial tumors (Fig. 10.16) occupy an intermediate position between the benign serous cystadenomas and the frankly malignant serous cystadenocarcinomas in their histologic features and prognostic aspects. On gross evaluation, the borderline serous tumors are similar to the previously described benign serous cystadenomas, which have papillary projections, but the borderline tumors possibly show an increased incidence of bilaterality. In addition, the papillary component is usually more abundant in the borderline lesions than in the perfectly benign serous cystadenoma. Survival in these lesions differs significantly from that in their obviously malignant counterpart (Fig. 10.17).

The histologic criteria characterizing the borderline tumors can be summarized as follows:

1. Stratification of the epithelial lining of the papillae
2. Formation of microscopic papillary projections or tufts arising from the epithelial lining of the papillae
3. Epithelial pleomorphism
4. Atypicality
5. Mitotic activity
6. No stromal invasion present.

In 1973, Hart and Norris reported a series of borderline mucinous tumors confined to either ovary or both ovaries at

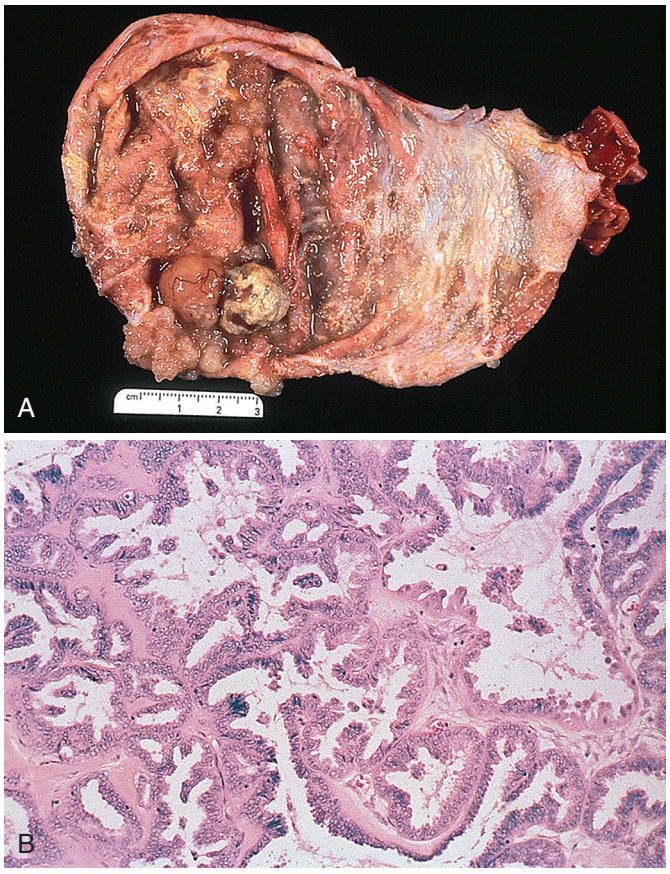

FIGURE 10.16 Borderline serous carcinoma. **A,** Gross appearance. **B,** Histologic section showing stratification of the epithelial lining in papillary projections.

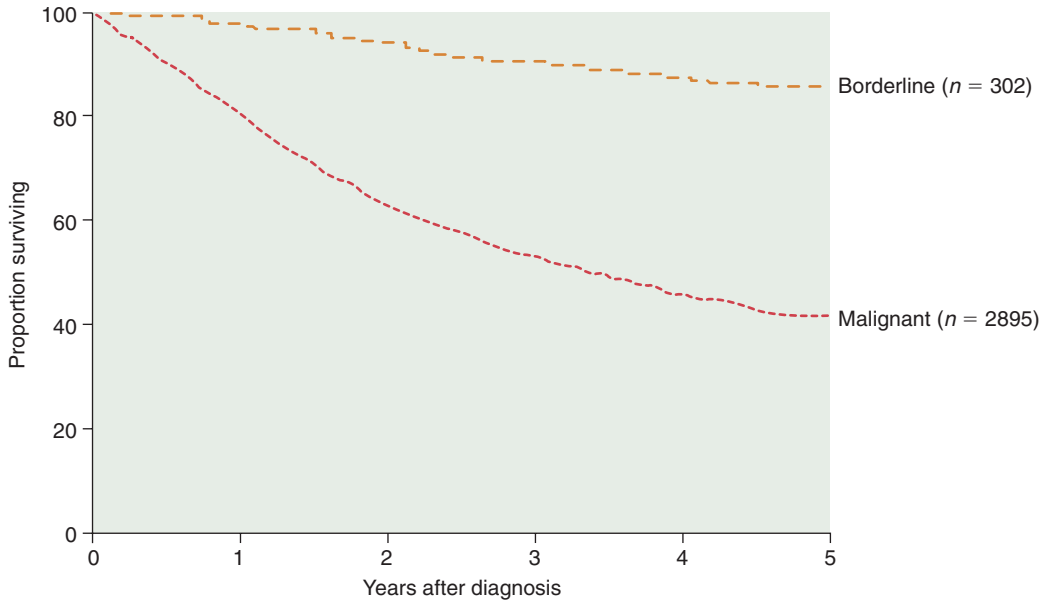

FIGURE 10.17 Carcinoma of the ovary: patients treated from 1900 to 1992. Survival by histology (n = 3197). (From FIGO Report. J Epidemiol Biostat Vol 3, 1998. Reprinted with permission of the publisher, Taylor & Francis Ltd., http://www.tandf.co.uk/journals.)

the time of diagnosis, with a corrected 10-year actuarial survival rate of 96%. These neoplasms do not differ significantly from their benign counterparts in gross appearance. They are multilocular, cystic, frequently voluminous masses with smooth outer surfaces. The inner lining, also similar to that of benign mucinous cystadenomas, is generally smooth, although papillary structures and solid thickening of the capsule have been observed in about 25% to 50% of lesions reported (Fig. 10.18). On microscopic examination, in contrast to benign mucinous cystadenoma, the epithelial lining of the borderline tumor is characterized by stratification of two or three layers. In the benign tumors, the cells show no atypia or pleomorphism, but the epithelium of the borderline lesions does demonstrate atypia, with irregular, hyperchromatic nuclei and enlarged nucleoli. Mitotic figures are also seen.

Trimble and Trimble reported an excellent review of epithelial ovarian tumors of low malignant potential in 1994. For serous and mucinous tumors of low malignant potential, the mean age at diagnosis falls close to 40 years, approximately 2 decades earlier than the mean age at diagnosis for invasive epithelial ovarian cancer. In a meta-analysis of 12 case-control studies conducted in the United States, Harris and colleagues found a mean age of 44 years for women with tumors of low malignant potential compared with a mean age of 52.9 years for women with invasive ovarian carcinoma. The meta-analysis conducted by the Collaborative Ovarian Cancer Group found protective factors against the development of tumors of low malignant potential to be pregnancy, breastfeeding, and use of oral contraceptives. A history of infertility increased the risk of tumors of low malignant potential (odds ratio [OR], 1.9), and the use of infertility drugs further increased the risk for development of a tumor of low malignant potential above that of women with no history of infertility (OR, 4.0).

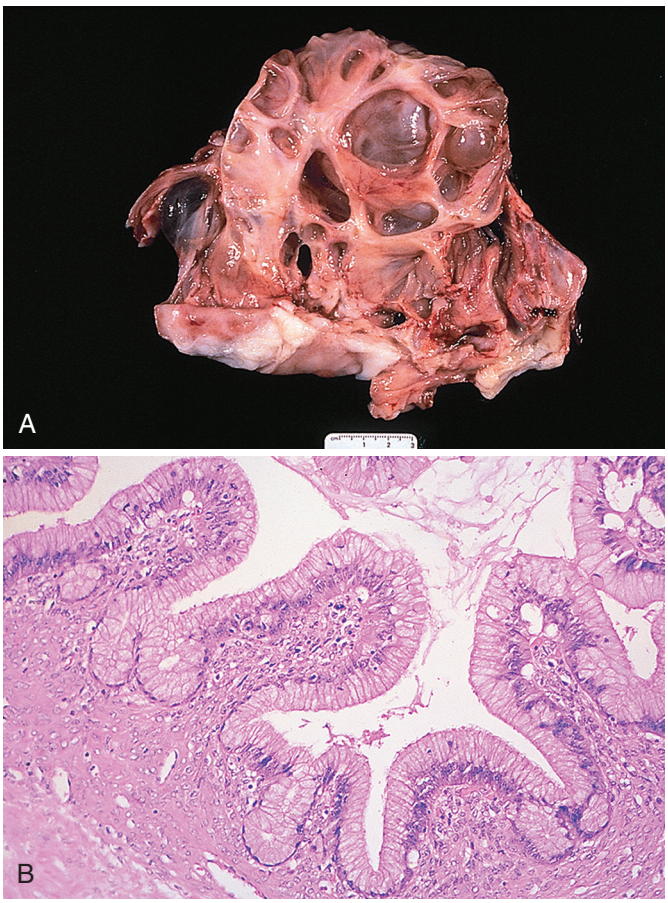

FIGURE 10.18 **A,** Mucinous tumor with low malignant potential. Gross appearance. **B,** Photomicrograph of mucinous tumor seen in *A*.

Kurman and Trimble reviewed survival in 22 studies of serous tumors of low malignant potential, excluding those patients with invasive peritoneal implants. For 538 patients with stage I disease, the survival rate was 99%, with a mean follow-up of 7 years. Even in the series of 415 patients with stage II and stage III disease, the survival rate was 92% with a mean follow-up of 7 years. In review of the causes of death in this series, three patients died of radiation-associated complications, nine died of chemotherapy-associated complications, eight died of bowel obstruction, and eight died of invasive carcinoma; 18 patients were reported as "dying of disease" without additional information. In short, more patients seemed to die with disease than of disease. In addition, more patients died of treatment-related complications than of bowel obstruction from progressive disease. For treatment of borderline lesions, the physician should strive to completely extirpate all grossly visible tumor. If disease is unilateral, a salpingo-oophorectomy or a carefully performed ovarian cystectomy is appropriate, on condition that a thorough evaluation of the other ovary (biopsy if necessary) is done. Julian and Woodruff evaluated 65 patients who had low-grade papillary serous carcinoma of the ovary and found that 100% of the 50 patients who had unilateral adnexectomy and 90% of the 10 patients who had complete operation (total abdominal hysterectomy and bilateral salpingo-oophorectomy) were alive at 5 years. Lim-Tan and colleagues described 35 patients with ovarian serous borderline tumors treated by unilateral cystectomy or bilateral cystectomy. Tumor persisted or recurred only in the ovary that had been subjected to cystectomy in two (6%) of the 33 patients, with stage I tumors in both the ipsilateral and contralateral ovary in one patient (3%) and only in the contralateral ovary in the other patient (3%). All of the patients were alive without evidence of disease 3 to 18 years after initial operation, with the average follow-up period of 7.5 years. Scattered reports of similar smaller series suggest that these lesions may be managed with ovarian cystectomy alone in patients desirous of further childbearing when acceptance of a small risk is appropriate.

If there is bilateral ovarian involvement, especially when papillary projections are found on the external surface of the tumor, or if peritoneal spread is noted, a more radical surgical approach, such as total abdominal hysterectomy with bilateral salpingo-oophorectomy and radical excision of involved pelvic peritoneum, is advocated. Peritoneal cytologic examination, partial omentectomy, and selected pelvic and periaortic lymphadenectomy should also be done in these patients with more advanced disease. Advanced (stage III) borderline lesions can occur with metastases to lymph nodes. The survival rate even with these advanced lesions is appreciable.

Several authors have described patients with ovarian serous borderline tumors with peritoneal implants. Gershenson and Silva report a 95% disease-free survival rate at 5 years and a 91% disease-free survival rate at 10 years. However, Bell and coworkers reported that 13% of patients died of tumor, and one patient was alive with widespread progressive tumor. The mortality rate resulting from tumor was 4% at 5 years and 23% at 10 years. Drescher and coworkers studied the significance of the DNA content and nuclear morphology in these lesions. Their results suggest that measurement of DNA ploidy and nuclear morphology by image analysis can provide important prognostic information in patients with borderline ovarian tumors. Some extraovarian implants are associated with irregular glandular structures in immature, desmoplastic, or inflamed stroma, and these represent a difficult diagnostic problem. Many also have a clear pattern of invasion of subjacent tissues and cellular features of malignancy. They thus exhibit a capacity for invasion not seen in the ovarian lesion and may represent an independent or autochthonous origin. Other bland cellular nests of cells in desmoplastic reactive granulation tissue do not invade the underlying tissue and are termed noninvasive compared with the invasive implants. Russell and Merkur reported that invasive implants are associated with a poor clinical outcome compared with the noninvasive group.

Gershenson and colleagues described seven assessable patients with invasive implants who underwent chemotherapy and a second-look surgery. Four of the patients had a response. No clear conclusion could be drawn about which agents were most active. A total of 39 patients with invasive implants were identified at their institution, and 12 (31%) developed progressive disease or a recurrence.

Kurman and Trimble have identified an aggressive subgroup of proliferative serous lesions, which they call micropapillary serous carcinoma. Seidman and Kurman found 11 patients with micropapillary projections, and according to Seidman and Kurman, these lesions should be classified as carcinomas, as should serous borderline tumors with invasive implants. The poor prognosis for these patients has prompted some clinicians to prescribe chemotherapy as an adjuvant to surgery.

The role of adjuvant therapy, whether radiotherapy or chemotherapy, in tumors of low malignant potential has not yet been established. Several prospective, randomized studies of adjuvant therapy in patients with invasive ovarian carcinoma have included patients with tumors of low malignant potential. From 1983 to 1992, the Gynecologic Oncology Group (GOG) studied 414 patients with low malignant potential lesions of the ovary. The purpose of the protocol was to evaluate the biologic behavior of these tumors, the effectiveness of melphalan chemotherapy in patients with clinically detectable residual disease after surgical staging and in patients with recurrent disease, and the response rate to cisplatin in patients who failed to respond to melphalan therapy. The preliminary conclusions were that ovarian serous tumors of low malignant potential limited to the ovary rarely recur. Conservative management with unilateral salpingo-oophorectomy or ovarian cystectomy is adequate therapy for women of reproductive age. The effectiveness of melphalan and cisplatin has yet to be analyzed.

Perhaps the largest study to date of borderline ovarian tumors is the **R**etrospective/prospective multicenter **o**utcome survey in **b**orderline **o**varian **t**umors (ROBOT) study, which was conducted in Europe. Du Bois et al. reported that of 950 patients with a confirmed borderline tumor, 7.8% recurred and 4.5% died during the follow-up period. Upon multivariate analysis, higher stage, incomplete staging, residual tumor, and fertility preservation surgery were independent factors for recurrence. Neither microinvasion nor micropapillary pattern yielded significance. Most recurrences (n = 74) were in the form of

borderline ovarian tumor ($n = 52$ or 70% of recurrences), but eight patients (11% of recurrences) developed high-grade serous ovarian cancer. Patients who recurred with invasive cancer had significantly poorer 5-year progression-free survival (PFS) (83% vs. 12%; $P < 0.0001$) and overall survival (98% vs. 50%; $P < 0.0001$) rates than those who recurred with borderline tumors.

It is clear that some patients with advanced disease will ultimately die of their tumor. It is not clear that adjuvant chemotherapy has any impact on survival. A strong clinical need currently exists to develop a mechanism for distinguishing lesions that are biologically aggressive from lesions that persist in a state of equilibrium, posing no threat to the patients' health and welfare.

Fertility Preservation

Operative treatment has traditionally been the mainstay of management in ovarian carcinoma. The technical aspects of the initial laparotomy have a greater bearing on outcome than do many subsequent therapeutic decisions. Hysterectomy with bilateral salpingo-oophorectomy continues to be the most cogent therapy for ovarian carcinoma. The opposite ovary is removed because of the frequency of bilateral synchronous tumors and the possibility of occult metastases, which in the normal-appearing opposite ovary have varied from 6% to 43%, depending on the report and stage of the disease. Because the uterine serosa and endometrium are often sites of occult metastasis and because the prevalence of synchronous endometrial carcinoma is relatively high, hysterectomy is also indicated. Because 3% to 17% of patients with ovarian cancer are younger than 40 years of age, some patients may consider options for fertility preservation in the setting of an adnexal mass.

Conservative therapy, designed by preservation of some ovarian tissue, appears to be safe, although no prospective trials have compared conservative surgery with bilateral salpingo-oophorectomy. Trimble and Trimble collected eight series (Table 10.9). In a study of these data, there were only 10 recurrences in 148 patients for an incidence of 6.8%. Zanetta and colleagues published their results with 99 women aged 40 years or younger with stage I ovarian carcinoma. Of the 99 women, 56 underwent fertility-sparing surgery, and 43 had more radical surgery with a median follow-up period of 7 years; they observed five recurrences (9%) of carcinoma in the women treated conservatively and five recurrences (12%) in those treated more radically. Two recurrences after conservative surgery involved the residual ovary (3.6%). These two women developed a borderline tumor in the contralateral ovary and were treated with surgery. More recent data from Schlaerth and colleagues from Memorial Sloan-Kettering Cancer Center evaluating 123 patients with stage I ovarian cancer, including 20 with preservation of the uterus and contralateral ovary, found no difference in 5-year PFS (84% vs. 78%) or survival (84% vs. 82%) for fertility-preserving versus standard surgical approaches. Wright and coworkers reviewed a large population database of patients with early-stage ovarian cancer and noted that neither ovarian nor uterine preservation had an effect on survival. Colombo and associates reported data of 99 patients younger than 40 years with stage I ovarian cancer. Conservative surgery was performed in 56 of the patients (36 stage Ia, 1 stage Ib, and 19 stage Ic). Relapses occurred in three patients assigned to stage Ia (grades I, II, and III). One recurrence was in the residual ovary, and the patient was rescued by surgery; the other two patients had relapses at distant sites and died as a result of the tumors. Seventeen patients who desired to become pregnant did so, for a total of 25 conceptions.

Some centers are studying the role of ovarian cystectomy alone for low-grade stage I epithelial neoplasms. Others have permitted patients with stage I lesions, grade II and III lesions, and stage Ic neoplasms to undergo ovarian tissue-sparing surgery followed by chemotherapy in an attempt to preserve fertility. These investigations await further observation and confirmation as to long-term safety. Chemotherapy administered after such ovarian tissue-sparing procedures may destroy the remaining ova, especially in patients older than 30 years.

It is estimated that 7% to 8% of stage I ovarian cancer cases occur in women younger than age 35 years. Considerations for conservative management of stage Ia ovarian cancer are listed in Table 10.10. Unilateral salpingo-oophorectomy may be the definitive treatment of a young woman of low parity found to

TABLE 10.10 Optimal Requirements for Conservative Management in Stage Ia Epithelial Ovarian Cancer

1. Well differentiated
2. Young woman of low parity
3. Otherwise normal pelvis
4. Encapsulated and free of adhesions
5. No invasion of capsule, lymphatics, or mesovarium
6. Peritoneal washings negative
7. Adequate evaluation of opposite ovary and omental biopsy result negative
8. Close follow-up probable
9. Excision of residual ovary after completion of childbearing

Modified from DiSaia PJ, Townsend DE, Morrow CP. The rationale for less than radical treatment for gynecologic malignancy in early reproductive years. *Obstet Gynecol Surv* 1974;29:581. Copyright © 1974 by The Williams & Wilkins Co.

have a well-differentiated serous, mucinous, endometrioid, or mesonephric carcinoma of the ovary. The tumor must be unilateral, well encapsulated, free of adhesions, and not associated with ascites or evidence of extragonadal spread. Peritoneal washings for cytologic examination should be taken from the pelvis and upper abdomen, and the opposite ovary should be evaluated for disease. If the opposite ovary is of normal size, shape, and configuration, surgical evaluation is not routinely done. Munnell and others have calculated the incidence of microscopic metastases in the opposite ovary to be approximately 12%. The paraaortic and pelvic wall nodes must be carefully palpated and sampled, peritoneal staging biopsies must be performed, and an adequate sample of the omentum must be taken for biopsy. In addition, the preserved pelvic organs should be reasonably normal because there is little to be gained by retaining the opposite ovary in a patient who is not fertile. With the finding of carcinoma in any of these areas, conservative surgery must be abandoned. After the patient has completed childbearing, some consideration should be given to the removal of the other ovary to eliminate the risk of another ovarian malignant neoplasm. Because the incidence of epithelial cancer of the ovary increases when a woman reaches the sixth decade of life and because a patient with a history of such a lesion harbors the unfortunate milieu that could promote another epithelial lesion, it is reasonable to remove the vestigial ovarian tissue after childbearing.

Cyst Rupture or Spill of Tumor

The subject of tumor spill has been controversial in gynecologic oncology for some time. The Federation of International Gynecologists and Obstetricians (FIGO) staging system was updated in 2014 to reflect several changes. Stage IC is now subclassified by whether the mass was ruptured preoperatively versus intraoperatively or had capsule involvement or whether there were positive washings or malignant ascites. Traditionally, upstaging to IC leads to a recommendation for the use of postoperative chemotherapy also. It is logical to assume that implantation and germination of cancer cells are conceivable and probable when a malignant cyst ruptures at the time of surgery. The data to support the independent prognostic significance of intraoperative cyst rupture are mixed, however. Other changes in the 2014 updated FIGO staging system include division of stage IIIA into IIIA1 and IIIA2 to microscopic extrapelvic disease involving retroperitoneal lymph nodes or microscopic peritoneal involvement and division of stage IV into IVA and IVB with the former including only malignant pleural effusion and the latter including hepatic or splenic parenchymal metastases or other extraperitoneal metastases.

Analyses of older studies in which complete surgical staging was not performed and contemporary chemotherapy regimens were not used make it difficult to understand the relevance of cyst rupture as a single variable (Table 10.11). Sjöval and associates described 247 patients with stage I disease who were at risk of spill. There was no difference in survival between the patients whose tumors had intact capsules and the patients in whom rupture occurred during surgery (78% vs. 85%, respectively). However, a significant difference in survival was found between patients in whom rupture occurred before surgery and those with intraoperative rupture (59% vs. 85%, respectively). The conclusion was that manipulation during surgery that results in puncture or rupture does not have a negative influence on the outcome for patients. However, rupture occurring at some interval before surgery may lead to seeding in the peritoneal cavity. Vergote and colleagues assessed 1545 stage I ovarian cancer patients and found that tumor differentiation or grade and cyst rupture were the two most important predictors for disease-free survival. Cyst rupture occurring before definitive surgery heralded a poorer prognosis than that occurring intraoperatively. Bakkum-Gamez and associates reported on 161 patients with stage I ovarian cancer, all of whom underwent thorough surgical staging. In a multivariate analysis, capsular rupture and positive peritoneal cytology were independent predictors of poorer disease-free survival. It is noted that rupture may occur as a result of laparoscopic removal and drainage, may occur by cyst wall weakening (necrosis, tumor penetration), or may be associated with adhesions and adhesion lysis required to remove the cyst. The effect of these confounding variables is difficult to separate, however.

TABLE 10.11 Recurrence Rates as a Function of Cyst Rupture

Series (Year)	Ruptured Neoplasm (%)	Unruptured Neoplasm (%)
Purola and Nieminen (1968)	18/30 (60)	83/100 (83)
Williams et al. (1973)	3/7 (43)	57/58 (98)
Parker et al. (1970)	16/27 (59)	12/20 (60)
Dembo et al. (1989)	98/119 (82)	168/199 (84)
Sevelda et al. (1989)	23/30 (76)	23/30 (76)

We believe that collection of cytology before the mass is manipulated provides important information. Cysts should be removed intact when possible, recognizing that coexisting conditions (endometriosis, adhesions, infection, inflammation) may make this impossible. In some cases, particularly with a large, simple cyst, aspiration by a needle attached to suction (with the ovary placed in a bag during MIS or the area draped off with dry laparotomy pads during open surgery) has been used to decompress a cyst. Our experience with this type of "controlled spill" is that it appears to be safe and has not adversely affected outcome. In cases of masses with solid components or a high suspicion for malignancy, we favor removing the mass intact. Most authors advocate platinum-based chemotherapy for at least three cycles in patients with stage IC disease secondary to tumor rupture. No prospective study comparing these different approaches has been reported.

Prophylactic versus Risk-Reducing Oophorectomy

The early diagnosis of ovarian carcinoma is as difficult and infrequent now as in the past. Although survival figures for this disease may be recently improving to a slight degree, the prognosis is still grave. The gynecologist frequently counsels women

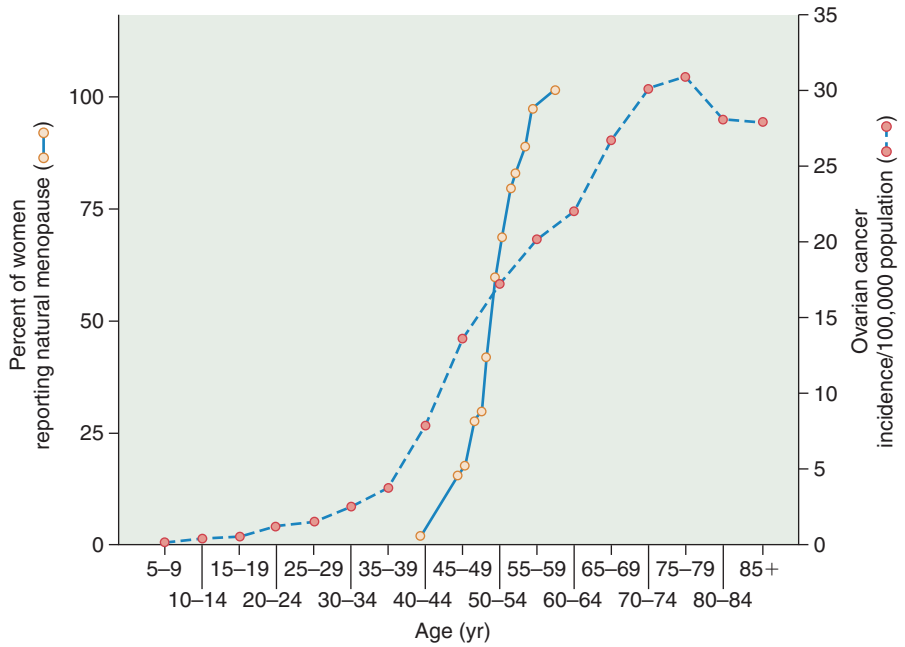

FIGURE 10.19 Incidence of ovarian cancer and the onset of natural menopause versus age.

with regard to strategies to reduce the risk of developing ovarian cancer. In one typical clinical scenario, a low-risk patient who is to undergo a hysterectomy for benign indications must be counseled as to the risk and benefits of removing the ovaries at the time of surgery (prophylactic oophorectomy).

At some time during their lives, 1% to 2% of all women develop ovarian carcinoma. The risk increases after 40 years of age, with a peak incidence between 55 and 60 years of age, closely paralleling the peak incidence of menopause in Western countries (Fig. 10.19). The function of the ovary lies in its role of ova production for procreation and as the primary site of estrogen production. After the need for ova has passed in a woman's life, only estrogen production remains an essential function. The adverse effects of oophorectomy on several metabolic parameters are well known; understanding of the endocrinology, sexuality, and psychology of postmenopausal patients (natural or surgical) has increased considerably during the past decade, and good methods of adequate substitution for the loss of ovarian function are now available.

In 1981, Grundsell and associates reported on a series of 352 women with ovarian carcinoma and studied the incidence of previous pelvic surgeries performed on these patients; 21 (6%) had undergone previous pelvic surgery, and 16 (4.6%) of these patients had surgery at some time after the age of 40 years. Others (Table 10.12) have reported similar results (Bloom, Gibbs, Grogan, Kofler, and Terz). McKenzie, Christ, and Paloucek reported that as many as 3.6% of women who have pelvic surgery with preservation of ovarian tissue will need subsequent surgery for benign lesions of the ovary, further influencing the argument for prophylactic oophorectomy.

Averette and Nguyen found that 18.2% of patients reported previous hysterectomy with ovarian conservation in a national survey of 12,316 ovarian cancer cases. Of these, hysterectomies were abdominal in 7.2%, vaginal in 4.2%, and unspecified in another 6.8%. In a subsequent analysis, Boike and associates found that 57.4% of hysterectomies were performed after the age of 40 years. Thus, a potential 1286 ovarian cancer cases could have been prevented if prophylactic oophorectomy had been practiced in women undergoing hysterectomy at the age of 40 years or later. Assuming an annual incidence of 24,000 new ovarian cases and that 5% to 14% of these cases had previous hysterectomies with conserved ovaries, it is estimated that at least 1000 cases could have been prevented if prophylactic oophorectomy were diligently practiced after the age of 40 years.

We are obviously influenced by the frequent task of caring for patients with advanced ovarian carcinoma. The occurrence of this disease in patients who had previous pelvic surgery and in whom the ovaries could have been removed is certainly frustrating. Randall and coworkers have shown that unilateral oophorectomy does not influence the subsequent incidence of ovarian carcinoma.

TABLE 10.12 Frequency of Prior Pelvic Surgery or Hysterectomy

Author (Year)	All Ages (%)	Age >40 Yr (%)
Bloom (1962)	10.6	
Grogan (1967)	8.2	
Terz (1967)	8.8	3.8
Gibbs (1971)	11.8	
Kofler (1972)	8.1	8.1
Grundsell (1980)	6.0	4.6
Averette and Nguyen (1994)	18.2	10.1

Removal of the contralateral ovary in women with an adnexal mass requires careful thought and scrutiny. Although benefits are appreciable including reduction of ovarian cancer risk, a large dataset including the Women's Health Initiative demonstrated that elective oophorectomy increases overall mortality, largely because of coronary heart disease. Elective oophorectomy before age 55 years doubled a woman's risk of dying from coronary heart disease by age 80 years (15.95% vs. baseline risk of 7.57%). Other known risks associated with elective oophorectomy include cognitive impairment caused by estrogen deficiency, increased risk of hip fracture, and decreased sexual function (Erekson, 2013). Women should be thoroughly informed about the possible adverse effects and the advantages to enable them to make an informed decision.

A second clinical scenario is that in a patient with a strong family history of breast or ovarian cancer or who harbors a known mutation in the *BRCA1* or *BRCA2* gene. These high-risk patients frequently seek consultation to undergo surgery to remove the ovaries to reduce the risk of development of ovarian cancer. Risk-reducing salpingo-oophorectomy (RRSO) has been evaluated in several populations of women at high risk for developing ovarian cancer. Women with known *BRCA1* mutations are estimated to have a lifetime risk of developing ovarian cancer from 39% to 46%, and those with *BRCA2* mutations have a risk from 12% to 20%. Removing the ovaries in this high-risk group of patients reduces the risk of ovarian cancer, with 0.8% to 1% of women subsequently developing a primary peritoneal cancer. In addition, premenopausal women undergoing RRSO have a 50% to 80% reduction in the risk of breast cancer. In a consensus statement by the SGO, women at high risk of ovarian cancer based on family history or *BRCA1* or *BRCA2* mutation should be offered RRSO when childbearing is complete or by age 40 years, whichever occurs first. It should be noted that in the setting of RRSO, some patients will be identified with an incidental early-stage cancer of the ovary or fallopian tube, and thus serial 2- to 3-mm sectioning is mandated to evaluate for occult carcinoma. Although the original recommendation was removal of both fallopian tubes and ovaries in women with hereditary risk, in women who are not yet ready to undergo oophorectomy, salpingectomy has been shown to be a safe and cost-effective strategy if delayed oophorectomy is performed once deemed acceptable by the patient (Kwon et al., 2013). RRSO should not be offered routinely for women at average risk for ovarian cancer because there are no data to support improved survival in these patients. Patients undergoing hysterectomy for other reasons (fibroids, endometriosis) should be counseled as to the risk and benefits related to salpingo-oophorectomy with reference to age. Risk reduction must be balanced against changes in cardiovascular, bone, and sexual health.

OUTLINE

Classification
Incidence, Epidemiology, and Etiology
Familial Ovarian Cancer
Signs, Symptoms, and Attempts at Early Detection (Screening)
Diagnostic Techniques and Staging
Therapeutic Options for Primary Treatment
Borderline Malignant Epithelial Neoplasms
Treatment of Malignant Epithelial Neoplasms
Maximal Surgical Effort
Role of Radiation Therapy
Radioisotopes
Chemotherapy
Clinical Trials
Dose-intense Chemotherapy
Immunotherapy
Intraperitoneal Chemotherapy
Extraovarian Peritoneal Serous Papillary Carcinoma
Small Cell Carcinoma of the Ovary
Follow-up Techniques and Treatment of Recurrences
Use of CA-125 Levels and Other Tumor Markers
Radiographic Imaging
Maintenance Therapy
Chemotherapy for Recurrent Disease and Targeted Therapies
Targeted Therapy
Surgery for Recurrent Disease
Rehabilitation
Conclusions on Management
Current Areas of Research

KEY POINTS

1. Ovarian cancer is the most lethal of all gynecologic cancers. Elderly women are more likely to develop ovarian cancer than young women.
2. Oral contraceptives decrease the incidence of ovarian cancer substantially.
3. Ovarian cancer may be inherited with increased risk being caused by a mutation in *BRCA1* or *BRCA2*, mismatch repair defect, or any number of other less common genes tested in the current panels.
4. A combination of surgery and chemotherapy is almost always recommended for treatment. The order depends on the extent of disease, volume, and location.
5. Significant strides have been made in survival as treatment and surgery have evolved.

Malignant neoplasms of the ovary are the cause of more deaths than any other female genital tract cancer. In the United States, there were approximately 21,290 new cases and 14,180 deaths in 2015 as a result of ovarian cancer. Ovarian cancer accounts for 5% of all cancers among women. In the United States, deaths from this cause occur at a rate of one every 44 minutes, and this disease will develop in one of every 68 women. Doctors and patients alike continue to be frustrated by our lack of understanding of the factors that lead to ovarian cancer and the failure to achieve a significant reduction in mortality.

CLASSIFICATION

The most practical classification scheme is based on the histogenesis of the normal ovary, shown in Table 11.1. The early development of the ovary is divided into four stages. During the first stage, undifferentiated germ cells (primordial germ cells) become segregated and migrate to the genital ridges, which are bilateral thickenings of coelomic epithelium. The second stage consists of proliferation of the coelomic epithelium and the underlying mesenchyme. During the third stage, the ovary becomes divided into a peripheral cortex and a central medulla. The fourth stage is characterized by the development of the cortex and involution of the medulla. The histogenetic classification categorizes ovarian neoplasms with regard to their derivation from coelomic epithelium (epithelial ovarian cancer), germ cells (germ cell tumors), and mesenchyme (sex cord-stromal tumors).

The majority (85%–90%) of malignant ovarian tumors are epithelial. They can be grouped into predominant histologic types as follows:

Serous cystadenocarcinoma	42%
Mucinous cystadenocarcinoma	12%
Endometrioid carcinoma	15%
Undifferentiated carcinoma	17%
Clear cell carcinoma	6%

The specific malignant histologic type has less prognostic significance than clinical stage, extent of residual disease, and histologic grade. Histologic grade, however, is an important

TABLE 11.1 Histogenetic Classification of Ovarian Neoplasms

Neoplasms derived from the coelomic epithelium
- Serous tumor
- Mucinous tumor
- Endometrioid tumor
- Mesonephroid (clear cell) tumor
- Brenner tumor
- Undifferentiated carcinoma
- Carcinosarcoma and mixed mesodermal tumor

Neoplasms derived from germ cells
- Teratoma
  - Mature teratoma
    - Solid adult teratoma
    - Dermoid cyst
    - Struma ovarii
    - Malignant neoplasms secondarily arising from mature cystic teratoma
  - Immature teratoma (partially differentiated teratoma)
- Dysgerminoma
- Embryonal carcinoma
- Endodermal sinus tumor
- Choriocarcinoma
- Gonadoblastoma

Neoplasms derived from specialized gonadal stroma
- Granulosa–theca cell tumors
  - Granulosa tumor
  - Thecoma
- Sertoli–Leydig tumors
  - Arrhenoblastoma
  - Sertoli tumor
- Gynandroblastoma
- Lipid cell tumors

Neoplasms derived from nonspecific mesenchyme
- Fibroma, hemangioma, leiomyoma, lipoma
- Lymphoma
- Sarcoma

Neoplasms metastatic to the ovary
- Gastrointestinal tract (Krukenberg)
- Breast
- Endometrium
- Lymphoma

TABLE 11.2 Probability for Females at Birth Developing Cancer by Age 85 Years in the United States

Site	Probability
All sites	1 in 3
Breast	1 in 9

TABLE 11.3 Primary Ovarian Neoplasms Related to Age

Type	Age <20 Yr (%)	Age 20–50 Yr (%)	Age >50 Yr (%)
Coelomic epithelium	29	71	81
Germ cell	59	14	6
Specialized gonadal stroma	8	5	4
Nonspecific mesenchyme	4	10	9

independent prognostic factor in patients with epithelial tumors of the ovary (Fig. 11.1). Because survival for patients with grade II and III tumors is more closely related, research studies frequently stratify by low-grade (grade I) and high-grade (grade II and III) tumors.

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

Approximately 22% of gynecologic cancers are of ovarian origin (Fig. 11.2), but 47% of all gynecologic cancer deaths occur in women who have ovarian cancer. Cancer of the ovaries is the fifth most frequently occurring fatal cancer in women in the United States and also ranks high as a cause of cancer death in Canada, New Zealand, Israel, and countries of northern Europe. Ovarian cancer will develop in approximately 14 of every 1000 women in the United States older than age 40 years (Table 11.2), but only four of the 14 will be cured. The remaining patients often develop repeated bouts of intestinal obstruction as the tumor spreads over the surface of the bowel, develop inanition and malnutrition, and quite literally starve. In a review of mortality trends in the United States, age-adjusted (to the 2000 US standard population) ovarian cancer mortality rates from 1975 to 2002 showed the absolute number of deaths increased, consistent with a growing and aging population. Over the past 30 years, mortality rates decreased for women younger than 65 years but increased for women older than 65 years, with some plateauing over the past 10 years. These changes may result from increased use of oral contraceptives in younger patients and a shifting of the survival curve to the right. Even when matched for stage, survival was worse in older women. In some cases, this may be a result of less aggressive treatment in the older woman and the higher percentage of low-grade disease in younger patients. Age-adjusted death rates were higher in whites than in blacks. Asians and Pacific Islanders, American Indian and Alaskan natives, and Hispanics have lower death rates than blacks.

Malignant neoplasms of the ovaries occur at all ages, including infancy and childhood (Fig. 11.3). Throughout childhood and adolescence, the rate of death from ovarian carcinoma in the United States is exceeded by those for leukemia; lymphomas; and neoplasms of the central nervous system, kidney, connective tissue, and bone. The major histologic types occur in

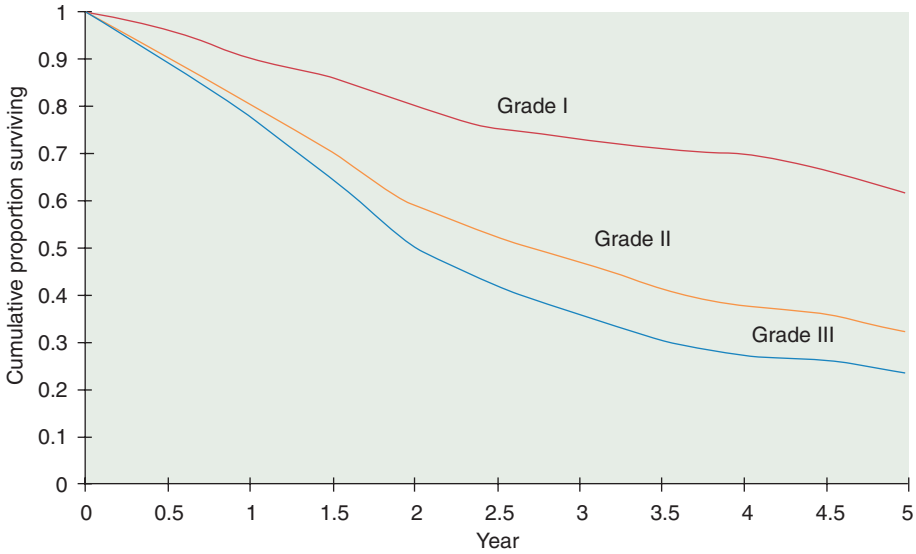

FIGURE 11.1 Serous cystadenocarcinoma of the ovary. Cumulative proportion surviving by degree of differentiation. (From International Federation of Gynecology and Obstetrics. *Annual Report on the Results of Treatment in Gynecological Cancer,* vol 22. Stockholm, 1994, Author.)

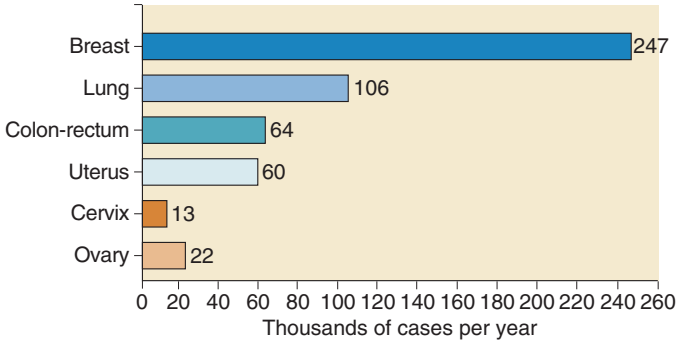

FIGURE 11.2 Leading sites of new cancer cases, 2016 estimates. Data from Cancer Facts and Figures 2016 estimates.

distinctive age ranges (Table 11.3). Whereas malignant germ cell tumors are most commonly seen in girls younger than age 20 years, epithelial cancers of the ovary are primarily seen in women older than age 50 years. Beginning at age 45 to 49 years, with a rate of 16.4 cases per 100,000, incidence increases progressively with age. The rate increases after the age of 60 years to 40 cases per 100,000 and then peaks at 61 cases per 100,000 in the age group 80 to 84 years. The largest absolute number of patients with ovarian cancer is found in the age group 60 to 64 years; more than one-third of the cases occur in patients 65 years or older. Elderly women are more likely than younger women to be in advanced stages of ovarian cancer at initial diagnosis, and the 5-year relative survival rate for elderly women is about half the rate (28.4%) observed in women younger than 65 years (56.6%).

Epidemiologic evidence strongly suggests that environmental factors play a major role in developing epithelial cancer of the human ovary. Highly industrial countries have the highest reported incidence, and physical or chemical products of industry may be causative factors. A notable exception is highly industrialized Japan, where rates for ovarian cancer have been among the lowest recorded in the world. Of interest, the incidence of ovarian cancer increases in Japanese immigrants to the United States and their offspring, eventually approaching that of Anglo-Saxon whites by the second and third generations. This suggests that causative carcinogens may be present in the immediate environment, such as food, personal customs, and other influences that change gradually during the cultural transition. To date, there are no firm clues as to which dietary items or other environmental contacts are specifically carcinogenic for the ovary.

A decreased incidence of ovarian cancer is related to less frequent ovulation. Danforth and coworkers prospectively examined risk of ovarian cancer in the Nurses' Health Studies and found that women who never breastfed faced a 1.5-fold risk of ovarian cancer compared with women who breastfed for longer than 18 months. These observations coincided with data illustrating a reduction in the disease incidence with the use of oral contraceptives (Table 11.4). The hypothesis that oral contraceptive use reduced the risk of epithelial ovarian cancer was suggested by Casagrande and associates in 1979. In 1982, Rosenberg and colleagues reported a case-control study in which combination oral contraceptives were used by 26% of the patients with ovarian cancer and 35% of the control participants. The relative risk estimate for combination oral contraceptive use was 0.6 (Table 11.5). The reduction in risk appeared to persist for as long as 10 years after use has ceased and to be greater for longer durations of use, but these results were not statistically significant. Their conclusion was that the use of combination oral contraceptives protects against epithelial ovarian cancer. The theory of "incessant ovulation" suggests that the epithelial lining of the ovary may be sensitive to the events of ovulation, which in turn can act as a promoting factor

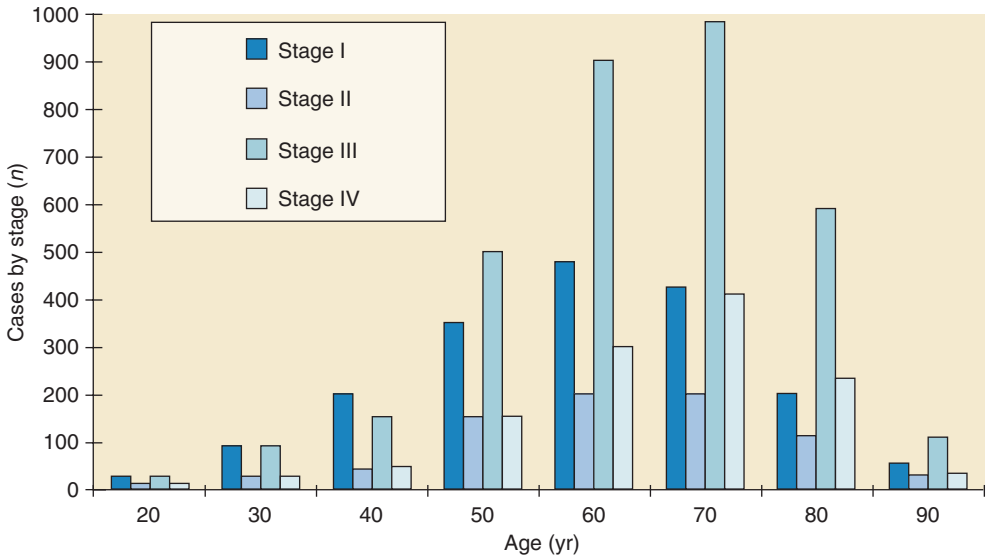

FIGURE 11.3 Obviously malignant ovarian epithelial tumors: age distribution by stage. (From International Federation of Gynecology and Obstetrics. *Annual Report on the Results of Treatment in Gynecological Cancer,* vol 22. Stockholm, 1994, Author.)

TABLE 11.4 Odds Ratio for Invasive Epithelial Ovarian Cancer According to Parity

			Population Studies		
Term Pregnancies (*n*)	Cases	%	Controls	Percentage	Odds Ratio

Reprinted by permission from the *New England Journal of Medicine.*

in the carcinogenic process. Gross and Schlesselman determined the effect of oral contraceptive use on the cumulative incidence of epithelial ovarian cancer from ages 20 to 40 years, 20 to 50 years, and 20 to 55 years and stratified these age categories by family history and parity. The number of epithelial ovarian cancer cases estimated to occur per 100,000 oral contraceptive users decreased with increasing duration of use. Their results suggest that 5 years of use by nulliparous women can reduce their ovarian cancer risk to the level seen in parous women who never use oral contraceptives, and 10 years of use by women with a positive family history can reduce their risk to a level below that of women whose family history is negative and who never use oral contraceptives. On the basis of these data, the recommendation is strongly made that premenopausal patients with risk factors for ovarian cancer use oral contraceptives when pregnancy is not being sought.

Over many years, studies have disagreed as to the association between fertility drug exposure and ovarian cancer. Whittemore and associates noted that infertile women treated with

infertility drugs had a 2.8 times increased risk of ovarian cancer compared with women without infertility. The risk was higher among women who did not become pregnant compared with the parous women. Specific drug exposure was not documented. Subsequent studies by Franceschi, Rossing, Venn, Shishan and colleagues disagreed as to whether induction with clomiphene or gonadotropins were associated with increased risk. The largest reported cohort drew 126 women with invasive epithelial ovarian cancer from a cohort of 54,362 women treated at all Danish infertility clinics from 1963 to 1968. The effects of four separate groups of fertility drugs were evaluated individually and in combination (gonadotropins, clomiphene citrate, human chorionic gonadotropin, and gonadotropin-releasing hormone). No convincing associations were found between use of these fertility drugs and ovarian cancer risk. The published data suggest that there is probably little relationship between fertility drug use and ovarian cancer. Further investigations are underway to clarify this association. The concept is appealing when one considers the reduction in incidence noted with the use of oral contraceptives and parity.

Whittemore and associates, in a population-based study, noted protection against ovarian cancer with increasing parity (see Table 11.4). McGowan and colleagues, on the basis of a study of 197 women with ovarian cancer, estimated that nulligravidae were 2.5 times more likely to have malignant ovarian tumors and 2.9 times more likely to have ovarian carcinoma of low potential malignancy than were women who had been pregnant three or more times. The risk of ovarian cancer in their series was further reduced among women who had been pregnant at least once. One possible interpretation could be that the endocrine state of pregnancy protects against ovarian cancer and that the lack of this protection places infertile women at higher risk for ovarian cancer. A second explanation could be that infertility and ovarian cancer result from a similar genetically abnormal gonadal status. This theory would explain why infertile women are more at risk than never-married and never-pregnant women.

In the large prospective Cancer Prevention Study II, Rodriguez and coworkers evaluated the use of acetaminophen and a possible relationship to ovarian cancer mortality. Women who reported using acetaminophen daily had a death rate from ovarian cancer 45% lower than that of women reporting no use (relative risk = 0.55; confidence interval [CI] = 0.27–1.09). In a case-control study, Cramer and associates had previously reported that the odds ratio was 0.52 for development of ovarian cancer among women who used the drug at least once a week for at least 6 months; lowest risk was found in women who used the drug daily and for more than 10 years. Cramer et al. also noted that the odds ratio of ovarian cancer was 0.75 (CI 0.52–1.10) for aspirin and 1.03 for ibuprofen.

Parazzini and colleagues studied the influence of various menstrual factors on the risk of epithelial ovarian cancer. They reported that the risk rose with later age at menopause and with early menarche. Studies of dietary fat have been inconclusive, and other dietary factors are not well characterized. Although the Women's Health Initiative investigators reported a low-fat diet was associated with up to a 40% reduction in ovarian cancer risk, several large cohort studies have not been able to demonstrate this. Because diet and exercise are potentially modifiable risk factors, continued investigation into their role is warranted.

Some have suggested that ovarian cancer may be initiated by a chemical carcinogen through the vagina, uterus, and fallopian tubes and that damaged ovarian surface epithelium from ovulation induces inflammation and mutation susceptibility. For years, Woodruff and coworkers suggested this hypothesis of migration of chemical carcinogens from the vagina to the pelvic peritoneum. Venter demonstrated with the use of radionuclides that upward migration is possible. Certainly, many different chemical substances could migrate to vulvovaginal areas and be implicated in carcinogenesis. The agent most extensively studied has been talc powder, but many of the studies that noted a slight increased risk of ovarian carcinoma in association with talc did not adjust for other factors (oral contraceptive use, family history) that are related to ovarian cancer. Others included low malignant potential tumors with their invasive cancers or did not correct for integrity of the female genital tract status. The relationship (if any) of talc to ovarian cancer would appear to be minimal at best.

No epidemiologic or experimental evidence exists to incriminate viruses in the development of neoplasms of the human ovary. Attempts to isolate viruses from cultures of human ovarian cancer cells have been unsuccessful to date. Because of its gonadotropic properties, mumps virus is an obvious candidate among known viruses for oncogenic activity in the ovary. At present, however, the evidence for mumps virus as an etiologic agent in ovarian cancer remains speculative.

Familial Ovarian Cancer

Familial hereditary ovarian cancer currently falls into three categories:

1. Site-specific familial ovarian cancer
2. Hereditary breast-ovarian cancer syndrome, in which there is an increased incidence of breast and ovarian carcinomas alone or in combination
3. Lynch syndrome type II, in which family members may develop a variety of cancers, including colorectal, endometrial, and ovarian cancer

Inherited genetic mutations are associated with approximately 10% of women who develop ovarian cancer. The mutation is inherited in an autosomal-dominant fashion (maternal or paternal transmission), and multiple family members are affected over several generations. First-degree relatives (mother or sister) are frequently involved.

True hereditary ovarian cancer and breast cancer mainly result from mutations of *BRCA1* and *BRCA2* genes. Individuals with these mutations (*BRCA1* and *BRCA2*) generally have a germline mutation (inherited mutated copy of the gene) in contrast to the more common somatic mutation (noninherited, or acquired) in most patients with ovarian cancer. *BRCA1* mutations are located on the long arm of chromosome 17q, and *BRCA2* mutations are located on chromosome 13q12. Lynch II syndrome arises as a result of inherited mutation in a family of DNA repair genes (MSH2, MLH1, PMS1, PMS2); this group

accounts for only a small number of inherited ovarian cancers. Initial evaluation of these germline mutations suggested an estimated risk of ovarian cancer of 39% to 46% for carriers of the *BRCA1* mutation but a lower rate of 10% to 20% for carriers of the *BRCA2* mutation. With more than 400 mutations identified in the *BRCA1* and *BRCA2* genes along with multiple polymorphisms, estimating risk is difficult. In most women with a strong family history who do develop ovarian cancer, the disease is sporadic in nature and not inherited. Houlston and colleagues evaluated 391 women who were self-referred to a screening clinic for familial ovarian cancer. Of these women, 290 (74%) appeared to have no clear inheritance pattern, and there was no increased risk of cancer in the first-degree relatives. There were 82 (21%) pedigrees compatible with multisite cancer family syndrome with a relative risk of about 6, or development of ovarian cancer in 1 of 16. In the 19 families with site-specific ovarian cancer, the relative risk for first-degree relatives was 39, with a lifetime risk of 1 in 2. Kerlikowske and associates reviewed published studies of familial ovarian cancers and used ovarian cancer incidence data from the Surveillance, Epidemiology, and End Results (SEER) database to estimate lifetime probabilities of ovarian cancer in these families. They noted that the lifetime probability of ovarian cancer for a 35-year-old woman was 1.6% in an individual without a family history of ovarian cancer. It increased to 5% if she had one relative and 7% if she had two relatives with ovarian cancer. These and other studies by Bourne and colleagues were based on family history pedigree and preceded *BRCA1* and *BRCA2* testing.

Claus and associates, using a previously fit autosomal-dominant genetic model, evaluated the Cancer and Steroid Hormone Study of 4730 patients with breast cancer aged 20 to 54 years and 4688 control subjects to estimate the proportions of breast and ovarian cases in the general population that are likely to result from breast and ovarian cancer susceptibility genes. About 10% of patients with ovarian cancer in the general population were estimated to be carriers of a breast or ovarian cancer susceptibility gene. The risks for ovarian cancer in carriers to the age of 60 years and 80 years were estimated to be about 10% and 27%, respectively. Carriers were predicted to have at least a 15-fold age-specific risk of ovarian cancer compared with noncarriers. Some ethnic groups appear to be at high risk for gene mutation, and the Ashkenazi Jews have been most extensively studied. In a large study by Struewing and associates, 5318 Jewish subjects had *BRCA1* and *BRCA2* evaluated, identifying 120 carriers. Carriers had a significantly elevated risk, with an estimated risk of 2% by age 50 years and 16% by age 70 years compared with the noncarrier risk of 0.4% by 50 years and 1.6% by 70 years. Metcalfe and colleagues performed *BRCA* testing for three founder mutations in 2080 self-identified Jewish women and found the *BRCA* mutation rate to be 1% (22 women) in an unselected population.

Frank and associates evaluated 283 women with breast cancer before age 50 years or ovarian cancer at any age and at least one first- or second-degree relative with either diagnosis for *BRCA1* followed by *BRCA2* analysis. Mutations were identified in 94 women (39%), including 59 of 117 (50%) from families with ovarian cancer and 35 of 121 (29%) from families without ovarian cancer. In women with breast cancer, mutations in *BRCA1* and *BRCA2* were associated with a 10-fold increased risk of subsequent ovarian cancer. Mutations were noted in 24 of 38 women (63%) who had ovarian cancer. In women from breast–ovarian cancer families, 30 of the germline mutations occurred in *BRCA2*. Of note in this study, the authors did not find Ashkenazi ancestry significantly increased in the identification of *BRCA1* or *BRCA2* mutation, suggesting the importance of a strong family history.

In considering women at high risk, two questions should be addressed: (1) Who should be tested? and (2) Are there screening or prophylactic measures that can be applied to decrease the risk? A family history of breast or ovarian cancer, particularly before the age of 50 years in a first-order relative, and Ashkenazi Jewish ancestry, are risk factors for *BRCA1* or *BRCA2* mutations. Family history, both maternal and paternal, should be obtained (three generations is desired), and age at diagnosis should be noted. Pathology reports or death certificates verify accuracy of history; there can be considerable errors from history alone. Lifetime empirical risks can be determined from this information and may suggest that testing for a gene mutation is indicated. The extensive evaluation of family history and counseling should be done before genetic testing. Interpretation and plan of action that will influence medical management should be discussed in detail before genetic testing is performed. Testing of family members known to have cancer before testing of the cancer-free members is recommended. If a suspect mutation is found in the family member with cancer, the relatives without cancer can be tested for that specific mutation. If the family member with cancer does not have a mutation, other relatives probably will not benefit from testing. In one study, women sought DNA testing most commonly because of concern about the potential cancer risk to their children and secondly for their own cancer surveillance and prevention.

In a consensus statement of the Cancer Genetics Studies Consortium, annual or semiannual screening with transvaginal ultrasonography (TVS) and determination of serum carcinoma antigen 125 (CA-125) levels beginning at age 25 to 35 years are recommended for *BRCA1* mutation carriers. Both of these tests carry relatively high false-positive and false-negative rates with low positive predictive value. Narod and associates found that oral contraceptives protected against ovarian cancer in patients with mutation in either the *BRCA1* or *BRCA2* gene.

Risk-reducing salpingo-oophorectomy after completion of childbearing, or age 40 years, in women at high genetic risk is associated with a significant reduction in the risk of *BRCA1*- or *BRCA2*-associated ovarian cancer. A National Institutes of Health (NIH) Consensus Conference recommended that women with two or more first-degree relatives with ovarian carcinoma be offered prophylactic oophorectomy after completion of childbearing or age 35 years. Prophylactic oophorectomy does not prevent subsequent primary peritoneal cancer, in which failure rates of 4% to 5% at 20 years after risk-reducing salpingo-oophorectomy (RRSO) were reported by Finch and colleagues. Rebbeck and associates clarified risk reduction estimates in their 2009 meta-analysis. They found RRSO was associated with an 80% risk reduction in *BRCA1*- or

BRCA2-associated ovarian, fallopian tube and peritoneal cancer, and a 50% risk reduction in *BRCA1*- or *BRCA2*-associated breast cancer.

A 2005 study by Pal and colleagues suggested that previous studies may have underestimated the frequency of *BRCA1* and *BRCA2* mutations. Of 209 patients with invasive cancer, 32 patients (15%) had mutations of *BRCA1* ($n = 20$) or *BRCA2* ($n = 12$). Based on their data, they suggested it may be reasonable to offer genetic counseling to any woman with an invasive, nonmucinous epithelial ovarian cancer, and subsequent studies have supported this observation. A 2014 Society of Gynecologic Oncologists (SGO) Clinical Practice Statement on Genetic Testing for Ovarian Cancer recommended women diagnosed with epithelial ovarian, tubal, and peritoneal cancers receive genetic counseling and be offered genetic testing even in the absence of a family history.

The Gynecologic Oncology Group (GOG) has conducted a study (GOG 199) of 2605 women at increased risk for developing ovarian cancer, either by known *BRCA* mutation or family history risk factors. Patients were enrolled after choosing either prophylactic oophorectomy or screening, and both groups followed with CA-125 levels and Risk of Ovarian Cancer Algorithm (ROCA) assessment. The study was designed to evaluate both the prospective incidence of new and occult ovarian cancers and to assess the ROCA and quality of life. In 2014, Sherman and colleagues reported a portion of the analysis of high risk women older than 30 years of age who elected RRSO. Clinically occult cancers were detected in 2.6% of high risk women (*BRCA1* mutation carriers, 4.6%; *BRCA2* mutations carriers, 3.5%; noncarriers, 0.5%), and further results from this trial will be forthcoming.

SIGNS, SYMPTOMS, AND ATTEMPTS AT EARLY DETECTION (SCREENING)

Although the wide range of ovarian tumor types generally presents in a similar manner, the diagnosis of early ovarian cancer is often more a matter of chance than a triumph of the scientific method. As the ovary enlarges (Fig. 11.4), there may be progressive compression of the surrounding pelvic structures, producing vague abdominal discomfort, urinary frequency, and "pelvic pressure" (Table 11.6). The insidious onset of ovarian cancer needs no elaboration. As the neoplasm reaches a diameter of 10 to 15 cm, it may account for abdominal enlargement. The notions that the development of ovarian cancer is "silent" and there are no early symptoms of ovarian cancer are a focus of the patient advocacy "listen for the whisper" educational efforts. Vague symptoms may be present for several months before the diagnosis. Such complaints are usually not recognized as anything more than gas or indigestion. **A high index of suspicion is warranted in all women between the ages of 40 and 69 years who have persistent gastrointestinal (GI) symptoms that cannot be diagnosed.** The majority of such nonspecific complaints are nonmalignant, causing the primary care physician to dismiss the possibility of ovarian cancer in many cases. Too frequently, it is only when the patient has gross abdominal enlargement marking the occurrence of ascites and abdominal carcinomatosis that appropriate diagnostic evaluation is undertaken.

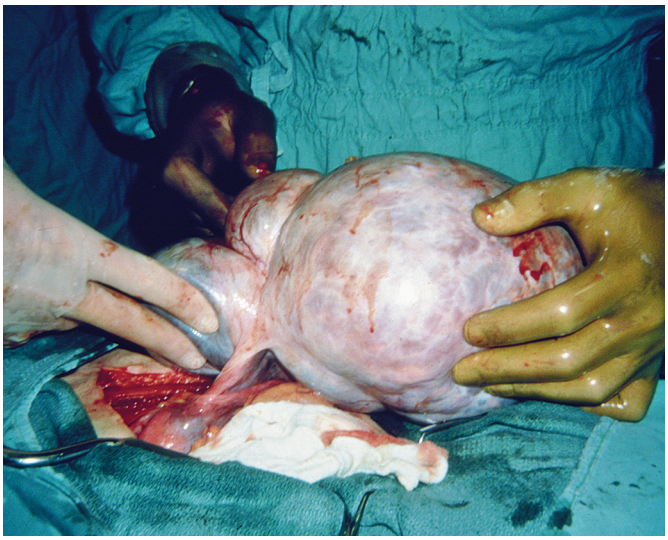

FIGURE 11.4 Large bilateral ovarian neoplasms: low-grade mucinous adenocarcinoma.

TABLE 11.6 Most Frequent Presenting Symptoms of Ovarian Cancer (Goff BA et al., 2000)

Symptom	Relative Frequency
Abdominal swelling	60%
Abdominal pain	40%
Dyspepsia	30%
Urinary frequency	30%
Weight change	10%

Methods for early diagnosis have been investigated in limited studies using cul-de-sac aspiration for peritoneal cytologic assessment and frequent pelvic examinations. All of these endeavors have failed to show a significant impact on early diagnosis of this disease. Most ovarian neoplasms grow quickly and painlessly. A persistent ovarian enlargement should be an indication to consider surgery, and the diagnosis is made by the pathologist. The size of the tumor does not indicate the severity of disease; indeed, many of the largest neoplasms are histologically benign, most commonly mucinous cystadenoma. Moreover, many large adnexal masses may be of nonovarian etiology. Nonovarian causes of apparent adnexal masses are diverticulitis, tubo-ovarian abscess, carcinoma of the cecum or sigmoid, pelvic kidney, and uterine or intraligamentous myomas. At the time of surgery, it may be difficult to discern the malignant potential of a particular ovarian neoplasm (Table 11.7). There is sufficient overlap of morphologic criteria to cause confusion. The diagnosis rests with the histologic examination of the specimen, and the error rate of frozen section ranges from 5% to 15%.

Immunologic diagnosis of subclinical ovarian cancer by means of identification of specific tumor-associated antigens in the serum has yet to materialize. Several tumor-associated antigens, including CA-125, have been identified and purified.

TABLE 11.7 Surgical Findings

	Benign	Malignant
Surface papilla	Rare	Very common

	Systemic lupus erythematosus

HAMA, Human antimouse antibody.

Research identifying patterns of protein fragments (proteomics) in patients with ovarian carcinoma requires validation in larger trials and a cost-effective way to implement.

It has been suggested that every woman should have a periodic pelvic examination, pelvic ultrasound examination, and CA-125 test to make sure she does not harbor an occult ovarian cancer. Enthusiasm for early detection of ovarian cancer is laudable. However, it has been calculated that 10,000 routine pelvic examinations would be required to detect one early ovarian cancer in a population of asymptomatic patients. For a low-incidence cancer such as ovarian cancer, cost-effective screening strategies require a positive predictive value (PPV) greater than 10%. This generally requires a technique specificity of greater than 99%, with a high sensitivity of greater than 75%. The majority of early trials of screening techniques did not meet this metric. Jacobs and colleagues studied 22,000 postmenopausal women screened with CA-125 determinations and have reported follow-up observed for a mean of 6.76 years; 767 women (3.5%) had elevated CA-125 values, of whom 49 (6%, or 0.0022% of the total screened) had cancer. One-third of these were early stage. Overall specificity was 97%, and sensitivity at 1 year and 7 years of follow-up was 75% and 57%, respectively. The PPV of 3% was not high enough to be an effective screening method, and there is no current role for screening with CA-125 levels in unselected women. Many conditions of a benign nature, and most GI tract malignant neoplasms may elevate the CA-125 concentration (Table 11.8). The value of ultrasonography in screening for early ovarian carcinoma has received much attention. Campbell and coworkers reported early detection of five primary ovarian cancers in approximately 5000 women screened by abdominal ultrasonography (Table 11.9). DePriest and associates studied postmenopausal women or women with a family history of ovarian cancer (24% of women) with TVS. They screened 6470 women with 14,829 scans; 90 women had persistent abnormalities on TVS and underwent surgery. Six primary ovarian cancers were found (five stage I and one stage

IIIb), and only four were epithelial. Sensitivity was 86%, and specificity was 99%, with a PPV of only 7% but with a negative predictive value (NPV) of 99.9%.

One strategy to improve the effectiveness of ovarian cancer screening would be to target populations at increased risk for the development of the disease, such as individuals with a positive family history of ovarian cancer. Bourne and colleagues reported the results of such a strategy in screening patients with TVS in combination with color-flow Doppler imaging and morphologic assessment. In the screening of 1601 patients, 57% required repeated TVS to confirm the presence of a mass. Six ovarian cancers were diagnosed (two stage I, three low malignant potential tumors, and one stage III). Karlan and associates reported screening of 597 patients with a family history of cancer by CA-125 measurement, TVS, and color-flow Doppler imaging. Initially, 115 patients had an abnormal finding on TVS, and 68 had abnormal CA-125 levels. After repeated TVS, because of abnormal findings of color-flow Doppler imaging, 19 patients underwent surgery. At the time of the report, one low malignant potential tumor had been diagnosed.

Bell and colleagues reviewed 25 studies on screening for ovarian cancer, 16 studies on women at average risk, and nine studies on women at higher risk. Many studies were limited by small numbers, imprecise methodology, scant follow-up, and single versus multimodality screening techniques. For women at average risk, 75% of primary cancers were stage I when they were detected with ultrasonography, and 50% were stage I when they were detected by multimodal screening (see Table 11.9). In women at higher risk, if low malignant potential tumors were excluded, only 25% were stage I. False-negative rates were also higher in the higher risk population than in the group at average risk. The false-negative data, when applied to a population with an annual incidence of 40 per 100,000, imply that 30 to 60 surgical procedures would be carried out for every cancer detected at annual gray-scale ultrasonography (assuming 100% sensitivity), and 2.5 to 15 surgical procedures would be carried out for every cancer detected by multimodal screening. Even if screening detects all ovarian cancers and these are treated with 100% success, the absolute reduction in mortality would be only 1 in about 2500 screened women per year. This is much smaller than the complication rate from unnecessary diagnostic surgery or recall for further tests.

Combining CA-125 levels with TVS has been explored as a means by which to improve predictive value. Skates and colleagues developed a risk of ovarian cancer (ROC) algorithm based on rising CA-125 that has been validated in a prospective cohort. Their initial validation PPV was high (19%); it has been applied to two large prospective trials. Buys and associates reported the ovarian portion of the Prostate, Lung, Colorectal and Ovarian Cancer (PLCO) trial, which randomized 78,216 women aged 55 to 74 years to annual screening with CA-125 and ultrasound versus usual care for up to 13 years. There was no reduction in the ovarian cancer mortality rate, and there was a 15% incidence of serious surgical complications in patients undergoing surgery for false-positive results. Retrospective application of the ROC algorithm by Pinsky and associates failed to show a survival benefit. Recently, Jacobs and colleagues reported results from the UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), which randomized 202,638 women aged 50 to 74 years to annual multimodality screening (MMS) with CA-125 interpreted with the ROC algorithm, annual ultrasound screening, or no screening. Although the incidence of ovarian cancer and mortality was similar in the primary analysis, there was a significant mortality reduction with MMS in patients who lived longer than 7 years, likely because of detection of earlier stage cancers. These results require further follow-up, cost-effectiveness strategies, and validation in daily practice but give some further insight into early detection strategies.

Currently, however, there are no reliable data that screening for ovarian cancer is effective in improving length and quality of life in women with ovarian cancer. Another strategy to improve sensitivity and specificity in screening for ovarian cancer involves the use of multiple serum tumor markers. Because fewer than 50% of patients with stage I ovarian cancer will have an elevated CA-125 concentration and because CA-125 can be elevated by benign and malignant conditions, the addition of other markers in the screening strategy could potentially improve predictive value. Yurkovetsky and colleagues reported the results of their screening panel of four biomarkers, with 86% sensitivity at 98% specificity for detecting early-stage disease, and additional studies looking at additional biomarkers are ongoing. These techniques may also offer useful guidelines for predicting therapeutic response and for treatment selection. The NIH Consensus Development Conference on ovarian cancer screening in 1994 reached the following conclusions: There is no evidence available yet that the current screening modalities of CA-125 measurement and TVS can be used effectively for widespread screening to reduce mortality from ovarian cancer or that their use will result in decreased rather than increased morbidity and mortality. Routine screening has resulted in unnecessary surgery with associated risks. Clearly, it is important to identify and validate effective screening modalities. Currently available technology for screening should be used in the context of clinical trials to determine the efficacy of these modalities and their effect on ovarian cancer mortality. In addition, research must be continued to identify additional markers and imaging techniques that will be useful. Although these same recommendations still hold, we may have better techniques for screening because the data from ongoing trials mature. If a woman has one first-degree relative with ovarian cancer (making her lifetime risk of developing the disease 5%) but no clinical trials are available to her, she may think that despite the absence of prospective data, this is sufficient risk for her to be screened. This opportunity for screening should be available to the woman and her physician.

If a woman were undergoing pelvic surgery, removal of the ovaries at that time would almost fully eliminate her risk of ovarian cancer (although there remains a small risk of peritoneal cancer). If the woman is premenopausal, discussion of estrogen replacement therapy is important before removal of the ovaries because the risk of premature menopause and the potential for osteoporosis may outweigh the risk of ovarian conservation and the potential for ovarian cancer.

DIAGNOSTIC TECHNIQUES AND STAGING

Routine pelvic examinations detect only one ovarian cancer in 10,000 asymptomatic women. However, pelvic examination remains the most practical means of detecting early disease. Pain is usually a late complication; it is seen with early disease only in association with a complication such as torsion; rupture; or, rarely, infection. The physician should have a high index of suspicion for an early ovarian neoplasm in any ovary palpated in a menopausal patient. These patients should be considered for immediate laparoscopy or laparotomy when ultrasound examination findings suggest malignant change (eg, complex mass, >5 cm, or intracystic papillations).

To help with evaluating a patient with a complex pelvic mass, the American College of Obstetricians and Gynecologists (ACOG), in conjunction with the SGO, published guidelines in 2002 that could help direct referral to or consultation with a gynecologic oncologist. Physicians should perform a pelvic examination and imaging as appropriate for the patient's symptoms or physical examination findings. For premenopausal women with a suspicious pelvic mass, referral to a gynecologic oncologist should be considered by at least one of the following: CA-125 level higher than 200 U/mL, ascites, abdominal or distant metastases, or one or more first-degree relatives with breast or ovarian cancer. For postmenopausal women with a concerning pelvic mass, consultation should be considered for any CA-125 elevation, ascites, nodularity or limited mobility, evidence of metastasis, or a first-degree relative with breast or ovarian cancer.

Routine laboratory tests are not of great value in the diagnosis of ovarian cancer but may help rule out other pelvic disorders. Pelvic ultrasonography may reveal calcifications consistent with myomas or benign teratomas. Colonoscopy and upper GI endoscopy may be helpful in patients who have lower or upper intestinal symptoms, respectively. Computed tomography (CT) with contrast enhancement may be helpful in identifying the extent of clinical disease. No imaging modality is conclusive, however, and suspicious pelvic masses, especially in postmenopausal women, should be evaluated surgically. In general, we recommend against needle biopsy of ovarian masses because such a procedure can result in spillage of malignant cells into the peritoneal cavity. Regardless of whether the fluid contains neoplastic cells, surgery will likely still be necessary to remove either the large benign neoplasm or to define the extent of the malignant process. In addition, up to 50% of ascitic fluid samples from patients with true ovarian malignant neoplasms will be negative for malignant cells on cell block analysis. Needle biopsy in a patient with a pelvic abdominal mass is therefore both unnecessary and potentially dangerous (Fig. 11.5).

The staging of ovarian cancer is surgical (Table 11.10) and based on the surgical and pathologic findings (Fig. 11.6). A longitudinal midline incision is recommended to remove the neoplasm and to visualize the entire abdominal cavity, including the undersurface of the diaphragm. A Pfannenstiel incision is ill advised in a patient suspected of having an ovarian malignancy. Ovarian cancer classically involves the entire peritoneal cavity (Fig. 11.7). Although lymphatic spread to retroperitoneal nodes is common in ovarian cancer, the disease most often spreads intraperitoneally; free-floating cells shed from the primary tumor are capable of implanting on any peritoneal surface. Any peritoneal fluid (ascites) found when the peritoneal cavity is opened should be aspirated and submitted for cytologic examination. In the absence of peritoneal fluid, washings should be taken by lavage of the peritoneal surfaces, including the undersurface of the diaphragm (Fig. 11.8). Care should be taken to visualize and palpate all peritoneal surfaces, particularly the diaphragm, the surface of the liver, the lateral abdominal gutters, and the small and large bowel mesentery. The omentum should be removed because microscopic disease is often present in the omentum that is not obvious grossly. Recommended surgical therapy is presented in sequence in Table 11.11. If the disease is limited to the pelvis, the primary tumor should be removed intact. All suspicious surfaces in the peritoneal cavity should be removed as biopsy specimens. This includes adhesions, which should be excised, not incised, because they often contain microscopic disease. Several studies have been performed to investigate the efficacy of "blind" peritoneal biopsies and routine retroperitoneal node dissections in the proper staging of early epithelial cancer of the ovary (Table 11.12). Proper staging is important for treatment planning and for providing an accurate prognosis (Table 11.13).

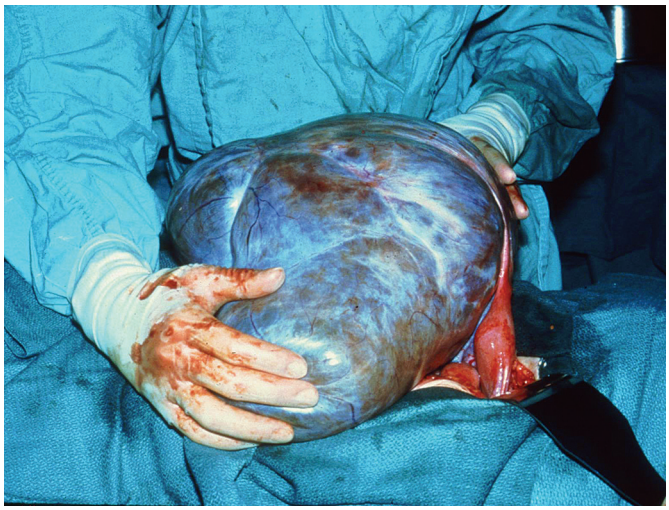

FIGURE 11.5 Large cystic tumors, similar to the illustration, are at risk of perforation and leakage at the time of paracentesis.

THERAPEUTIC OPTIONS FOR PRIMARY TREATMENT

Borderline Malignant Epithelial Neoplasms

Over the past 4 decades, investigators have described a subset of epithelial ovarian tumors whose histologic and biologic features lie between those of clearly benign and frankly malignant ovarian neoplasms. These borderline malignant neoplasms account for approximately 15% of all epithelial ovarian cancers and share molecular characteristics with low-grade ovarian cancers. They have also been called proliferative cystadenomas

TABLE 11.10 Carcinoma of the Ovary: Staging Classification Using the Federation of International Gynecologists and Obstetricians (FIGO) Nomenclature

FIGO Stage	Description
I	Tumor confined to ovaries or fallopian tube(s)
IA	Tumor limited to one ovary (capsule intact) or fallopian tube; no tumor on ovarian or fallopian tube surface; no malignant cells in the ascites or peritoneal washings
IB	Tumor limited to both ovaries (capsules intact) or fallopian tubes; no tumor on ovarian or fallopian tube surface; no malignant cells in the ascites or peritoneal washings
IC	Tumor limited to one or both ovaries or fallopian tubes, with any of the following: IC1: Surgical spill IC2: Capsule ruptured before surgery or tumor on ovarian or fallopian tube surface IC3: Malignant cells in the ascites or peritoneal washings
II	Tumor involves one or both ovaries or fallopian tubes with pelvic extension (below pelvic brim) or primary peritoneal cancer
IIA	Extension and/or implants on uterus and/or fallopian tubes and/or ovaries
IIB	Extension to other pelvic intraperitoneal tissues
III	Tumor involves one or both ovaries or fallopian tubes or primary peritoneal cancer with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes
IIIA	IIIA1: Positive retroperitoneal lymph nodes only (cytologically or histologically proven): IIIA1(i) Metastasis ≤10 mm in greatest dimension IIIA1(ii) Metastasis >10 mm in greatest dimension IIIA2: Microscopic extrapelvic (above the pelvic brim) peritoneal involvement with or without positive retroperitoneal lymph nodes
IIIB	Macroscopic peritoneal metastasis beyond the pelvis ≤2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes
IIIC	Macroscopic peritoneal metastasis beyond the pelvis >2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes (includes extension of tumor to capsule of liver and spleen without parenchymal involvement of either organ)
IV	Distant metastasis excluding peritoneal metastases Stage IVA: Pleural effusion with positive cytology Stage IVB: Parenchymal metastases and metastases to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)

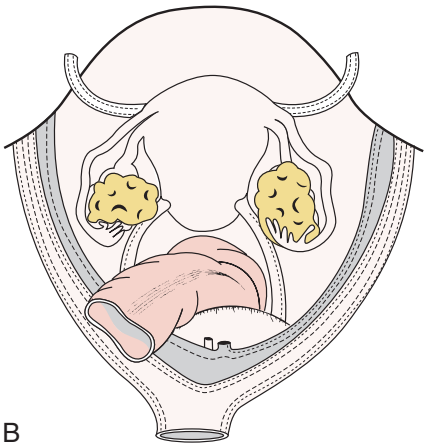
and tumors of low malignant potential and are more completely discussed in Chapter 10. Compared with invasive epithelial ovarian cancer, epithelial borderline tumors affect a younger population and may have a 10-year survival rate approaching 95% (see Chapter 10). Although symptomatic recurrence and death may rarely develop as late as 20 years after therapy, these neoplasms are correctly labeled as being of low malignant potential. Most gynecologic oncologists recommend conservative therapy, especially in patients who are desirous of further childbearing and have stage IA disease (see Chapter 10). We have found surgical excision of disease the most effective therapy and when necessary have used repeated explorations, reserving chemotherapy for patients who develop ascites or whose tumor changes histologic features or demonstrates rapid growth (Fig. 11.9).

Treatment of Malignant Epithelial Neoplasms



The most common epithelial cancers of the ovary are histologically categorized as serous, mucinous, endometrioid, and clear cell (mesonephroid) types (Figs. 11.10 to 11.13). Most large studies demonstrate that these different histologic types have similar outcomes with existing therapy, stage for stage and grade for grade. Mucinous and endometrioid subtypes are more commonly found in earlier stages. There are ongoing studies to investigate targeted therapies in certain cell types, most notably mucinous and clear cell cancers. Based on our current data, however, prognosis, survival, and therapy for these various forms of epithelial cancer will be considered collectively.

The unifocal theory of ovarian epithelial cancer growth suggests that the disease initially grows locally, invading the capsule and mesovarium, and then invades adjacent organs by local extension and lymphatic spread. Cells on the surface exfoliate into the peritoneal cavity, where they circulate and implant on free peritoneal surfaces. Local and regional lymphatic metastasis may involve the uterus, fallopian tubes, and pelvic and aortic lymph nodes.

Woodruff suggested a multifocal mechanism of disease spread, whereby the entire coelomic epithelium can give rise to this lesion after exposure to carcinogenic agents that enter the peritoneal cavity from the vagina through the fallopian tubes. Indeed, the lesion could then originate in a multifocal distribution, "like a measles rash," over large portions of the coelomic epithelium. Although the early precursors leading to advanced ovarian cancer are incompletely understood, more current molecular evidence favors the unifocal origin theory.

In the past decade, as risk-reducing salpingo-oophorectomy has become more common, a moderate body of literature suggests that a significant percentage of "ovarian cancers" may actually arise in the fallopian tube fimbria with metastasis to the ovaries. Kindelberger and colleagues have reported a potential causal relationship based on identification of tubal intraepithelial carcinomas (TIC) and analysis of p53 mutations therein.

Regardless of origin, the most important prognostic variable for each patient is the extent, or "stage," of disease. A staging

system has been devised that allows treatment results in patients with similar prognostic factors to be compared among different institutions. Survival is affected by the cancer stage, grade of differentiation, gross findings at surgery (Table 11.14), amount of residual tumor after surgery, and additional treatment required.

Stages IA, IB, and IC

Careful surgical staging is critical in the management of stage I invasive ovarian cancer and should include bilateral salpingo-oophorectomy, hysterectomy, omentectomy, and pelvic and aortic lymph node sampling, with peritoneal biopsies and washings. Accurate staging forms the cornerstone of clinical decision-making regarding the type and duration of adjuvant therapy.

Pelvic and aortic lymph nodes may be involved 10% to 20% of the time in apparent stage I disease, and lymphadenectomy

is an important diagnostic and therapeutic procedure. Baiocchi and associates reviewed their experience in 242 women who had pelvic and aortic lymphadenectomy in whom cancer was apparently confined to the ovaries (stage I), and nodal metastasis was found in 32 patients (13%). Patients with serous adenocarcinoma had the highest incidence of node metastasis (25%). Those with grade III lesions had 39% metastasis compared with 6% with grade I and grade II cancers. There were 33 women with low malignant potential tumors, and seven (21%) had nodal metastasis. When only one to three nodes were involved, metastases were usually ipsilateral, but these patients could also have metastases to the common iliac or aortic nodes. Positive aortic nodes were also found in the absence of positive pelvic nodes. Accumulated reports of lymph node metastases in clinical stage I ovarian cancer patients are shown in Table 11.15. Without thorough surgical staging, occult metastasis may be present and missed, leading to inadequate subsequent therapy. Many studies have addressed this item (Table 11.16).

The use of adjuvant therapy and its role in stage I ovarian cancer continues to be investigated. Through three GOG studies in early-stage (I and II) ovarian cancer, the use of platinum combination therapy became the preferred regimen as it demonstrated better survival outcomes and an improved, although not statistically significant, toxicity profile over intraperitoneal (IP) colloid 32P.

European investigators have also reported their experience with platinum-based therapy in early-stage ovarian cancer. The European gynecologic groups reported a combined analysis of the International Collaborative Ovarian Neoplasm (ICON) 1 and the Adjuvant Chemotherapy In Ovarian Neoplasm (ACTION) trials. More than 900 patients with early-stage ovarian cancer received either platinum-based adjuvant chemotherapy or observation until chemotherapy was indicated. After a median follow-up period of more than 4 years, the improved overall survival (OS) (82% chemotherapy vs. 74% observation) and recurrence-free survival (76% vs. 65%, respectively) rates at 5 years favored treatment with platinum-based therapy. Although not all patients had undergone comprehensive staging, a subgroup analysis of these patients was reported. In another European Organization for Research and Treatment of Cancer (EORTC)-ACTION trial of 448 patients, the authors noted that the benefit of chemotherapy was limited to patients who lacked comprehensive surgical staging, questioning the necessity of adjuvant therapy in the patient with well-staged early ovarian carcinoma.

The next evolution of GOG trials involved the addition of paclitaxel to a platinum-based regimen because the treatment protocols for advanced-stage disease had demonstrated improved survival by replacing cyclophosphamide with paclitaxel. GOG 157 evaluated carboplatin (AUC 7.5) and paclitaxel (175 mg/m^2) in high-risk, early-stage disease, randomly assigning patients to three versus six chemotherapy cycles. Over a 3-year interval, 457 patients were enrolled and evaluated after a median follow-up period of 6.8 years. Although the recurrence rate was 24% lower with the six cycles ($P = 0.18$), OS was similar for the two arms (hazard ratio [HR], 1.02). The study concluded that the additional three cycles contributed to increased toxicity (11% grade III/IV neurotoxicity vs. 2% with only three cycles) without an OS advantage. Building on the hypothesis that low-dose paclitaxel may have antiangiogenesis activity, GOG 175 tested whether the addition of 24 weekly paclitaxel treatments (60 mg/m^2) to the initial three cycles of carboplatin and paclitaxel would improve outcomes. Although the recurrence rate was 20% lower in patients receiving extended paclitaxel, the result was not statistically significant, and there was no appreciable difference in OS.

In the young woman with stage IA disease who is desirous of further childbearing, unilateral salpingo-oophorectomy may be associated with minimal increased risk of recurrence, provided a careful staging procedure is performed and due consideration is given to grade and apparent self-containment of the neoplasm. After conservative treatment for invasive ovarian cancer, term delivery rates have been reported as high as 30%, and successful pregnancy outcomes have been reported after adjuvant chemotherapy. Conservative surgery is generally not recommended for patients with clear cell or carcinosarcoma or grade III tumors and when disease is present outside the ovaries. A careful discussion regarding the risks and benefits of this approach is essential because Maltaris and colleagues reported that 12% of patients undergoing fertility-sparing ovarian cancer surgery experienced recurrence, and 4% of patients died from their disease.

In the management of stage I ovarian cancer, the physician must weigh the possible benefits of adjuvant chemotherapy against the risks. It appears reasonable to not recommend adjuvant therapy for patients with stage IA, IB, grade 1 and 2 lesions who have been comprehensively staged. Patients with stage I, grade 3 and stage IC disease present a more difficult problem because the incidence of recurrence in this group approaches 50% in some series. We favor treatment with platinum-based combination chemotherapy even though no clear data show a survival advantage over single-agent therapy. Because combination therapy is our best treatment for metastatic disease, it is difficult to withhold the apparent best therapy from a group of patients who may have the best situation for a chemotherapy "cure." In addition, this group is usually younger and better able to tolerate combination chemotherapy.

Stages IIA, IIB, and IIC

In most institutions, the therapy of choice for stage IIA and stage IIB disease is staging surgery followed by platinum-based combination chemotherapy. Although historically the role of pelvic and abdominal irradiation and IP 32P has been described, the radioisotope and irradiation treatment approaches have faded from frontline therapy for ovarian carcinoma. Careful surgical staging is essential to successful treatment planning. A combined analysis of GOG 95 and 157 revealed that the stage II patients represented a disproportionate percentage of the recurrences. The GOG now includes stage II patients in their clinical trials of patients with advanced-stage disease. Outside of a clinical trial, patients with stage II disease should be managed in a similar fashion to optimally debulked stage III disease.

Stage III

In addition to surgical staging, every reasonable effort should be made to remove all visible metastatic tumors. Retrospective studies have strongly suggested that the survival rate in patients with stage III disease is related to the amount of residual tumor after surgery, such that patients with no macroscopic residual tumor appear to have the best prognosis after primary chemotherapy (Table 11.17 and Fig. 11.14). Most centers prefer combination platinum-based chemotherapy for this group of patients because of the excellent response rates reported in the literature (see later section on combination chemotherapy and IP therapy).

The duration of multiple-agent therapy is usually six cycles. If after primary chemotherapy the patient has no clinical evidence of disease (clinical complete response), a second-look procedure was often considered in the past to ascertain the presence of subclinical residual disease. However, a secondary data analysis of GOG 158 suggested no apparent outcome advantage from second-look surgery. For the most part, second-look surgery is no longer recommended.

Stage IV

The ideal management of stage IV disease is to remove as much cancer as possible and to administer chemotherapy after

surgery. The role and benefit of surgical cytoreduction in these patients is detailed in the next section. The OS is worse for this group of patients than for those of other stages, as expected (Fig. 11.15).

Maximal Surgical Effort

The goal of primary surgery for advanced ovarian cancer should be to remove all visible tumor and to use all reasonable surgical means to do so (Fig. 11.16). In the 1970s, Griffiths and coworkers evaluated the importance of postsurgical tumor residual by using a multiple linear regression equation with survival as the dependent variable to control simultaneously for the multiple therapeutic and biologic factors that contribute to the ultimate outcome in the individual patient. The most important factors proved to be histologic grade of the tumor and size of the largest residual mass after primary surgery. In Griffiths et al.'s original

study, the operation itself contributed nothing to survival unless it effected reduction in the size of the largest residual tumor mass below the limit of 1.6 cm.

Cytoreductive or "debulking" procedures have gained considerable attention in the management of ovarian cancer. The concept is to reduce the residual tumor burden to a level at which subsequent chemotherapy can be most effective. A careful dissection by a well-trained gynecologic oncologist can often remove disease that on first impression appear to be unresectable (Fig. 11.17). Removal of large ovarian masses and omental involvement may reduce the tumor burden by 80% to 99%. The theoretical value of debulking procedures lies in reducing the number of tumor cells and the advantage this affords to adjuvant therapy. This is especially relevant in bulky chemosensitive solid tumors such as ovarian cancer, in which removal of large numbers of cells in the resting phase (G0) may propel the residual cells into the more vulnerable proliferating phases. Several careful retrospective studies have repeatedly demonstrated improved survival rates in patients who can be surgically reduced to minimal tumor burden. The GOG has attempted to better define primary cytoreductive surgery with a detailed analysis of the results of surgery in patients with advanced disease. Their initial study compared survival of the patients with stage III disease who were found at surgery to have abdominal disease of 1 cm or smaller with that of patients found to have disease larger than 1 cm but whose tumors were surgically cytoreduced to 1 cm or less. If surgery was the only important factor, survival should have been equivalent in both groups. This was not the case. Patients found to have small-volume disease survived longer than did patients who had cytoreduction to small-volume disease at surgery, suggesting that the tumor biology also carries prognostic significance. In a second study, GOG investigators evaluated the effect of the diameter of the largest residual disease on survival in patients with suboptimal cytoreduction. They demonstrated that cytoreduction so that the largest residual mass was 2 cm or less resulted in a significant survival benefit, but all residual diameters larger than 2 cm had equivalent survival (Fig. 11.18). Therefore, unless the mass could be cytoreduced to 2 cm or less, residual diameter did not influence survival. In evaluating

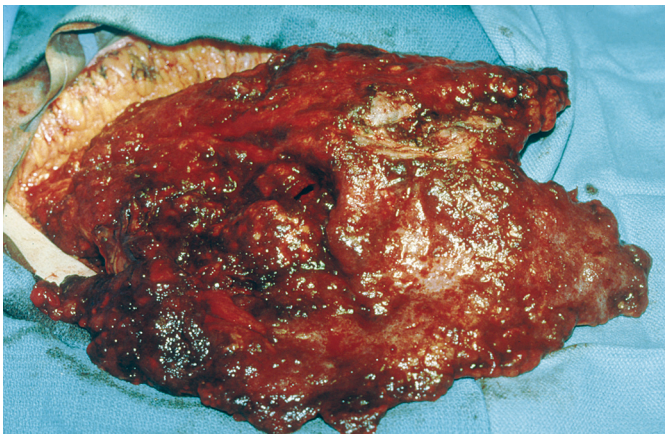

FIGURE 11.17 A large omental cake of ovarian cancer exceeding 25 cm in greatest measurement.

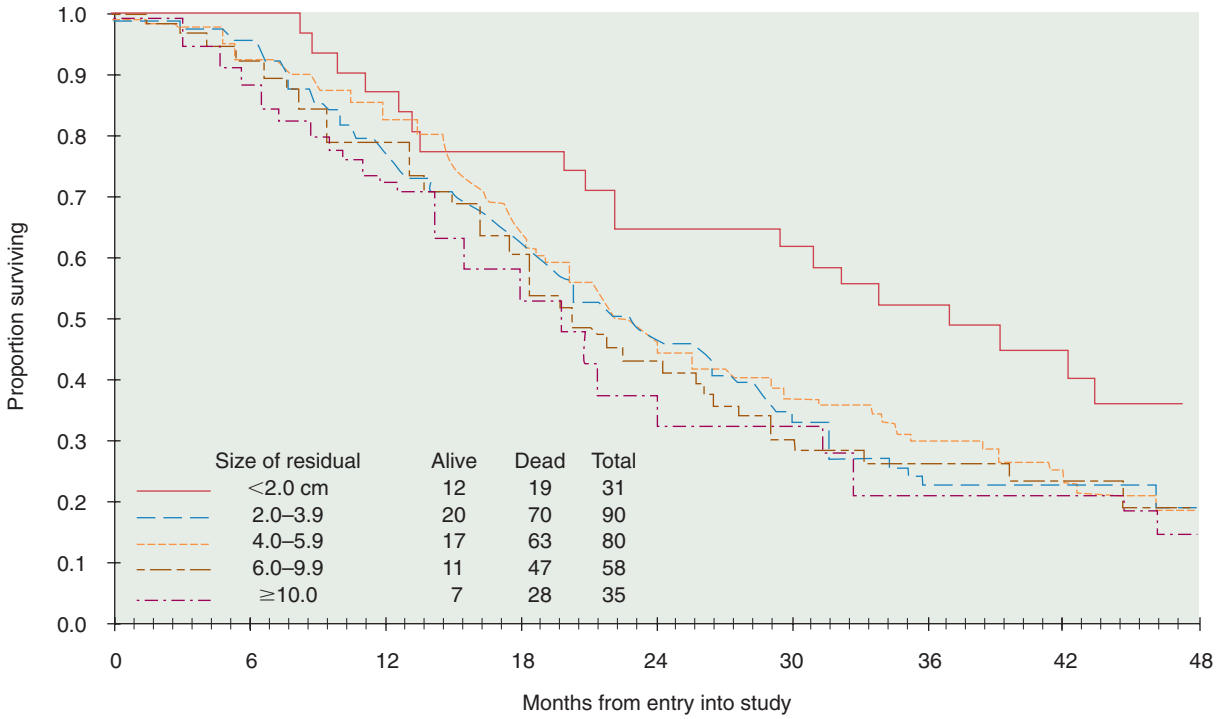

FIGURE 11.18 Survival by maximal diameter of residual disease. (From Hoskins WJ, McGuire WP, Brady MF, et al. optimal and suboptimal cytoreduction, these GOG investigators showed that three distinct groups emerged: microscopic (no visible) residual, residual disease of less than 2 cm, and residual disease of greater than 2 cm (Fig. 11.19). It is clear from these studies that whereas patients with microscopic disease had a 4-year survival rate of about 60%, patients with gross disease 2 cm or less had a 4-year survival rate of 35%. However, patients whose disease could not be cytoreduced to 2 cm or less had a 4-year survival rate of less than 20%. Most striking, however, was the failure of cytoreductive surgery to improve survival unless the largest diameter of residual disease was 2 cm or less. The effect of maximal cytoreductive surgery can be seen in the percentage of negative second-look procedures (Table 11.18).

An inverse correlation between the amount of residual disease after surgery and OS has been consistently associated. In 2002, Bristow and associates published a meta-analysis of published studies at the time, in which the impact of cytoreduction was clearly demonstrated. By comparing currently available studies of advanced ovarian cancer patients undergoing surgical cytoreduction, they demonstrated that for each 10% increase in the proportion of patients undergoing optimal cytoreduction, the median survival rate increased by 5.5% to 6%. Although the current accepted definition of "optimal cytoreduction" is no visible residual tumor smaller than 1 cm in greatest dimension, the best reported outcomes occur in patients who have complete cytoreduction or no visible residual disease.

In an effort to remove visible tumor deposits and achieve optimal cytoreduction, gynecologic oncologists frequently perform radical surgical procedures beyond those required for standard staging. Eisenkop and associates described 163 consecutive patients assigned to stage IIIC and stage IV. Complete cytoreduction could be performed in 86% of patients using an array of radical procedures. The overall median survival time was 54 months, but it was 62 months in those whose tumors were optimally debulked. Aletti and colleagues reported that for patients cytoreduced to low-volume residual disease, their favorable survival was directly associated with the need for radical surgery. Two sites that often require radical operations to clear are tumor metastases to the bowel and to the upper abdomen. Multiple investigators have reported the utility and safety of large or small bowel resection, which may be necessary

in up to 50% of cases to achieve optimal cytoreduction and has been associated with a subsequent improvement in survival. Upper abdominal cytoreduction has also been shown to be safe and effective but may require additional training or assistance. Cliby and colleagues reported procedures such as liver resection, splenectomy, and diaphragm resection to be possible and associated with an acceptable morbidity. Chi and coinvestigators demonstrated that the addition of upper abdominal procedures to achieve optimal cytoreduction resulted in a median survival time longer than 5 years, which was comparable to that of patients who did not require these extensive procedures for optimal cytoreduction. Improvements in surgical cytoreduction have developed in consort with additional advances in intensive care and postoperative care, allowing additional benefits for our ovarian cancer patients.

The role of cytoreductive surgery in stage IV cancers has been investigated. Several studies have suggested that optimal debulking can be performed in many of these patients with beneficial effect. Liu and associates described 47 patients with stage IV cancers, of which 14 (30%) were optimally debulked to less than 2 cm residual. The median survival time was 37 months in the patients in whom the cancer was optimally debulked compared with 17 months in the patients in whom the cancer was suboptimally debulked. A study by Chi and colleagues identified 92 patients; optimal debulking was achieved in 45% with a median survival time of 40 months compared with 18 months for suboptimal debulking. A recent ancillary study by the GOG demonstrated that the ability to achieve cytoreduction to less than 5 cm residual disease in stage IV patients rendered some survival advantage, although the most favorable subgroup was patients reduced to no visible residual disease. Aletti and colleagues also demonstrated that using radical procedures to perform cytoreduction to no visible residual disease resulted in median survival times longer than 3 years in stage IV patients. For patients known or suspected to have thoracic metastases, the use of video-assisted thoracic surgery (VATS) can be diagnostic, potentially therapeutic, or both. Positive findings on VATS may allow for intrathoracic cytoreduction in select cases or may indicate which patients are best served with neoadjuvant chemotherapy as a result of unresectable pleural disease.

Even though cytoreductive surgery consistently appears to have therapeutic value, controversy continues. The primary unresolved issue is whether the poor prognosis with bulky disease is caused by the presence of increased tumor burden (in which case cytoreductive surgery is of potential benefit) or whether it is associated with differences in tumor biology or a decreased sensitivity to chemotherapeutic regimens. (If these possibilities are indeed the case, cytoreductive surgery is not likely to have a major impact on survival.) The implication is that patients who have disease that can be cytoreduced are a select group with good prognoses on the basis of factors independent of the surgery. Furthermore, if chemotherapy is delayed because of complications of surgery, this may have a deleterious effect on long-term survival. The percentage of patients with advanced ovarian cancer who can effectively undergo cytoreductive surgery seems to range from 43% to 87%, depending on the investigators reporting. This difference may not only reflect the individual skills of the surgeons but also may be influenced by different referral patterns and other selection factors. Neoadjuvant chemotherapy has been investigated as a means by which to address this issue; these studies are described in the subsequent section.

The role of lymphadenectomy in patients with advanced disease continues to be debated. Lymph node involvement is common in patients with advanced disease (>50%); the question is whether lymphadenectomy improves survival. It has been suggested by some that metastases in lymph nodes do not respond well to chemotherapy, and therefore these potential metastatic sites should be removed. Opponents state that recurrence most frequently occurs in the peritoneal cavity, and therefore lymph node status has little impact on the overall disease course. Several studies have come to somewhat different conclusions. Parazzini and associates evaluated 456 women with stage III or IV disease entered in a prospective randomized chemotherapy trial. There were 161 patients with positive nodes. They noted grade 3 tumors to have a greater number with positive nodes compared with grade 1 or grade 2 tumors. This was also true of stage IV compared with stage III cancer. They did not find a difference in survival between those with positive nodes and those with negative nodes. Scarabelli and colleagues evaluated lymph node status in 98 patients with stage IIIC to IV disease who had no gross residual disease after surgery compared with 44 patients who did not undergo lymphadenectomy. Survival was significantly improved if lymphadenectomy was done (Cox analysis). In 2005, Panici and coinvestigators reported their prospective multicenter analysis of 427 advanced ovarian cancer patients randomly assigned to lymphadenectomy or removal of bulky nodes only. Although progression-free survival (PFS) was improved in patients undergoing lymphadenectomy, OS was not different. The 2005 retrospective analysis of 889 patients enrolled in the Scottish Randomised Trial in Ovarian Cancer (SCOTROC-1) was conducted. The analysis demonstrated that optimal debulking (<2 cm) was more commonly achieved in patients accrued from the United States, Europe, and Australia than in patients recruited from the United Kingdom (71% vs. 58%). Comparison of the UK and non-UK patients who had no visible residual disease demonstrated a better survival for the non-UK patients, and the authors attributed this to the fact that non-UK patients more commonly underwent primary lymphadenectomy, suggesting a potential therapeutic benefit. It has been our practice to do pelvic and aortic lymphadenectomy routinely if the patient's tumor can be optimally debulked. Benefits of lymphadenectomy in patients with bulky residual disease remain questionable. It currently seems appropriate that patients with a diagnosis of advanced ovarian cancer should undergo resection of all masses when technically feasible.

Because a suboptimal surgical effort confers no survival benefit and adds only postoperative morbidity, accurate methods to determine which patients could be successfully resected would be useful. Both preoperative imaging and initial laparoscopy have been investigated as methods to determine the likelihood of success. Most imaging series have used preoperative CT scan

to assess factors that could predict an optimal cytoreduction. Although sets of radiographic risk factors have been described, these have had poor predictive value because the majority of patients (62%–86%) identified as having "poor prognostic indicators" have been able to undergo optimal cytoreduction. Similarly, laparoscopy in advanced ovarian cancer has limitations in terms of how complete an assessment of the IP space is possible, and metastases at port sites have been reported. Wang and associates reviewed the literature to determine risk factors that may contribute to early recurrence at the port site. Of the gynecologic cancers, ovarian cancer was the most common malignant neoplasm with subsequent port site metastasis. Metastasis to the port site was more common if ascites and IP carcinomatosis were present. The earliest time from laparoscopy to port site metastasis was 8 days; however, the clinical significance of port site metastases is unclear because they often clinically resolve with systemic therapy.

Whether a suboptimal primary surgery can be improved upon by subsequent surgical cytoreduction after chemotherapy is controversial. The EORTC group reported its initial experience with interval debulking surgery in patients with advanced ovarian carcinoma after unsuccessful primary cytoreductive surgery. Patients received three courses of cisplatin and cyclophosphamide and were then randomly assigned to receive interval debulking surgery or no further surgery. All patients received six courses of chemotherapy. There were 278 patients evaluated, and the median survival rate was 26% versus 20% (surgery vs. no surgery; $P = 0.012$). Debulking surgery was an independent prognostic factor in multivariate analysis. After adjustment for all prognostic factors, surgery reduced the risk of death by 33% ($P = 0.008$). GOG investigators conducted a similar study. This study (GOG 152) enrolled 550 patients, all of whom had initial primary surgery by a gynecologic oncologist. Patients who were suboptimally debulked (residual tumor >1 cm) received three cycles of paclitaxel plus cisplatin. Patients were randomized to continued chemotherapy or to a secondary surgical cytoreduction and then continued chemotherapy. Neither the PFS nor the relative risk of death was improved with the additional interval surgery. The authors speculate that the patients in the GOG study may also have undergone more aggressive primary surgery than the patients in the EORTC study, and this may have accounted for the difference in results. Most important, one could summarize these two studies by concluding that patients with advanced ovarian cancer are deserving of at least one maximal effort at cytoreduction, preferably by a gynecologic oncologist.

Although a maximal primary surgical effort appears to be a cornerstone of potential long-term survival, the timing of the surgical effort remains a focus of debate. In patients with borderline performance status, based on age, compromising medical disease, and extensive effusions (especially pleural or pericardial), and in patients with extensive abdominal disease, unlikely to be effectively debulked, strong consideration should be given to initiating therapy with neoadjuvant chemotherapy. After two to four cycles, a good clinical response to chemotherapy may provide an opportunity for an effective surgical debulking with an acceptably low complication rate. Before initiating chemotherapy, the diagnosis of ovarian, tubal, or peritoneal cancer should be confirmed by cytology or minimally invasive surgery. Neoadjuvant chemotherapy treatment (followed by surgical debulking) results have been reported in small retrospective reports of between 20 and 90 patients and generally report survival outcomes similar to those of patients who have been suboptimally cytoreduced. A meta-analysis of these studies by Bristow et al. and Chi et al. demonstrated that the use of neoadjuvant chemotherapy was associated with a reduction in survival of approximately 4 months with every preoperative cycle, implying that surgical intervention should be performed as soon as is feasible. However, Vergote and colleagues have reported results from the large randomized EORTC noninferiority trial of patients with advanced ovarian cancer treated with primary surgery followed by chemotherapy versus neoadjuvant chemotherapy for three cycles followed by surgical cytoreduction and three additional cycles of chemotherapy. Complete resection of all macroscopic disease was the strongest predictor of OS. They demonstrated comparable survival outcomes (~29 months in both arms), and overall the results favored neoadjuvant chemotherapy given the lower surgical morbidity compared with the primary surgery group. Another trial evaluating the role of neoadjuvant chemotherapy, Chemotherapy Or Upfront Surgery in Ovarian Cancer Patients (CHORUS), randomized women with stage III or IV ovarian cancer to receive upfront surgery followed by six cycles of chemotherapy (carboplatin and paclitaxel) or three cycles of chemotherapy, surgery, and then three additional cycles of completion chemotherapy. A total of 550 women were evaluated, and the OS time was 22.6 months in the primary surgery group compared with 24.1 months in the primary chemotherapy group. The authors also reported a lower rate of grade 3 or 4 postoperative adverse events and deaths in the primary chemotherapy group, concluding that the primary chemotherapy approach is noninferior to the primary surgery approach. Although the neoadjuvant approach is a reasonable option for some patients, it is important to recognize several criticisms to the study. Both studies reported low rates of primary optimal cytoreduction (~40% in both studies) and low median OS compared with other contemporary ovarian cancer trials. Therefore, neoadjuvant chemotherapy has not been widely adopted as an equivalent primary treatment option in the United States, and further studies are ongoing.

Role of Radiation Therapy

With improvements in chemotherapy and surgery for ovarian cancer, radiation therapy rarely plays a role in primary therapy. The systemic pattern of spread makes effective radiation therapy difficult, and with bulky residual disease, radiation therapy is particularly ineffective. Studies by the GOG and others demonstrated the extent to which the addition of radiation did not improve outcomes even before the current era of highly active chemotherapy. Some special problems are listed in Table 11.19. The entire abdomen must be considered at risk; therefore, the volume that must be irradiated is large, resulting in multiple limitations for the radiotherapist. However, consideration of

TABLE 11.19 Special Problems in Ovarian Cancer

Limits of tumor spread often unknown
Variability of radiosensitivity
Total tumor burden usually large
Free mobility of tumor cells within the abdominal cavity
Radiation dosage restricted by neighboring organs
Infrequent detection of early disease

TABLE 11.20 Dose Restrictions

Tolerance of small intestine
Limited tolerance of kidneys
Bone marrow depression
Radiation enteritis caused by large volume of intestine irradiated
Adhesive peritonitis

radiotherapy for specific histologies and isolated recurrences is being further studied. Dose restrictions are listed in Table 11.20.

Radioisotopes

Numerous trials have been conducted comparing IP 32P with or without pelvic radiation with whole abdominal radiation or single-agent chemotherapy in various clinical settings of ovarian cancer. Because IP 32P has failed to demonstrate improved outcomes, can be associated with increased complications, and is "technique intensive," it is rarely considered for contemporary treatment planning.

Chemotherapy

The evolution of chemotherapy agents for advanced ovarian cancer over the past 30 years has been significant. Ovarian cancer was one of the first solid malignant tumors demonstrating responsiveness to chemotherapy. Effectiveness of the various chemotherapy treatments has been measured by response rates (usually complete plus partial responses), negative second-look rates, PFS, and OS. All of these outcome measures can be subject to error. Even survival outcomes can be compromised by the fact that many patients receive a number of variously active chemotherapy treatments over their treatment history.

The earliest agents used for the treatment of ovarian carcinoma (1970–1980) were predominantly the alkylating agents melphalan (also called phenylalanine mustard, Alkeran, L-PAM, and L-sarcolysin), cyclophosphamide, chlorambucil, and thiotepa. Response rates were usually reported in the 20% to 60% range, but median survival rates for patients with advanced ovarian cancer were often in the range of 10 to 18 months, quite inferior to most outcomes from today's clinical trials. Antimetabolites, such as 5-fluorouracil and methotrexate, were also used in many of the earlier trials, especially in combination with alkylating agents. The contemporary use of these agents in epithelial ovarian cancer is rare to nonexistent.

The late 1970s and 1980s saw the introduction of combination chemotherapy regimens, such as Hexa CAF (hexamethylmelamine, cyclophosphamide, doxorubicin, and 5-fluorouracil) and CAP (cyclophosphamide, doxorubicin, and cisplatin). By the early 1980s, combination therapy was the standard treatment for most patients. The 1980s also witnessed the introduction of cisplatin and later carboplatin. The introduction of these platinum compounds increased response rates to the 50% to 80% range and increased median survival periods to the 12- to 30-month range in most studies. The wide range was often attributable to select patient populations, with the "suboptimal" debulked patients having the 12- to 18-month survival times and the "optimal" debulked patients having the 18- to 30-month survival times. The platinum compounds have remained an integral component of treatment to this day.

The 1990s saw the introduction of paclitaxel, an agent first extracted from the stripped bark of the Pacific yew tree, *Taxus brevifolia.* Paclitaxel, now chemically synthesized, demonstrated a new mechanism of action by promoting microtubular assembly and stabilizing tubulin polymer formation, thus inhibiting rapidly dividing cells from completing the mitotic process. The initial single-agent paclitaxel response rates in patients with refractory ovarian cancer were in the 25% to 35% range. Contemporary drug development continues to look at new formulations of the taxane group. Docetaxel in several studies has shown equivalent efficacy to paclitaxel with a different side effect profile, and other modified taxanes such as Abraxane and CT-2103 have been evaluated.

The past 2 decades have also seen the introduction of additional cytotoxic agents with demonstrated activity in ovarian cancer, including topotecan, a topoisomerase I-inhibitor; a pegylated liposomal encapsulated form of doxorubicin; and gemcitabine. These three drugs were tested in the frontline setting by the GOG 182/ICON-5 clinical trials, discussed later.

For the past decade, there has been considerable interest in developing agents targeting specific molecular targets. Two important categories of targeted therapies in ovarian cancer have been angiogenesis inhibitors, of which bevacizumab has been most widely studied, and poly(ADP-ribose) polymerase (PARP) inhibitors. Immune therapies continue to be in development and will continue to be a therapeutic focus in the next decade.

Clinical Trials

The relatively low rates of response to most single agents stimulated investigators to search for combination schedules. In the "modern" era, platinum-based combinations have proved to be the most successful. Pertinent clinical trials relating to early-stage disease are discussed earlier in this chapter, and the following discussion focuses on trials for advanced ovarian cancer.

Development of ovarian cancer combination chemotherapy through the 1980s and 1990s saw transition from doxorubicin–cyclophosphamide (AC), to cyclophosphamide–doxorubicin–cisplatin (CAP), to cyclophosphamide-platinum, and finally to taxane–platinum as the evolving standard of care. The trials performed by the GOG as well as European investigators were primarily responsible to developing these standards. In 1986, GOG 47 reported results comparing CAP to AC, with improved response rate, response duration, and PFS but not OS in the whole cohort. Subgroup analysis of patients with measurable disease (227 of 440 assessable patients) did show

improved OS, and the potential advantage of incorporating platinum therapy was recognized. GOG 52 evaluated CAP versus cyclophosphamide–cisplatin alone in optimally cytoreduced patients and demonstrated equivalent PFS and OS endpoints. With less toxicity by withholding doxorubicin, cyclophosphamide–cisplatin became the "standard" arm for many clinical trials in the late 1980s and early 1990s. Before abandoning doxorubicin completely, four trials were considered in a meta-analysis that specifically evaluated the benefit of doxorubicin in ovarian cancer. Considering only pathologic complete responses, the study showed a constant small benefit for CAP, highest in the North-West Oncology Group (GONO) and Danish Ovarian Cancer Group (DACOVA) studies. By pulling together these data in a meta-analysis, it was possible to detect a statistically significant benefit of pathologic complete responses (6%) and OS (7%) with CAP. However, because in three trials the dose intensity was greater for CAP than for cyclophosphamide–cisplatin, to what extent the benefit of CAP is from greater dose intensity or from doxorubicin itself remains unsolved.

In the 1990s, paclitaxel became available on trial, and GOG 132 evaluated 614 patients with suboptimally debulked cancer who were treated in a three-arm protocol comparing cisplatin alone, paclitaxel alone, and a combination of the two drugs. Neither PFS nor OS was different among the three arms, but significant crossover to the other drug in the single-drug arms muddled somewhat the clarity of the outcome data. Some interpreted the results of this study to indicate that a platinum agent should be a component of primary therapy. With some evidence for efficacy, the paclitaxel–cisplatin combination was compared to the existing standard, cyclophosphamide–cisplatin. The GOG 111 study randomized 386 patients with large-volume disease to paclitaxel–cisplatin versus cyclophosphamide–cisplatin. In the paclitaxel arm, administration of paclitaxel before cisplatin was important to optimize response and minimize toxicity. In terms of therapeutic efficacy, the cisplatin–paclitaxel arm produced a significantly greater overall response rate (73% vs. 60%) and clinical complete response rate, but the frequency of pathologic complete response was similar between the two arms. The paclitaxel arm showed significant improvements in PFS (18 vs. 13 months) and OS (38 vs. 24 months). The risk of progression was 32% lower among those treated with the paclitaxel regimen, and the risk of death was 39% lower (Fig. 11.20). A European-Canadian Intergroup trial (OV-10) had a study design similar to GOG 111, testing the replacement of cyclophosphamide with paclitaxel. This study included patients with optimal and suboptimal stage IB, IIB, III, and IV. Again, the clinical response rate was superior for the paclitaxel arm (59% vs. 45%), with a subsequent 25% reduction in the rate of death. The combination of paclitaxel and cisplatin became the standard for combination first-line chemotherapy for the treatment of epithelial ovarian carcinoma.

When combined with cisplatin, paclitaxel requires an extended infusion interval (24 hours) to prevent unacceptable neuropathy. This administration schedule was inconvenient, prompting many community providers to replace cisplatin with carboplatin, with which paclitaxel did not require this extended

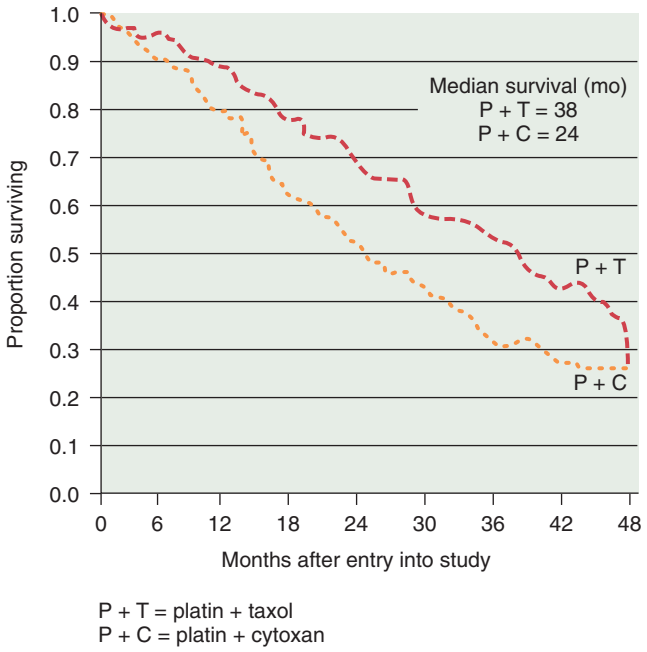

FIGURE 11.20 Survival by treatment group. (Modified from McGuire WP, Hoskins WJ, Brady MF, et al. Cyclophosphamide and cisplatin compared with paclitaxel and cisplatin in patients with stage III and stage IV ovarian cancer. *N Engl J Med* 1996;334:1. Copyright © 1996 Massachusetts Medical society. All rights reserved. Adapted 2006 with permission.)

infusion. Several groups conducted equivalency trials to compare paclitaxel (175–185 mg/m^2) and carboplatin (AUC 5–7.5) with the standard cisplatin–paclitaxel regimen. The GOG conducted GOG 158 on the optimal (<1 cm) patient population as a noninferiority trial. The relative risk (RR) of progression on the paclitaxel plus carboplatin arm was equivalent (RR = 0.88; 95% CI, 0.–-1.03), and toxicity was greater on the paclitaxel plus cisplatin arm. Similar findings regarding therapeutic equivalence and toxicity preference for carboplatin over cisplatin were reported by the Arbeitsgemeinschaft Gynäkologische Onkologie (AGO) Ovarian Cancer Study Group. The combination of intravenous (IV) paclitaxel and carboplatin replaced paclitaxel and cisplatin as the standard first-line chemotherapy for ovarian cancer.

Care must always be taken in interpreting response rates as a correlate for survival rates. Too often a chemotherapeutic regimen will produce an excellent response rate but not affect the OS rate. Therefore, the clinician must await longer term studies of combination chemotherapy to accurately understand its impact on survival of patients. Omura and colleagues reported a sobering analysis of two large GOG studies of multiagent chemotherapy in epithelial ovarian cancer. In this analysis of 726 women with stage III or stage IV disease, excellent follow-up had been obtained. The authors concluded that the impact of chemotherapy to date had been modest. Fewer than 10% of their patients were progression free at 5 years, and late failures continued to occur, even beyond 7 years. Sutton and coworkers reported a 7% disease-free survival rate at 10 years. Unfortunately, the superiority of any particular

combination of chemotherapeutic agents as reflected by statistically significant improvement in long-term survival remains unproved. Although carboplatin appears to be the most active agent in epithelial cancer of the ovary, there is still controversy that combining it with other agents improves outcome.

In vitro testing of chemotherapy resistance or sensitivity has been investigated for at least 3 decades without clarification of its role in either primary or recurrent disease. Multiple technologies are currently in use, and there is a need to identify the relative value of this testing modality.

Dose-intense Chemotherapy

Dose intensity refers to the amount of chemotherapy to which a cancer is exposed per unit of time; this is generally assumed to be reflected by the dose of drug in milligrams per square meter of body surface area per unit of time. The theory is well grounded in preclinical work showing that as the concentration of drug in culture medium increases, the fraction of surviving cancer cells decreases logarithmically. The cell kill for a particular drug frequently follows a sigmoidal curve, indicating a point at which continued dose escalation will yield little improvement in results. To determine whether dose intensity is important clinically, randomized trials are needed. The GOG did design such a trial in patients with large-volume, advanced disease. A total of 458 patients were entered into the study and were randomly assigned to low-dose cisplatin 50 mg/m^2 plus cyclophosphamide 500 mg/m^2 every 3 weeks for eight cycles or high-dose cisplatin 100 mg/m^2 plus cyclophosphamide 1000 mg/m^2 every 3 weeks for four cycles (same total dose in half the time). In patients with measurable disease, the overall response and clinical complete response rates were equivalent. There was no difference in PFS or OS in the subsets of patients with measurable or nonmeasurable disease. The results of this study did not support the concept that increased dose intensity will produce greater therapeutic effect of cisplatinum or cyclophosphamide. Colombo and associates reported a randomized trial in patients with advanced disease who were given cisplatin 75 mg/m^2 every 3 weeks for six cycles or cisplatin 50 mg/m^2 per week for 9 weeks (same total dose in half the time). Again, no significant differences were seen in clinical or pathologic complete response rates, PFS, or OS. Although neither of these randomized trials of pure dose intensity in cisplatin showed an advantage for a higher dose intensity across a clinically relevant range of doses, other lines of evidence have been cited to support the use of higher dose schedules.

In trials conducted by the National Cancer Institute (NCI) of the United States, even higher dose intensities of cisplatin in conjunction with hypertonic saline to protect the kidneys had been stated to yield higher response rates than more standard doses. A closer examination of these data reported by Rothenberg and coworkers shows confusing results. In patients with large-volume disease, the NCI regimen complete response rates were no different (11% vs. 12%) than the GOG results with CAP, as reported by Omura, regimens with a 3.3-fold difference in dose intensity of cisplatin. In patients with small-volume disease, the NCI regimen complete response rates were not statistically different (38% vs. 30%) from the GOG results with a two-drug combination of cisplatin plus cyclophosphamide, as reported by Omura in 1989. There appears to be no evidence from these data to support the importance of dose intensity of cisplatin over a 3.3-fold range of doses. At least 11 randomized trials have compared standard doses of carboplatin- or cisplatin-based chemotherapy with double doses of the same platinum analogs. Most of these trials showed no advantage in most outcome parameters. A second meta-analysis of the Levin and Hryniuk meta-analysis (in which it appeared that dose intensity had a positive impact on response rate and survival) suggested that platinum dose intensity is unimportant, although intensity of all administered drugs is important, as is tumor residual volume at initiation of therapy.

Katsumata and colleagues from the Japan GOG reported their results of their phase III trial in advanced ovarian cancer evaluating IV carboplatin and paclitaxel dosed every 3 weeks versus IV carboplatin with weekly dose-dense paclitaxel. For each 3-week cycle of therapy, the weekly dose-dense arm received 240 mg/m^2 of paclitaxel versus 180 mg/m^2 of paclitaxel in the control arm. PFS and 3-year OS were significantly improved in the weekly paclitaxel arm (28 vs. 17 months, 72% vs. 65%), with a higher incidence of grade III and IV anemia. Pignata and colleagues reported results from the similar Multicentre Italian Trials in Ovarian Cancer 7 (MITO-7) trial but showed no difference in PFS or OS for weekly versus paclitaxel every 3 weeks. GOG investigators for GOG 262 investigated this question of carboplatin plus weekly paclitaxel versus paclitaxel every 3 weeks in a similar manner to the Japanese Gynecologic Oncology Group (JGOG), with the addition of with or without bevacizumab in each arm. Preliminary results reported no difference in PFS between the arms if bevacizumab was received, but without bevacizumab, the weekly paclitaxel arm had improved PFS.

For 2 decades, high-dose chemotherapy with autologous bone marrow transplantation (ABMT) or peripheral blood stem cell support has been reported for several solid tumors, and there has been a tendency for improved response rates but a relatively short period of disease-free survival in most of the reports reviewed. Many reports show that even in advanced cases, the most important factor for long-term survival after high-dose chemotherapy is the completeness of the primary cytoreductive surgery. Most of the reports in the literature with high-dose chemotherapy with ABMT have been phase II trials of patients with a mixed response to first-line chemotherapy. The best response and survival have been in patients who had had a complete response to pretransplantation chemotherapy. The MD Anderson group reported its experience of 96 patients undergoing transplantation, of whom 43% were in clinical remission. The overall 6-year survival rate was 38% and was 53% in the clinical remission group. Bengala and colleagues reported the results of the European Group for Blood and Marrow Transplantation (EBMT) for 91 patients in first complete remission treated with high-dose chemotherapy and ABMT. The median survival time was 44 months, and they were unable to identify a subgroup more likely to benefit. These reported median survival times are not significantly better than that with use of paclitaxel as second-line therapy. However, the

toxicity of high-dose chemotherapy is a serious concern, as is the additional expense. Although interesting, it appears that targeting of patients for high-dose therapy with bone marrow support cannot be considered standard therapy and should only be done as part of an established national protocol so that information can be obtained to increase our knowledge of this therapy.

Immunotherapy

In the past 3 decades, there has been considerable interest in combining chemotherapy with immunotherapy for better results in patients with epithelial cancer of the ovary. The GOG and others have investigated immunomodulating agents such as *Corynebacterium parvum* and bacille Calmette-Guérin (BCG). Results have been conflicting as to whether nonspecific immunostimulation combined with chemotherapy improves survival.

The potential role of immune response modifiers in the treatment of ovarian cancer has been investigated. Ovarian cancer is a suitable model for biologic therapies because the peritoneal cavity is capable of mounting an inflammatory response to many stimuli, and this response has been shown to induce an antitumor effect. Early experimental observations confirmed that ovarian cancer is a suitable prototype tumor in which to evaluate novel immunotherapeutic and chemoimmunotherapeutic approaches. Berek and coworkers have reported that recombinant interferon alfa has clinical activity in patients with small-volume residual disease. Numerous phase II trials, using substances such as tumor necrosis factor, interleukin-2, and the like, along with other studies using combinations of cytokines have failed to demonstrate significantly improved outcomes. Combining biologic immune response modifiers with standard chemotherapy has proved to be more difficult than initially conceived because of overlapping toxicities. In view of this, it seems prudent to await proven efficacy before attempting to launch the phase III trials with biologic immune response modifiers.

Recent results from trials using programmed cell death protein 1 (PD-1) inhibitors, such as nivolumab and avelumab, have shown some promise. PD-1 is a T-cell "programmed cell death" receptor on T cells that can blocked by a tumor-secreted ligand, inactivating the T cell and allowing the cancer to evade the host immune system. Competitive blockade of this ligand should allow improved cancer immune regulation, and initial results reported by Brahmer and associates in melanoma, non–small cell lung cancer, renal cell cancer, and ovarian cancer were promising. Hamanishi and colleagues have reported their initial results with nivolumab in a cohort of patients with platinum-resistant ovarian cancer, with an encouraging safety profile and activity, including two durable responses. NRG Oncology and others have open trials investigating this mechanism in ovarian cancer. We await the results of these endeavors as to whether these novel treatments will show the same promise in ovarian cancer that has been demonstrated thus far in melanoma.

Intraperitoneal Chemotherapy

Ovarian cancer is predominantly a disease limited to the peritoneal cavity for most patients. For some chemotherapeutic agents, IP administration offers pharmacokinetic advantages, including high IP drug concentration and longer exposure in the peritoneal cavity. Although IP chemotherapy proposals date back decades, it has only been over recent years that the accumulated clinical trial data favor this approach.

Results from randomized trials, listed in Table 11.21, summarize the experience of clinical trials conducted since the mid-1980s. These studies, all primary therapy trials, compare IV chemotherapy with combined IV and IP chemotherapy. The initial IP study demonstrating that IP chemotherapy may represent a survival advantage was a combined Southwestern Oncology Group (SWOG)/GOG trial (SWOG 8501 and GOG 104). The study compared IV cisplatin and IV cyclophosphamide with IP cisplatin and IV cyclophosphamide in patients with less than 2-cm-diameter residual disease. The IP arm produced a median survival of 49 months compared with 41 months for the IV arm, with an HR of 0.77. However, critics pointed out that the subsequent introduction of paclitaxel to our frontline treatment may have neutralized this apparent advantage for IP therapy. The other concern is that accrual was extended beyond the initial study design for patients with 0- to 0.5-cm residual disease, and still this subgroup failed to demonstrate superior survival (51 months vs. 46 months; HR, 0.80). One would have expected the treatment difference to be most pronounced in this patient subgroup. Partly because of these issues, IP therapy was not uniformly supported as producing a survival advantage over the current IV standard, carboplatin-paclitaxel.

Another GOG study, GOG 114, reported in 2003, compared IV cisplatin and paclitaxel (six cycles) with high-dose (AUC, 9) carboplatin IV (two cycles) plus six cycles of IV paclitaxel and IP cisplatin in patients with stage III disease less than or equal to 1-cm diameter residual. The median survival for the IP arm was 67 months versus 51 months for the IV arm and was statistically significant. Because the patients in the IV arm did not receive the extra two cycles of the high-dose carboplatin, critics were hesitant to support IP delivery as the reason for the survival improvement.

The most recently reported GOG study, GOG 172, compared IV paclitaxel (135 mg/m^2/24 hours) followed by either IV cisplatin (75 mg/m^2) on day 2 or by IP cisplatin (100 mg/m^2) on day 2 and IP paclitaxel (60 mg/m^2) on day 8—each arm for six cycles at 21-day intervals. The patient population was similar to GOG 114—stage III, less than 1 cm diameter residual. The median survival for the IP arm was 66.9 months compared with 49.5 months for the IV arm (HR, 0.71), results remarkably similar to the preceding study, GOG 114 (Fig. 11.21). This survival advantage prompted an NCI alert that IP therapy should be considered for first-line treatment for women with optimally cytoreduced advanced ovarian cancer.

However, this study reported significant toxicity for the IP arm, with double-digit percentage grade III or IV toxicities. Additionally, 33% of patients experienced catheter-related complications, which may be decreased with the use of a venous catheter with a subcutaneous access port overlying the lower ribs (Fig. 11.22). Not surprisingly, in GOG 172, only 42% of patients on the IP treatment received the complete six of IP therapy, and 48% received three or fewer cycles of IP chemotherapy. However,

in total, 83% of the patients on the IP arm completed six cycles of chemotherapy (IP, IV, or both). An ancillary study of GOG 114 and 172 by Tewari and colleagues reported that the risk of death decreased by 12% for each cycle of IP chemotherapy completed. Although the IP-treated patients reported a significantly worse quality of life before cycle four and 3 to 6 weeks posttreatment, there was no difference in quality of life between the IP or IV arms 1 year after treatment, except for moderate neurotoxicity (paresthesias) being more common in the IP arm. Despite the evidence for a survival advantage from IP therapy and the resultant NCI clinical alert, IP therapy has not been accepted universally as a result of issues with catheter placement and therapy-associated toxicities. GOG 252 was designed to address issues of toxicity in IP chemotherapy and includes the question of weekly paclitaxel therapy in advanced ovarian cancer. The trial included a modification of the winning arm in GOG 172 with IP cisplatin dose reduced to 75 mg/m^2 and paclitaxel given over 3 instead of 24 hours, a second arm with IP carboplatin AUC 5 replacing the IP cisplatin, and a third arm using carboplatin AUC 6 every 3 weeks with weekly paclitaxel 80 mg/m^2 for 3 weeks per cycle. Preliminary results indicate no difference in toxicity or PFS for the three arms. All three arms appear to be more toxic than standard carboplatin–paclitaxel therapy every 3 weeks but less toxic than the winning IP arm of GOG 172. No OS data are available at the current time, and no definitive recommendations for altering standard of care can be made (Fig. 11.23).

Extraovarian Peritoneal Serous Papillary Carcinoma

Extraovarian peritoneal serous papillary carcinoma, or "primary peritoneal carcinoma," is a recognized clinical-pathologic entity in which peritoneal carcinomatosis of ovarian serous type is found in the abdomen or pelvis. Similar tumor deposits may be found on the surface of the ovary, but histologic evidence of primary or in situ ovarian carcinoma is either absent or insignificant. The tumor deposits are rarely noninvasive (borderline). This entity was first reported as "mesothelioma resembling

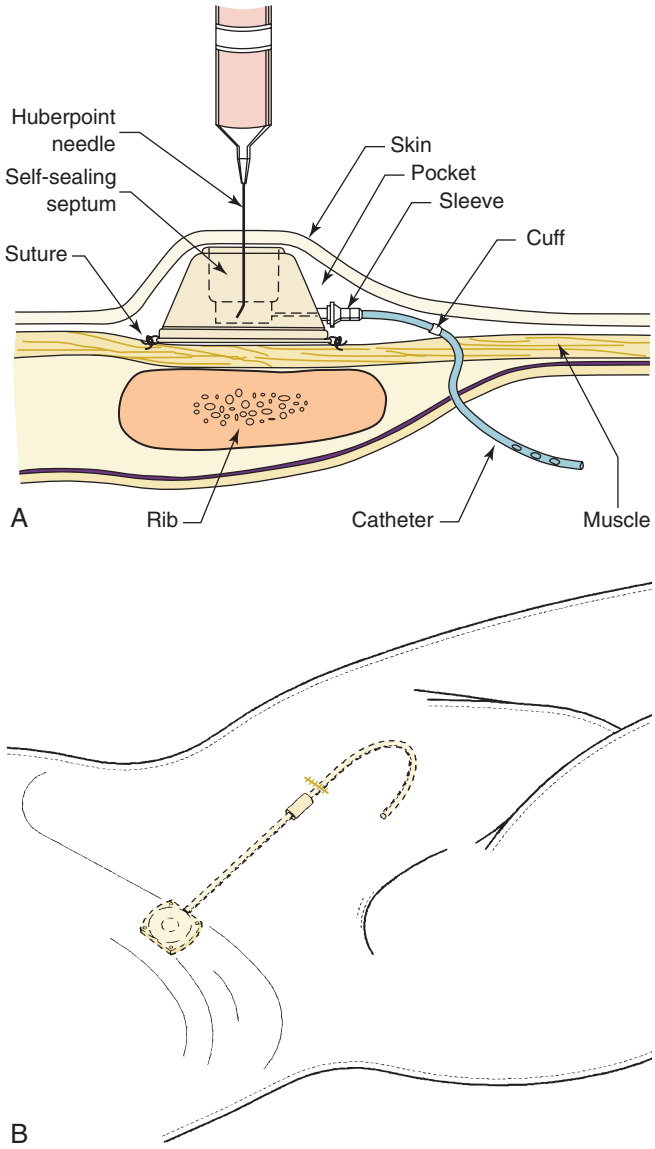

FIGURE 11.22 A, Implanted peritoneal access catheter with a subcutaneous self-sealing port providing a path for intraperitoneal therapy. B, Intraperitoneal chemotherapy.

papillary ovarian adenocarcinoma" by Swerdlow in 1959. Parmley and Woodruff, in 1974, demonstrated that pelvic peritoneum had the potential to differentiate into a Müllerian type of epithelium. This entity is different from mesothelioma. The malignant neoplasm spreads inside the peritoneal cavity, invading mostly the omentum, with minimal or no involvement of the ovary. Peritoneal studding is commonly present with psammoma bodies. Although usually serous, other cell types have been demonstrated. This entity has been identified in women who have had previous oophorectomies. The GOG has developed criteria for the diagnosis of extraovarian peritoneal carcinoma (Table 11.22).

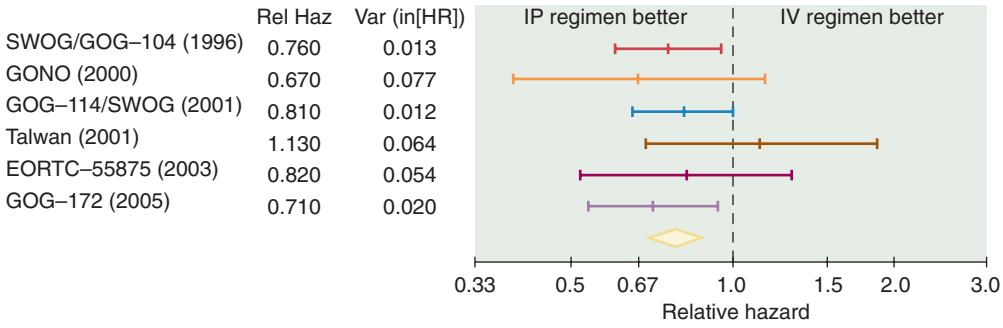
Experience with extraovarian serous neoplasia of this type has been compared with clinical outcomes of homologous ovarian tumors of similar stage and grade. Fromm et al., Dalrymple et al, and others have reported series with generally similar outcomes when equivalent therapy regimens to ovarian cancer are given. A GOG trial of cisplatin and cyclophosphamide in these patients demonstrated a response similar to that in women with papillary serous ovarian cancer.

Our experience has been that these patients generally respond to therapy in a manner similar to patients with serous papillary carcinoma of the ovary. Because many characteristics of this entity and serous ovarian cancer are similar, the GOG accepts patients with extraovarian peritoneal carcinoma into its protocols of epithelial ovarian cancer. CA-125 measurements also appear similar in both groups of patients. There have been reports suggesting a higher incidence of polyclonal cell populations in peritoneal carcinoma than in the generally monoclonal ovarian cancers, which may lead to higher rates of chemoresistance. Although most reports show similar survival rates between ovarian and peritoneal cancers, this polyclonal nature has been suggested to explain those series showing a decreased survival rate in peritoneal cancer. There appears to be an increased incidence of extraovarian peritoneal cancers in patients with a hereditary predisposition for development of ovarian cancer. In Piver et al.'s report of women at high risk for hereditary ovarian cancer, extraovarian cancer developed after prophylactic oophorectomy in almost 2%, 10 times greater than the lifetime incidence in the general population. *BRCA1* mutations appear to arise in a similar number of women with extraovarian and primary ovarian cancers.

TABLE 11.22 Gynecologic Oncology Group Criteria for Diagnosis of Extraovarian Peritoneal Carcinoma

Both ovaries must be either physiologically normal in size or enlarged by benign process.

Involvement in extraovarian sites must be greater than involvement on the surface of either ovary.



Microscopically, the ovarian involvement must be:

- Nonexistent
- Confined to ovarian surface epithelium or underlying cortical stromal involvement of no more than 5 mm

Histologic characteristics are primarily serous type, similar or identical to ovarian serous papillary adenocarcinoma.

Small Cell Carcinoma of the Ovary

Small cell carcinoma of the ovary is a specific histopathologic entity that is rare, highly aggressive, and primarily affects children and young women between the ages of 10 and 40 years. The first 11 cases were documented by Dickersin and colleagues in 1982. Many, but not all, patients with this lesion have an associated hypercalcemia. Neuron-specific enolase may be both a histologic marker (immunohistochemistry) and a serum marker for this disease. Various chemotherapeutic agents have been suggested with minimal success. Young and associates reported on the poor prognosis of these patients, with only 33% of women with stage Ia tumors alive and no survivors with advanced stage disease. In general, similar chemotherapy regimens used for small cell lung carcinoma will be used to treat this

χ^2 heterogeneity (5 d.f.)= 3.1, $P = 0.68$
Hazard ratio (HR) is not reported for the GONO study but it is calculated from the available data reported.
HR is not reported for the Greek study.

disease. Pautier and colleagues have reported the most promising regimen to date: a combination of cisplatin, doxorubicin, etoposide, and cyclophosphamide, with, if complete remission is achieved, high-dose chemotherapy with carboplatin, etoposide, cyclophosphamide, and stem cell support. Of 27 patients treated, 21 were stage II to IV and 18 complete responses were seen. Median duration of the 18 complete responses was 30 months, and 10 patients went on to receive high-dose chemotherapy. The OS rate at 3 years was 49%. Further study of this devastating group of tumors is necessary.

FOLLOW-UP TECHNIQUES AND TREATMENT OF RECURRENCES

Ovarian cancer is insidious in that it is late to cause symptoms, and thus follow-up examinations are imperative to detect early recurrence. The optimal follow-up strategy for asymptomatic patients who have advanced ovarian cancer after initial treatment remains undecided. Important considerations are divided between more passive and active approaches to follow-up. Currently, the National Comprehensive Cancer Network (NCCN) practice guidelines in oncology recommend surveillance of patients after the completion of primary therapy regardless of stage. This follow-up includes a comprehensive physical examination every 2 to 4 months for the first 2 years, every 6 months for the next 3 years, and then annually after 5 years. Laboratory studies, such as blood counts and chemistry profiles, should be done as indicated.

Use of CA-125 Levels and Other Tumor Markers

The oncology practice guidelines also recommend that the measurement of CA-125 level, or other relevant tumor markers, should be assessed at each follow-up evaluation if the level was initially elevated. CA-125 is an antigenic determinant of a murine immunoglobulin Ig1 monoclonal antibody that was raised against an epithelial ovarian carcinoma cell line and is expressed in more than 80% of nonmucinous epithelial ovarian cancers.

Multiple CA-125 determinants are associated with a mucin-like glycoprotein of more than 200,000 daltons. Traces of the antigen are expressed in adult tissues derived from the coelomic epithelium, including mesothelial cells lining the pleura, pericardium, and peritoneum, and from the epithelial component of the female reproductive system. Thus, there are other causes of elevated CA-125 levels, which include both gynecologic and nongynecologic conditions. Acute inflammatory processes involving the pelvic area and other regions of the body may increase CA-125. These may include acute hepatitis or pancreatitis, chronic liver disease, colitis, congestive heart failure, diverticulitis, arthritis, and pneumonia, to name a few.

The radioimmune assay was developed to detect CA-125 in serum and body fluids. The day-to-day coefficient of variability for the assay is approximately 15%. Consequently, a doubling or halving of antigen levels has been considered significant. If a cut-off of 35 U/mL is chosen for the upper limit of normal, elevated CA-125 levels should be found in 1% of apparently normal blood bank donors, 6% of patients who have benign disease, 28% of individuals who have nongynecologic malignant neoplasms, and 82% of patients who have surgically demonstrable epithelial ovarian cancer. Niloff and coworkers reported detection of elevated CA-125 in sera from patients who have advanced fallopian tube, endometrial, and endocervical adenocarcinomas. In epithelial ovarian carcinoma, rising or falling levels of CA-125 have correlated with disease progression or regression in more than 90% of patients. In the report by Niloff et al., when CA-125 levels returned to less than 35 U/mL, findings of second-look surveillance procedures were in fact normal in 14 of 36 cases, but in no instance was a nodule larger than 1 cm found. Persistently elevated CA-125 levels have been associated consistently with persistence of disease. Recurrence of disease has been heralded by elevations of CA-125 in 85% of patients whose tumors shed the antigen. Elevated CA-125 levels

preceded disease recurrence by 1 to 14 months with a mean of 5 months in one study reported by Knapp and Friedman. Elevation of CA-125 in hepatocellular disease and in chronic peritonitis is important to note but should not compromise the utility of CA-125 as a marker for monitoring ovarian cancer.

A rapid regression of the serum CA-125 level to normal limits shortly after commencement of chemotherapy has been shown to be associated with a higher frequency of negative results at second-assessment surgery. Levin reported that almost all patients who subsequently come to a negative second-look laparotomy have serum CA-125 levels within normal ranges within 3 months of primary cytoreductive surgery. Buller and colleagues have shown that a favorable outcome is associated with a steep regression curve of serum CA-125 levels after cytoreductive surgery and chemotherapy. These investigators demonstrated that patients in whom the CA-125 level reverts sharply to within the normal range by the third course of chemotherapy after surgery have a survival that is markedly improved over that of the patients who have an elevation of CA-125 levels before their fourth course of chemotherapy. Buller and coworkers described the regression curve of the serum CA-125 level as "S." Indeed, they have suggested that patients with a delayed "S" curve (regression of the elevated value) possibly should be considered for alternative therapy rather than persisting with the same chemotherapeutic regimens. Hogberg and Kagedal demonstrated that 23 patients with a serum CA-125 half-life shorter than 16 days during induction chemotherapy had an estimated survival of 68% at 59 months after second-look operation. This is compared with a survival rate of 18% in 49 patients with a serum CA-125 half-life longer than 16 days. However, one must be aware that normal levels may also accompany disease, with tumors up to 2 cm, in one-third or more of cases.

An elevation of CA-125 in the posttreatment surveillance period is usually related to recurrence of tumor, even if clinically otherwise undetectable. It remains controversial if patients should restart chemotherapy based on CA-125 elevation alone. The EORTC conducted a randomized study of early treatment for ovarian cancer relapse based on CA-125 level alone versus clinical or symptomatic recurrence. They evaluated 527 patients, approximately 265 in each group, and found no difference in OS rate between the two groups, even though patients in the arm evaluating CA-125 levels were treated earlier. Thus, they concluded that routine measurement of CA-125 may not be warranted. However, it is important to note that patients in this study were predominantly treated with second-line chemotherapy. Therefore, the role of secondary cytoreductive surgery, discussed in detail later, for asymptomatic recurrences may not have been accounted for, and the survival benefit of early detection based on CA-125 level may be underestimated for this group. Therefore, at this time, construction of the specific plan of follow-up should be individualized to each patient's needs.

In addition to CA-125, other tumor markers are being investigated for the detection of recurrent disease. Currently, the human epididymis protein 4 (HE4) has gained interest as a biomarker of recurrence. In a recent study, HE4 was shown to be elevated several months before CA-125 levels, implying a potential role for early detection of recurrent disease. Other studies have evaluated the markers including glycodelin, matrix metalloproteinase 7 (MMP7), in addition to HE4 and CA-125. The combination of these biomarkers was found to be useful for the detection of relapse before the onset of clinically detectable disease. However, these tests are in their infancy, and larger studies need to be conducted to confirm their efficacy.

Radiographic Imaging

For patients demonstrating a complete response to primary therapy, the NCCN guidelines recommend the use of radiographic imaging as clinically indicated. This may include the use of CT scan, magnetic resonance imaging (MRI) scan, or positron emission tomography (PET)/CT scan. The detection of recurrent disease on radiographic imaging varies dependent on modality and the size and location of disease. CT and MRI studies detected recurrent tumor in 66% to 95% of cases. However, most often failed to detect small-volume disease and disease located on visceral surfaces. Recently, PET/CT scan with F-18 fluorodeoxyglucose for the evaluation of recurrent ovarian cancer has been used. This modality has been shown to detect disease recurrence, particularly when patients presented with rising CA-125 levels and negative or equivocal CT scan or MRI. Although one must be aware of the limitations, namely physiologic uptake of the FDG (fluorodeoxyglucose), particularly in the GI and urinary systems, and misalignment with CT scan secondary to bowel peristalsis and respiratory movements, FDG-PET/CT has become a more common imaging choice.

FDG-PET/CT scan not only offers the benefit of functional and anatomic imaging but also allows for the ability to locate small-volume disease in locations not amenable to physical examination and the ability to differentiate metabolically active disease from inactive disease. In an effort to detect small lesions, PET/CT scan was performed for suspected recurrence and confirmed by surgical exploration or clinical follow-up. The investigators reported PET/CT scans had a sensitivity of 93% to 95% and specificity of 97% to 100%, suggesting that PET/CT may be used for posttherapy evaluation of recurrent ovarian cancer. Thus, PET/CT scan may provide valuable prognostic information, similar to second-look operations, without the associated morbidity.

However, the role of radiographic imaging for routine surveillance is less clear. In a retrospective case-control study, investigators evaluated survival impact based on the asymptomatic versus symptomatic detection of ovarian cancer. The common practice in this study was CT scanning of the abdomen and pelvis at 6-month intervals for the first 2 years followed by annually for the next 3 years. The authors reported a significant difference in postrecurrence survival favoring those detected asymptomatically on imaging (45 vs. 29.4 months). However, these tests are not without costs and should be evaluated in a prospective fashion to determine the true benefit. Until then, the decision to evaluate asymptomatic patients for recurrent disease with imaging should be individualized.

Maintenance Therapy

In addition to surveillance, patients with a complete response after primary therapy may be candidates for maintenance

therapy, which is chemotherapy given with the intention of extending the disease-free interval and improving OS. Currently, the role of maintenance therapy, or consolidation therapy, is still under investigation, which includes identifying the ideal agent(s) and dosages, the treatment interval, and the length of treatment.

As one of the most active agents in the primary setting, platinum agents are a natural choice for maintenance therapy. In patients with advanced disease who achieved a complete response after six cycles of chemotherapy, Kim and colleagues evaluated the role of three additional cycles of platinum and paclitaxel compared with observation (control arm). The authors noted that both groups demonstrated similar survival outcomes. Additional studies have evaluated the efficacy of single-agent carboplatin and IP cisplatin for maintenance therapy; however, similar to the aforementioned study, no survival advantage was ascertained.

Several randomized studies have also been conducted studying the role of paclitaxel for maintenance therapy. In one randomized study, six additional cycles of paclitaxel were compared with observation. The investigators reported no difference in PFS or OS at 3 years. Weekly paclitaxel (80 mg/m^2) for 12 weeks was evaluated after primary therapy, and the investigators reported a 2-year survival rate of 94% and acceptable tolerability. In contrast, a study by the GOG (protocol 178) compared three cycles with 12 cycles of paclitaxel after a complete clinical response. The study was closed early by the Data Safety Monitoring Board when a planned interim analysis demonstrated a progression-free interval advantage of 7 months for the extra 9 months of treatment. However, a follow-up report failed to demonstrate any survival advantage, which was difficult to interpret because the early closure caused the trial to be underpowered for this endpoint. Currently, the GOG (protocol 212) is conducting a study randomly assigning patients to monthly paclitaxel, paclitaxel poliglumex, or observation for 12 months after the completion of primary therapy. Until the results of this trial are available, the role of paclitaxel for maintenance therapy remains to be determined.

Two trials evaluating the role of bevacizumab combined with carboplatin and paclitaxel and bevacizumab maintenance therapy in the first-line setting have recently been reported. Bevacizumab is a potent antitumor therapy that targets vascular endothelial growth factor (VEGF) and for which there are multiple phase II trials demonstrating efficacy in recurrent ovarian cancer. GOG 218 randomly assigned women with advanced ovarian cancer after initial debulking surgery to one of three treatment arms: (1) standard carboplatin and paclitaxel for six cycles, (2) carboplatin–paclitaxel plus bevacizumab for six cycles, and (3) carboplatin–paclitaxel plus bevacizumab for six cycles followed by bevacizumab for up to an additional 16 cycles. PFS was improved in the bevacizumab-throughout arm, with OS similar in all three groups. Oza and colleagues reported the results of a large European trial, ICON seven, evaluating chemotherapy (carboplatin–paclitaxel) versus chemotherapy plus bevacizumab plus bevacizumab maintenance in a similar patient population. PFS and OS were similar in both arms, but a predefined high-risk subgroup (stage IV or suboptimal) did have improved OS. The demonstrated activity of bevacizumab against ovarian cancer may require more time to define how best to use this activity to improve survival.

In addition to platinum and paclitaxel, studies have been conducted evaluating the impact of numerous other chemotherapy agents, including topotecan, pegylated liposomal doxorubicin, and altretamine, which also failed to demonstrate a survival advantage. Over the past decade, biologic agents have also been investigated, such as oregovomab, a monoclonal antibody targeting CA-125 antigen; tanomastat, a matrix metalloproteinase inhibitor; and pazopanib, a multikinase inhibitor. However, none of these agents demonstrated a survival benefit. Additional trials are in progress to clarify the potential role for maintenance therapy.

Chemotherapy for Recurrent Disease and Targeted Therapies

Advanced epithelial ovarian cancer is a highly chemosensitive solid tumor with responses in the range of 70% to 80% to first-line chemotherapy, including a high proportion of complete responses. Most patients, however, eventually relapse and ultimately die of chemoresistant disease. Even with platinum-based chemotherapy, fewer than a quarter of the patients with an initial advanced disease diagnosis are alive at 5 years. In all forms of ovarian epithelial cancer, second-line chemotherapy has to date been disappointing. When effective drug combinations are initially used and fail, there is a very limited chance of inducing a sustained remission or cure with a second or third drug or combinations. Response and control of malignant effusions can frequently be achieved, but these are usually of progressively shorter duration. Most gynecologic oncologists attempt to treat these patients with use of a reasonable second-line regimen usually consisting of active chemotherapeutic agents that have not been used in the first treatment plan (Table 11.23). The selection of therapy is based on the following factors: (1) potential for platinum sensitivity, (2) number of previous regimens, (3) potential cumulative toxicities, (4) patient performance status and symptoms, and (5) patient choice.

Patients whose disease recurs within 6 months of achieving a complete clinical response to front-line platinum-based therapy are deemed "platinum resistant." In comparison, patients who respond and have a progression-free interval of more than 6 months off treatment are defined as "platinum sensitive" or, more appropriately, chemotherapy sensitive. The response rates to second-line therapy are strikingly different in these two groups of patients. Blackledge and associates, in an analysis of 92 patients receiving five different second-line regimens, found that the interval off platinum-based therapy was a strong predictor of response. This observation held for both platinum-based and non–platinum-based second-line regimens. A response rate of less than 10% was observed for patients with a treatment-free interval of less than 6 months compared with up to 90% for those with an interval more than 21 months (Table 11.24).

Seltzer and coworkers reported a 72% response rate, including a 36% complete response rate, to second-line therapy with cisplatin in 11 patients who had achieved complete response

From Blackledge G, Lawton F, Redman C, Kelly K. Response of patients in phase II studies of chemotherapy in ovarian cancer: implications for patient treatment and the design of phase II trials. *Br J Cancer* 1989;59:650.

to platinum-based, first-line chemotherapy. Markman and coworkers reported a 77% response rate to cisplatin in patients who had received no treatment for more than 24 months compared with 27% in women whose treatment-free interval remained 5 to 12 months. Similarly, Eisenhauer and associates reported a 43% response rate to carboplatin in patients whose treatment-free interval was more than 12 months compared with 10% in those whose treatment-free interval was less than 12 months. These findings make it mandatory that we define the populations of patients in clinical trials of second-line therapy. Phase II trials should include multiple adequately sized cohorts, such as patients with platinum-sensitive disease and those with platinum-refractory disease. In addition, patients should probably be stratified by the length of their treatment-free interval. In general, in phase II trials, response rates of more than 25% to 30% are expected for active agents being tested in the platinum-sensitive population, and response rates of greater than 10% to 15% are considered promising in the platinum-resistant population.

A current issue of debate is whether recurrent ovarian cancer is better managed by sequential single-agent therapy or combination chemotherapy. Two European reports suggest combination therapy is superior. One trial (ICON4/AGO-OVAR 2.2) reported on more than 800 patients. The patient population was "very platinum sensitive," with more than 75% of the patients having more than a 12-month platinum-free interval. After a median follow-up of 42 months, analysis showed the combination had a 2-year survival rate of 57% versus 50% for the platinum-only treated patients, and the median survival difference was 29 months versus 24 months. This study has been the subject of some criticisms. The study was an analysis of multiple parallel trials conducted by difference groups involving five countries and 119 hospitals. The platinum agent was either cisplatin or carboplatin. The treatments were given monthly. A number of the patients had not previously received a taxane, and there was no difference in outcome if the patient previously received a taxane in their primary therapy. Thus, considering most patients receive a taxane and carboplatin for primary therapy in the United States, the application of this experience to our US population is questioned. Other smaller studies, including a Spanish study (Grupo Español de Investigación en **Cáncer** de Ovario [**GEICO**]), also suggested the observation that combination therapy in the refractory setting may offer better outcomes. However, in general, in patients with disease-free intervals of longer than 12 months, the tendency is to retreat with taxane plus platinum combinations.

In addition to the rechallenge with platinum, single-agent paclitaxel is often used in the treatment of recurrent disease. In patients with platinum-sensitive disease, although rechallenge with platinum-based combination is favored, paclitaxel as a single agent has moderate response rates, ranging from 20% to 45%. Even in the platinum-resistant disease setting, standard-dose paclitaxel has been shown to produce response rates of 22% to 23%. Kohn and associates evaluated higher doses of paclitaxel, which required hematologic support, and observed a 48% response rate in platinum-refractory patients. As with other agents, these responses were generally of short duration. Nonetheless, paclitaxel should figure prominently in the consideration of second-line therapy for patients who have platinum-resistant disease. In a phase II GOG study, weekly paclitaxel (80 mg/m^2) in the platinum- and paclitaxel-resistant population demonstrated a response rate of more than 20% and was found to be well tolerated. The importance of dose intensity in this setting is being explored in randomized studies throughout the world. The results will have important implications for paclitaxel dose in combination regimens, which are being evaluated both as first- and second-line therapy.

Along with platinum and paclitaxel, three chemotherapeutic agents have received the most interest in evaluating their role in the treatment of recurrent ovarian cancer: gemcitabine, pegylated liposomal doxorubicin, and topotecan. In addition to activity in recurrent disease, these agents offer the strategy of extending the platinum-free interval. Discussed in detail later, these agents have been widely incorporated into clinical trials,

in both primary (first-line), second-line recurrent, and third-line recurrent disease settings.

The GOG reported a positive phase II trial with a 5-day topotecan (1.5 mg/m^2) regimen (every 21 days), demonstrating a 33% response rate and median response duration of 11.2 months. Even in patients with platinum-resistant disease response rates range from 13% to 17%. Fatigue, anemia, and thrombocytopenia were the prominent toxicities. A weekly regimen of topotecan, administering 3.5 to 4 mg/m^2 on days 1, 8, and 15 on a 28-day cycle has also been used, and data comparing the weekly with 5-day regimen have shown improved efficacy with the 5-day regimen. In a phase II study, the use of 5-day topotecan (1.0 mg/m^2) with carboplatin (AUC, 5) in a platinum-sensitive group not only demonstrated a response rate of 40% but also was well tolerated. Thus, topotecan as part of a combination regimen seems to be a promising therapeutic choice for patients with recurrent ovarian cancer.

Gordon and coinvestigators reported a phase III trial in patients with refractory ovarian cancer comparing pegylated liposomal doxorubicin (Doxil), 50 mg/m^2 every 28 days, with topotecan, 1.5 mg/m^2 per day for 5 days every 21 days. In the platinum-refractory patient group, there was no survival difference. In the platinum-sensitive group, there was a 30% decrease in the risk of death for the pegylated liposomal doxorubicin-treated patients (median survival, 108 weeks vs. 70 weeks). Pegylated liposomal doxorubicin has demonstrated response rates up to 26% in the platinum-resistant group, making it an attractive option in this patient population. Recently, pegylated liposomal doxorubicin was studied as combination therapy in recurrent disease. In the CALYPSO (Caelyx in Platinum Sensitive Ovarian patients) trial, carboplatin in combination with either pegylated liposomal doxorubicin or paclitaxel was evaluated in a randomized trial for patients with relapsed, platinum-sensitive disease. PFS was 11.3 months for the pegylated liposomal doxorubicin arm compared with 9.4 months for the paclitaxel arm, resulting in an 18% reduction in risk of recurrence. Although generally well tolerated, dose-limiting toxicity includes palmar–plantar erythrodysesthesia.

Although gemcitabine has demonstrated modest activity as a single agent in the refractory setting, in combination with a platinum, most commonly cisplatin, the activity appears substantial. Nagourney and colleagues reported results of treatment with cisplatin (30 mg/m^2) plus gemcitabine (600–750 mg/m^2) on days 1 and 8 in a 21-day cycle. They reported 26% complete responses and 44% partial responses (70% overall response rate) with a median time to progression, for responders, of 7.9 months (range, 2.1–13.2 months). Neutropenia, anemia, thrombocytopenia, nausea and vomiting, and peripheral neuropathy were problematic toxicities. Additional studies suggest that gemcitabine may reverse cisplatin resistance and may be a useful combination for both platinum-sensitive and platinum-resistant groups.

Bevacizumab for the treatment of ovarian cancer in the recurrent setting has also demonstrated activity. In 62 patients, both platinum-sensitive and platinum-resistant patients, single-agent bevacizumab (15 mg/kg every 21 days) demonstrated a response rate of 21%. In a predominantly platinum-resistant group, bevacizumab (15 mg/kg every 21 days) resulted in a 16% overall response rate. Although GI perforation rates ranged from 0% to 11% in these studies, both cohorts were composed of patients who had received multiple chemotherapy regimens before the use of bevacizumab. Bevacizumab has also been studied in combination with other agents. The addition of bevacizumab to cytotoxic agents has also been shown to have activity in this setting. Response rates range from 15% to 43% and include combinations with gemcitabine, taxanes, cyclophosphamide, liposomal doxorubicin, 5-fluorouracil, and erlotinib. In platinum-sensitive disease, bevacizumab plus chemotherapy was evaluated in the multicenter OCEANS (Ovarian Cancer Study Comparing Efficacy and Safety of Chemotherapy and Anti-Angiogenic Therapy In Platinum-Sensitive Recurrent Disease) trial, reported by Aghajanian and colleagues. Patients were randomized to carboplatin–gemcitabine, with or without bevacizumab, and followed until progression. Response rate (79% vs. 57%) and PFS (12 vs. 8 months) were significantly improved with bevacizumab, although the later reported OS (not the primary endpoint) showed no difference. In platinum-resistant disease, Pujade-Lauraine and colleagues reported similar findings form the AURELIA (Avastin Use in Platinum-Resistant Epithelial Ovarian Cancer) trial. Patients with platinum-resistant disease were randomized to investigator's choice chemotherapy without or without bevacizumab, and the study powered to PFS as the primary endpoint. Significant improvements in response rate and PFS were seen in the patients receiving bevacizumab; the OS trend was not significant.

Intraperitoneal therapy (discussed elsewhere in this chapter) has been used with several antineoplastic agents as second-line therapy in ovarian cancer. Activity is essentially limited to patients with small-volume residual disease (<0.5 cm in maximal diameter) when the second-line therapy program is initiated. In the absence of a randomized phase III trial, the ultimate impact of these surgically documented responses on survival is difficult to evaluate. Although rare, long-term disease-free survival in patients with small-volume refractory disease has been reported after IP therapy.

There is limited evidence of sustained benefit from second-line therapy in patients with ovarian cancer. Overall, only modest response rates with short durations of response have been reported. In addition, there has been a lack of consistency in these studies with regard to key definitions, such as platinum sensitivity compared with platinum resistance. Future second-line trials should clearly define their patients in these two categories. It may also be necessary to discuss paclitaxel-sensitive versus paclitaxel-resistant lesions in the future. Platinum-sensitive patients are appropriate for pilot studies of platinum combinations incorporating different cytotoxic mechanisms of action and dose schedule investigations. Patients with platinum resistance are good candidates for novel investigational approaches and studies of drug resistance. Various other agents, such as hexamethylmelamine, 5-fluorouracil, etoposide, and others, rarely induce modest short-duration responses.

Radiation to the abdomen and pelvis has been used in select second-line situations. Whole-abdomen irradiation with a pelvic boost has been given in patients with minimal disease at

second-look surgical reassessment for ovarian carcinoma. With limited follow-up, some studies report as many as 30% of such patients have remained in remission. However, our experience is that with longer follow-up periods, more than 90% of patients will have recurrence, even in this optimal group.

Targeted Therapy

The area with the most rapid development in regard to ovarian cancer treatment is in the area of targeted therapeutics. Secondary to the toxicities and emerging resistance, alternatives or additions to chemotherapy are coming to the forefront. This is best demonstrated with bevacizumab, described earlier, which has been studied in the primary and recurrent setting and in maintenance therapy. Multiple other agents are now under investigation.

Tyrosine kinase inhibitors, which target vascular endothelial growth factor receptors (VEGFR), inhibit an important target in ovarian cancer. The most studied agent in this group, cediranib, has demonstrated response rates of 41% and 29% in platinum-sensitive and platinum-resistant groups, respectively. As a result of this activity, cediranib is being further evaluated in the phase III randomized trial ICON-6 in conjunction with carboplatin and paclitaxel in the primary setting.

Poly(ADP-ribose) polymerase inhibitors have recently garnered interest in ovarian cancer treatment. PARP is an enzyme responsible for the repair of DNA single-strand breaks. Inhibition of the PARP repair mechanism is particularly effective in tumors in which homologous double-stranded repair mechanism is also deficient, such as in patients with *BRCA* mutations. Olaparib, a PARP-1 inhibitor, was not only well tolerated but demonstrated good response rates ranging in patients with a known *BRCA* mutation. Ledermann and colleagues reported the results from their randomized phase 2 "Study 19" evaluating olaparib maintenance therapy versus placebo in platinum-sensitive recurrent ovarian cancer patients. Patients enrolled had received a median of three prior therapies, and approximately 22% of patients in each arm had a germline *BRCA* mutation. Median PFS was significantly improved with olaparib maintenance (8.4 vs. 4.8 months), but an interim analysis showing no improvement in OS likely prevented US Food and Drug Administration (FDA) approval for this indication. Recently, Domchek and colleagues reported a 34% response rate for olaparib oral monotherapy in *BRCA1* or *BRCA2* mutation carriers with recurrent ovarian cancer and three or more lines of therapy, including a 30% response in platinum-resistant tumors, leading to FDA approval for this indication. Studies have shown that many sporadic epithelial cancers may be *BRCA* deficient as a result of inactivation of a *BRCA* allele despite intact BRCA gene status. Thus, the use of PARP inhibitors, alone or in combination, is now being studied in epithelial ovarian cancer irrespective of *BRCA* status.

Inhibition of the epidermal growth factor receptor (EGFR), which affects cell proliferation, angiogenesis, and apoptosis, has emerged as a possible therapeutic option for patients with ovarian cancer. Agents in this category may inhibit EGFR through tyrosine kinase inhibition (erlotinib, gefitinib, CI-1033) and monoclonal antibodies (trastuzumab, cetuximab). Patients with refractory, recurrent ovarian cancer have demonstrated modest activity to EGFR inhibitors. Currently studies are evaluating the role of EGFR in the recurrent and maintenance setting, both as a single agent and in combination with other cytotoxic or biologic agents. A multitude of other molecular agents have also been evaluated in epithelial ovarian cancer. VEGF-trap, which inhibits VEGF and platelet growth factors, targets angiogenesis and has shown some activity in the platinum-resistant group and are under further investigation. The mTOR (mammalian target of rapamycin) inhibitors (temsirolimus, everolimus, deforolimus) target the PI3K/AKT/mTOR pathway and have recently been studied in phase II evaluations. The use of this agent in combination with other biologic and cytotoxic therapy is currently underway. Other agents being further evaluated include platelet-derived growth factor inhibitors, multikinase inhibitors (sorafenib, dasatinib), and folate receptor inhibitors.

The advent of molecular targets has been promising to date; however, it is still premature in understanding its true role. As information regarding the genetics of cancer and activity at the cellular level increases, this class of agents will have more applicability in cancer care. However, improving our understanding into these agents, providing selective use in specific populations, and maximizing efficiency in conjunction with cytotoxic therapies will be of continued importance.

Surgery for Recurrent Disease

Because recurrence is the rule than the exception for women with ovarian cancer, the role of surgery for recurrent disease both generally and selectively has been evaluated. The philosophy of secondary cytoreductive surgery is sometimes similar to that of primary cytoreductive surgery: Reduce disease burden to enhance the effectiveness of chemotherapy. However, surgery in the recurrent setting is also used selectively when it can make the most impact: a single remaining tumor mass resistant to multiple prior lines of chemotherapy or a single area of recurrence after years of treatment-free interval. To date, there are no prospective trials comparing secondary cytoreductive surgery with chemotherapy. Although several retrospective studies have shown benefit in specific groups of patients, the role of secondary cytoreductive surgery may be limited to select patients. Factors associated with a perceived survival benefit include patients with a good performance status; a longer disease-free interval, typically more than 12 months; and patients with disease localized to one or two sites. The most significant contributor to OS is the ability to resect all macroscopic disease at the time of recurrent disease. This has been demonstrated in a European multi-institutional review (Descriptive Evaluation of preoperative Selection KriTeria for OPerability in recurrent OVARian cancer [DESKTOP OVAR]) that showed that only patients who were able to undergo complete resection of recurrent disease benefit from surgical intervention. This finding was also reported in a meta-analysis, confirming that the only factor associated with survival benefit was complete resection of disease. Presently, the role of cytoreductive surgery in the recurrent setting is being evaluated in two prospective studies, DESKTOP II and a GOG study (protocol 213). Ideally, these

studies will help elucidate the ideal patients and the true role of surgery for patients with recurrent ovarian cancer. Until the results are available, therapy should be individualized.

When the focus of care shifts from a curative intent to quality of life, surgery may play a role in the relief of symptoms. Although the risks and morbidity from invasive procedures must be considered, several situations during the terminal stages of the disease may be amenable by surgical intervention. Most commonly, this pertains to patients who develop an intestinal obstruction. Surgery may afford relief of symptoms by resecting the area followed by reanastomosis or performing an intestinal bypass. To decrease morbidity, patients with a distal obstruction may be excellent candidates for a diverting ostomy or intraluminal stent placement. For patients with a more proximal obstruction, endoscopic or percutaneous placement of a gastrostomy tube may provide symptomatic relief. Although occurring less frequently than GI blockage, malignant urologic obstructions may also occur with recurrent disease. To minimize morbidity, and depending on the location of the obstruction, treatment options include the placement of ureteral stents, percutaneous nephrostomy tubes, or a suprapubic catheter.

Patients with refractory disease may also develop ascites that significantly compromise their quality of life. This may result in a multitude of symptoms, including abdominal pain or discomfort and respiratory embarrassment. Unfortunately, some patients develop ascites that cannot be controlled by systemic chemotherapy, and they may require periodic aspiration. Although a palliative paracentesis may be adequate, patients with refractory, symptomatic ascites may benefit from the use of a long-term catheter. Patients may be found to have pleural effusions during the time of primary or recurrent disease diagnosis, which may present with symptoms of respiratory compromise. This may be a direct result of pleural disease or indirect result secondary to abdominal ascites. Similar techniques for the management of ascites can be used for pleural effusions. Thoracentesis (Fig. 11.24), which may be used for immediate relief of symptoms, is often used. When patients develop refractory reaccumulations, they may require insertion of an indwelling pleural catheter or chest tube drainage followed by pleurodesis. Pleurodesis can be performed with the instillation of bleomycin (60–120 mg) or talc into the pleural cavity and offers the highest probability of successful palliation.

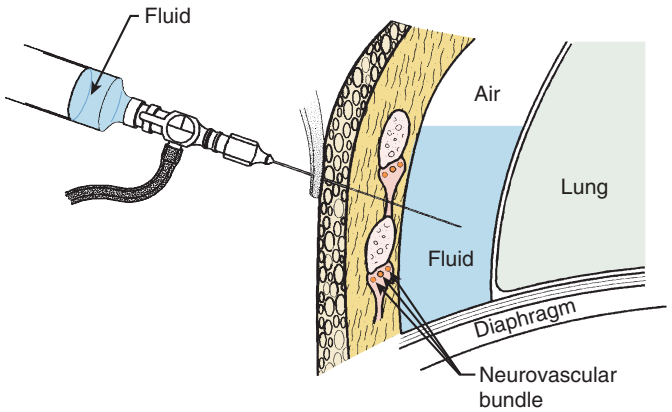

FIGURE 11.24 Thoracentesis.

REHABILITATION

The nature of ovarian cancer is such that the major vital organs (lungs, heart, liver, and kidneys) remain unaffected. The disease itself and its therapy appear primarily to attack the GI tract. Indeed, the terminal event for most patients who succumb to this disease is electrolyte imbalance caused by prolonged GI obstruction, malnutrition, and significant protein and electrolyte loss from repeated paracentesis and thoracentesis. It is necessary to support these patients with various forms of alimentation during therapy to sustain them sufficiently to tolerate the somewhat vigorous therapy often prescribed. The placement of semipermanent Silastic IV catheters (eg, Hickman, Broviac, or Groshong) greatly facilitates the ability to support these patients (Fig. 11.25). Some clinicians prefer to gain IV access by means of a device (Port-A-Cath) implanted in the subcutaneous tissue. Many centers can arrange IV alimentation at home for patients who are unable to take sufficient nourishment by mouth. Home pharmacy services are available in many areas, and IV medications, including analgesics, can be administered at home by pump infusion devices through these semipermanent IV catheters.

In general, the most discouraging aspect in the management of patients with ovarian cancer is the apathy of many physicians. In truth, these diseases are discouraging, but a determined attitude is medically sound and reassuring to the patient. Significant numbers of patients referred to oncologic centers as "unresectable" not only have had their tumor debulked but also have responded nicely to postoperative therapy. Still other patients have survived complicated combinations of multiple surgical and adjuvant therapies. A positive approach to the disease, which restores hope in the patient with this devastating illness, is justified on that basis alone.

CONCLUSIONS ON MANAGEMENT

Although adenocarcinoma of the ovary remains one of the solid tumors most sensitive to chemotherapeutic regimens, the mortality rate from this disease remains high. Progress over the past 30 years has been modest, and although there has been some improvement in survival, there is significant opportunity to do better (Table 11.25). There appears, however, to be great promise with newer developments in the management of this disease.

When treating a patient with ovarian cancer, the following general principles should be kept in mind. An optimal surgical procedure should be carried out whenever possible. This is defined as the removal of all visible tumor with the intent to leave no macroscopic residual disease. It is not possible to advocate any one operation for all patients, and the clinician must make a judgment at the time of surgery. Unquestionably, patients with small residual tumor volumes have a better prognosis with any postoperative therapy. Even when optimal debulking is not possible, bilateral salpingo-oophorectomy, total

abdominal hysterectomy, and omentectomy can afford temporary improvement of symptoms for the patient. Second, the use of a chemotherapeutic regimen, containing platinum and taxane, plays an integral role in the care of patients with advanced disease. Recent advances in the route of administration (IP chemotherapy), use of dose-dense paclitaxel, and addition of bevacizumab are encouraging and further improvements need to be verified with ongoing clinical trials. Physicians should offer patients treatment on clinical trials whenever available.

Advances in genetics have helped increase our understanding regarding the natural history of ovarian cancer. Tumor suppressor genes such as *BRCA1*, *BRCA2*, and p53 and oncogenes including K-ras and erb-b2 are known to be altered in a fair number ovarian cancer cases. Developing specific targets

for known genetic or cellular functions within tumors has become a popular area of interest and shows potential in early studies.

The role of continued surveillance for recurrent disease continues to evolve; thus, it is important to counsel patients on symptoms of recurrence, thus providing early intervention. When a recurrence is detected, multimodality treatment options, including surgery and chemotherapy, are available. Although, to date, therapies for recurrent disease have been short-lived with modest efficacy, promising new combinations of chemotherapy and biologic agents are being studied in hopes of improving outcomes.

CURRENT AREAS OF RESEARCH

Over the past several decades, the majority of advances in ovarian cancer treatment have resulted from phase III trial outcomes. These results include the combination of more effective chemotherapeutic agents, more effective route of administration, better understanding of drug resistance, and the addition of biologic response modifiers as a new modality, each strategy improving the outcome for this devastating group of malignant neoplasms.

Chemotherapy has proved curative in some types of advanced cancers and is useful as an adjunct to surgery and radiotherapy in many others. That 90% of the cures with chemotherapy occur in 10% of the tumors that affect humans is a perplexing biologic problem that appears to be related to the greater propensity of some tissue to develop specific and permanent resistance to chemotherapy of a broad nature. A discussion of tumor cell resistance is beyond the scope of this section; however, understanding and overcoming the mechanisms by which tumor resistance occurs will be necessary to improve treatment outcomes.

Although much has been learned about ovarian cancer and treatment modalities, the surface has just been scratched. With the explosion of new techniques to explore the genetic, immunologic, and molecular biology of this disease, many avenues for research are open and need exploration. The establishment of the NRG tumor and serum bank will continue to allow further investigation into these and many other aspects of molecular biology.

In addition to biologic targets, there are data supporting experimental therapies, such as gene therapy. Although gene therapy in its infancy, if the genetic defect is identified, the gene could be replaced. Many types of gene therapy are possible: immunogene, antioncogene, and tumor suppressor gene; anti–growth factor and cytokine gene drug resistance; and genes that are associated with apoptosis. All of these may be attractive, and preliminary studies have been started. Because of the emergence of chemotherapy resistance, new agents that have non–cross-resistance properties and novel approaches to modulations or targeting are sought. Many new drugs are in the pipeline to be evaluated in phase II studies.

More recently, receiving much deserved attention is a focus on patient's quality of life. Reliable and valid tools for measuring quality of life on multiple facets have been developed and are being incorporated into study protocols by the NRG and other cooperative group studies. These areas of study include symptoms related to cancer and surgical intervention, toxicities associated with therapy, and factors related to psychological stress. Other topics of interest include measurements of pain management, sexual function, and social support. This area is a challenge, and continuing studies will improve our ability to deliver optimal comprehensive care to our patients.

OUTLINE

Germ Cell Tumors
- Classification
- Clinical Profile
- Staging
- Treatment Options
- Recurrences in Germ Cell Cancer
- Treatment Toxicity
- Dysgerminoma
- Endodermal Sinus Tumor (Yolk Sac Tumor)
- Embryonal Carcinoma
- Polyembryoma
- Choriocarcinoma
- Mixed Germ Cell Tumors
- Teratoma

Tumors of Germ Cell and Sex Cord Derivation
- Gonadoblastoma
- Mixed Germ Cell–sex Cord Stromal Tumor

Tumors Derived From Special Gonadal Stroma
- Classification, Clinical Profile, and Staging
- Treatment
- Granulosa–stromal Cell Tumors
- Thecomas
- Fibromas and Sclerosing Stromal Cell Tumors
- Sertoli-Leydig Cell Tumors
- Sex Cord Tumor With Annular Tubules
- Gynandroblastoma
- Steroid Cell Neoplasms

Tumors Derived From Nonspecific Mesenchyme

Malignant Lymphoma

Metastatic Tumors to the Ovary

Malignant Ovarian Tumors in Children

KEY POINTS

1. Germ cell tumors are classified according to degree of differentiation. Two classes exist: undifferentiated germ cell tumors, which include dysgerminoma and gonadoblastomas, and differentiated tumors, which include all other germ cell tumors.
2. Most germ cell tumors are found in the second and third decades of life.
3. Surgery is the preferred initial approach in the treatment of germ cell cancers.
4. Recurrences usually occur within 2 years of initial diagnosis.
5. Granulosa cell tumors are typically ovarian cancers of low grade.

GERM CELL TUMORS

Classification

Ovarian germ cell tumors consist of several histologically different tumor types that arise from primordial germ cells of embryonic gonad and sex-stromal derivatives. This class of ovarian tumors is rare, accounting for 1% to 2% of all ovarian malignancies. The concept of germ cell tumors as a specific group of gonadal neoplasms evolved over the past 5 decades and has become generally accepted (Fig. 12.1). This theory is based primarily on the common histogenesis of these neoplasms and the frequent presence of histologically different tumor elements within the same mass. Additionally, histologically similar neoplasms occur in extragonadal locations along the line of migration of the primitive germ cells from the wall of the yolk sac to the gonadal ridge, and there is remarkable homology between the various tumor types in men and women. In no other group of gonadal neoplasms has this homology been better illustrated. An example of this is the striking similarity between the testicular seminoma and its ovarian counterpart, the dysgerminoma. These were the first neoplasms to become accepted as originating from germ cells. A number of classifications of germ cell neoplasms of the ovary have been proposed over the past few decades. A modification of the classifications originally described by the pathologist Gunner Teilum in the 1950s is shown in Table 12.1. This schema is similar to that proposed by the World Health Organization (WHO), which divides the germ cell tumors into several groups, including neoplasms composed of germ cells and "sex" stroma derivatives.

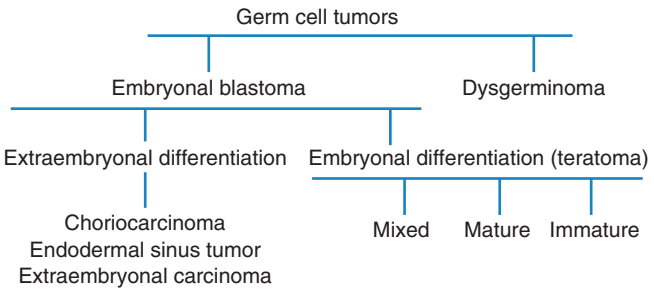

FIGURE 12.1 Classification schema of germ cell tumors of the ovary.

TABLE 12.1 Classification of Germ Cell Neoplasms of the Ovary

GERM CELL TUMORS
Dysgerminoma
Endodermal sinus tumor
Embryonal carcinoma
Polyembryoma
Choriocarcinomas
Mixed malignant germ cell tumor
Teratoma
• Immature (solid, cystic, or both)
• Mature
• Solid
• Cystic
• Mature cystic teratoma (dermoid cyst)
• Mature cystic teratoma (dermoid cyst) with malignant transformation
Monodermal or highly specialized
• Struma ovarii
• Carcinoid
• Neuroectodermal
• Others
TUMORS COMPOSED OF GERM CELLS AND SEX CORD–STROMAL DERIVATIVE
Gonadoblastoma
Mixed germ cell–sex cord stromal tumor

TABLE 12.2 Relative Frequency of Ovarian Neoplasms

Type	Frequency (%)
Coelomic epithelium	50–70
Germ cell	15–20
Specialized gonadal stroma	5–10
Nonspecific mesenchyme	5–10
Metastatic tumor	5–10

Germ cell tumors are classified according to the degree of differentiation. Two classes exist:

1. **Undifferentiated germ cell tumors, which include dysgerminoma and gonadoblastoma**
2. **Differentiated tumors, which include all other germ cell tumors.**

Differentiated tumors are further classified based on whether the tumor differentiates histologically into embryonic or extraembryonic structures. Extraembryonic tumors include choriocarcinoma and endodermal sinus tumors. Embryonal tumors include embryonal carcinoma, polyembryoma, and teratomas, the latter of which may be mature, immature, monodermal, or highly specialized. Dysgerminomas, immature teratoma, yolk sac tumors, and mixed tumors make up more than 90% of all malignant germ cell tumors. Finally, it is important to recognize that germ cell tumors clinically behave in part on whether they are histologically pure, consisting of only one cell type, or mixed. Tumors such as embryonal carcinoma, choriocarcinoma, and polyembryoma rarely exist in pure form and have a poorer prognosis. The clinical behavior of germ cell tumors typically conforms to the most aggressive histologic subtype present in mixed tumors. Treatment, therefore, should be predicated on this knowledge.

Clinical Profile

Germ cell tumors present at all stages of disease and are typically curable. **Germ cell tumors represent 20% of all ovarian** (Table 12.2) **neoplasms of which 97% are benign and only 3% are malignant.** There are no known risk factors predisposing women to germ cell tumors, **although most tumors occur in young women.** A Surveillance, Epidemiology and End Results (SEER) database review of malignant germ cell tumors from 1973 to 2002 revealed the highest incidence of disease in the 15- to 19-year-old age group. Because these tumors occur predominantly in reproductive age groups, it is not surprising that they are encountered commonly during pregnancy. **Dysgerminomas and teratomas are the most common germ cell tumors diagnosed during pregnancy or after delivery.** Surgical evaluation and treatment, including chemotherapy if necessary, can be safely performed in the second and third trimesters. Although rare reports of familial clustering of ovarian and testicular germ cell tumors have been described in the literature, there is no known syndrome or genetic abnormality conferring susceptibility to germ cell malignancies.

With respect to race, Asian and black women are affected by malignant germ cell tumors three times as frequently as white women and often have a worse prognosis. For example, SEER database results from 1988 to 2004 revealed improved survival in white women compared with black women, a finding attributable to a more favorable stage distribution and histology in whites. In this study, white patients were twice as likely as black patients to have dysgerminomas and one and a half times less likely to have immature teratomas. Advanced-stage tumors were also more common in black patients. Nevertheless, on multivariate analysis, race was not an independent predictor for survival after controlling for histology and stage of disease. Similarly, Smith et al. evaluated the incidence and survival rates of women with malignant germ cell tumors over a 30-year period from 1973 to 2002. In this study, malignant germ cell tumors were noted more often among Asians and Pacific Islanders and Hispanics compared with non-Hispanics. When women

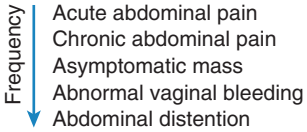

FIGURE 12.2 Initial symptoms in young patients with malignant germ cell tumors.

were stratified by race and ethnicity, nonwhite women had a higher incidence of germ cell tumors than whites. The reasons for these racial differences in prevalence and outcomes are unknown.

According to SEER data, germ cell tumors are associated with excellent 5 and 10-year survival rates in excess of 91%. Survival rates are lower for older women and those with advanced-stage disease. Dysgerminomas have the most favorable survival rates among the histologic subtypes. A reduction in the number of women with distant and unstaged disease has been noted throughout the years, which suggests that these tumors are being diagnosed earlier.

Most of these lesions are found in the second and third decades of life and are frequently diagnosed by finding a palpable abdominal mass, often associated with pain (Fig. 12.2). Except for benign cystic teratoma, ovarian germ cell tumors are usually unilateral, rapidly enlarging abdominal masses that often cause considerable abdominal pain. At times, the pain is exacerbated by rupture or torsion of the neoplasm. One of the classic initial signs of a dysgerminoma, for example, is hemoperitoneum from capsular rupture of the tumor as it rapidly enlarges, although this may occur with any germ cell tumor. Asymptomatic abdominal distention, fever, or vaginal bleeding is occasionally the presenting complaint. Isosexual precocious puberty has also been described, occurring in young patients whose tumors express human chorionic gonadotropin (hCG).

The tumors typically present at an early stage and spread by direct extension, seeding abdominal and pelvic peritoneal surfaces, and by hematogenous and lymphatic spread. Hematogenous spread to the lungs and liver parenchyma is more common in germ cell malignancies than in epithelial ovarian cancer, as is lymphatic spread. Many germ cell tumors produce serum markers that are specific and sensitive enough to be used clinically in following disease progression. A detailed discussion of individual tumor markers is presented in the sections on specific tumor types.

Staging

Germ cell tumors should be staged surgically in the same manner as epithelial ovarian cancers and in accordance with the guidelines of the International Federation of Gynecologists and Obstetrician (FIGO). Because germ cell tumors occur more frequently in young patients, extirpation of the disease involves decisions concerning childbearing and probabilities of recurrence. Adjuvant chemotherapy is the standard of care for women with germ cell malignancies except for those with stage Ia dysgerminoma or stage Ia grade I immature teratoma. Comprehensive staging therefore allows patients to be appropriately risk stratified and selected for surveillance versus adjuvant therapy. **The recommended staging procedures for germ cell tumors consists of a laparotomy; a sampling of ascitic fluid if present; cell washings; a careful exploration of the abdomen and pelvic cavity; omentectomy; and random biopsies of the paracolic gutters, pelvic sidewalls, cul de sac, vesicouterine reflection, and diaphragm. If extensive disease is present in the abdominal cavity, omentectomy and cytoreduction to optimal residual disease should be performed if possible. Pelvic and paraaortic lymph node sampling should be performed, but a complete lymphadenectomy is not necessary.** Bulky lymph nodes, if present, should be removed. Based on an analysis of SEER data, the prevalence of lymph node metastasis in germ cell malignancies is 18%. Dysgerminomas have the highest prevalence of nodal disease at 28% followed by mixed germ cell tumors at 16% and immature teratomas at 8%. After controlling for age, race, stage, and histology, **positive lymph nodes remained an independent predictor of poor survival on multivariate analysis.**

Despite the prognostic significance of positive lymph nodes and the obvious benefits of guiding adjuvant therapy, comprehensive surgical staging is frequently not performed. In a paper evaluating compliance with surgical staging guidelines, only three patients of 131 with germ cell malignancies had complete staging performed. Failure to perform recommended lymph node sampling was the most common reason for noncompliance (97%) followed by no omentectomy (36%) and no cytologic washings (21%). The decision to proceed with another operation for patients who have not been staged at their initial surgical procedure is controversial because patients with recurrences can often be salvaged with chemotherapy. According to a study from the Centre Léon Bérard in Lyon and the Institut Curie in Paris, the risk of recurrence was significantly higher (hazards ratio [HR], 4.5; 95% confidence interval [CI], 1.5–13.3) in unstaged patients who clinically appeared to have stage I disease and were observed after surgery versus another cohort treated with adjuvant chemotherapy. Among the unstaged patients, relapses occurred in five of 13 patients who underwent surveillance but none of the seven patients who received adjuvant treatment recurred. Data from the Pediatric Oncology Intergroup suggest that deviations from standard staging requirements do not adversely affect survival. In this study, the recommended surgical guidelines were seldom followed in this pediatric population, and the 6-year survival rate was 93.3% in girls with stage IV disease.

Laparoscopy is less common in patients with ovarian germ cell tumors given the larger size of these tumors, the solid components they contain, and the risk of tumor spillage and cyst rupture. Shim et al. evaluated laparoscopic management of early-stage malignant nonepithelial ovarian tumors to determine the feasibility and safety of a minimally invasive approach. This study included 20 patients with sex cord stromal tumors (SCSTs) and eight with malignant germ cell tumors. The median primary tumor diameter was 10.4 cm, and laparoscopic pelvic and paraaortic lymph node dissection was performed in nine cases. Tumors were removed through a 10-mm port using an endoscopic specimen retrieval system to prevent tumor spillage. For a mass that did not fit in the retrieval system, hand-assisted

laparoscopic surgery was performed. All patients in this study had stage I disease. No intraoperative complications occurred. Five patients received adjuvant chemotherapy. The median follow-up period was 34.5 months during which time one patient recurred and was treated with chemotherapy. No patient died of the disease.

In patients with suspected early-stage disease, laparoscopy may represent a preferred surgical route and in several studies has been shown to be comparable with traditional open procedures. Prado et al. introduced guidelines to apply when considering a laparoscopic technique, such as careful case selection, adequately trained teams, use of an endobag for tumor removal, and minimizing tumor manipulation to decrease rupture of the mass. For advanced stage disease, it may not be feasible to attempt a laparoscopic procedure.

Treatment Options

Surgery is the preferred initial approach in patients with suspected germ cell tumors for both diagnostic and therapeutic intent. The extent of primary surgery is dictated by intraoperative findings and the reproductive desires of the patient. If childbearing has been completed, then a bilateral salpingo-oophorectomy and hysterectomy are performed in addition to a full staging procedure. However, if preservation of fertility is desired, then every attempt should be made to perform a unilateral salpingo-oophorectomy and staging while preserving the uterus and contralateral ovary. The safety of such an approach has been well established in the literature. **In select cases such as stage Ia dysgerminoma and stage Ia grade I immature teratoma, unilateral salpingo-oophorectomy is thought to be curative and is all that is required.** All other cases will likely require adjuvant therapy. In all cases of apparent unilateral disease confined to the ovary, the contralateral ovary should be carefully evaluated. Although **dysgerminoma is the only germ cell malignancy with a propensity for bilaterality (10%–20% of cases),** other histologic subtypes occasionally involve both ovaries. The contralateral ovary, if abnormal, should be biopsied or a cystectomy performed. If the frozen section confirms a diagnosis of malignancy, then the ovary should be removed. Frozen section is highly accurate for nonteratomatous sex cord stromal and germ cell tumors. If the contralateral ovary appears normal, then it should be left alone. Some clinicians have advocated performing a wedge biopsy of a normal-appearing contralateral ovary in cases of dysgerminoma to detect subclinical or microscopic disease. We recommend avoiding wedge biopsy of a normal-appearing ovary because of the potential for surgical complications such as hemorrhage or adhesion formation that may affect future fertility. Boran et al. evaluated pregnancy outcomes, menstrual function, and survival rates of patients after fertility sparing surgery for ovarian dysgerminomas. Twenty-three patients met inclusion criteria and underwent conservative surgical management with a median follow up time of 71 months. Regular menstruation after treatment resumed in 82% of the patients, and three primiparous patients had singleton live births after treatment.

The excellent response of germ cell malignancies to adjuvant chemotherapy has allowed a tailored approach to the surgical management of this disease in women desiring fertility preservation. Although **unilateral salpingo-oophorectomy should be considered the standard procedure** in such cases, recently, some clinicians have advocated ovarian cystectomy in select cases of immature teratoma. Beiner and colleagues reviewed eight cases of immature teratoma treated with ovarian cystectomy, including three with grade I, four with grade II, and one with grade III. Five of the eight patients received postoperative adjuvant chemotherapy. There were no recurrences in 4.7 years of follow-up, and three patients delivered a total of seven babies. The authors concluded that ovarian cystectomy with adjuvant chemotherapy appeared to be satisfactory therapy for early-stage immature teratoma if close follow-up was available, but more studies were needed to evaluate cystectomy alone as a surgical management option. This management strategy should be approached with caution, especially for other histologic germ cell subtypes, which may not share the same prognosis as early-stage immature teratoma.

Patients with bulky disease in the abdomen, pelvis, and retroperitoneum should undergo surgical cytoreduction to optimal residual disease. The literature to support this recommendation comes, primarily, from small retrospective studies. In a Gynecologic Oncology Group (GOG) study by Slayton and colleagues, patients with completely resected disease failed subsequent VAC (vincristine, dactinomycin, and cyclophosphamide) chemotherapy in 28% of the cases compared with 68% of cases with incomplete resection. In the same study, 82% of patients with bulky residual disease failed chemotherapy compared with 55% with minimal residual disease. Subsequently, the GOG published results showing that patients with clinically nonmeasurable disease after surgery treated with PVB (cisplatin, vinblastine, and bleomycin) remained progression free in 65% of cases compared with 34% of patients with measurable disease. Patients with optimal cytoreduction did better than those with unresectable bulky disease. This study also helped establish the efficacy of cisplatin-based chemotherapy for germ cell tumors. Finally, Williams and colleagues showed that patients with completely resected stage II or III disease treated with cisplatin, etoposide, and bleomycin had similar tumor-free recurrence rates as those with disease limited to the ovary. These studies provide the bulk of evidence to support cytoreductive surgery in germ cell cancers.

In patients with bulky metastatic disease, a normal-appearing uterus and contralateral ovary may be preserved, allowing for future fertility options if desired. Tangir and colleagues reviewed 64 patients with germ cell malignancies treated with fertility-preserving surgery. Ten patients had stage III disease (five IIIc, two IIIb, and three IIIa), and eight of the 10 women successfully conceived. Survival data were not included in the analysis. Zanetta and colleagues evaluated 138 women with germ cell malignancies of all stages treated with fertility-sparing surgery, 81 of whom received adjuvant chemotherapy. Survival was comparable between patients treated with radical surgery and fertility-sparing surgery after a mean follow-up period of 67 months. Similarly, Low and

colleagues retrospectively reviewed 74 patients with germ cell malignancies of all cell types treated with conservative surgery. Forty-seven patients were treated with adjuvant chemotherapy. Fifteen patients had stage III to IV disease. After 52 months of follow-up, patients with advanced disease had a 94% survival rate, comparable to historical survival rates.

In summary, patients with germ cell malignancies should undergo operative evaluation, staging, and cytoreduction. If future fertility is not desired, surgical treatment should be identical to that for epithelial ovarian cancers. If preservation of fertility is desired, conservation of the uterus and contralateral ovary and maximal cytoreduction should be performed if possible. Despite the success of surgical management, surgeons should recognize the excellent response of these tumors to chemotherapy when aggressive and potentially morbid resections of metastatic and retroperitoneal disease are considered.

Surveillance for Stage I Tumors

As previously noted, **historically, in the gynecologic oncology literature, only patients with stage Ia dysgerminoma or stage Ia grade I immature teratoma of the ovary have been treated conservatively without adjuvant chemotherapy.** Although the recurrence rate approaches 20% for these patients, curative chemotherapy is administered after the recurrence. The recommendation for adjuvant treatment of any nondysgerminomatous histology is at odds with contemporary management practices of testicular germ cell tumors in which all patients with stage I disease are followed with observation only as standard practice. Rustin and Patterson published provocative data on their 37-year experience with a liberal surveillance policy for patients with stage I germ cell tumors of the ovary. In their first report, 24 patients with stage Ia germ cell tumor (nine dysgerminoma, nine pure immature teratoma, and six endodermal sinus tumor with or without immature teratoma) were followed without chemotherapy after surgery. The 5-year overall survival rate was 95%, and the disease-free survival rate was 68%. Eight patients had a recurrence or developed a second primary germ cell tumor and required chemotherapy. All but one who died of a pulmonary embolus were salvaged with chemotherapy. In their second publication, 37 patients with stage Ia germ cell malignancies were followed with surveillance only after surgery. Twenty-two percent of dysgerminoma and 36% of nondysgerminoma patients had a recurrence. All but one of these patients were successfully salvaged and cured with cisplatin-based chemotherapy at the time of recurrence. The overall disease-specific survival rate was 94%. It is unlikely that randomized trials addressing the safety of this approach in ovarian germ cell tumors will be performed. Given the potential serious toxicity associated with bleomycin, etoposide, and cisplatin (BEP) chemotherapy, managing patients with stage 1 germ cell tumors of the ovary with surveillance is a reasonable option if they have been adequately staged.

Second-Look Laparotomy

The role of the second-look laparotomy (SLL) in germ cell tumors of the ovary is unclear. Williams, when reporting the experience of the GOG, noted that in patients with complete tumor resection followed by BEP chemotherapy, 43 of 45 patients had no evidence of tumor or mature teratoma only at the time of the SLL, suggesting that there is no value of SLL in patients with completely resected disease. There were 72 patients with advanced, incompletely resected tumors who received chemotherapy followed by SLL. Of 48 patients who did not have teratomatous lesions in their primary surgery, 45 had no tumor. The three patients who had persistent tumors died of their disease despite aggressive therapy. **These authors think that the role of SLL is rarely, if ever, beneficial with an optimal cytoreduction followed by adequate chemotherapy.** However, patients in this series who had incompletely resected tumors at initial surgery and had teratomatous elements present may benefit from SLL. There were 24 patients who had teratomatous elements in the primary tumor and 16 who had progressive or bulky mature elements at SLL. Four patients had residual immature teratoma. Fourteen of the 16 with residual teratoma and six of the seven with bulky disease remained tumor free after secondary cytoreduction. Therefore, **the subgroup of patients that garner a survival benefit from SLL are those with incompletely resected disease with teratomatous elements at primary surgery.** The use of advanced imaging technologies such as positron emission tomography (PET) and computed tomography (CT) imaging may further reduce the impact of SLL. Preliminary studies suggest positive and negative predictive values of 100% and 96%, respectively, for PET imaging in seminomas looking for residual disease after chemotherapy, suggesting the possibility of similar results for germ cell malignancies.

Radiation Therapy

In the past, radiation therapy was traditionally used as adjuvant therapy for patients with germ cell malignancies and dysgerminomas in particular. Dysgerminomas are sensitive to radiation therapy with overall survival rates of between 70% and 100%. However, with the recent advances and success rates seen with combination chemotherapy, radiation therapy is rarely used today.

Chemotherapy

Current management strategies offer even patients with advanced malignancies an excellent chance at long-term control or cure. Because approximately 20% of patients with germ cell malignancies treated with surgery alone will be expected to recur, **patients, except those with stage Ia dysgerminoma and stage Ia grade I immature teratoma, should be treated with adjuvant chemotherapy to reduce the risk of recurrent disease.** VAC (vincristine, Adriamycin, and cyclophosphamide) was the first combination chemotherapy regimen widely used for treatment of these tumors. The GOG used VAC therapy to treat 76 patients with nondysgerminomatous germ cell tumors in the 1970s. Twenty-one percent of patients with stage I disease, 28% with completely resected disease, and 18% with immature teratomas failed VAC therapy, suggesting limited efficacy in these subgroups. However, 15 of 22 patients (68%) with advanced-stage or incompletely resected ovarian germ cell malignancies failed VAC therapy with a median progression-free

survival (PFS) time of 8 months. VAC was also ineffective for approximately 50% of patients with endodermal sinus tumors (ESTs). Although the GOG subsequently treated 48 patients with stages I to III completely resected ESTs with VAC for six to nine courses. Thirty-five (73%) patients were free of disease with a median follow-up time of 4 years. Gershenson and associates also reported 18 of 26 (69%) patients with pure EST were free of tumors after VAC therapy. As a result of the success of cisplatin-based regimens in the treatment of testicular germ cell tumors, VAC was gradually replaced by VBP (vinblastine, bleomycin, and cisplatin). This transition resulted in an improvement in overall survival rate to 71%; however, failures still occurred even in patients with good prognosis at the conclusion of primary surgery. The GOG evaluated VBP in patients with stage III and IV or recurrent malignant germ cell tumors, many with measurable disease after surgery. Ninety-seven patients were treated, and this therapy produced a substantial number (43%) of durable complete responses. The overall progression-free interval at 24 months was approximately 51%.

In a landmark trial in testicular cancer in the 1980s, Williams et al. demonstrated improved survival and less neurotoxicity when etoposide was substituted for vinblastine. Subsequent smaller trials in ovarian germ cell tumors also demonstrated encouraging results. Williams reported the GOG experience with 93 patients who were given BEP as adjuvant treatment for malignant germ cell cancers of the ovary. Forty-two were immature teratomas, 25 were ESTs, and 24 were mixed germ cell tumors. At the time of Williams' report, 91 of 93 patients had no evidence of disease after three courses of BEP with a median follow-up time of 39 months. One patient developed acute myelomonocytic leukemia 22 months after diagnosis, and a second patient developed lymphoma 69 months after treatment. Dimopoulos and colleagues reported a similar result from the Hellenic Cooperative Oncology Group. Forty patients with nondysgerminomatous tumors were treated with BEP or PVB. With a median follow-up time of 39 months, five patients developed progressive disease and died. Only one of the five who failed received BEP. Most recently, de La Motte Rouge and associates reported on 52 women with endodermal sinus tumor, 35 of whom had stage I or II tumors and 17 with stage III or IV disease. All were treated with BEP. After a median follow-up time of 68 months, the 5-year overall survival and disease-free survival rates were 94% and 90%, respectively. In this series, fertility-sparing surgery was performed in 41 cases, and pregnancy was achieved in 12 of 16 (75%) women who attempted to conceive, demonstrating that conservative surgery plus chemotherapy resulted in an appreciable number of successful pregnancies after treatment.

The combination of bleomycin, etoposide, and cisplatin (BEP) has become the standard of care for ovarian germ cell tumors (Table 12.3). Treatment with BEP leads to cure in most women with malignant ovarian germ cell tumors and is well-tolerated. The BEP regimen consists of cisplatin 20 mg/m^2 and etoposide 100 mg/m^2 daily for 5 days and bleomycin 20 U/m^2 on day 1. The recommended treatment consists of three to four courses of BEP administered every 3 weeks in either inpatient or outpatient settings. Williams did demonstrate efficacy of carboplatin and etoposide in patients with stage IB to III dysgerminoma; none of the patients recurred after a median follow-up time of 7.62 years. However, contemporary data from studies with men with germ cell tumors showed cisplatin was superior to carboplatin, and the trial was closed early. Several investigators have also tried to determine if a 3-day BEP regimen is equally effective and decreases the occurrence of febrile neutropenia. Dimopoulos and colleagues demonstrated the safety and efficacy of outpatient BEP administered over 3 days using a lower dose of bleomycin in women with dysgerminoma or early-stage, optimally debulked nondysgerminoma malignancies. Likewise, the Taiwanese GOG investigated a 3-day BEP regimen. In this study, a regimen consisting of bleomycin (15mg/m^2; daily total dose <25 mg) and etoposide (100 mg/m^2) were administered on days 1 through 3, and cisplatin (100 mg/m^2) was administered on day 1 at 21-day intervals for 3 to 4 cycles. Among 239 patients, 159 had early-stage disease, and 53 had advanced-stage disease. When compared with early-stage disease, those with advanced disease had an approximately 20-fold increased risk of disease recurrence and a 19.2-fold increased risk of disease related mortality. Among patients with early-stage, optimally debulked tumors, the 3-day regimen did not adversely affect survival.

Controversy exists regarding the efficacy of high-dose cisplatin used in combination with etoposide and bleomycin (HDBEP). Several adult trials in testicular germ cell malignancies have suggested improved efficacy compared with standard-dose cisplatin, but other studies have not seen this association. Cushing and colleagues, however, evaluated HDBEP in 74 pediatric patients with ovarian germ cell malignancies. The HDBEP regimen consisted of high-dose cisplatin at 200 mg/m^2/d for 5 days with etoposide, 100 mg/m^2/d for 5 days, and bleomycin, 15 mg/m^2/d for 1 day per cycle. This study found no difference in overall survival and increased toxicity with the HDBEP regimen. These studies have not been replicated in

TABLE 12.3 VAC, VBP, and BEP Regimens

Regimen	Dosage Schedule
VAC	
Vincristine, 1.5 mg/m^2	Weekly IV administration for 12 wk (maximum dose 2.5 mg)
Dactinomycin, 0.5 mg	5-day IV course every 4 wk
Cyclophosphamide,	5-day IV course every 4 wk 5–7 mg/kg
VBP	
Vinblastine, 12 mg/m^2	IV every 3 wk for four courses
Bleomycin, 20 U/m^2	IV q wk for seven courses (maximum dose eighth course given in 30 U/m^2) wk 10
Cisplatin, 20 mg/m^2	Daily × 5 every 3 wk for three or four courses
BEP	
Bleomycin, 20 U/m^2	IV q wk × 9 (maximum dose, 30 U)
Etoposide, 100 mg/m^2	IV days 1–5 q 3 wk × 3
Cisplatin, 20 mg/m^2	IV days 1–5 q 3 wk × 3

adults with ovarian germ cell malignancies. Currently, there is no established role of high-dose therapy in ovarian germ cell tumors.

Current management strategies for germ cell malignancies use chemotherapy in an adjuvant setting and to treat recurrent disease. Completely resected disease treated in this fashion can be cured nearly 100% of the time. Metastatic or incompletely resected tumors, however, may fare worse but still have excellent long-term survival rates and should be treated aggressively with adjuvant chemotherapy.

Neoadjuvant Chemotherapy

Because the majority of patients with malignant ovarian germ cell tumors are diagnosed when the disease is in an early stage, most patients are treated with surgery followed by chemotherapy. In patients with widespread disease, neoadjuvant chemotherapy (NACT) may be warranted. Few trials, and certainly no randomized trials, are available to answer the question regarding utility in these patients. However, Talukdar et al. evaluated the use of NACT using four cycles of BEP followed by fertility-sparing surgery in 23 patients with bulky disease compared with 43 patients who underwent primary debulking surgery with FIGO stage III or IV disease during the same time period. The WHO criteria for response to chemotherapy were used, with a complete response defined as the complete disappearance of all clinically detectable disease and normalization of tumor markers. A partial response was defined as 50% or greater reduction in tumor size and decrease in tumor markers. After NACT, 21 patients showed a response to treatment with 16 achieving a complete response and five with a partial response. Eighteen of 21 patients in the NACT group were then able to undergo fertility-sparing surgery, and those with residual disease were given an additional two cycles of BEP. Of the evaluable patients, 21 of 23 patients survived with a median disease-free survival period of 211 months. Lu et al. also investigated the role of neoadjuvant treatment in a group of 127 women with yolk sac tumors. After a median follow-up period of 46 months, there was no significant difference in recurrence rate between the NACT and primary debulking group. For women presenting with advanced, bulky disease, or medical comorbidities, initial studies suggest a role for NACT.

Recurrences in Germ Cell Cancer

Even in cases of advanced-stage disease, the majority of patients with germ cell malignancies are cured with a combination of primary surgery and adjuvant combination platinum-based chemotherapy. All patients with germ cell malignancies, especially those with early-stage disease treated with conservative therapy for curative intent, warrant close follow-up. Patients with early-stage dysgerminoma treated with salpingo-oophorectomy alone, for example, have disease recurrence in 15% to 25% of cases. Studies evaluating surveillance strategies for ovarian germ cell tumors and SCSTs have not been performed; therefore, recommendations are based on expert opinion. Patients should be seen every 2 to 4 months for the first 2 years after treatment at which point they can transition to annual visits. Surveillance should include a thorough physical examination and serum tumor markers. Radiologic scans should be reserved for elevations in tumor markers or concerning physical exam findings or symptoms, but for patients without elevated tumor markers, imaging within the first 2 years may be helpful.

Recurrences usually occur within 2 years of primary therapy and can be treated successfully. **The value of secondary cytoreductive procedures in patients with germ cell malignancies has not been studied.** Given the sensitivity of these malignancies to combination chemotherapy regimens, it is highly likely that metastatic lesions will respond to subsequent chemotherapy, limiting the value of secondary cytoreduction. Yet cytoreduction remains an effective management option for isolated lesions. The optimal chemotherapy regimen in recurrent disease is unknown. Historically, studies have included both patients with advanced primary disease and recurrent disease in the same trial. The recurrent cohorts in these trial are often very small, less than 10 patients, limiting significant conclusions about therapy. **Recurrences after chemotherapy are defined as platinum resistant or platinum sensitive, a classification with clinical significance because platinum-resistant disease is not thought to be curable.** For patients with platinum-resistant or platinum-refractory disease, optimal treatment has not been defined, and the prognosis overall is poor. The group at the MD Anderson Cancer Center noted 42 primary therapy failures in 160 patients with germ cell tumors. Vincristine, actinomycin-D, and cyclophosphamide were the principal agents used during the first 10 years of the study period. Cisplatin-based combination therapy was used more extensively in the late 1970s and 1980s. Salvage therapy varied with 24 patients receiving surgery and 34 patients receiving chemotherapy. Of patients receiving chemotherapy, 11 were treated with VAC and 11 with a platinum-based regimen. The median survival time for the entire group was 19 months. The PFS time was 6.8 months with a range of 0.9 to 24 months. No patient had disease recurrence longer than 2 years from initial diagnosis. More recently, male patients with platinum-resistant or platinum-refractory germ cell tumors have been treated with combination chemotherapy consisting of gemcitabine, oxaliplatin, and paclitaxel. This regimen has an acceptable toxicity profile, a 51% overall response rate, and a 39% complete or tumor marker–negative response rate. The median response duration was 8 months.

Treatment Toxicity

Given the favorable long-term outcomes associated with modern surgical management and combination platinum-based chemotherapy, the long-term effects of treatment must be considered carefully. Because many patients undergo conservative surgery for their disease, **meticulous surgical technique is essential to avoid future infertility related to surgically induced pelvic adhesive disease. Equally important is avoiding unnecessary hysterectomies and biopsies of normal-appearing contralateral ovaries.** Women with fertility-sparing surgery can be expected to have the same survival outcome as those patients treated with standard surgery. A review of SEER data from 1988 to 2001 involving 760 patients with germ cell malignancies concluded that the overall survival rate of patients treated with fertility-sparing surgery (n = 313) was

not statistically different from those who underwent standard surgery. This study revealed that the use of fertility-sparing surgery also had increased over the study period. Two-thirds of the patients had stage I to II disease, and one third had stage III to IV disease. The most common histologic subtype was immature teratoma (55%) followed by dysgerminoma (32%).

Although successful, concern exists over potential toxicity of the BEP regimen. Namely, bleomycin is associated with acute and long-term pulmonary toxicity, etoposide with the risk of secondary malignancies, and cisplatin with nephrotoxicity. Controversy exists over whether baseline pulmonary function testing is required before initiating bleomycin. Data from retrospective trials and testicular cancer literature suggest carboplatin and etoposide is an acceptable regimen for patients who cannot tolerate BEP.

The long-term effect of combination chemotherapy in germ cell malignancies is less clear. **Of particular concern is the risk of development of acute myelogenous leukemia (AML) associated with etoposide use. This risk appears to be dose and schedule dependent.** AML rarely develops in patients receiving three cycles or less of etoposide or cumulative doses of less than 2000 mg/m^2. It is estimated that the risk of developing AML is 0.4% if these cutoff values are used. Leukemia, when it occurs, typically is seen within 2 to 3 years after treatment. An analysis of the risk-to-benefit ratio favors the use of etoposide in advanced germ cell malignancies, in which one case of etoposide-induced AML would be expected to occur for every 20 patients cured.

The long-term effects of chemotherapy on gonadal function appear to be minimal. Most younger patients can expect a return to normal ovarian function and reproductive potential with no additional risk of congenital malformations in their offspring. The most significant risk factor for impaired fertility is age and type of treatment administered. Although ovarian failure is a risk associated with chemotherapy, factors such as older age at treatment, higher drug doses, and long duration of therapy appear to confer higher risk. Childhood cancer patients treated with standard contemporary agents such as BEP have the greatest likelihood of preservation of fertility, resumption of normal menstrual cycles, and normal sexual development by virtue of the higher number of follicles present in young women compared with older women. Although normal menstrual cycles will likely resume in reproductive-age women, data suggest an increased risk of diminished ovarian reserve resulting in a significant reduction in the probability of pregnancy by 50%. Reproductive-aged women are likely to have reduced ovarian volume compared with control participants, fewer antral follicles on ultrasonography, and lower levels of inhibin B and estradiol on cycle days 2 to 5. Alkylating agents such as cyclophosphamide are far more likely to cause toxicity to the gonads than other chemotherapeutic agents. In one study, alkylating agents had an odds ratio (OR) of 4 for causing premature ovarian failure compared with platinum agents (OR, 1.8) or plant alkaloids (OR 1.2).

There is some literature to suggest that gonadotropin-releasing hormone (GnRH) agonists may be cytoprotective for primordial follicles when given during chemotherapy. Most of these data are retrospective; however, recently, Badawy and colleagues reported on a prospective randomized trial in 80 breast cancer patients younger than age 40 years who were randomly assigned to GnRH agonists with chemotherapy or chemotherapy alone. Ninety percent of study patients resumed menses, and 70% resumed spontaneous ovulation within 8 months of completing therapy compared with 33% and 26% of control patients, respectively. In the setting of germ cell malignancies, in which younger age at diagnosis is the norm, these patients should be counseled on the risks and benefits of GnRH agonists as well as consultation with a reproductive endocrinologist.

Dysgerminoma

Dysgerminoma is the most common germ cell malignancy, accounting for 1% to 2% of primary ovarian neoplasms and for 3% to 5% of ovarian malignancies. **Dysgerminoma may occur at any age from infancy to old age,** but most cases occur in adolescence and early adulthood (Fig. 12.3). They also present at a relatively early stage:

Stage Ia	65%–75%
Stage Ib	10%–15%
Stages II and III	15%
Stage IV	5%

Dysgerminoma consists of germ cells that have not differentiated to form embryonic or extraembryonic structures (Fig. 12.4). The stroma is almost always infiltrated with lymphocytes and often contains granulomas similar to those seen in sarcoidosis. Occasionally, dysgerminoma contains isolated gonadotropin-producing syncytiotrophoblastic giant cells. An elevated serum lactate dehydrogenase or hCG level may be present in these patients. Grossly, the tumor may be firm, fleshy, cream colored, or pale tan; both its external and cut surfaces may be lobulated. **A few dysgerminomas arise in females with sex chromosome abnormalities, particularly those with pure (46,XY) or mixed (45,X, 46,XY) gonadal dysgenesis or testicular feminization (46,XY). In such cases, the dysgerminoma often develops in a previously existing**

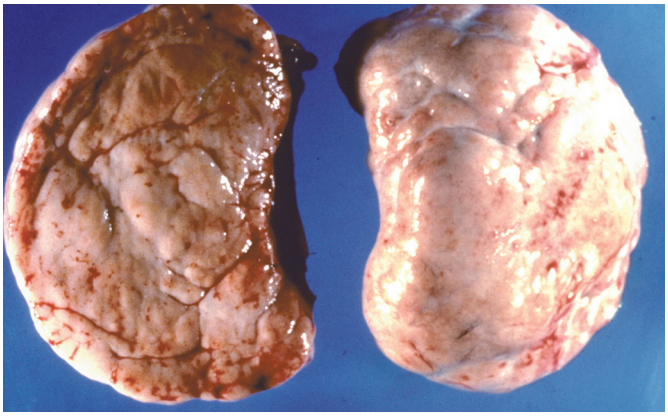

FIGURE 12.3 Large (25-cm) solid mass of the right ovary in a 16-year-old girl with stage Ia dysgerminoma.

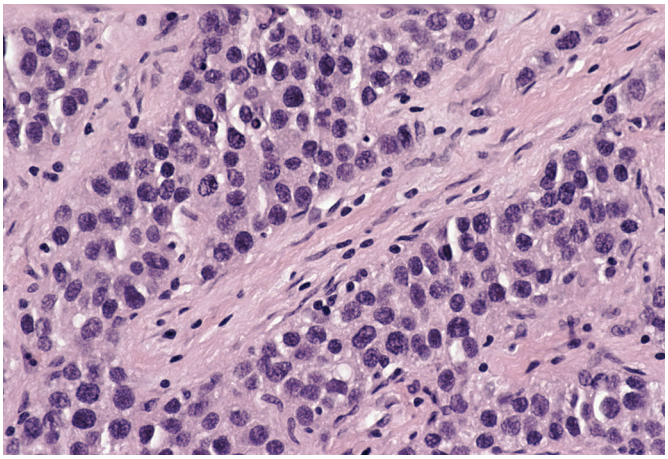

FIGURE 12.4 Dysgerminoma is characterized histologically by the presence of large, round, ovoid, or polygonal cells with stroma infiltrated by lymphocytes.

TABLE 12.4 Results of Conservative and Nonconservative Surgery in Stage Ia Dysgerminoma of the Ovary

	10-Year Survival Rate	
	Conservative Surgery (%)	Nonconservative Therapy* (%)

gonadoblastoma. The symptoms of dysgerminoma are similar to those observed in patients with other solid ovarian neoplasms. Large, rapidly growing tumors may lead to a relatively short duration of symptoms. **The most common initial symptoms are abdominal enlargement and the presence of a mass in the lower abdomen.** When the tumor is small and moves freely, its capsule is intact. Large lesions, however, may rupture or adhere to surrounding structures. Rupture can lead to peritoneal implantation, resulting in an increase in stage. Occasionally, menstrual and endocrine abnormalities may be the initial symptoms, but these symptoms tend to be more common in patients with dysgerminoma combined with other neoplastic germ cell elements, especially choriocarcinoma. In several cases, the tumor has been found incidentally at cesarean section or as a cause of dystocia. **Dysgerminoma is the most common malignant ovarian neoplasm observed in pregnancy.** The relatively common finding of dysgerminoma in pregnant patients is nonspecific and relates to the age of the patient rather than to the pregnant state. **Dysgerminoma is the only germ cell tumor in which the opposite ovary is frequently involved with the tumor process (10%–20% of cases).** Kurman and Norris reported a 20% incidence of disease in the serially sectioned normal appearing opposite ovary. **Dysgerminomas are notable by their predilection for lymphatic spread and their sensitivity to irradiation and chemotherapy.** The lymph nodes in the vicinity of the common iliac arteries and the terminal part of the abdominal aorta are typically the first to be affected. Occasionally, there may be marked enlargement of these lymph nodes, with a mass evident on abdominal examination. The lesion can spread from these abdominal nodes to the mediastinal and supraclavicular nodes. Hematogenous spread to other organs occurs later. Any organ can be affected, although involvement of the liver, lungs, and bones is most common.

Because 85% of all patients with dysgerminomas are younger than 30 years, conservative therapy and preservation of fertility are major considerations. In patients in whom unilateral salpingo-oophorectomy is performed, careful inspection of the contralateral ovary and exploration to rule out disseminated disease are mandatory. The authors' routine is not to wedge or bivalve the opposite ovary if it has a normal size, shape, and consistency. In a review of the literature, more than 400 cases of dysgerminoma were reported. Seventy percent of patients had stage I disease at diagnosis, and only 10% involved both ovaries. Schwartz and colleagues reported four patients with metastasis to the contralateral ovary and preservation of that ovary with subsequent chemotherapy. All patients were alive and had no disease 14 to 56 months after diagnosis. **Assessment of the retroperitoneal lymph nodes is an important part of the initial surgical therapy because these neoplasms tend to spread to the lymph nodes, particularly to the high paraaortic nodes.**

Conservative surgery without radiation or adjuvant chemotherapy in stage Ia lesions has resulted in excellent outcomes (Table 12.4). Several prognostic factors in dysgerminoma influence the decision to use adjuvant chemotherapy in early stages of the disease. Some authors suggest that in patients with large tumors (>10 cm), there is a greater chance of a recurrence; therefore, adjuvant therapy should be given. Today, most agree that tumor size is not prognostically important, and these patients do not require additional therapy. Although there is presently no good evidence that the behavior of an individual tumor can be assessed from its histologic appearance, we do know that the presence of other germ cell elements worsens prognosis. Data regarding the prognostic significance of age is inconsistent. **The long-term survival rate is almost 90% across all patients who have stage I lesions.**

De Palo and associates reported on 56 patients who had pure dysgerminomas. In their study, 44 patients underwent lymphangiography, and a positive study resulted in the restaging of 32% of patients. Diaphragmatic implants were not found in any patients, and positive cytologic findings were obtained in only three patients. The 5-year relapse-free survival rates were 91% in patients with stages Ia, Ib, and Ic; 74% in those with stage III retroperitoneal disease; and 24% in patients who had stage III peritoneal disease. Peritoneal involvement of any kind was associated with a poor prognosis if disease had extended to the abdominal cavity. All patients with stage III disease received postoperative radiation therapy.

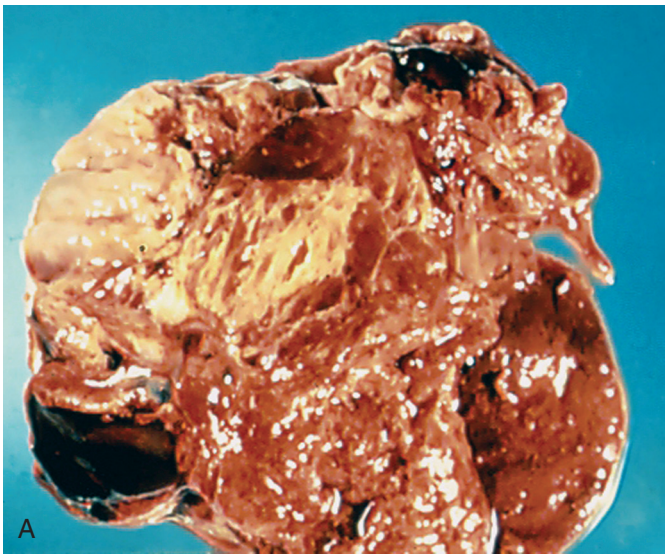
These patients should be followed closely and have periodic examinations because approximately 90% of recurrences appear in the first 2 years after initial therapy. Fortunately, most recurrences can be successfully eradicated by salvage therapy including surgery, chemotherapy, and potentially radiation therapy. Recurrences should be treated aggressively with reexploration and cytoreductive surgery. The removed tissue should be examined carefully for evidence of germ cell elements other than dysgerminoma. Some presumed recurrent dysgerminomas have been found to be mixed germ cell tumors and should be treated accordingly.

Although radiation therapy has been successful in treating dysgerminomas, **chemotherapy has become the treatment of choice** because radiotherapy is associated with a high incidence of gonadal failure. **The success rate of chemotherapy is as good as that of radiation, and preservation of fertility is possible in many patients, even those with bilateral ovarian disease.** Weinblatt and Ortega reported on five children with extensive disease who were treated with chemotherapy as the primary therapeutic modality. Three of the five children were alive and free of disease at the time of the report, suggesting a therapeutic approach to extensive childhood dysgerminoma that spares pelvic and reproductive organs.

The common association of dysgerminoma with gonadoblastoma, a tumor that almost always occurs in patients with dysgenetic gonads, indicates that there is a relationship between dysgerminoma and genetic and somatosexual abnormalities. Patients with these genetic abnormalities should be offered gonadectomy after puberty to prevent the development of gonadoblastoma or dysgerminoma. Phenotypically normal females suspected of having a dysgerminoma should be evaluated with a karyotype, especially if ovarian conservation is desired. **Patients with pathology reports that reveal streak gonads or gonadoblastomas should also be karyotyped. If a Y chromosome is present, the retained contralateral ovary should be removed to prevent neoplasia.** Historically, fertility-sparing surgery has not been offered to patients with dysgerminoma associated with gonadoblastoma because of the frequent occurrence of bilateral tumors and the absence of normal gonadal function. Investigation of the genotypes and karyotypes of all patients with this neoplasm is recommended by some, especially if any history of virilization or other developmental abnormalities is elicited. In vitro fertilization can be used in patients without gonads. Therefore, it may be prudent to preserve the uterus in patients in whom the ovaries must be removed. In most cases, the authors leave the uterus. This is particularly important in prepubertal patients because in these patients, other signs of abnormal function (eg, primary amenorrhea, virilization, and absence of normal sexual development) are lacking.

Often lesions that consist primarily of dysgerminoma elements contain small areas of more malignant histology (eg, embryonal carcinoma or endodermal sinus tumor). If tumor markers such as alpha-fetoprotein (AFP) or hCG are elevated, a strong suspicion of mixed lesions should be entertained. **When the dysgerminoma is not pure and these more malignant components are present, the prognosis and therapy are determined by the more malignant germ cell elements,** and the dysgerminoma component is disregarded.

Endodermal Sinus Tumor (Yolk Sac Tumor)



Endodermal sinus tumors are the second most common form of malignant germ cell tumors of the ovary, accounting for 22% of malignant germ cell lesions in one large series. The median age at diagnosis is 19 years old, and **three-fourths of thepatients are initially seen with a combination of abdominal pain and abdominal or pelvic mass.** Endodermal sinus tumors are **characterized by extremely rapid growth and extensive intraabdominal spread;** almost half the patients seen by a physician complain of symptoms of 1 week's duration or less.

Acute symptoms can alternatively be caused by torsion of the tumor and may lead to the diagnosis of acute appendicitis or a ruptured ectopic pregnancy. These yolk sac tumors are almost always unilateral. The tumor is usually large with most tumors measuring between 10 and 30 cm. On the cut surface, they appear gray-yellow with areas of hemorrhage and cystic, gelatinous changes. These neoplasms are highly malignant; they metastasize early and invade the surrounding structures. Intraabdominal spread leads to extensive involvement of abdominal structures with tumor deposits. Metastases also occur via the lymphatic system. **AFP levels are often elevated.**

Endodermal sinus tumors are thought to originate from germ cells that differentiate into the extra embryonal yolk sac because the tumor structure is similar to that found in the endodermal sinuses of the rat yolk sac. The tumors consist of scattered tubules or spaces lined by single layers of flattened cuboidal cells; loose reticular stroma; numerous scattered para-aminosalicylic–positive globules; and, within some spaces or clefts, a characteristic invaginated papillary structure with a central blood vessel **(Schiller-Duval body)** (Fig. 12.5). Frequently, intracellular and extracellular hyaline droplets that represent deposits of AFP can be identified throughout the tumor.

Historically, the prognosis for patients with endodermal sinus tumor of the ovary was unfavorable. Most patients died of the disease within 12 to 18 months of diagnosis. Until multiple-agent chemotherapy was developed, there were only a few known 5-year survivors, most of whom had tumors confined to the ovary. Kurman and Norris reported no long-term survivors in 17 patients with stage I tumors who were receiving adjunctive radiation or single alkylating agent, dactinomycin, or methotrexate. Gallion and colleagues reviewed the literature in 1979 and found that only 27% of 96 patients with stage I endodermal sinus tumors were alive at 2 years. The tumor is not sensitive to radiation therapy, although there may be an initial response. Optimal surgical extirpation of the disease has been advocated, but this alone is unsuccessful in producing a significant number of cures.

With surgery and multiagent chemotherapy, however, there have been optimistic reports of sustained remissions. In several cases, the tumor consisted of endodermal sinus tumors admixed with other neoplastic germ cell elements, frequently dysgerminoma. The clinical course in most patients with tumors composed of endodermal sinus tumor associated with dysgerminoma

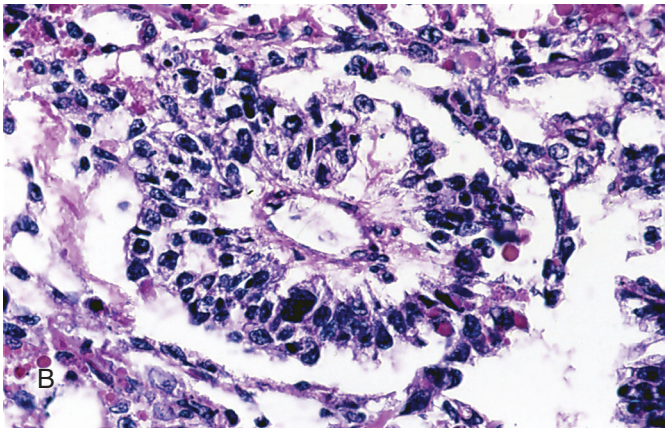


FIGURE 12.5 Endodermal sinus tumor. A, Gross appearance with areas of hemorrhage and gelatinous necrosis. B, Microscopic appearance with isolated papillary projections containing single blood vessels and having peripheral lining of neoplastic cells (Schiller-Duval body).

or other neoplastic germ cell elements does not differ greatly from that in patients with pure endodermal sinus tumors. Mixed germ cell lesions often contain endodermal sinus tumors as one of the types present.

From a practical point of view, **serum AFP determination is considered to be a useful diagnostic tool in patients who have endodermal sinus tumors and should be considered an ideal tumor marker.** It can be useful when monitoring the results of therapy and for detecting metastasis and recurrences after therapy. As noted earlier, many investigators use AFP as a guide to the number of courses needed for an individual patient. In many cases, only three or four courses have placed patients into remission with long-term survival. Levels of hCG and its beta subunit (beta-hCG) have been found to be normal in patients with endodermal sinus tumor.

Embryonal Carcinoma

Embryonal carcinoma is one of the most aggressive ovarian malignancies (Fig. 12.6). The neoplasm closely resembles the embryonal carcinoma of the adult testes, a relatively common tumor. However, it represents only 4% of malignant ovarian germ cell tumors in the ovary, and its confusion with choriocarcinoma and ESTs in the past accounts for its late identification as a distinct entity. It usually manifests as an abdominal mass or pelvic mass occurring at a mean age of 15 years. More than half of the patients have hormonal abnormalities, including precocious puberty, irregular uterine bleeding, amenorrhea, or hirsutism. The tumors consist of large primitive cells with occasional papillary or glandlike formations (Fig. 12.7). The cells have eosinophilic cytoplasms with distinct borders and round nuclei with prominent nucleoli. Numerous mitotic figures, many atypical, are seen; scattered throughout the tumor are multinucleated giant cells that resemble syncytial cells.

These tumors secrete hCG from syncytiotrophoblast-like cells and AFP from large primitive cells, and these tumor markers can be used to monitor progress during therapy. This

TABLE 12.5 Comparison of Embryonal Carcinoma With Endodermal Sinus Tumor

	Endodermal Sinus Tumor ($n = 71$)	Embryonal Carcinoma ($n = 15$)
Median age (yr)	19	15
Prepubertal status (%)	23	47
Precocious puberty (%)	0	43
Positive pregnancy test	None (0/15)	All (9/9)
Vaginal bleeding (%)	1	33
Amenorrhea (%)	0	7
Hirsutism (%)	0	7
Survival, stage I patients (%)	16	50
Human chorionic gonadotropin	Negative (0/15)	Positive (10/10)
α-Fetoprotein	Positive (15/15)	Positive (7/10)

From Kurman RJ, Norris HJ. Endodermal sinus tumor of the ovary: a clinical and pathological analysis of 71 cases. *Cancer* 1976;38:2404.

tumor probably arises from primordial germ cells, but it develops before there is much further differentiation toward either embryonic or extraembryonic tissue. In a review of 15 patients, Kurman and Norris reported an actuarial survival rate of 30% for the entire group; for those with stage I tumors, the survival rate was 50% (Table 12.5). This result is significantly better than the survival rate for endodermal sinus tumors for the same period of time and before the advent of multiple-agent adjuvant chemotherapy.

Polyembryoma

Polyembryoma is a rare ovarian germ cell neoplasm that consists of numerous embryoid bodies resembling morphologically normal embryos. Similar homologous neoplasms occur more frequently in the human testes. To date, only a few ovarian polyembryomas have been reported. **In most cases, the polyembryoma has been associated with other neoplastic germ cell elements, mainly the immature teratoma. Polyembryoma is a highly malignant germ cell neoplasm.** It is usually associated with invasion of adjacent structures and organs and metastases confined to the abdominal cavity. The tumor is not sensitive to radiotherapy, and its response to chemotherapy is unknown.

Choriocarcinoma

Choriocarcinoma, is a rare, highly malignant tumor that may be associated with sexual precocity. Gestational choriocarcinomas of the ovary contain paternal DNA and are further classified into **primary gestational choriocarcinoma associated with ovarian pregnancy or metastatic choriocarcinoma arising in other parts of the genital tract, mainly the uterus.** Nongestational choriocarcinomas are germ cell tumors that differentiate toward trophoblastic structures. Only nongestational choriocarcinoma of the ovary is discussed here. **In most cases, the tumor is admixed with other neoplastic germ cell elements, and their presence is diagnostic of nongestational choriocarcinoma. The tumor, in common with other malignant germ cell neoplasms, occurs in children and young adults. Its occurrence in children has been emphasized; in some series, 50% of cases occurred in prepubescent children.** This high incidence in children may result from the previous reluctance of investigators to make the diagnosis in adults.

Choriocarcinomas secrete hCG, leading to manifestations of isosexual precocious puberty with mammary development, growth of pubic and axillary hair, and uterine bleeding. In adult patients, the increased production of hCG may cause signs of ectopic pregnancy. Estimation of urinary or plasma hCG levels is a useful diagnostic test in these cases. Historically, the prognosis of patients with choriocarcinoma of the ovary was unfavorable, but modern chemotherapy regimens have effectively improved survival.

Mixed Germ Cell Tumors

Mixed germ cell tumors contain at least two malignant germ cell elements. Dysgerminoma is the most common component, 80% in Kurman and Norris' report and 69% in material from the MD Anderson Hospital. Immature teratoma and EST are also frequently identified; embryonal carcinoma and choriocarcinoma are seen only occasionally. It is not unusual to see three or four different germ cell components. In 42 patients treated at the MD Anderson Hospital from 1944 through 1983, nine patients were treated with surgery alone, and another six patients received radiation therapy; all developed recurrences. To improve outcomes, the most malignant cell type should drive the selection of the adjuvant chemotherapy regimen.

Teratoma

Mature Cystic Teratoma

Accounting for more than 95% of all ovarian teratomas, the dermoid cyst, or mature cystic teratoma, is one of the most common ovarian neoplasms. Teratomas account for approximately 15% of all ovarian tumors. They are the most common ovarian tumors in women in the second and third decades of life. Most benign cystic lesions contain mature tissue of ectodermal, mesodermal, or endodermal origin. **The most common elements are ectodermal derivatives such as skin, hair follicles, and sebaceous or sweat glands, accounting for the characteristic histologic and gross appearance of teratomas** (Fig. 12.8). **These tumors are usually multicystic and contain hair intermixed with foul-smelling, sticky, keratinous and sebaceous debris. Occasionally, well-formed teeth are seen along with cartilage or bone.** If the tumor consists of only ectodermal derivatives of skin and skin appendages, it is a true dermoid cyst. A mixture of other, usually mature tissues (gastrointestinal, respiratory) may be present.

The clinical manifestation of this slow-growing lesion is usually related to its size, compression, or torsion or to a chemical peritonitis secondary to intraabdominal spill of the cholesterol-laden debris. The latter event tends to occur more commonly when the tumor is large. **Torsion is the most frequent complication, observed in as many as 16% of the cases in one large series, and tends to occur more commonly during pregnancy, the puerperium, and in children and younger**

FIGURE 12.8 Benign cystic teratoma. **A** and **B**, Gross appearance. **C**, Microscopic view of ectodermal elements (skin and skin appendages). **D**, Immature neural elements evident.

patients. Severe acute abdominal pain is usually the initial symptom, and the condition is considered to be an acute abdominal emergency. **Mature cystic teratomas are said to comprise 22% to 40% of ovarian tumors in pregnancy,** and 0.8% to 12.8% of reported cases of mature cystic teratomas have occurred in pregnancy. **Rupture of a mature cystic teratoma is an uncommon complication,** occurring in approximately 1% of cases, but it is much more common during pregnancy and may manifest during labor. **The immediate result of rupture may be shock or hemorrhage, especially during pregnancy or labor,** but the prognosis even in these cases is favorable. **Rupture of the tumor into the peritoneal cavity may be followed by a chemical peritonitis caused by the spill of the contents of the tumor.** This may result in a marked granulomatous reaction, leading to the formation of dense adhesions throughout the peritoneal cavity. Infection is an uncommon complication of mature cystic teratoma and occurs in approximately 1% of cases. The infecting organism is usually a coliform, but *Salmonella* spp. infection causing typhoid fever has also been reported. Removal of the neoplasm by ovarian cystectomy or, rarely, oophorectomy is adequate therapy. Malignant degeneration of mature teratomas is a rare occurrence. **When it occurs, the most common secondary tumor is a squamous cell carcinoma.** The prognosis and behavior of this secondary malignancy are similar to those of squamous cell cancers arising in other anatomic sites and appear to be highly dependent on stage. There is no consensus on treatment recommendations; however, patients with stage I to II disease treated with platinum-based chemotherapy and whole-pelvic radiation have a chance for long-term survival. Although squamous cell carcinoma in this setting is usually an incidental finding at pathology, preoperative risk factors include age older than 50 years, tumor size greater than 10 cm, and elevated concentrations of squamous cell carcinoma antigen and carcinoma antigen 125 (CA-125).

Mature Solid Teratoma

Mature solid teratoma is a rare ovarian neoplasm and a very uncommon type of ovarian teratoma. The histologic components in a mature solid teratoma are similar to those found in an immature solid teratoma, which occurs mainly in children and young adults. The presence of immature elements immediately excludes the tumor from this group; by definition, only tumors composed entirely of mature tissues may be included. The tumor is usually unilateral and is adequately treated by unilateral oophorectomy. Although this neoplasm is considered benign, mature solid teratomas may be associated occasionally with peritoneal implants that consist entirely of mature glial tissue. Despite the extensive involvement that may be present, the prognosis is excellent.

Immature Teratoma

Immature teratomas consist of tissue derived from the three germ layers—ectoderm, mesoderm, and endoderm—and, in contrast to the much more common mature teratoma, **they contain immature or embryonal structures.** These tumors have had a variety of names, including solid teratoma, malignant

teratoma, teratoblastoma, teratocarcinoma, and embryonal teratoma. These names arose because immature teratomas have been incorrectly considered mixed germ cell tumors or secondary malignant tumors originating in mature benign teratomas. Mature tissues are frequently present and sometimes may predominate. **Immature teratoma of the ovary is an uncommon tumor, comprising less than 1% of ovarian teratomas.** In contrast to the mature cystic teratoma, which is encountered most frequently during the reproductive years but occurs at all ages, **the immature teratoma occurs most commonly in the first 2 decades of life and is almost unknown after menopause. By definition, an immature teratoma contains immature neural elements.** According to Norris and associates, **the quantity of immature neural tissue alone determines the grade.** Neuroblastoma elements, glial tissue, and immature cerebellar and cortical tissue may also be seen. **These tumors are graded histologically on the basis of the amount and degree of cellular immaturity.** The range is from grade I (mature teratoma containing only rare immature foci) through grade III (large portions of the tumor consist of embryonal tissue with atypia and mitotic activity). Generally, older patients tend to have lower grade primary tumors compared with younger patients. When the neoplasm is solid and all elements are well differentiated histologically (solid mature teratoma), a grade 0 designation is given (Table 12.6).

Immature teratomas are almost never bilateral, although occasionally a benign teratoma is found in the opposite ovary. These tumors may have multiple peritoneal implants at the time of initial surgery, and **the prognosis is closely correlated with the histologic grade of the primary tumor and the implants.** Norris and coworkers studied 58 patients with immature teratomas and reported an 82% survival rate for patients who had grade I primary lesions, 63% for grade II, and 30% for grade III (Table 12.7). These results antedate the use of multiple-agent chemotherapy.

Multiple sections of the primary lesion and wide sampling of the peritoneal implants are necessary to properly grade the tumor. In most cases, the implants are better differentiated than the primary tumors. Both the primary lesion and the implants should be graded according to the most immature tissue present. Patients with mature glial implants have an excellent prognosis; those with immature implants, however, do not.

To date, the histologic grade and fertility desires of the patient have been the determining factors regarding extent of surgical therapy and subsequent adjuvant therapy. Because the lesion is rarely bilateral in its ovarian involvement, the present method of **therapy consists of unilateral salpingo-oophorectomy with wide sampling of peritoneal implants. Total abdominal hysterectomy with bilateral salpingo-oophorectomy does not seem to be indicated because it does not influence the outcome for the patient.** Although some authors have advocated cystectomy alone for early-stage, low-grade disease, this management strategy should be approached with caution. Radiotherapy has also been shown to have little value. **If the primary tumor is grade I and all peritoneal implants are grade 0, no further therapy is recommended. However, if the primary tumor is grade II or III or if implants or recurrences are grade I, II, or III, triple-agent chemotherapy is frequently recommended.** The recommendation to use adjuvant chemotherapy in high-grade stage I disease is based on studies performed before meticulous surgical staging of germ cell malignancies was routine. Cushing and colleagues evaluated surgical therapy alone in 44 pediatric and adolescent patients younger than the age of 15 years who had completely resected immature teratomas of all grades. Thirty-one patients had pure immature teratomas, and 13 patients had immature teratomas with microscopic endodermal sinus tumor foci. The 4-year event-free and overall survival rates for both groups were 97% and 100%, respectively. The authors concluded that surgery alone was curative for most children and adolescents with completely resected ovarian immature teratomas of any grade and advocated avoiding adjuvant chemotherapy in this group.

In previous trials including SLL, these patients were free of immature elements but retained peritoneal implants containing exclusively mature elements. This was labeled chemotherapeutic retroconversion of immature teratoma of the ovary and is a similar if not identical syndrome as the "growing teratoma syndrome" described in testicular nonseminomatous germ cell tumors. All of these patients had uneventful follow-ups with the mature implants apparently remaining in static states. Growing teratoma syndrome (GTS) is characterized by the persistence or development of an enlarging mass during or after adjuvant chemotherapy. Normalization of tumor markers is also seen, and on pathologic analysis, only mature teratoma

TABLE 12.6 Immature Teratoma Grading System

Grade	Thurlbeck and Scully	Norris et al.
0	All cells well differentiated	All tissue mature; rare mitotic activity
1	Cells well differentiated; rare small foci of embryonal tissue	Some immaturity and neuroepithelium limited to low-magnification field in any slide (×40)
2	Moderate quantities of embryonal tissue; atypia and mitosis present	Immaturity and neuroepithelium does not exceed three low-power microscopic fields in any one slide
3	Large quantities of embryonal tissue; atypia and mitosis present	Immaturity and neuroepithelium occupying four or more low magnification fields on a single slide

TABLE 12.7 Immature (Malignant) Teratomas

Grade	Patients (*n*)	Tumor Deaths (%)
1	22	4 (18)
2	24	9 (37)
3	10	7 (70)

is noted in the specimen. Treatment of this syndrome is challenging, but surgery is diagnostic and is also the mainstay of therapy. Few cases of GTS are reported in the literature; thus, many current strategies are taken from reports of GTS after testicular nonseminomatous germ cell tumors. Byrd et al. reported on five cases of GTS in women undergoing treatment of early and advanced stage ovarian germ cell tumors. All women received BEP after surgery. GTS occurred 1 to 6 months after completion of chemotherapy in women with advanced disease and at 1 and 11 years in the two women with stage I disease. All patients in this cohort required extensive surgery but remain alive and well with no evidence of disease at last follow-up. For patients with this syndrome, maximal cytoreductive efforts should be undertaken because they offer optimal diagnostic and therapeutic benefit.

Monodermal or Highly Specialized Teratomas

Struma ovarii. Another tumor thought to represent the unilateral development of benign teratoma is **struma ovarii, which consists totally or predominantly of thyroid parenchyma.** This is an uncommon lesion and should not be confused with benign teratomas, which contain small foci of thyroid tissue. Between **25% and 35% of patients with strumal tumors will have clinical hyperthyroidism.** The gross and microscopic appearances of these lesions are similar to those of typical thyroid tissue, although the histologic pattern may resemble that in adenomatous thyroid. **These ovarian tumors may undergo malignant transformation, but they are usually benign and easily treated by simple surgical resection.**

Carcinoid tumors. **Primary ovarian carcinoid tumors usually arise in association with gastrointestinal or respiratory epithelium, which is present in mature cystic teratoma.** They may also be observed within a solid teratoma or a mucinous tumor, or they may occur in an apparently pure form. Primary ovarian carcinoid tumors are uncommon; approximately 50 cases have been reported. The age distribution of patients with ovarian carcinoid tumors is similar to that of patients with mature cystic teratoma, although the average age may be slightly higher in ovarian carcinoid tumors. Many patients are postmenopausal.

One-third of the reported cases have been associated with the typical carcinoid syndrome despite the absence of metastasis. This is in contrast to intestinal carcinoid tumors, which are associated with the syndrome only when there is metastatic spread to the liver. Excision of the tumor has been associated with the rapid remission of symptoms in all of the described cases and the disappearance of 5-hydroxyindoleacetic acid from the urine. The primary ovarian carcinoids are only occasionally associated with metastasis; metastasis was observed in only 3 of 47 reported cases in one review. The prognosis after excision of the primary tumor is favorable, and in most cases, a cure results.

Strumal carcinoid is an even rarer entity and represents a close admixture of the previously discussed struma ovarii and carcinoid tumors. Strumal carcinoids may actually represent medullary carcinoma, resulting in thyroid tissue. Most cases follow a benign course.

TUMORS OF GERM CELL AND SEX CORD DERIVATION

Tumors of germ cell and sex cord derivation are unique, rare tumors that are composed of two distinct populations of cells closely admixed but with different origins. The two histologic types of tumors that fall into this category are gonadoblastomas and mixed germ cell–SCSTs. Gonadoblastomas are benign tumors of the ovary that occur in dysgenetic gonads and are frequently associated with the development of a malignant germ cell component. The risk of developing a malignant germ cell component increases with age, such that prepubertal girls at the time of gonadectomy are very unlikely to have an associated malignant germ cell tumor, but the risk of malignancy approaches 100% for women in their 20s. Mixed germ cell–SCTSs occur in chromosomally normal gonads and are less frequently associated with malignant germ cell tumors than gonadoblastomas.

Gonadoblastoma

Gonadoblastoma is a rare ovarian lesion that consists of germ cells that resemble those of dysgerminoma and gonadal stroma cells that resemble those of a granulosa or Sertoli tumor. Sex chromatin studies usually show a negative nuclear pattern (45,X) or a sex chromosome mosaicism (45,X/46,XY). Gonadoblastomas usually arise in dysgenetic gonads, but the presence of dysgenetic gonads, a Y chromosome, or a Y fragment is not required; very rare cases of gonadoblastomas have been reported in normal women with normal ovaries and a normal karyotype. Because **patients with XY gonadal dysgenesis have a very high risk of gonadoblastoma and a nearly 100% risk of associated malignant germ cell tumor with advancing age, these patients are recommended to undergo prophylactic bilateral oophorectomy after puberty. Patients who have a gonadoblastoma usually have primary amenorrhea, virilization, or developmental abnormalities of the genitalia,** and the discovery of gonadoblastoma is made in the course of investigation of these conditions. It is poorly understood why some patients with these lesions become virilized and others do not. Although there is a correlation between the virilization of patients with gonadoblastoma and the presence of Leydig or lutein-like cells, this relationship is not consistent, and some virilized patients have tumors free of these cells. Another common initial sign is the presence of a pelvic tumor. **Most patients with gonadoblastoma (80%) are phenotypic women, and the remainder are phenotypic men with cryptorchidism, hypospadias, and internal female secondary sex organs.** Among the phenotypic women, 60% are virilized, and the remainder appear normal. **The prognosis of patients with gonadoblastoma is excellent if the tumor and the contralateral gonad, which may be harboring a macroscopically undetectable gonadoblastoma, are excised. Bilateral involvement is identified in approximately 50% of cases. The association with dysgerminoma is seen in 50% of cases and with other more malignant germ cell neoplasms in an additional 10%.** In view of this, the concept that these lesions represent an in-situ germ cell malignancy appears valid. When gonadoblastoma

is associated with or overgrown by dysgerminoma, the prognosis is still excellent. **Metastases tend to occur later** and more infrequently than in dysgerminoma arising de novo. Complete or partial regression of virilization usually occurs after excision of the gonads. Exogenous estrogen therapy is given for periodic bleeding. The authors leave the uterus even after removing both gonads. Cyclic hormone therapy is indicated in these young women. Ovum transfer has been successful in patients who have had both ovaries removed. **Although gonadoblastomas themselves are benign, treatment should follow the usual tenets for surgical staging if a malignant component is identified.**

Mixed Germ Cell–sex Cord Stromal Tumors

Mixed germ cell–SCTSs are less common than gonadoblastomas **and occur in phenotypically normal women with normal karyotypes and normal gonads.** These tumors are usually identified in girls younger than age 10 years; however, they rarely may be seen in reproductive-age women. Although **clinically benign, these mixed tumors are associated with a malignant germ cell component in 10% of cases.** When this tumor is identified in postpubertal girls, the risk of a malignant germ cell tumor rises to 80%. **Isosexual precocity may be seen. Similar to gonadoblastoma, the most common germ cell tumor identified is dysgerminoma.** However, unlike gonadoblastoma, in which the sex cord element is usually mature, in mixed tumors, the sex cord element is usually less mature. Histologic features may resemble characteristics of multiple SCSTs such as retiform patterns or annular tubules and may not be characteristic of a single SCST type. They are usually large and unilateral tumors and metastasize or recur infrequently. **Because of the unilateral nature, unilateral oophorectomy and staging if a malignant germ cell component is identified is all that is required.** Because these patients are usually young and are phenotypically, anatomically, and karyotypically normal, surgical management should be guided by fertility preservation and appropriate staging if malignancy is identified.

TUMORS DERIVED FROM SPECIAL GONADAL STROMA

Classification, Clinical Profile, and Staging

This category of ovarian tumors includes all those that contain granulosa cells, theca cells and luteinized derivatives, Sertoli cells, Leydig cells, and fibroblasts of gonadal stromal origin. These tumors originate from the ovarian matrix and consist of cells from the embryonic sex cord and mesenchyme. **As a group, SCSTs are found in all age groups, with the age-related incidence increasing throughout the fifth, sixth, and seventh decades of life. These tumors account for approximately 5% of all ovarian tumors;** however, functioning neoplastic groups of this variety comprise only 2%. Approximately 90% of hormonally active ovarian tumors belong to this category and are associated with physiologic and pathologic signs of estrogen or androgen excess (or both), including isosexual precocity, hirsutism, abnormal bleeding, endometrial hyperplasia or carcinoma, and increased breast cancer risk. **Of ovarian cancers, 5% to 10% belong in the SCST group; most of these (70%) are granulosa cell tumors, which are low-grade malignancies with a relapse rate of 10% to 33%. Because SCSTs have a propensity for indolent growth, they tend to recur late. The average time to recurrence is between 5 and 10 years; some recur as late as 20 years after the initial diagnosis. Most authors report a 10-year survival rate of 90% for stage I disease and 0% to 22% for stage III.** Prognostic factors shown to affect survival in multivariate analysis by Chan and colleagues include age younger than 50 years, tumor size smaller than 10 cm, and absence of residual disease. An analysis of SEER data from 1988 to 2001 including 376 women with SCST confirmed age younger than 50 and early-stage disease (I and II) as significant prognostic factors for improved survival. Observational studies have shown an improvement in relative and overall survival for SCST over time, likely attributable to the increased recognition of the importance of cytoreduction and residual disease on overall survival and accurate staging resulting in more favorable stage at diagnosis. SCSTs are staged surgically in accordance with FIGO guidelines and staging recommendations for ovarian epithelial tumors.

Treatment

The definitive treatment of SCST is based on findings encountered during complete surgical staging, the reproductive desires of the patient, and the histologic type of tumor. The majority of SCSTs are benign or low malignant potential tumors. As a result, surgical therapy is adequate in most cases and remains the cornerstone of treatment. **In patients who desire to retain fertility, unilateral salpingo-oophorectomy with preservation of the uterus and contralateral ovary and full surgical staging is appropriate therapy for patients with stage IA disease. Advanced-stage disease and disease in older women should be managed with complete staging and hysterectomy with bilateral salpingo-oophorectomy.** Although scientific evidence suggesting benefit is lacking, most authors recommend **aggressive attempts at complete cytoreduction if possible** when faced with advanced-stage, metastatic, or bulky disease. Secondary cytoreduction is controversial, although there may be a survival or palliative benefit for patients with focal recurrent disease.

Although **contemporary surgical practice mandates routine staging lymphadenectomy,** the therapeutic value of routine lymphadenectomy is uncertain. There is no doubt that staging lymphadenectomy is prognostic and is clinically useful in guiding adjuvant therapy decisions. Brown and colleagues recently reported on 262 patients with SCST of the ovary. Fifty-eight patients underwent lymphadenectomy as part of staging, and none were found to have positive lymph nodes. Of the 117 patients who eventually had a recurrence, six patients (5.1%) had nodal metastasis at the time of recurrence. Three of these patients had negative nodes at the time of initial staging. These authors concluded that lymphadenectomy could be omitted as part of surgical staging of ovarian SCST because lymph node metastasis at time of diagnosis is rare. Similar findings have been reported by Chi and colleagues, who noted no lymph node metastasis in 16 of 68 patients with granulosa cell tumors

who underwent pelvic lymph node dissection as part of surgical staging or 13 of 68 patients who underwent paraaortic lymph-node sampling. Thirty-four patients ultimately experienced recurrence, 33 of which were incompletely staged at their initial operation. Only 15% of recurrences involved the retroperitoneum. In the context of these reports, it may be reasonable to omit routine pelvic and paraaortic lymphadenectomy. The surgeon should perform careful lymph node assessment and resect pathologically enlarged nodes. Similarly, the surgeon should perform standard staging lymphadenectomies in women in whom there is uncertainty regarding the precise histology of the ovarian neoplasm,

Two special clinical situations require additional surgical evaluation. **Because estrogen-secreting ovarian tumors are associated with endometrial hyperplasia or cancer in 25% to 50% and 5% to 10% of cases, respectively, surgical evaluation should include dilation and curettage of the uterine cavity, regardless of the benign or malignant nature of the ovarian primary. If malignancy in the uterus is encountered, it should be managed accordingly. Additionally, because sex cord tumors with annular tubules (SCTAT) associated with Peutz-Jegher syndrome (PJS; discussed later) can be associated with adenoma malignum of the cervix, it is imperative that the endocervix be evaluated with an endocervical curettage.** Although these ovarian tumors are benign, postoperative follow-up and surveillance of the cervix are required.

Patients with early-stage disease (IA or IB) may be treated with surgical therapy alone and expect an excellent prognosis. However, those with stage IC or greater disease should be counseled about adjuvant therapy despite strong evidence suggesting survival benefit. The most common chemotherapy **regimen is BEP. Brown and colleagues published results demonstrating taxane activity in patients with SCST as well.** In this study, a 42% response rate was noted in the setting of recurrent, measurable disease. In a subsequent study, Brown and colleagues directly compared BEP with taxanes in women with SCST. In this study, there was no difference in PFS, overall survival, or response rates in patients with newly diagnosed tumors treated with BEP compared with taxanes. In patients with recurrent measurable disease, BEP had a higher response rate compared with the taxane regimens (71% vs. 37%), a finding that is not statistically significant. In this study, the presence of a platinum compound in the taxane regimen correlated with response, suggesting that a **platinum and taxane combination is active in SCST tumors and may have equivalent efficacy but with lower toxicity compared with the standard BEP.**

The effectiveness of radiation therapy for SCST is controversial and unclear. There are small case series in the literature that would suggest that isolated incompletely resectable primary disease or pelvic recurrent disease may respond to radiation therapy. Because of the size and retrospective nature of these reports, no definitive conclusion can be drawn regarding the utility of radiation in this setting.

Granulosa–stromal Cell Tumors

Granulosa–stromal cell tumors include granulosa and theca cell tumors, and fibromas. They account for the majority of SCST.

TABLE 12.8 Granulosa Cell Tumor: Age Distribution of 118 Cases

Age	Patients (*n*)
Child	3
12–40 yr	27
41–50 yr	28
51–60 yr	32
60–79 yr	28
Total	**118**

Based on data from Evans AT 3rd, Gaffey TA, Malkasian GD Jr, Annegers JF. Clinicopathologic review of 118 granulosa and 82 theca cell tumors. *Obstet Gynecol* 1980;55:213.

They occur about as frequently in women in the reproductive age group as they do in women who are postmenopausal, with a peak incidence in perimenopausal women between ages 50 and 54 years. Only about 5% of granulosa cell tumors occur before puberty (Table 12.8). A number of risk factors have been associated with granulosa cell tumors, but most are not reproducible and have unknown clinical and biologic significance. A study by Boyce et al. evaluated risk factors for ovarian granulosa cell tumors and noted an independent association between nonwhite race and obesity as a hyperestrogenic state in the development of granulosa cell tumors; parity and oral contraceptive use had a protective effect.

Most granulosa and theca cells produce estrogen, but a few are androgenic. The exact proportion of these neoplasms that have function is not known because the endometrium is often not examined microscopically, and appropriate preoperative laboratory tests are not done. About 80% to 85% of granulosa cell and theca cell neoplasms are palpable on abdominal or pelvic examination, but occasionally an unsuspected tumor is found when a hysterectomy is done on a patient who has abnormal bleeding as a result of endometrial hyperplasia or endometrial carcinoma. Most patients present either with nonspecific symptoms such as awareness of an abdominal mass, abdominal pain, abdominal distention, or bloating. Some patients present with an acute abdomen as a result of internal tumor rupture and hemorrhage with resultant hemoperitoneum. **About 15% of patients with cystic granulosa cell tumors are first examined for an acute abdomen associated with hemoperitoneum.** In premenopausal women, menstrual irregularities or secondary amenorrhea may be the presenting symptom.

Granulosa cell tumors vary greatly in gross appearance (Fig. 12.9). Sometimes they are solid tumors that are soft or firm, depending on the relative amounts of neoplastic cells and fibrothecomatous stroma that they contain. They may be yellow or gray, depending on the amount of intracellular lipid in the lesion. **More commonly, the granulosa cell tumor is predominantly cystic and, on external examination, may resemble mucinous cystadenoma or cystadenocarcinoma. However, when sectioned, the cyst is generally found to be filled with serous fluid or clotted blood.**

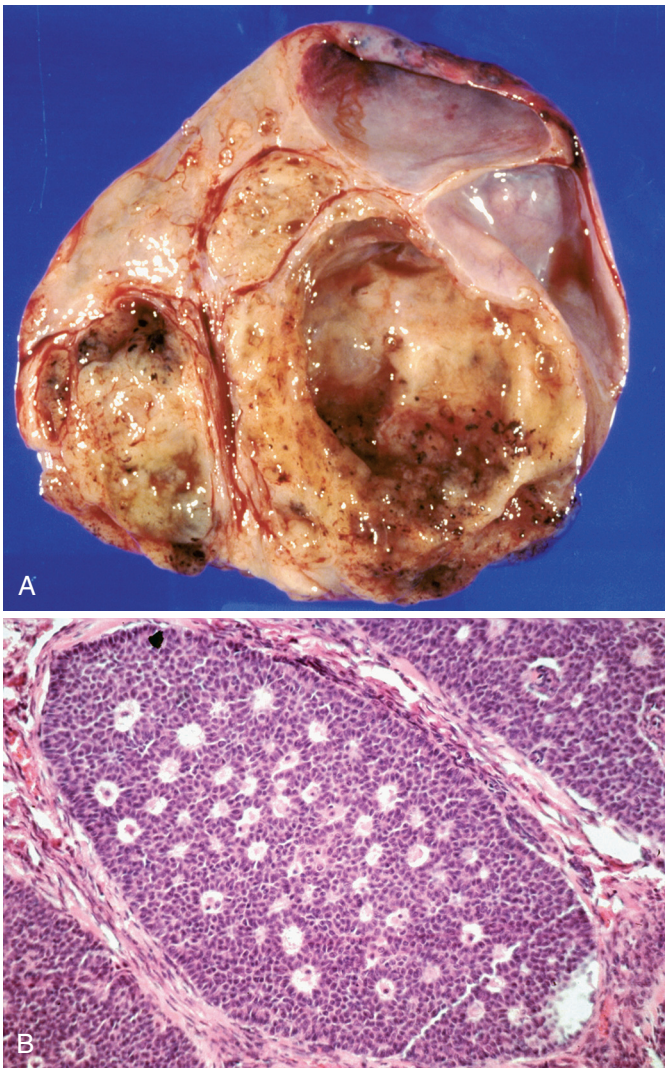

FIGURE 12.9 Granulosa cell tumor of the ovary. A, Gross appearance. B, Microscopic appearance with Call-Exner bodies.

Granulosa cell tumors occur in two subtypes: adult and juvenile. **Adult granulosa cell tumors account for approximately 95% of all granulosa cell tumors.** They occur more commonly in postmenopausal patients and are the most common estrogen-producing tumor. Although uncommon, adult granulosa tumors can be found in children. Abnormal endometria in these patients, such as hyperplasia or even carcinoma of the endometrium, are not uncommon. A study by Evans and associates from the Mayo Clinic of 76 patients who had granulosa cell tumors and in whom endometrial tissue was available shows a **high incidence of endometrial stimulation** (Table 12.9). In another study, one-third of patients had atypical endometrial cells. In postmenopausal women, vaginal bleeding is common as a result of stimulation of the endometrium. **Approximately 10% of patients with this lesion will harbor an endometrial carcinoma, usually of the well-differentiated type.** Other estrogenic effects may also be noted (eg, tenderness or swelling of the breast), and vaginal cytology may show an increase in maturation of the squamous cells. Rarely, androgenic effects may be present in which hirsute changes occur, or progestational effects may be noted on histologic evaluation of the endometrium.

TABLE 12.9 Granulosa Cell Tumor in 76 Patients

Endometrial Histology	Patients (*n*)	Patients (%)
Proliferative endometrium	19	25
Atrophic endometrium	5	7
Hyperplastic endometrium	42	55
Adenocarcinoma	10	13

Based on data from Evans AT 3rd, Gaffey TA, Malkasian GD Jr, Annegers JF. Clinicopathologic review of 118 granulosa and 82 theca cell tumors. *Obstet Gynecol* 1980;55:213.

Histologically, fibrothecomatous components are common, and the cytoplasm is usually scanty. **The typical coffee-bean grooved cells are present.** Cells may be arranged in clusters or rosettes surrounding a central cavity and, when present, resemble primordial follicles called **Call-Exner bodies**. A high degree of tumor cell atypia or mitosis is uncommon. **Adult granulosa cell tumors are typically low-grade malignancies that demonstrate indolent growth and present as stage I disease in more than 90% of cases.** Unilateral disease is most common, but bilateral disease may be found in up to 10% of cases. **The most important prognostic factor is surgical stage.** A study by Kobel et al., in an attempt to understand the molecular pathogenesis of granulosa cell tumors, identified a somatic FOXL2 402C→G mutation, which was present in almost all adult-type granulosa cell tumors and may represent areas of future study for targeted treatments.

The majority of juvenile granulosa cell tumors are found in young adults, and most occur during the first 3 decades of life. Most juvenile granulosa cell tumors are hormonally active, producing estradiol, progesterone, or androgens. **Most of the juvenile granulosa cell tumors that occur in children result in sexual precocity with the development of breasts and pubic and axillary hair. Irregular uterine bleeding may also be present.** Thyromegaly may also occur. Juvenile tumors that are hormonally active may have a more favorable prognosis than inactive tumors, presumably resulting from earlier presentation as a result of the signs and symptoms associated with hormonal activity. Similar to the adult subtype, most of these tumors are limited to one ovary. Ninety-eight percent present with stage I disease. Histologically, thecomatous components are common; cytoplasm is abundant. Mitosis may be numerous; the nuclei are dark and do not usually have the grooved coffee-bean appearance. Pleomorphism may also be present. Juvenile tumors rarely demonstrate Call-Exner bodies. Even though these tumors appear to be less well differentiated than the adult type, the cure rate is quite high for early-stage disease. **In contrast to adult cell types that are typically indolent and recur late, juvenile types are aggressive in advanced-stage disease with recurrence and death occurring within 3 years after diagnosis.**

On the basis of their differentiation, granulosa cell tumors should be divided into two general categories: well differentiated and moderately differentiated. The former pattern may have various presentations, including microfollicular, macrofollicular, trabecular, solid tubular, and watered silk. Tumors in the moderately differentiated category have a diffuse pattern that has also been designated "sarcomatoid." Although many authors have made attempts, no distinct correlation between histologic structure and prognosis has yet been substantiated. It is important that undifferentiated carcinomas, adenocarcinomas, and carcinoids should not be misdiagnosed as granulosa cell tumors, which they may superficially resemble. Each of these tumors has a strikingly different prognosis.

True granulosa tumors are low-grade malignancies, the majority of which are confined to one ovary at the time of diagnosis. Only 5% to 10% of the stage I cases will subsequently recur, and they often appear more than 5 years after initial therapy. The prognosis for these patients is excellent: Long-term survival rates from 75% to 90% have been reported for all stages (Fig. 12.10). **These lesions are adequately managed during the reproductive years by removing the involved ovary and ipsilateral tube with full surgical staging. The uterus and uninvolved adnexa should be removed in the perimenopausal and postmenopausal age groups, which is the treatment for other benign or low malignant potential tumors.** In a series from the Mayo Clinic, 92% of the patients had survived 5 to 10 years (76 patients, 82% of whom had stage I lesions). The recurrence pattern in this same series (18.6% overall recurrence rate) revealed that 23% of the recurrences were more than 13 years after initial therapy. Most of the recurrences occurred in preserved genital tract structures. These kinds of data have prompted some authors to recommend that the preserved internal genitalia be removed in perimenopausal patients in whom preservation may have been appropriate during the childbearing period.

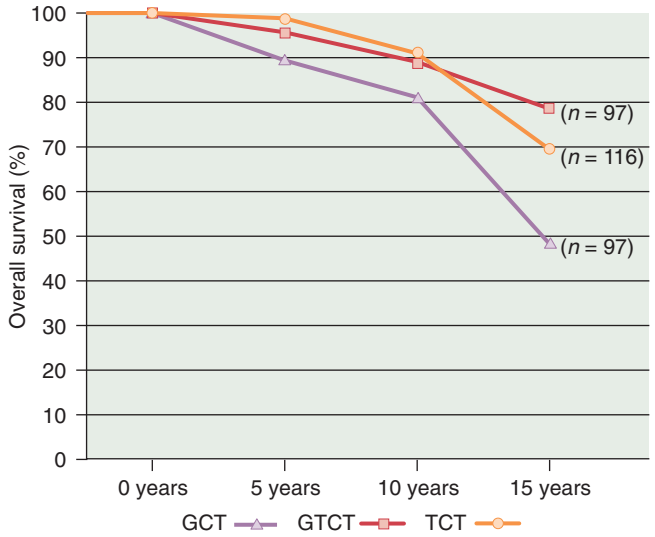

FIGURE 12.10 Granulosa–theca cell tumors from the Emil Novak Ovarian Tumor Registry (1999). *GCT,* granulosa cell tumors; *GTCT,* granulosa-theca cell tumors; *TCT,* theca cell tumors. (Modified from Cronje HS, Niemand I, Bam RH, Woodruff JD. Review of the granulosa-theca cell tumors from the Emil Novak Ovarian Tumor Registry. *Am J Obstet Gynecol* 1999;180:323.)

Several studies address prognostic factors in granulosa cell tumors of the ovary. The most important prognostic factor is stage. Other than stage, mitotic activity, DNA ploidy, and S-phase fractions have been evaluated. In a study of 54 patients from Sweden, patients with mitotic rates of 4 of 10 high-power fields (hpf) had no deaths, but all patients with 10 of 10 hpf died, with the longest survival being 4 years. Patients with mitotic rate of 4 to 10/10 hpf had a median survival of 9 years. Fortunately, most patients had mitotic counts of 4 of 10 hpf. In another smaller study, among the two-thirds of the patients studied who were found to have euploid tumors, only one patient died of disease, but four of five patients with aneuploid tumors died of disease. S-phase fraction did not correlate with any clinical or histologic parameters. Recently the Hellenic Cooperative Oncology Group reported on 34 patients with adult granulosa cell tumors of the ovary. In this study, stage and the presence of residual disease were noted to have prognostic significance for overall survival on univariate analysis. Tumor rupture during surgery was also prognostic for disease-free survival. Thirteen patients with unresectable disease were evaluated for response to chemotherapy. Six of seven patients who responded to first-line platinum-based chemotherapy had complete responses to therapy, demonstrating the importance of platinum agents in treating this tumor type.

Inhibin is a nonsteroidal polypeptide hormone that is secreted by granulosa cells of the ovary. This hormone is secreted throughout the menstrual cycle and during pregnancy but not in postmenopausal women. A study by Mom et al. investigated the value of serum inhibin A and B for the assessment of disease status. Thirty patients with stage I to III granulosa cell tumors were included in the study with pre- and posttreatment measurements of inhibin A and B obtained. Inhibin A and B were elevated in these patients and negative in control participants. The sensitivity of inhibin A for diagnosis was 67% with a specificity of 100% compared with 89% and 100%, respectively, for inhibin B; therefore, inhibin B appears to reflect disease status more accurately than inhibin A.

In collective series, the relationship of tumor to the level of inhibin appears to be very good. However, there have been conflicting reports relative to specificity because inhibin may also be secreted by many other ovarian neoplasms, including mucinous ovarian epithelial neoplasms. Nevertheless, **serum inhibin levels have an important role as a marker for monitoring patients under therapy and for detection of tumor recurrence, and although both inhibin A and inhibin B have utility as tumor markers, inhibin B has increased sensitivity (89% vs. 67%) with equivalent specificity (100%) for the diagnosis of recurrent granulosa cell tumor and should be used preferentially when available.** Other tumor markers include Müllerian inhibiting substance (MIS) and estradiol. Estradiol is not used clinically because of poor sensitivity, and MIS, although demonstrating excellent specificity, is only used for research purposes. Tumor markers, when elevated in the surveillance setting, are typically followed by imaging to localize

disease recurrence. In granulosa cell tumors, PET/CT has been shown to have variable F-18 fluorodeoxyglucose avidity, ranging from none to mild avidity, resulting in a potential false-negative study result.

Often, recurrent tumors have been treated effectively by means of reoperation, radiation therapy, chemotherapy, or a combination thereof. Although radiation therapy has been advocated for these tumors by many authors, careful search of the literature shows little evidence relating enhanced curability to the use of radiation therapy. A prospective study has never been done to compare one form of therapy with another for patients who have advanced or recurrent disease. The question of adjuvant radiotherapy in a postmenopausal woman found to have granulosa cell tumor is often an issue. Case reports are available and describe therapies used in recurrent granulosa cell tumors.

We recommend no further therapy for patients who have stage I lesions. Adverse prognostic factors that have been reported include large tumor size, bilateral involvement, intraabdominal rupture of the neoplasm, nuclear atypia, and a high mitotic rate. There appears to be agreement that the histologic pattern of the neoplasm has no predictive value. **Stage II or III or recurrent granulosa cell tumors are probably best treated with systemic chemotherapy.** Metastatic and suboptimally reduced disease should also be aggressively treated with combination chemotherapy because response rates as high as 83% have been reported. The GOG has evaluated BEP in a nonrandomized study of advanced or recurrent granulosa cell tumors of the ovary. Fifty-seven evaluable patients received four cycles of BEP followed by a reassessment laparotomy. Only 38 patients agreed to SLL, and 14 (37%) had negative results. Obviously, BEP is an active combination in these patients with advanced disease. Additionally, the following drugs have been used singly or in combination and appear to be effective: etoposide plus cisplatin; cyclophosphamide, doxorubicin, and cisplatin; paclitaxel and carboplatin; or a platinum agent alone. Reviews of the literature suggest that most granulosa cell tumors respond to hormonal therapy, and although data are sparse, aromatase inhibitors have been useful in the management of granulosa cell tumors in several reported cases. In a case report by Schwartz and Huang, a patient was identified with a recurrent granulosa cell tumor and was given anastrazole at the time of her third recurrence. This treatment caused rapid normalization of inhibin B. Ultimately, she showed partial response to therapy, but a later CT scan showed disease progression and she required further surgical resection. Subsequently, she later required external-beam radiation therapy and, on further monitoring, remained disease free for 3 years.

The natural history of patients with recurrences is prolonged, thus making analysis of any therapy very difficult in terms of overall survival. This is especially true of therapy used in an adjuvant setting. Although responses have been reported with paclitaxel alone, paclitaxel and carboplatin in combination, BEP, GnRH agonists, medroxyprogesterone acetate, megestrol, and alternating megestrol and tamoxifen, there are no good data to guide therapy in this setting. The role of biologic agents in the treatment of recurrence is unclear. Although some studies have shown significant expression of platelet-derived growth factor receptor (PDGFR) alpha and beta in granulosa cell tumors, raising the possibility of response to drugs such as imatinib mesylate, other investigators have documented low levels of c-kit, c-Abl, and PDGFR, suggesting limited efficacy of this class of agent.

Thecomas

Thecomas are less common than granulosa cell tumors, but they have similar appearances. They **are solid fibromatous lesions that show varying degrees of yellow or orange coloration.** Whereas granulosa cell tumors are found to be bilateral in 2% to 5% of patients, **thecomas are almost always confined to one ovary.** On microscopic examination, most tumors in the granulosa–theca cell category are found to contain both cell types. If more than a very small component of granulosa cells is present, the term *granulosa cell tumor*, rather than *granulosa–theca cell tumor*, is generally applied. The designation *theca cell tumor* or *thecoma* should be reserved for neoplasms that consist entirely of benign theca cells.

Thecomas consist of neoplastic cells of ovarian stromal origin that have accumulated moderate to large amounts of lipid. Sometimes such tumors contain clusters of lutein cells, in which case the term *luteinized thecoma* is often used. Occasionally, tumors fall into a gray zone between thecomas and fibromas. Although the latter also arise from ovarian stromal cells, they differentiate predominantly in the direction of collagen-producing fibroblasts. Tumors in the gray zone may be designated as *thecoma-fibromas*. They are almost always unilateral and virtually never malignant. Several tumors have been reported in the literature as malignant thecomas, but at least some of these are better interpreted as fibrosarcomas or diffuse forms of granulosa cell tumors. **In cases in which preservation of fertility is important, a thecoma may be treated adequately by unilateral oophorectomy. However, total hysterectomy with bilateral salpingo-oophorectomy is recommended in most postmenopausal and perimenopausal women. Because thecomas are typically one of the most hormonally active SCSTs, 15% to 37% and 25% of cases are associated with endometrial hyperplasia and carcinoma, respectively,** and endometrial sampling should be performed. Patients typically present with abnormal bleeding and an abdominal or pelvic mass.

Fibromas and Sclerosing Stromal Cell Tumors

Fibromas are the most common SCST and occur primarily in postmenopausal women, although they can occur in any age group. **They are not hormonally active tumors. Fibromas are typically benign tumors**; however, recently, cellular fibromas have been described and are considered to be of low malignant potential. Fibrosarcomas, by contrast, are rare but considered highly aggressive tumors. The behavior of these tumors is correlated with mitotic activity and degree of anaplasia.

Fibromas may be associated with ascites or hydrothorax as a result of increased capillary permeability thought to be a result of vascular endothelial growth factor production. Meigs syndrome (ovarian fibromas, ascites, and hydrothorax)

is uncommon and usually resolves after surgical excision of the fibroma. Gorlin syndrome, or nevoid basal cell carcinoma syndrome, is a rare inherited predisposition to multisystem abnormalities, including ovarian fibromas. Because of the benign nature of fibromas, surgical excision is all that is required.

In contrast to most SCSTs, sclerosing stromal cell tumors typically present in the second and third decades of life, although they can occur in adolescents and premenarchal girls. They may be clinically undetectable or grow to a very large size. They are considered benign, occur unilaterally, and are hormonally inactive except in very rare cases. Clinical symptoms include premature menarche; menstrual irregularities; pain; and uncommonly, ascites. Imaging characteristics reveal predominately solid masses with hypervascularity, although complex cystic masses may be seen. Tumor markers are not elevated.

Sertoli-Leydig Cell Tumors

Sertoli-Leydig cell tumors contain Sertoli cells or Leydig cells in varying proportions and degrees of differentiation. The degree of differentiation contributes to the malignant potential of these tumors. Most well-differentiated tumors are clinically benign. Size greater than 5 cm, necrosis, nuclear atypia, vascular invasion, and high mitotic rate (>5 per 10 hpf) increase the likelihood of a malignant course. Because less well-differentiated neoplasms within this category may recapitulate the development of the testes, the terms *androblastoma and arrhenoblastoma* have been used as synonyms for *Sertoli-Leydig cell tumors*. However, their connotation of associated masculinization is misleading because some of these tumors have no endocrine manifestation, and others may even be accompanied by an estrogenic syndrome. Nevertheless, the WHO has selected *androblastoma* as an alternate term for *Sertoli-Leydig cell tumor*.

These neoplasms account for fewer than 0.5% of all ovarian tumors but are among the most fascinating from pathologic and clinical viewpoints. They are typically unilateral tumors and confined to the ovary in 97% of cases. **They occur in all age groups but are most often encountered in young women (between the ages of 20 and 30 years), who usually become virilized** (Fig. 12.11)**.** Although rare in children, the clinical presentation is typically one of isosexual pseudoprecocity. **In immunocytochemical studies, testosterone appears to be localized predominantly within the Leydig cells, but estrogen and androstenedione are produced by many of the same cells.** Thus, one can appreciate the spectrum of the clinical presentation of this fascinating neoplasm. **Classically, there is progressive masculinization that is heralded by hirsutism, temporal balding, deepening of the voice, and enlargement of the clitoris. Other patients may manifest secondary amenorrhea, breast atrophy, and a marked increase in libido.**

Sertoli-Leydig cell tumors can be described in terms of differentiation and the presence or absence of heterologous elements, distinctions that have clinical relevance. Sertoli-Leydig cell tumors with heterologous elements may contain various unusual cell types, but the degree of differentiation of the tumors is probably of greater importance in determining its prognosis than is its content of unexpected tissue. Although these tumors have a distinctive histologic pattern that facilitates diagnosis, antibody markers can aid in the differential diagnosis, such as inhibin.

FIGURE 12.11 Enlarged clitoris in a patient with a Sertoli-Leydig cell tumor (arrhenoblastoma).

In the report by Young and Scully, only 29 of 220 tumors of this type were clinically malignant. None of the 27 well-differentiated tumors and only four of 100 tumors of intermediate differentiation were known to be clinically malignant. A total of 59% of poorly differentiated tumors and 19% of heterologous tumors displayed malignant behavior. Zaloudek and Norris reported on **64 intermediate and poorly differentiated neoplasms. Only three of 50 patients with stage I disease developed a recurrence** (Table 12.10). The 5-year survival rate in all of their patients was 92%.

The overall 5-year survival rate of patients with Sertoli-Leydig cell tumors has been reported to range from 70% to more than 90%. Because these tumors occur predominantly in young women and are bilateral in fewer than 5% of cases, conservative removal of the tumor and adjacent fallopian tube is justifiable if preservation of fertility is an important consideration and if there is no evidence of extension beyond the involved ovary. Removal of the tumor will halt, but not fully reverse, the masculinizing process. Similar to granulosa cell tumors, they are considered to have low malignant potential. There are no solid data to suggest that adjuvant therapy has any value in preventing a recurrence in patients with stage I lesions. **Tumors with poor differentiation, heterologous elements, advanced stage, or recurrent lesions should be treated with adjuvant chemotherapy.** Again, **BEP chemotherapy is often recommended.** In the unusual patient who has an advanced or recurrent Sertoli-Leydig cell tumor, chemotherapy appears to be effective, although the experience is very limited.

TABLE 12.10 Management of Germ Cell and Sex Cord Stromal Tumors

Neoplasms	Suggested Surgery	Postoperative Chemotherapy	Reassessment Laparotomy
Dysgerminoma	Unilateral S&O when confined to one ovary: preserve normal-appearing ovarian tissue	BEP for 3 cycles if the patient is not adequately staged or if stage II–IV	Not necessary unless a recurrence is suspected
Endodermal sinus	Debulk: attempt to preserve fertility	BEP for 3–4 cycles; follow with AFP titers	Same as above
Embryonal carcinoma	Same as above	BEP for 3–4 cycles; follow with β-hCG titers	Same as above
Malignant teratoma	Same as above	BEP or VAC for 3–4 cycles	Same as above
Granulosa cell	Unilateral S&O for young patients with stage Ia disease; otherwise TAH, BSO	BEP for 3–4 cycles; GnRH agonists for advanced disease	Same as above
Sertoli-Leydig cell	Same as above	BEP or VAC for 3–4 cycles for advanced disease	Same as above

AFP, Alpha-fetoprotein; *BEP,* bleomycin, etoposide, and cisplatin; *β-hCG,* β-human chorionic gonadotropin; GnRH, gonadotropin-releasing hormone; *S&O,* salpingo-oophorectomy; *VAC,* vincristine, dactinomycin, and cyclophosphamide.

Sex Cord Tumor With Annular Tubules

Sex cord tumor with annular tubules (SCTAT) represents a unique ovarian tumor that appears as a histologic intermediate between granulosa and Sertoli-Leydig cell tumors. SCTATs account for 6% of SCSTs. This tumor typically presents in the third to fourth decade of life and is usually unilateral. Presenting complaints are usually abnormal vaginal bleeding or postmenopausal bleeding, a testament to the endocrine activity of these tumors. Both estrogen and progesterone production have been reported. **Approximately 30% of SCTAT tumors are associated with PJS. Tumors associated with PJS are benign but are associated with adenoma malignum of the cervix in 15% of cases.** Because adenoma malignum has a relatively high mortality rate, these patients deserve careful evaluation and follow-up. **In contrast, SCTAT, which is not associated with PJS, has a 20% malignancy rate.** Malignant SCTAT seems to spread via the lymphatics with typical metastatic sites being the pelvic, paraaortic, and supraclavicular lymph nodes. There is limited experience in the literature with these tumors. Clinically, they should be managed in a similar manner to other SCSTs. Combination chemotherapy (BEP) may be helpful in patients with advanced disease. Because SCTAT represents an intermediate cell type between granulosa cell and Sertoli-Leydig cell tumors, SCTAT may express inhibin or MIS. Inhibin and MIS can be used as markers for recurrence, however, the utility of these tumor markers in this disease is uncertain.

Gynandroblastoma

Rarely, a gonadostromal tumor contains unequivocal granulosa cell elements combined with tubules and Leydig cells that are characteristic of arrhenoblastomas. Designated as gynandroblastomas, these mixed tumors may be associated with either androgen or estrogen production, and they can be expected to behave as low-grade malignancies similar to the individual components. The diagnosis of gynandroblastoma depends on histologic examination rather than the clinical and laboratory findings. The WHO definition of gynandroblastoma is very strict; therefore, tumors matching these exact specifications are rare.

Steroid Cell Neoplasms

Steroid cell neoplasms (also known as lipid cell neoplasms) are a heterologous group of tumors that have in common a parenchyma composed of polygonal cells that contain lipid. They include neoplasms that have been designated as hilus cell tumors, Leydig tumors, adrenal rest tumors, stromal luteomas, or masculinovoblastomas. Stromal luteomas are benign tumors, which account for 25% of steroid cell neoplasms and occur 80% of the time in postmenopausal women. They commonly present with postmenopausal bleeding, thought to result from a hyperestrogenic state from either direct secretion of estrogens by the tumor or secretion of androgens with subsequent conversion to estrogen. Estrogen secretion predominates, however. Leydig cell tumors are unilateral and are found commonly in the medulla or hilus regions of the ovaries. These tumors are androgen-secreting tumors and are not thought to be malignant. Reinke crystals, which normally occur in mature Leydig cells of the testes, are often found in these neoplasms, and their presence may be interpreted as signifying a benign lesion. **Steroid cell tumors (not otherwise specified)** are tumors that cannot be characterized as stromal luteomas or Leydig cell tumors. They **are androgenic tumors that may be associated with paraneoplastic manifestations such as hypercalcemia, erythrocytosis, or ascites. In 20% of cases, they will have spread to contiguous organs at the time of surgery. Tumors that have microscopic cellular pleomorphism with high mitotic activity or the presence of necrosis should be considered malignant.**

TUMORS DERIVED FROM NONSPECIFIC MESENCHYME

Benign and malignant tumors, including fibromas, hemangiomas, leiomyomas, soft tissue sarcomas, lymphomas, and rare neoplasms, may arise in the ovaries from nonspecific supporting tissues that are common to most organs. The most common and most important tumors in this category are fibroma and lymphoma.

MALIGNANT LYMPHOMA

Malignant lymphoid tumors of the genital tract are rare; however, the ovaries are the most common sites affected. Most commonly this represents ovarian involvement in overt systemic disease, almost always of the non-Hodgkin type. There has been debate as to whether lymphoma can arise de novo

in the ovary; lymphoid aggregates do exist in normal ovarian tissue, which could give rise to such a lesion.

Patients with disease localized to one ovary usually do well with unilateral surgical resection followed by systemic chemotherapy. The use of chemotherapy is based on the principle that ovarian lymphoma must be considered a localized manifestation of systemic disease. The prognosis for such patients is much better than that of patients with obvious systemic disease.

METASTATIC TUMORS TO THE OVARY

The ovary is frequently the site of metastasis from certain primary carcinomas. **Approximately 10% of ovarian tumors are not primary in origin. The most common source of metastatic disease is the endometrium.** Many metastatic adenocarcinomas, particularly those that exhibit mucinous differentiation, can mimic primary ovarian adenocarcinomas. Immunohistochemistry (CK7 and CK20) staining has been widely used to aid in distinguishing primary from secondary ovarian adenocarcinoma. This is particularly true in the case of ovarian endometrioid carcinoma, which, according to Scully, is associated with a similar tumor in the endometrium in one-third of cases.

There are four possible pathways of spread to tumors to the ovary:

- **Direct continuity**
- **Surface papillation**
- **Lymphatic metastasis**
- **Hematogenous spread**

Lymphatic metastasis is undoubtedly the most common pathway for spread to the ovary. The rich network of lymph nodes and lymphatic channels in the pelvis readily explains the metastatic pathway of tumors in the uterus and contralateral ovary. The rare finding of clusters of tumor cells limited to lymphatics in the medulla of the ovary in cases of breast carcinoma confirms that this is the pathway of spread to the ovary. As yet, no one has convincingly described the pathway of metastasis to the ovaries from cancer of the stomach. It is known that the lymphatic channels that drain the upper gastrointestinal tract ultimately link up with the lumbar chain of lymph nodes. Ovarian lymphatics drain into the lumbar nodes. This could be the route of spread to the ovaries in these cases.

The latest reports confirm adenocarcinoma of the colon as the most frequent nongynecologic primary site of metastatic disease to the ovary, with breast cancer in second place. These lesions are characterized microscopically by the presence of large acini similar to those of primary intestinal carcinomas. Grossly, they may form solid metastases but more often appear as large, partly cystic tumors with areas of hemorrhage and necrosis (Fig. 12.12). In such cases, they are easily confused with cystic forms of primary ovarian cancers. Regarding labs, carcinoembryonic antigen (CEA) levels exceeding 5 ng/mL are often found in patients with gastrointestinal carcinomas. In particular, values above 20 ng/mL in the setting of colorectal cancer are often associated with metastatic disease. Buamah et al. published a study on 155 patients with elevated CA-125 levels, 47 of whom had ovarian cancer and 38 with colorectal cancer. In this population, the ratio of CA-125 to CEA appeared to be excellent for differentiation between ovarian cancer and nonovarian cancers because all 47 patients with ovarian cancer had a ratio greater than 25.

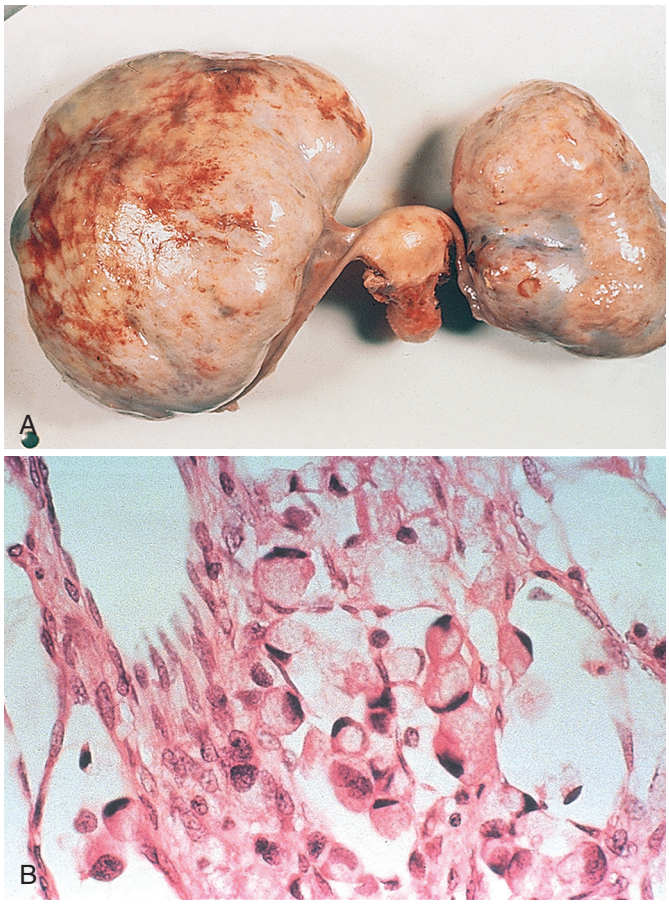

FIGURE 12.12 Metastatic tumor to the ovary from adenocarcinoma of the colon. **A,** Gross appearance. **B,** Histologic appearance. Note the large acini similar to those of the intestinal carcinoma.

Metastatic adenocarcinomas of large intestinal origin have become more common than Krukenberg tumors in the past 2 decades with the gradual decline in the incidence of carcinoma of the stomach. **The term *Krukenberg tumor* should be reserved for metastases that contain significant numbers of signet-ring cells in a cellular stroma derived from the ovarian stroma.** This restriction is important because tumors with these microscopic characteristics also have distinctive gross pathologic and clinical features. **Almost all metastasize from the stomach, but some arise in the breast, intestine, or other mucous gland–containing organs.** Krukenberg tumors form a solid, often uniform mass, the sectioned surface of which typically exhibits gelatinous necrosis and hemorrhage. **Metastases from carcinomas of the breast are among the more common surgical specimens of the ovary, especially if one includes those found incidentally.** They are almost always incidental findings in therapeutic oophorectomy and rarely form symptomatic masses that require surgical removal.

Cases of metastatic ovarian carcinoma have occurred in which the clinical presentation was consistent with hormonal activity. Both androgen and estrogen excretion have been described. Endometrial hyperplasia has been described in postmenopausal patients with metastatic ovarian carcinomas, presumably indicating estrogen activity within the metastatic lesion or its normal tissue capsule.

MALIGNANT OVARIAN TUMORS IN CHILDREN

The differential diagnosis of adnexal masses in children and adolescents is wide and encompasses a variety of ovarian and fallopian tube lesions. Ovarian tumors, cysts, and torsion are more frequent indications for surgical intervention in infancy and childhood than is commonly realized. The majority of patients in this age group with an adnexal mass can present with pelvic or abdominal pain, which is the most commonly reported symptom, accompanied by nausea, vomiting, and fever, symptoms that may mimic appendicitis.

In childhood, ovarian tumors are the most frequent neoplasms of the female genital tract and account for approximately 1% of all malignancies in patients from birth to 17 years of age. Tumors of germ cell origin constitute approximately 70% of ovarian tumors in children. The evaluation of an adnexal mass in a pediatric or adolescent patient is similar to that of an adult to include appropriate laboratory studies and inclusion of tumor markers. Pediatric ovarian malignancies are rare; therefore, only 36% to 63% of ovarian malignancy cases in adolescents and children are identified correctly before surgery.

The most common germ cell tumor in this patient population are dysgerminomas, constituting 9.5% to 11% of childhood ovarian tumors and 24.5% of pediatric ovarian malignancies. It is also important to examine for features of precocious puberty to include presence of axillary and pubic hair and breast and areolar development in children presenting with a pelvic mass. Isosexual precocious puberty is associated with ovarian tumors in 5% of patients; however, approximately 16% of children with ovarian tumors present with premature secondary sexual development. **Granulosa–theca cell tumors are by far the most common ovarian neoplasms found in these patients with isosexual precocity and adnexal enlargement.**

Treatment of adnexal masses must be balanced with the imperative to maintain the child's reproductive and developmental potential. A study by Park et al. reported on 42 pediatric and adolescent girls with malignant ovarian germ cell tumors. The median age of the patients was 12 years with immature teratoma as the most common tumor type. All patients underwent fertility-sparing surgery with the preservation of one adnexa and the uterus. Thirty-one patients received adjuvant chemotherapy with BEP. The 5-year disease-free survival rate for this patient population was 85%. Ablin reported on a study of 17 children with ovarian germ cell tumors treated with multiple-agent chemotherapy. Of the 17 patients, 13 showed complete responses to therapy, suggesting that survival rates in this group of patients have improved significantly with modern chemotherapy. Lack and coworkers reported that granulosa–theca cell tumors in the premenarche patient accounted for 4% of childhood ovarian tumors at their institution from 1928 to 1979. The average age of diagnosis of their 10 patients was 5 years, and precocious "pseudopuberty" was the most common presentation. These 10 lesions were solitary; five were on the right side, and five were on the left side, with an average diameter of 12 cm. All 10 patients survived at least 10 years, and salpingo-oophorectomy was curative despite tumor spillage in two patients. Fortunately, few ovarian masses are malignant and can be adequately treated using conservative surgery in combination with platinum-based chemotherapy.

Fallopian Tube Cancer

Erica R. Hope, MD, G. Larry Maxwell, MD, Chad A. Hamilton, MD

OUTLINE

Introduction
Traditional Characteristics
Epidemiology, Classification, and Etiology
Symptoms and Signs
Emerging Paradigms
Fallopian Tube Cancer and *BRCA* Mutations
Occult or Intraepithelial Fallopian Tube Cancer Found During Risk-Reducing Surgery
Serous Tubal Intraepithelial Carcinoma
Fallopian Tube Cancer and Serous Tubal Intraepithelial Carcinoma Beyond *BRCA*
Clinical Implications
Conclusion

KEY POINTS

1. Fallopian tube cancer (FTC) was historically thought to be a rare cancer. Now, most high-grade serous carcinomas are thought to arise from the fallopian tube as opposed to the ovary.
2. The triad of pain, metrorrhagia, and leukorrhea is considered pathognomonic for FTC.
3. *BRCA1* and *BRCA2* carriers are at increased risk for FTC and should undergo extensive sectioning of the fallopian tubes during risk-reducing surgery.
4. Serous tubal intraepithelial carcinoma is a precursor lesion to high-grade serous carcinoma.
5. Early salpingectomy with delayed oophorectomy is currently being studied and may become an option in high-risk women to decrease mortality and maintain quality of life.

INTRODUCTION

Primary fallopian tube cancer (FTC) was traditionally considered an exceedingly rare gynecologic malignancy. Few pelvic serous tumors met rather strict diagnostic criteria for FTC, and the disease site was overshadowed by the clinicopathologically similar and far more common high-grade serous ovarian carcinoma (HGSOC). Over the past decade, mounting evidence implicates carcinogenic processes beginning in the fallopian tube as the true origin of the majority of extrauterine high-grade serous carcinomas (HGSCs) inclusive of both HGSOC and primary peritoneal carcinoma (PPC). Indeed, the most recent International Federation of Gynecologists and Obstetricians (FIGO) staging has recognized the commonality of these tumors in a unified staging system, and a broad international collaboration recommended fairly dramatic changes for assigning the site of origin for HGSC aligning with a paradigm of fallopian tube origin. This chapter describes FTC from what could be considered a historical perspective followed by a discussion of the precursor lesions and additional evidence leading to current models of carcinogenesis of FTC and by extension most extrauterine HGSCs.

TRADITIONAL CHARACTERISTICS

Epidemiology, Classification, and Etiology

Based on primary site classifications set forth by Hu and later modified by Sedlis, adenocarcinoma of the fallopian tube accounted for fewer than 0.2% of cancer diagnoses among women annually with an incidence of 0.41 per 100,000. The most complete systematic review to date comparing FTC versus HGSOC found few significant differences in FTC and HGSOC relative to risk factors, clinicopathology, and molecular biology. Notably, the reviewed studies defined FTC in traditional terms as set forth by Hu and later Sedlis.

In 1950, Hu and colleagues suggested diagnostic criteria for the diagnosis of tubal cancer: (1) the main tumor grossly should be in the fallopian tube; (2) histologically, the tubal mucosa should be involved with a papillary pattern; and (3) if the tubal wall is involved to a large extent, transition from benign to malignant tubal epithelium should be identified. Sedlis and colleagues modified these criteria in 1978: (1) the main tumor arises from the endosalpinx, (2) the histologic pattern reproduces the epithelium of tubal mucosa, (3) transition from the benign to malignant tubal epithelium is demonstrable, and

(4) the ovaries or endometrium are either normal or contain a tumor that is smaller than the tumor in the tube.

Using the above definitions, a few characteristics relative to both risk factors and presentation are uniquely associated with primary FTC. A number of investigators implicate chronic tubal inflammation in tubal carcinogenesis. The initial association was with tuberculosis, and sporadic reports of fallopian tube carcinoma with coexisting tubercular salpingitis continue. Although histologic features of old pelvic inflammatory disease or endometriosis are frequently noted on examination of the tube and changes consistent with chronic healed salpingitis have been found in the contralateral tube of patients with unilateral FTC, evidence supporting such inflammatory changes as precursors to the development of carcinoma is inconsistent.

Symptoms and Signs
