Preface

This is to continue the North American Chinese Overseas Transportation Association (NACOTA) tradition of organizing at least two major transportation conferences each year, one in Washington D.C. and the other in China. The 9th ICCTP in Harbin represents the NACOTA summer conference in 2009, which is jointly hosted with Harbin Institute of Technology with the sponsorship of the Transportation and Development Institute (T&DI) of American Society of Civil Engineers (ASCE). In the past five years, NACOTA has held its summer conferences in Wuhan, Dalian, Xi'an, Shanghai, and Chengdu, at a different city each year to generate grassroots impact and promote NACOTA.

Established in January 1996, NACOTA is a non-profit professional organization with its members working or studying in the transportation or related fields and who are interested in contributing to the transportation development in China. The main objectives of NACOTA include: promote transportation development in China by providing knowledge and expertise through its members; strengthen the links between transportation professionals and students in North America and other parts of the world and their counterparts in China; promote networking among Chinese overseas transportation professionals and students; and disseminate information on state-of-the-art transportation developments and major events in China to NACOTA members, partners, and friends.

Only since a couple of years ago have NACOTA started producing conference proceedings. As we continue to generate widespread interest in such events, we have gained a great deal of experience in organizing large conferences and producing high quality articles in the proceedings. This year, for example, a total of 948 papers were received from authors of eight countries and regions, including Mainland China, Taiwan, the United States, Canada, United Kingdom, Germany, Japan, and Korea. To ensure the quality of the ICCTP 2009 proceedings, rigorous technical evaluation and English editing efforts had been made. As a result, only about 50% of the submitted papers were accepted for publication in the ICCTP 2009 proceedings. Those selected papers cover all the twelve key theme areas of transportation as planned for the conference.

As NACOTA continues to grow we hope more people will join our organization as a member, a partner, or a friend. Only with your continued support and contributions can we carry on the NACOTA tradition to best benefit you and the society.

Acknowledgements

The editorial board of this proceedings and the executive committee of 9th International Conference for Chinese Transportation Professionals (ICCTP 2009) would like to thank all the authors who submitted their papers to this conference. Those papers selected for publication were revised multiple times and the authors were very cooperative and supportive during the process.

Harbin Institute of Technology (HIT) kindly hosted the ICCTP 2009 conference and offered numerous supports to ensure a successful conference. The hard work from HIT faculty, staff, and students definitely deserve kudos. The T&DI of ASCE not only sponsored the conference, but also helped recruiting volunteers for English-editing the papers. These volunteers' helps were essential for the quality of this proceedings and their timely efforts are highly appreciated. In particular, special gratitude goes to Dr. Louis F. Cohn and Ms. Eva Lerner-Lam for their advice and to Ms. Donna Dickert and Mr. Jonathan C. Esslinger for their hard work to publish the proceedings.

ICCTP 2009 is the 9th summer conference of NACOTA. We would like to thank the members of NACOTA, Board of Directors, and Advisory Committee for their advice and consistent support. In particular, we want to recognize the contribution and timely support of Dr. Fang (Clara) Fang who handled the financial duties throughout the entire process for NACOTA.

Lastly, we would like to thank all the conference organizers, staff, editors (including English editors), and ICCTP 2009 participants for their contributions and hope that everyone finds the proceedings both informative and enjoyable.

Table of Contents

Transportation Safety

Information Needs of Urban Transit Travelers—The Case of Wuhan, China 1
Zhengdong Huang, Xuejun Liu, and Jie Li

Study on the Rational Size of the Box Girder Used in Cable-Stayed Bridge Based on ANSYS 8
Xia-lin Yang, Xue-xian Sun, Ya-ping Wu, and Xiao-dong Mao

Research on the Crashworthiness of Two-Layer Thin-Walled Structures 15
Shourne Xiao, Qiyu Shan, Guangwu Yang, and Hanzhen Chen

Effects of Roadway Lighting Level on the Pedestrian Safety 21
Huaguo Zhou and Ping Hsu

Analysis of a New Combined Micropile Structure for Preventing Slope Slippage and Its Application in a Practical Project 30
S. G. Xiao, K. Cui, D. P. Zhou, and J. Feng

Experimental Research on the Mechanical Parameter of Fly Ash Soil 41
Han-bing Liu, Chang-yu Li, and Hai-bin Wei

The Bearing Character of Bridge Piles in Karst Areas 49
Hourong Kang, Xiedong Zhang, and Hong Li

The Analysis of Traffic Landscape from Users' Perspective: The Case of the Zhangjiang Tram 56
Na Li, Xiaohong Chen, and Wen Xiong

Traffic Incident Acoustic Recognition Based on Wavelet Decomposition and SVM 65
Xianglong Luo, Qisheng Wu, and Guohong Niu

Gray-Periodic Extensional Combinatorial Model for Road Traffic Accidents in Cold Regions 71
Shi An and Lilan Li

A Multi-Objective Decision Model of Traffic Rescue Service Site Location on Road 80
Gan Chai, Chengwei Fang, Jiaxiang Zhou, and Shui Wan

The Method of Road Safety Analysis Based on Two-Dimensional Speed Difference **87**
Xingwang Liu and Jingmei Wu

Risk Evaluation for Highway Transportation of "Toxic Gas" Hazardous Materials—Based on a Back Propogation (BP) Neural Network **93**
Kai-zheng Liu and Hao-zue Liu

Study on Different Residual and Weight Coefficient in Model Updating of Bridge Structure **100**
Jie Li, Min-shui Huang, and Hong-ping Zhu

Study on a Passageway Location Model on Underground Expressway **108**
Yucong Hu, Bingqiang Situ, Wenzhou Jin, and Qin Liu

Optimum Choice for the Construction Management Plan Based on Entropy Weight **115**
Yong-Fen Ruan, Jin-Ping Wang, Wang Dong, and Mou Jie

Lane Change Behavior Character and Its Influence to Traffic Safety on Urban Roads **122**
Y. Zhang, Q. Huang, M. Zhang, and X. Yu

Study on the Rules of Crash Distribution **129**
X. Zhong, X. Chen, and Z. Wei

Quick Maintenance for Tunnel Lining Voids with Polymer Grouting Technology **136**
Jianguo Xu, Fuming Wang, and Bo Wang

Safe Spacing Research Based on the Theory of Cellular Automation on Freeways in Foggy Weather **142**
Q. Shi, Z. Huang, and W. Liu

Simulation of Turning Stability Control for Two-Motor-Drive Electric Vehicles **150**
Shaobo Xie, Cheng Lin, Peng Liu, and Xiaowei Zhang

The Simulation Analysis of Passenger Evacuation in One Metro Station Based on Exodus **157**
Y. F. Ye, Q. F. Hu, and H. W. Huang

Research of Company Freight Traffic Generation Prediction Models in **164**

High-Tech Park
Ke Zheng and Yaping Zhang

Bending Vibration Suppression of High Speed Railway Passenger Car Body 171
Caihong Huang, Jing Zeng, and Ren Luo

Analysis of Deformation Characteristics of Collision Vehicles Using Close-Range Photogrammetry 177
Z-M. Tao and Y-L. Pei

Traffic Safety Evaluation of the 30 Provincial Capital in China Based on Principal Component Analysis 185
Sheqiang Ma, Chunfu Shao, Zhuanglin Ma, and Dong Liu

Study on Spatial Information Model and Database of Traffic Facilities Management Systems Based on ArcGIS 192
Y. Wang, S. Dong, H. Kui, T. Gao, H. Yu, H. Wang, and Y. Liu

Expressway Data De-Noised Approach Based on Wavelet Analysis 198
Zhenjun Wang, Jizhen Guan, Jianling Yu, and Jing Liu

Influence Analysis of Deep Discount Policy on Public Transit Ridership 204
Yan Han, Hongzhi Guan, and Xuejiao Fang

Design and Validation of Wireless Dynamic Testing System for Bridge Based on the 941B Type Vibration Sensor 211
Zhonglong Li, Lianzhen Zhang, Xiaodi Zhu, Hongjiang Gu, and Zitian Jiang

Application of Fractal Theory in Pavement Surface Texture Measurement 219
Yan Yuan, Anxing Lai, and Yun Que

Research on Application of Externally Prestressing for Simple-Continuous Bridge 226
Kejian Sheng, Rongda Li, and Zonglin Wang

Restraint Efficacy Analysis and Structure Optimization for the Design of Airplane Metal Chocks 234
Fuhai Li, Hongbin Gu, and Hongyu Yao

The Comparison of Three Getting Signal Control Delay Video Methods at Signalized Intersection 241
Huiling Zhang, Keping Li, Hongbo Qian, and Guimin Su

Enhancing Immersion through Adjusting Parameters of Vehicle Driving Simulator 247
Xiaobo Zhou, Shunying Zhu, Hong Wang, and Bing Liu

A Calculation Method for the Information Utility of Traffic Guide Signs 254
Li-Li Zhu, Jian-Jun Shi, and Xin-dong Chen

Safety Evaluation Methods of Road Traffic Based on Gray Cluster Theory 260
L. Wei and Z. Guan

Road Traffic Control Information and Traffic Resource Analysis System 268
Hui Zhang, Zhongzhen Yang, Yonglei Jiang, and Haigui Kang

Research on the Crashworthiness Optimization of Curved-Road Concrete Barriers 277
Zhengbao Lei, Lan Liu, Zuo Peng, and Shijing Hou

Highway Accidents Analysis with Panel Data Model 287
T. Xu, X. Sun, Y. He, and C. Xie

The Impacts of Differential Speed Limits on Speed 294
Shicui Liu, Xiaoduan Sun, Yulong He, and Shuzhan Hou

Study on the Influence of Coarse Aggregate on the Pavement Performance of Road Cement Concrete 300
Ai-qin Shen, Jian-ping Xiong, Jun-hui He, and Tai-jun Liu

Research on the Competitiveness of China's Ports 307
B. Liu and C. Liu

Equilibrium Model of Trip Modes in Road Traffic and Orientation of Charge Policy 317
Linlin Wu, Qifen Zha, and Jianyi Liu

Analysis of the Influence of Emergent Incident on Expressways by Simulation 323
M. Li, W. Jin, and S. Fang

Optimization of Regional Traffic Structure from the Perspective of Sustainable Development 330
Linlin Wu, Qifen Zha, and Jianyi Liu

Performance Evaluation of Waterproof Bond Layer Materials Based on 336

Grey Target Theory
Xin Yu

Probabilistic Pedestrian-Vehicle Conflict Micro-Model in Non-Signal Controlled Multi-Lane Segments **343**
S. Lu, S. Fang, and S. Zheng

Research on Simulation of Train Tracing Operation Based CBTC **351**
Z. Ma, X. Chai, and L. Chong

Research on Rapid Curing Technology of Lime-Flyash-Cement Stabilized Macadam **357**
Yuanzhao Chen, Zhenxia Li, and Xuancang Wang

Experimental Research on Shear Connectors' Stress of Composite Beam Bridge under Complex Stress Condition **365**
Shibo Zhang, Ronghui Wang, Junping Zhang, and Lingling Gong

A Retrograde Vehicle Detection Method Based on the Optical Flow Field **371**
You-ting Zhao, Xi-ying Li, and Zhen-bo Wang

Research on a Risk Analysis System of Vessel-Bridge Collision **378**
Tao Fu, Junjie Wang, and Junjian Zhang

Methods of Setting Maximum Speed Limits on Freeways **384**
Guozhu Cheng and Yulong Pei

Study on the Carrying Capability of Preplanned Regional Earthquake Evacuation Corridor Based on Macro-Simulation **390**
Yang Wang, Zhijie Li, Jing Cao, and Xiaokuan Yang

The Analysis of Traffic Flow State on Foggy Expressway Based on Fuzzy Clustering **398**
Jianjun Wang, Chenfeng Xie, Zhenwen Chang, and Jingjing Zhang

Research on the Impact of Drivers' Heart Rate on Longitudinal Slope of Freeway Tunnel **405**
Jianyou Zhao, Cao He, and Yanni Shi

A Study on Cable-Removing Scheme of the Cable-Stay System of the Zhijing River Bridge **413**
Jianjun Wei and Nianhe Chen

Design Theory for Speed Control by Using Constant Edge Rate **419**
Bing Liu, Shunying Zhu, Hong Wang, Jing Xia, and Qinmei Sun

Optimization of Dynamic Dispatching Decisions of Local Wagon-Flows in Terminals with IRTS **425**
Zuoan Hu and Yusong Yan

Laboratory Evaluation of the Warm Mix Asphalt Performance in Liaoning **433**
Yanhai Yang, Huaizhi Zhang, and Yaodong Wu

Model of High Speed Railway Wheel Ovalization **440**
Xueshan Zhang, Xinbiao Xiao, and Xuesong Jin

From Time Based Speed Series to Behavior Sequence: The Transformations and Applications of VTDR Data **449**
Zhenfeng He and Zhenzhi Huang

Road Safety in Sections under Mixed Flow Traffic Environment **456**
Sisi Liu, Xiaoduan Sun, and Yulong He

Analysis on Vehicle No-Sideslip Single Side Skid Equivalent Frictional Coefficient **463**
Yongheng Yue, Qiang Zhao, and Qingdong Xia

Discussion on Methods of Traffic Routes' Alignment Survey and Application of Principle of Least Squares **470**
Yubao Liang, Baoxi He, Shaotang Liu, and Qianli Ma

A Study on Speeding Driving Based on Expected Speed **480**
Chen Hu, Xiaoduan Sun, and Shicui Liu

Vehicle Tracking from Videos Based on Mean Shift Algorithm **486**
Chang-Zhen Xiong, Yi-Gui Pang, Zheng-Xi Li, Ya-Li Liu, and Ying-Hong Li

The Evaluation of Micro-Benefit on Highway Construction Investments **494**
Hong Chen, Yujia Tian, Dianliang Xiao, and Fengxia Wang

Noise Source Identification and Noise Reduction of a Double Crank Four Ring-Plate-Type Cycloid Reducer **501**
B. Yang, Y. Liu, and X. Zhang

Analysis Model for Operating Speed on Two-Lane Secondary Highway **507**

Dianliang Xiao and Yujia Tian

Study on the Method for Calculating Ship Squat in the Restricted Channel **515**

Zhong-Yi Zheng, Long-Hui Gang, and Hong-Xi Li

A Study on Driver's Dynamic Visual Characteristics **521**

Fei Song and Xiao-kuan Yang

Study of Hydrodynamic Pressure on the Cylindrical Pile-Cap Pier in Deep Water Subjected to Seismic Action **528**

Haopeng Liu, Bo Song, and Guoming Zhang

Influencing Factors Contributing to Rear-End Collisions on Highways: PCA Based Investigation and Findings **536**

H. Jun, H. Xu, Y. Pei, and H. Ji

Passenger Transport Demand Prediction for Newly-Built Regions **542**

Maomin Zhang and Yisheng Liu

The Method to Identify Black Spots of Long Highway Tunnel **549**

Zhuanglin Ma, Chunfu Shao, Shengrui Zhang, and Juan Zhang

Study on the Relationship of Traffic Flow Complexity and Traffic Conflict on Urban Road **555**

Zhihong Xu, Xuewu Chen, and Meikin Zhang

Control and Monitoring of Surface Subsidence for Shallow Tunnel under Existing Railway **562**

Xinzheng Wang and Liying Xing

Voids Classification Standard for Cement Concrete Pavement Slabs Based on Service Life **569**

Sheng Zeng and Jia Xu

Design of 3D Virtual Simulation and Evaluation System for Road Traffic Signs **575**

Haifeng Jiang, Zhiyong Zhang, Jian Chen, and Zhengpeng Fang

Using VISSIM to Calculate the Capacity of Urban Expressway Interchange **583**

X. Zang and W. Zhou

RGB Based Crowded Pedestrian Counting in Red Light Time **590**

G. Y. Zhang, Q. Zhao, Z. W. Luo, and H. Wei

Impact of Posted Speed Limits on Operating Speed in Urban Expressways **597**

H. Wang, X. Sun, B. Li, and Y. He

Nonparametric Analysis of Timely Distribution of Traffic Crash **605**

Yaping Zhang, Xiang Lan, Ke Zhang, Lihua Liu, and Xu Yao

Evaluation of Fire Risk at Highway Tunnels **611**

Jing Huang, Shao Yun Ren, and Wei Zhang

The Analysis of Rural Road Safety and Its Strategies **618**

Feng Sun

A Traffic Accident Reconstruction Study on Continuous Collision of Three Cars **624**

Qiang Yu, Lang Wei, and Tao Chen

Study on the Preventive Maintenance Time for Asphalt Pavement **630**

Ronghue Ying, Ting Wu, Lijuan Wang, and Zhaoguang Hou

Wavy Road Elevation Measurement Based on the Principle of Inertia **637**

Y. Han and H. Wang

Investigation of Relationship between Level of Service and Safety **643**

Xuesong Wang, Hangfei Lin, and Xiaohong Chen

Research and Application of Graphic-Attributes Integration Based on Web GIS in Aviation Accident Investigation **650**

Rui-shan Sun, Ding Yuan, and Zi-nan Xie

Study and Implementation on JPEG Image Enhancement System of Tire Mark **656**

Tao Chen and Lang Wei

Analysis of Characters and Causes of Road Traffic Accident Migration **662**

Chengwu Jiao, Manjuan Yang, and Yubo Hao

A Time-Varying Route Optimization Model for Urban Hazmat Transportation **669**

Yunpeng Wang, Wencai Sun, Shiwu Li, Weiyuan Sun, Jingjing Tian, Haiwei Wang, Hui Wang, Yi Chen, and Gang Cao

A Speed Limit Model of Vehicle for Urban Road Hazmat Transportation **676**
Yunpeng Wang, Wencai Sun, Shiwu Li, Gunan Li, Jingjing Tian, Hui Wang, and Wanji Chen

Risk Assessment of Road Operation Environment under Atrocious Weather Condition **683**
Yan Ma, Zhong-yin Guo, Hua Guo, and Yong-gang Xu

Study on Accident Reconstruction Model Based on Reverse-Reasoning Method **693**
Lili Zheng, Tongqiang Ding, Jianfeng Xi, Jian Sun, and Jiang Li

Evaluation Study of the Median Markings in Undivided Highway Tunnels **700**
Fengxiang Guo, Jian Xiong, Hongqi Liu, Huasen Wan, and Yaqin Qin

The Numerical Analysis of Sound and Vibration from a Tire by FEM and BEM **706**
Liang Chang, Wang-Xin Xiao, and Wei-Ping Xie

Technology Research on the Vehicle Collision Accident Self-Alarm System **712**
Zhe-Wen Tian, Jia-Qi Xu, Qian Feng, Shuai Lei, and Xiao-Ming Mei

Research on Pedestrian Safety under Rapid Development of Motorization **719**
Shuling Wang, Zhili Lui, Jifu Guo, and Yanyan Chen

Gradually Rolling Prediction of the Use-Level of Road Network Based on BP Neural Network **725**
Tao Zhang, Xiang-shen Hou, Xin-kai Li, Hai-min Jing, and Bing-qian Zheng

Identification of Hazardous Locations Based on Integrated Highway Safety State Analysis **733**
Yan Wang and Zhongyin Guo

Analysis of Crowd Behavior in Route Choice Based on Dynamic Programming **742**
Xiaobei Jiang, Hui Xiong, and Hongwei Guo

Vehicle Dynamics Model in Two-Dimension Collision Accident **751**
Yi Cao, Yu-long Pei, and Wen-sen Xiang

Vehicle Trajectory Model in Two-Dimension Collision Accidents **757**
Yu-long Pei, Yi Cao, and Jun Ai

ABSTRACT:

While the structure and functions of transit information systems have been widely explored, there exist bottlenecks of information quality. Transit information providers need to understand the travelers' needs correctly. To find out the structure of transit information needs, a survey on transit travelers has been conducted in Wuhan, China. It is discovered that the transit travelers in Wuhan rely heavily on conventional means in making trip plans, and the potential of internet-based spatial transit information service has not yet been fully explored. The investigation reflects the current situation of intelligent transit passenger service, as well as the potentials of development in the future.

INTRODUCTION

One of the major components of an Advance Public Transportation System (APTS) is the Transit Traveler Information System (TTIS). An important objective of TTIS is to provide accurate and opportune information so as to attract more travelers. This is accomplished by incorporating routes, fares, schedules and other dynamic data, into one cohesive database for such applications as pre-trip planning and in-vehicle information provision (Casey and Labell, 2000). Transit information service involves a variety of strategies and methods, ranging from paper route maps to interactive trip planning.

The development of the Information and Communication Technologies (ICT) has facilitated dissemination of traveling information. Real-time bus location and web-based information delivery system have been deployed and tested (Maclean and Dailey, 2002). Transit information service requires efficient transit data model, which in most cases makes use of spatial data modeling technologies. The system may be constructed in a web-based GIS framework so that transit passengers may plan their trips interactively (Peng and Huang, 2000). From the last decade, many cities have been providing public transit information through internet and mobile service (Lu, 1999). Good data quality and reliable bus system operation are important factors for the success of TTIS.

While the structure and functions of transit information systems are widely explored, there exist bottlenecks of information quality. A TTIS should satisfy the information needs of transit travelers. However, there has been inadequate study on the type and structure of information for this purpose. Previous studies have identified varied usefulness of different types of information. Chorus *et al* (2007) have found out that there is basically a genuine need for time-related and cost-related information. For the more advanced types of information, travelers especially need those that make travelling 'easier', rather than that facilitate advanced searching possibilities. Another research declares that real-time information yields only very modest improvements in passenger service measures such as the origin-to-destination travel times and the variability of trip times (Hickman and Wilson, 1995).

To find out the type and structure of transit information needs, a survey on transit traveler has been conducted in Wuhan, China. The questionnaire for the survey concerns with evaluation of current transit system, means and contents of information acquisition, as well as expectation of types of information in the future. This paper introduces the survey structure and describes the outcomes and implications from the survey.

SURVEY DESIGN AND IMPLEMENTATION IN WUHAN, CHINA

Wuhan administration covers a total area of 8,494 square kilometers, with a total population of 8 million. The built-up area is 356 square kilometers, which served by a transit system of 216 bus routes and 1,800 stop platforms. The bus transit system has an average route length of 18.65 km, and a high overlapping rate of 5.0. These two indicators are much higher than those of the national standard. From the perspective of spatial distribution, bus stops are evenly deployed, which covers more areas than by the national standard (Huang, 2003).

The objectives of the survey are to clarify the structure and content of information needs in bus transit trips, and to evaluate the level of information service in existing operational system. The content of the field survey is comprised of four aspects. These are basic information of respondents, status of bus transit service, trip information needs, and bus transfer. The contents of these aspects are:

- The basic information section includes gender, age, monthly income, residence place, and transport vehicle ownership.
- Questions on the status of bus transit service concern with how the traveler evaluate Wuhan bus transit as a whole system, including easiness of information acquisition, service quality, walking distance at trip ends.
- The main section of the survey is the information needs in transit travel, aiming at acquiring the contents and degree of information needs. The questions concern with way and source of acquiring trip information, as well as expected information source and media.

- The section of transfer investigates the situation and problems encountered in bus transfer.

The questionnaire has totally 19 questions, printed on two sides of one sheet. In the summer of 2007, the field survey was conducted on sites around bus stops, squares and public activity centers. Among the 2,000 valid feedbacks, 52.8% are young respondents between the age of 20 to 30, and 54.7% are males.

FINDINGS FROM THE SURVEY

Transit environment in Wuhan

Bus transit system in Wuhan is the dominant mode of public transport. Other modes include several passenger ferry lines, as well as a nine-kilometer light rail that attracts few trips. Two big rivers and several large lakes shape the city into a unique spatial structure, which partly explain the high overlapping rate of bus lines. The survey investigates the current situation by inviting the respondents to evaluate the bus transit system. Three aspects are involved, i.e., the performance, time cost at trip ends, and easiness of information acquisition.

- Transit performance: Average transfer times and ticket price are appreciated by transit travelers, accounting for 36.4% and 38.5% respectively. However, punctuality and driving behavior are two big problems, which indicate a low system performance.
- Time cost at trip ends: 78.5% of the respondents walk to their boarding bus stops from their origins. With regard to the time cost in reaching the origin stop, 49.0% of the travelers are found to be “within 5 minutes”, and 31.6% fall between “5 to 10 minutes”. Similar trend has been found for walking time from last alighting stop to destination (**Figure 1**). These reflect the rational spatial distribution of bus stops in Wuhan.
- Easiness of information acquisition: Although more bus travelers regard “very easy” than those feeling “difficult”, the majority (75.3%) of respondents report “easy” for acquiring information.

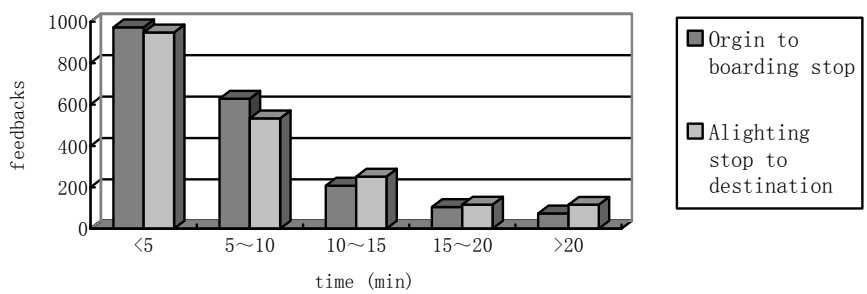

Figure 1. Time cost at both ends of transit trip.

STRUCTURE OF INFORMATION NEEDS

Bus travelers may need information on boarding stops, routes, transfers and schedule. It was envisaged that there is varied degree of demand on these factors. Four choices are provided for the expected information needs, including boarding stop, trip route, trip time and transfer stop. Respondents may make multiple choices in the form. Results reveal that exact information on boarding stop and trip route are slightly more attractive to travelers, with approximately 40% selection each. Choices of trip time and transfer stop are selected by 33% of the respondents each (**Figure 2**). The revealed choices have also indicated a slight gender difference. Although this is a question with multiple choices, we have identified limited forms with multiple selections. Among the 2,000 respondents, 431 people made two choices, 137 people made three choices, and 94 people selected all four choices.

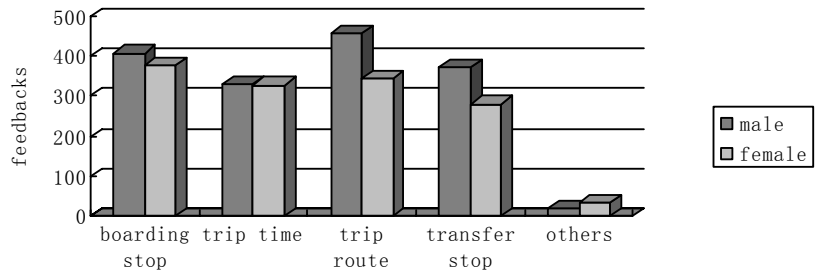

Figure 2. Expected bus transit information by gender.

For pre-trip planning, nearly half of the respondents (926 cases) would pursue least transfer times. This can be partly explained by the current route-based fare system, i.e., each route has a fixed fare regardless what distance the traveler takes, and the passenger needs to buy a ticket upon boarding. Bus travelers are also seeking least travel time and distance (770 cases), as well as shortest walking distance at both bus trip ends (663 cases). Other less selected choices include cheap fare and comfortableness.

MEANS OF INFORMATION ACQUISITION IN TRANSIT TRAVEL

The survey investigates revealed and expected information acquisition, as well as a comparison between two types of information delivery. Listed information sources in the survey include stop plate, paper map, friends, internet, telephone, and mobile SMS.

- Revealed information source: The most popular information source that travelers are utilizing reveals to be stop plates (1163 cases) and asking family member or colleagues or friends (817 cases). Travelers also frequently use transport maps (400 cases) and internet searching (394 cases). Telephone inquiry (150 cases) is less popular information source. It is also found out that female travelers have a

stronger inclination than the males in asking people for trip advice.

- Expected information source: The option of asking people is not included in this question, which makes it possible to emphasis the importance of the future information source. The stop plate remains to be the most popular information source (1114 cases). Internet searching (638 cases) is regarded as a very important means, while paper map (388 cases), mobile SMS (353 cases) and telephone inquiry (331 cases) are less popular in the expectation. These data indicate that bus travelers are expecting some improvements on the information and communication technology.
- Information media: Two options were given for the preference in internet searching, i.e., text-based and map based. Conforming to previous envision, most travelers would prefer internet maps (1299 cases). In fact, maps provide more spatial orientation for travelers, but a system providing maps is more expensive.

TRANSFER ISSUES

Convenience of transfer is an important indicator for transit performance. Issues related to transfer include the connection of transfer platforms, walking distance in transfer and transfer time.

- Connections between transfer platforms: Two major problems on transfer platforms are identified from the investigation. The first one is that a stop is composed of two or more platforms, and a transfer has to be carried out between them (853 cases). But there is no clear transfer guidance between the links. The other problem is a consequence from the multi-platform layout, i.e., travelers cannot find the correct platform at a stop (835 cases). Also, there are complains on long walking distance (632 cases).
- Walking distance in transfer: Many transfers are made by walking less than 50m with no crossing (745 cases), and by waiting at the same platform (513 cases). All other situations receive moderate number of feedbacks between 260 and 310 cases. This indicates the complex transfer situation in Wuhan.
- Transfer time: A majority of transfers are made within 10 minutes, with 652 cases of “less than 5 minutes” and 1036 cases of “5 to 10 minutes”. However, regarding “longest waiting time ever experienced”, 73.3% of the reporters claim that they have experienced waiting more than 15 minutes in a transfer.

DISCUSSION AND CONCLUSIONS

The survey outputs reflect the current situation of bus information needs in the city of Wuhan, China. Firstly, finding stop platforms in complicated spatial surroundings and long transfer distance are main problems. Secondly, transit travelers in Wuhan are trying to seek trips with least transfers, which conforms to early

findings from other cities in China (e.g. Yang et al., 2000). Thirdly, bus travelers are mostly using conventional methods to acquire trip information, including inquiring other people, reading on stop plates and browsing maps. The trip information is usually acquired during bus trips, with very little proportion of pre-trip planning. Fourthly, data from existing sources has low quality in terms of spatial location and transfer guidance. Finally, real time bus information provision is still far from implementation.

A complete bus trip consists of a series of activities, including finding and walking to the boarding stop, traveling on bus, possible transit transfer, and traveling from alighting stop to destination. The survey on structure and content of information needs helps to identify key factors in bus trips. Findings from the survey also justify a multi-layer representation of transit system, such as the multi-tier transit data model proposed by Huang et al (2007).

The survey may also provide information for predicting transit trip activities, such as choice of information source, preference among alternatives, and selection of transfer types. These activities are related to the travelers' socio-economic status.

ABSTRACT:

By using the structural analysis program ANSYS, finite element models are established based on a box girder with varying thickness of the bottom slab , thickness of the inclined web, inclination of the inclined web, thickness of the vertical web, and thickness of the top slab of cable-stayed bridge. In order to consider the effects of the adjacent zone out of the girder section, the internal forces of the two-end surface that were obtained by the horizontal shaft system analysis were exerted on each model. Also, the weight, cable force, and pre-stressed force including girder longitudinal, diaphragm transverse and inclined web vertical direction are considered. Based on the above, the three-dimensional stresses of the box girder with different working situation are analyzed. By the result of above static analysis, the reasonable proposals on thickness of the bottom slab and thickness of the inclined web and inclination of the inclined web and thickness of the vertical web and thickness of the top slab of cable-stayed bridge are proposed. Analysis shows that the stress distributions of main girder are reasonable when the bottom slab thickness is around 30cm, the inclined web thickness is around 30cm, the inclined web inclination is 150 ~152°, the vertical web thickness is around 40cm and the top slab thickness is around 22cm.

Key Words: cable-stayed bridge; box girder; finite element analysis; reasonable sizes.

1 INTRODUCTION

In recent years, a large number of cable-stayed bridges were designed with the main girder of good bending and torsion resistance properties, their sizes also gradually became light and slim. What should not be overlooked is that many existing cable-stayed bridges' main girder, in the construction stage and the use stage, particular in the use stage, experienced varying degrees of cracking. Based on a

bridge girder section's type and size, the cable-stayed bridge box girder space stress analysis method was used, combining the structural analysis program ANSYS. Five different thickness of the bottom slab, five different thickness of the inclined web, five different inclinations of the inclined web, five different thickness of the vertical web and four different thickness of the top slab for the main girder were analyzed by using the finite element analysis method. Thus, the rational box-size for the cable-stayed bridge was proposed.

2 FINITE ELEMENT ANALYSIS MODEL

In order to analyze the influence of various parameters on the stress distribution for the box girder, the finite element models are as follows: the original size of a bridge (the bottom slab thickness is 18cm), increases to 24cm, 30cm, 35cm, and 40cm;); the inclined web thickness increases to 24cm, 30cm, 35cm, and 40cm ; (the bottom slab thickness increases to 35cm; The inclination angle of bottom slab and inclined web is 149.40°), the inclination angle changes to 144.83° , 147.24° , 151.27° , and 152.96° , the inclination angle of inclined web changed with the width of bottom slab. The original size of a bridge (the bottom slab increases to 35cm, the inclined web increases to 30cm), the vertical web thickness increases to 30cm, 35cm, 40cm and 45cm and the original size of a bridge (the bottom slab increases to 35cm, the inclined web increases to 30cm, the vertical web thickness increases to 40cm), the top slab thickness increases to 30cm, 35cm, 40cm. 20 finite element models of the box girder were established for the main gird.

The stress analysis of space needed to choose a segment from the main girder, then the local stress analysis can be conducted. In general, when we analyze the local stress, we should first analyze the structure in a spatial structure as a whole, then choose the local segment as the analyzed object according to the Saint-Venant principle, which should meet the boundary displacement and the forcing state.

2.1 Structure and load

A bridge girder is a pre-stressed concrete structure. The box girder is a two-box single room with inclined web and inverted trapezoidal cross section, with the opening width of 13.25 m, the bottom slab thickness and web thickness of 18 cm, the top slab thickness of 22 cm, and the vertical web thickness of 25 cm, Figure 1 is the girder cross-section.

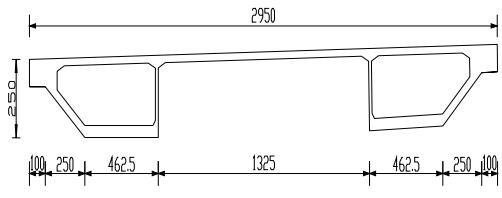

Fig1. Cross section of girder (cm)

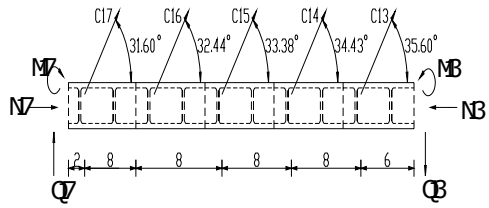

Fig2. Boundary force of girder（m）

As shown in Figure 2, we research the 40 m girder's spatial stress effect under the internal forces in the end, the cable force, self-weight, and pre-stressed force. The

internal force in the end and the cable force are based on analysis of the plane-frame, and are imposed on the girder as loads. The directions in Figure 2 are all positive.

2.2 The establishment of spatial finite element model

As seen from the cable-stayed bridge box girder structure, the cable-stayed bridge's box girder structure is more complex, so we select the 8-node hexahedral element, which can fit the structure better when meshing the structure.

The internal forces on the end of the girder, which was calculated from the plane beam element, and the internal forces applied on the girder by the stay-cable were applied on the corresponding position. To calculate facilitate, to minimize error, the axis forces were applied on the top slab, bottom slab, and the inclined web uniformly (scattered in individual nodes). The moment that was regarded as couple of forces, according to the principle of static equivalent, was applied on the structure. The role of the pre-stressed steel and the stay-cable were considered as the node force. The self-weight of the girder was also considered in the analysis.

3 THE RESULTS AND ANALYSIS

3.1 Comparative analysis of stress of box girder with different thickness of bottom slab.

As seen in the figure 3(a), with increasing bottom slab thickness, the main tensile stress in the bottom slab generated by different working conditions is equal at different positions. However, the maximum main tensile stress decreases gradually in bottom slab. At the same time, when the thickness is more than 30 cm, the value is lower than the tensile strength design value of C50 concrete. As seen in figure 3(b), with increasing bottom slab thickness, the absolute main compressive stress decreases gradually. At the same time, when the thickness is more than 30 cm, the value is lower than the compressive strength design value of C50 concrete. As seen in figure3(c), with increasing bottom slab thickness, the absolute main compressive stress in the vertical web decreases gradually and all of the compressive stress values are lower than the compressive strength design value of C50 concrete. As seen in figure 3(d), the main tensile stress distribution in the inclined web is the same. The value appears at the bottom zone in the inclined web, a zone at the junction of the inclined web, the bottom slab, and the transverse girder. However, when the thickness of the bottom increases, the value increases gradually. When the thickness changes from 18 cm to 30 cm, the maximum value show a decreasing trend. However, when the thickness of bottom slab increases to 35cm and 40cm, the maximum value again shows a clearly rising trend, at the same time, the maximum values are all higher than the stress strength design value of C50 concrete. As seen in figure 3(e), with increasing bottom slab thickness, the absolute value decreases gradually in inclined web. At the same time, when the thickness is greater than 30cm, the value can meet the requirement of the stress strength design value of C50 concrete. As seen in figure 3(f), the maximum main tensile stress in the inside of the solid rib appears at the center area when the bottom slab is different. When the value

changes from 18cm to 30cm, the maximum value shows a decreasing trend. When the value changes from 35cm to 40cm, the maximum value shows a rising trend again. Most importantly, when the bottom thickness is 30 cm, the maximum value is the relative minimum value. When the bottom thickness is 24cm and 35cm, the maximum value is basically the same. However, when the bottom slab thickness is 18cm and 40cm, the maximum value is greater than the tensile strength design value of C50 concrete.

3.2 Comparative analysis of stress of box girder with different thickness of inclined web.

Three-dimensional stress distribution characteristics in various regions of the girder are mostly the same as above. In order to better understand the changes of stress for the girder with the different thickness of the inclined web, the stresses under different working conditions are shown in Table 1.

Table1 Peak stress (N • mm^{-2}).

Thickness (mm)	σ_1 *(bottom slab)*	σ_3 *(bottom slab)*	σ_3 *(vertical web)*	σ_1 *(inclined web)*	σ_3 *(inclined web)*	σ_1 **(solid rib)**
18	2.36	-22.01	-17.11	3.00	-28.23	2.28
24	2.13	-18.56	-17.01	1.37	-25.38	2.01
30	2.34	-17.99	-16.68	1.48	-24.63	2.09
35	2.62	-17.62	-16.73	1.83	-24.99	1.97
40	4.13	-18.48	-17.02	2.10	-23.91	1.50

3.3 Comparative analysis of stress of box girder with different inclination angles of inclined web

In order to better understand the changes of stress for the girder with different inclination angles of the inclined web, the stresses under different working conditions are shown in Table 2.

Table2 Peak stress ($N \cdot mm^{-2}$).

inclination angle (°)	σ_1 *(bottom slab)*	σ_3 *(bottom slab)*	σ_3 *(vertical web)*	σ_1 *(inclined web)*	σ_3 *(inclined web)*	σ_1 **(solid rib)**
144.83	2.52	-22.42	-15.84	2.25	-28.42	2.65
147.24	2.62	-21.28	-16.37	3.01	-27.28	2.27
149.40	2.36	-22.01	-17.11	3.00	-28.23	2.28
151.27	2.43	-21.74	-17.23	2.56	-27.74	2.50
152.96	2.10	-21.89	-17.19	2.04	-27.89	2.64

3.4 Comparative analysis of stress of box girder with different thickness of vertical slab.

In order to better understand the changes of stress for the girder with different thickness of the vertical slab, the stresses under different working conditions are shown in Table 3.

Table3 Peak stress ($N \cdot mm^{-2}$).

Thickness (mm)	σ_1 *(bottom slab)*	σ_3 *(bottom slab)*	σ_3 *(vertical web)*	σ_1 *(inclined web)*	σ_3 *(inclined web)*	σ_1 **(solid rib)**
25	2.34	-17.99	-16.68	1.36	-24.63	2.09
30	2.36	-18.26	-16.56	1.39	-24.68	1.82
35	2.18	-17.27	-17.09	1.48	-25.03	1.81
40	2.11	-17.53	-17.11	1.91	-25.39	1.87
45	2.03	-17.08	-16.43	1.81	-24.91	1.89

3.5 Comparative analysis of stress of box girder with different thickness of top slab

In order to better understand the changes of stress for the girder with different thickness of the top slab, the stresses under different working conditions are shown

in Table 4.

Table4 Peak stress (N • mm^{-2}).

Thickness (mm)	σ_1 *(bottom slab)*	σ_3 *(bottom slab)*	σ_3 *(vertical web)*	σ_1 *(inclined web)*	σ_3 *(inclined web)*	σ_1 **(solid rib)**
22	2.11	-17.53	-17.11	1.91	-25.39	1.87
30	3.36	-17.36	-17.72	2.70	-25.18	1.89
35	2.87	-18.27	-18.53	2.67	-25.93	1.42
40	2.70	-19.53	-19.16	2.79	-26.89	1.39

4 CONCLUSION

(1)It is necessary for the Cable-Stayed Bridge to have sufficient bottom slab thickness. However, the thickness should be controlled within a certain range.

(2) Every indicator is reasonable when the bottom thickness is about 30 cm, the inclined web thickness is about 30 cm ,the inclination angle of the inclined web is about 150 ~152° , the vertical web thickness is about 40 cm, and the top slab thickness is about 22 cm.

(3) The bottom slab and inclined web are extremely unfavorable; greater importance should be attached to them in the design phrase and the construction phrase.

(4) The cable-stayed bridge with the double-box single-room girder structure under loading has complex spatial characteristics, so it is impossible to analyze the structure mechanical characteristics accurately in detail, it is necessary to make space analysis for the structure.

Abstract

In order to design the appropriate crashworthy structure of a locomotive vehicle, the two-layer thin-walled structures were taken as research objects. The efficient non-linear explicit dynamic finite element analysis software, ANSYS/LS-DYNA, was adopted to research the energy absorption characteristics of the one-layer thin-walled structure and the two-layer, thin-walled structure. The results have shown that the evaluation parameters (the energy-absorbing efficiency, the buffer index) of energy absorption characteristics of two-layer, thin-walled structures are better than those of one-layer structures. An idea of using two-layer thin-walled structure as an energy-absorbing element of a crashworthy vehicle is put forward. The results of simulation on two-layer, thin-walled structures with different shapes have also shown that the dimensions of the inner-layer have effect on energy absorption characteristics.

Key words: *Crashworthiness, Thin-walled structure, Non-linear finite element*

1 Introduction

With the increase of train speed, train accidents have threatened safety of passengers and brought huge economic losses to railroads. After research about the history of railway accidents, we have found that these accidents can not be avoided even if many active protection technologies are used on the train. In order to protect the safety of passengers and reduce loss from accidents, many passive technologies were applied to high-speed trains. Many simulation and experiment research projects, which related to crashworthiness vehicle design and energy-absorbing device(Abramowicz,1984; Hanssen,2000; Karagiozova,2001; Scholes,1993), were carried out by researchers whose work mainly focused on energy absorption characteristics of one-layer, thin-walled structures. Because enormous energy will be generated in a high-speed collision, one-layer structures cannot meet energy-absorbing requirements. In this paper, we take two-layer, thin-walled structure as an energy-absorbing element and analyze its energy absorption characteristics through simulation.

2 Theoretical foundation

The collision problem of locomotive vehicle structure has many

characteristics, such as large displacement, large rotation, large deformation and large strain, and is affected by material constitutive relation, structural failure, frictional contact and other factors. After simulating the entire collision process by dynamic non-linear finite element method, we can obtain the deformation, speed, acceleration and stress and strain distribution of elements.

The collision problem of large deformation usually costs a lot of calculation time. In order to avoid solving large-scale simultaneous equations and improve accuracy and efficiency of calculation, an explicit algorithm is often chosen in analysis.

At the time of t_N, a semi-discrete form of deformation differential equation is expressed by the following equation (FANG, 2005):

$$M\ddot{q}_N = P_N - F_N, \qquad (1)$$

Where, M is lumped mass matrix, $\ddot{q}_N$ is acceleration vector, P_N is overall load vector, F_N is overall equivalent node force vector of element stress field.

A single-point integral algorithm is used in element calculation, and hourglass mode produced by single gauss integral method is controlled in the program.

Taking hourglass viscous damping for example, after adding it to Eq. (1), Eq. (1) is transformed to Eq. (2):

$$M\ddot{q}_N = P_N - F_N + H_N \qquad (2)$$

Where, H_N is the hourglass viscous damping vector of the structure.

Contacts inevitably exist in the collision process. And after introducing contact force F_C, Eq. (2) will be transformed to Eq. (3):

$$M\ddot{q}_N = P_N - F_N + H_N + F_C \qquad (3)$$

The explicit central difference method is adopted in time integral.

$$\dot{q}_{(N+1)/2} = \dot{q}_{(N-1)/2} + \Delta t_N \ddot{q}_N \qquad (4)$$

$$\dot{q}_{N+1} = \dot{q}_N + \Delta t_{(N+1)/2} \ddot{q}_{(N+1)/2} \qquad (5)$$

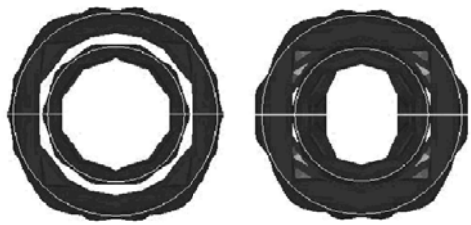
$$\Delta t_N = (\Delta t_{(N-1)/2} + \Delta t_{(N+1)/2})/2 \qquad (6)$$

Where, $\dot{q}_{(N-1)/2}$ is the node velocity vector at the time of $t_{(N\text{-}1)/2}$, $\dot{q}_{(N+1)/2}$ is the node velocity vector at the time of $t_{(N+1)/2}$, and q_N is the node displacement vector at the time of t_N.

3 Simulation methods of collisions in two-layer thin-walled structures

Two-layer cylindrical thin-walled structure belongs to a combined cylindrical shell, namely, cylindrical shells with different radiuses which are encased together. It has two failure forms under axial load, as shown in Figure 1.

For the first form, as shown in Figure 1(a), the distance between the inner and outer shells is large, regular axisymmetric deformation happens in the cylindrical shell, and the two shells do not interact in the process of compression deformation. For the second form, as shown in Figure 1(b), the distance between the inner and outer shells is small, the deformation of the two shells interplays after puckering happens, and collision characteristics of the two-layer structure change greatly due to interaction (JIA,2006).



(a) Two-layer cylindrical shell without interaction (b) Two-layer cylindrical shell with interaction

Figure 1. Interaction between inner and outer shell in two-layer cylindrical shell.

3.1 Geometric model

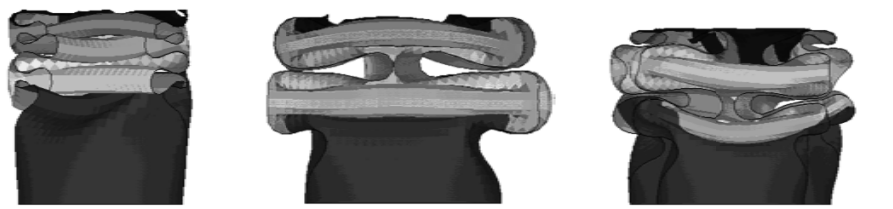
For the analysis of two-layer cylindrical shell, its thickness is 1.5mm and length is 200mm. The diameter of outer shell is 75mm, and that of the inner is 65mm, 60mm, 55mm, 50mm and 45mm, respectively. In order to compare with energy absorption characteristics of two-layer cylindrical shell, a one-layer shell is analyzed, and its diameter is 75mm, 65mm, 60mm, 55mm, 50mm and 45mm, respectively.

3.2 Simulation method

A prescribed constant velocity is applied on a rigid plate which to used to crush the cylindrical shell. The bottom of the tubes are fixed to a stationary rigid plane in the whole process. Two types of contact are employed in numerical analysis. For the cylindrical shell itself, an automatic single-surface contact is adopted to take into account contact for itself during deformation, while an automatic node-to-surface contact is applied between cylindrical shell and rigid plate. The static friction coefficient and dynamic friction coefficient between all surfaces in contact are assumed to be 0.2 and 0.15, respectively.

4 Simulation results and comparison

Compression deformations are shown in Figure 2, including deformations of the two-layer cylindrical shell (its diameter of inner layer is 55mm, and that of outer layer is 75mm) and the one-layer cylindrical shell (its diameter is 55mm and 75mm, respectively). As shown in Figure 2, the number and size of the plastic hinge generated by the two-layer cylindrical shell under the axial load are different from that of the one-layer shell.



(a) Compression form of one-layer shell (its diameter is 55mm) (b) Compression form of one-layer shell (its diameter is 75mm) (c) Compression form of two-layer shell

Figure 2. Comparison form between one-layer shells and two-layer shell.

Energy-deformation curves are shown in Figure 3, and axial

force-deformation curves are shown in Figure 4. The energy absorbed by the two-layer cylindrical shell is higher than total energy absorbed by two one-layer shells. Compared to the one-layer shell, the axial force curve of the two-layer cylindrical shell is gentler, and the fluctuation of load is smaller in the distance of run from 40mm to 135mm. Axial peak force of two-layer cylindrical shell is also smaller than that of one-layer cylindrical shell.

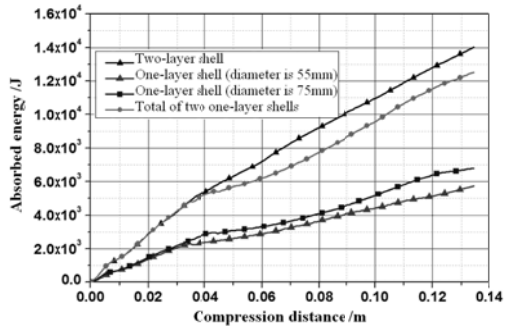


Figure 3. Energy-deformation curves.

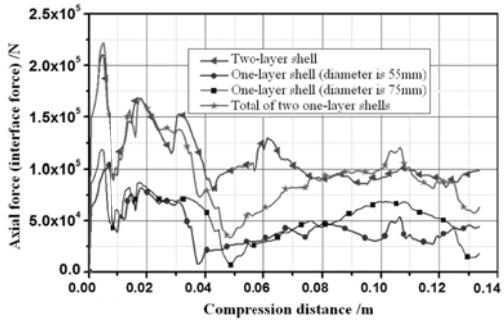

Figure 4. Axial force-deformation curves.

4.1 Comparison of energy absorption capacity

To evaluate energy absorption capacity of energy-absorbing element, we should consider not only total absorbed energy but also SEA (specific energy absorption, namely, absorbed energy per unit mass), because the level of absorbed energy is proportional to SEA. The simulation results are presented in Table 1 and Table 2.

Table 1. Comparison of SEA between one-layer cylindrical shells.

Energy absorption capacity	Diameter of single cylindrical shell /mm					
	45	50	55	60	65	75
Absorbed energy /J	5178	5469	5755	5983	6124	6808
Mass /g	332.80	369.74	406.70	443.68	480.66	554.6
SEA /J/g	15.56	14.79	14.15	13.48	12.74	12.28

Table 2. Comparison of SEA between two-layer cylindrical shells.

Energy absorption capacity		Diameter of two-layer shell (inner+outer) /mm				
		45+75	50+75	55+75	60+75	65+75
Sum of two one-layer shells	Absorbed energy /J	11986	12277	12563	12791	12932
	Mass /g	887.40	924.34	961.30	998.28	1035.3
	SEA /J/g	13.51	13.28	13.07	12.81	12.49
Two-layer shell	Absorbed energy /J	13493	13607	14018	13610	13297
	Mass /g	887.40	924.34	961.30	998.28	1035.2
	SEA /J/g	15.21	14.72	14.58	13.63	12.84
Comparison between sum of two one-layer shells and two-layer shell	Increase of absorbed energy /%	12.57	10.83	11.58	6.4	2.82
	Increase of SEA /%	12.51	10.84	11.55	6.4	2.80

From the results we can see that:

(1) For the one-layer shell, the SEA decreases with increase of the diameter of one-layer cylindrical shells (with the same thickness).

(2) The energy absorbed by the two-layer cylindrical shell is higher than total energy absorbed by two one-layer shells. Increased amplitudes for energy absorbed by two-layer cylindrical shells are as high as 6%~12.57%, except the two-layer cylindrical shell with an inner diameter of 65mm.

(3) The SEA of two-layer cylindrical shells is higher than that of one-layer cylindrical shells.

(4) The space between two shells affects length of the plastic hinge produced by the two-layer cylindrical shell, and that affects energy absorption capacity. The SEA of the two-layer cylindrical shell combined closely is higher than that of two-layer cylindrical shell combined loosely. In these two-layer cylindrical shells, energy absorbed by two-layer cylindrical shell, in which the diameter of inner shell is 55mm, is the highest; the second is that with the diameter of the inner shell of 60mm, the SEA decreases with the increase in diameter of the inner shell as well.

4.2 Comparison of buffer capacity

Buffer capacity, which is defined as a ratio between axial peak force and mean crash force, is an important index for evaluation of energy absorption characteristics of energy-absorbing element. If buffer capacity is small, peak force is relatively small, impact is relatively stable in the process of deformation, and the degree of damage to the passenger is relatively small too. The simulation results of peak force and buffer index are presented in Table 3 and Table 4.

Table 3. Axial force and buffer index of one-layer cylindrical shell.

	Diameter of two-layer shell /mm					
	45	50	55	60	65	75
Axial peak force /kN	94.8	97.9	103.6	106.9	110.9	118912
Mean crash force /kN	38.4	40.5	42.6	44.3	45.4	50430
Buffer index	2.47	2.42	2.43	2.41	2.44	2.36

Table 4. Axial force and buffer index of two-layer cylindrical shell.

		Diameter of two-layer shell (inner+outer)/mm				
		45+75	50+75	55+75	60+75	65+75
Sum of two one-layer shells	Axial peak force /kN	213.7	216.8	222.5	225.8	229.8
	Mean crash force /kN	88.8	90.9	93.1	94.7	95.8
	Buffer index	2.41	2.38	2.39	2.38	2.40
Two-layer Shell	Axial peak force /kN	195.0	203.2	210.5	219.5	226.6
	Mean crash force /kN	100.0	100.8	103.8	117.3	98.5
	Buffer index	1.95	2.02	2.03	1.87	2.30
Comparison between sum of two one-layer shells and two-layer shell	Decrease of axial peak force /%	8.78	6.30	5.40	2.82	1.39
	Decrease of buffer index /%	18.97	15.45	15.22	21.53	4.09

The simulation results show that:

(1) For the one-layer shell, the buffer index decreases with the increase in diameter of the one-layer cylindrical shell (with the same thickness), but the change is not evident.

(2) The peak force of the two-layer cylindrical shell is less than the sum of two one-layer cylindrical shells.

(3) The buffer index of the two-layer cylindrical shell is less than that of the one-layer cylindrical shell, in other words, buffer capacity of two-layer cylindrical shell is better than that of one-layer cylindrical shell.

5 Conclusions

(1) The energy absorbed by the two-layer cylindrical shell under axial load is more than the total energy absorbed by two one-layer shells. The SEA of the two-layer cylindrical shell is higher than that of one-layer cylindrical shell, and its impact performance is improved significantly.

(2) The axial peak force of the two-layer cylindrical shell is less than the sum of two one-layer cylindrical shells evidently.

(3) The buffer capacity of two-layer cylindrical shell is superior to one-layer cylindrical shell, which can improve control ability to overload.

ABSTRACT

The level of roadway lighting is an important factor for the safety of roadways during the nighttime, especially for pedestrians. Past studies have shown that over fifty percent of pedestrian crashes occurred during nighttime. Most of these were fatal and severe injury crashes. These results make it clear that proper design and timely maintenance of street lighting will definitely help improve the safety of the roadway system. To evaluate the roadway lighting systems and maintain their functionality, it is essential to perform field lighting measurements. Currently, field measurements of roadway lighting systems are often conducted by handheld light meters at a short sample section of roadways. The evaluation of an entire corridor or a longer roadway section is difficult when using the traditional manual measurement methods. This study addresses this difficulty by developing a mobile lighting measurement system that can be used to collect massive lighting level data in a safe and efficient way.

In this study, a mobile lighting measurement system was developed and installed in a test vehicle to collect illuminance data along a corridor of U.S. 19 in Pinellas County, Florida. The night time pedestrian crash data were collected for a three year period. The preliminary study shows that the frequency of nigh time pedestrian crash at low lighting level segments is much higher than those segments with a high illuminance level.

CE Database subject headings: Traffic Safety, Pedestrian Safety, Roadway Lighting.

INTRODUCTION

Background

This paper summarize some preliminary results of a research project funded by the Florida Department of Transportation (FDOT) District 7 to collect all required data and to perform an evaluation of highway lighting levels on the State-maintained roadways within the District. Specifically, the main objective of this project is to measure the maintained illuminance levels in the roadway areas. This paper covers

the basic concepts of newly developed lighting measurement strategies and a case study on U.S. 19 to exam the relationship between the street lighting level and night time pedestrian crashes.

Problem Statement

Roadway lighting is one of the key elements of roadway system in regards to safety. A Federal Highway Administration study (1990) reported that, in the United States, nighttime crash rates are five times higher than daytime crash rates. More to the point, approximately 50 percent of the fatalities occur during the nighttime and only 25 percent of the vehicle miles are driven during the nighttime. These statistics clearly indicate that the improvements to nighttime driving environment might help reduce nighttime crash rates. In the past, many studies were conducted to investigate the impacts of installation of street lighting on roadway safety. Most studies indicated that roadway safety was positively impacted in the way that reduced the number of crashes, injuries, and fatalities.

Proper design and timely maintenance are two vital factors for street lighting systems to be effective and beneficial to road users. The design itself needs to consider many factors and requires expertise in many areas, such as civil, electrical, and lighting engineering. The newly installed system should be evaluated to assure that roadway lighting levels meets the design standards. Initial design might be perfect; however, as time passes, the system may not work as well as when initially installed. In order to maintain the effectiveness and functionality of street lighting systems after design, it should be inspected to assess how well the system is maintained.

Currently, roadway lighting levels are often measured with handheld light meters. After roadway lighting systems are designed, the design programs can establish a grid on the pavement surface and then use the estimated illuminance values at these points on the grid to determine the average value and the uniformity ratios (avg/min and max/min). To manually collect illuminance data using handheld light meters on all of the roadways in District 7 represents an enormous data collection task. This data collection effort would also put the people operating the light meters in the middle of the roadways during nighttime low-lighting conditions, creating a potential safety concern for both data collection personnel and other roadway users.

In order to address these concerns, CUTR proposed to develop new measurement strategies for collecting the lighting data in a manner that minimizes the risk exposure for the data collection personnel. The original idea is to measure the lighting level on a moving vehicle using a combination of lighting meters and Distance Measurement Instrument (DMI). The illuminance data recorded by a light meter will match the location data from GPS or DMI.

An additional area of concern to the District is maintaining adequate lighting levels in crosswalk areas for the safety of pedestrians. The Department has indicated a desire for research on street lighting levels that are adequate for the needs of the pedestrian. Similarly, to the work being done for the automobile, strategies also must be

developed to measure the light levels on pedestrian facilities in a manner that is safe and efficient.

LITERATURE REVIEW

Past studies, research projects, standards and guidelines related to the street lighting data collection, design and the evaluation of the roadway lighting systems were reviewed and summarized.

Lighting System Design

Design of a roadway lighting system is a joint effort of engineers from various areas of specialization. Gazzar *(2002)* divided the design process into four steps to help the designer come up with better decisions. The four design steps are described briefly as follows.

Step 1: An initial study should be conducted to identify the roadway elements and also specifications of the roadway. The design criteria of different elements require individual considerations. As an example, a pedestrian crosswalk area usually requires higher levels of lighting. Lighting level requirements also vary by the functional classification of roadways. One must acquire all the data related to the design area for an effective and efficient lighting system.

Step 2: Fixture and luminaire selection requires one to be familiar with detailed specifications of the equipment available in the market. It is impossible to review the technical specifications of all equipment on the market. One can simplify the process by determining the standards and the limitations. A good selection of fixtures and luminaire will make the remaining steps of the design process more convenient for the designer.

Step 3: The location of the fixtures and poles can be determined by use of readily available software for this purpose. CAD files of the roadway can be imported to the software and the process can be conducted. In addition, the software usually assists fixture selection by importing the electronic file which includes photometric characteristics of a fixture.

Step 4: Verification of the lighting design criteria can also be conducted by the design software. There are three design criteria considered for roadway lighting systems design, which are explained in the following subchapters.

Roadway Lighting Design Criteria

Illuminance, luminance, and small target visibility are three criteria for verification of roadway lighting design in the standard practice.

Illuminance

Illuminance is defined as the amount of light flux that falls on the surface at a certain distance from the light source. The standard units of illuminance used in practice are foot candle (English) and lux (Metric). The surface under consideration for

illuminance determination in roadway lighting is the pavement surface. Horizontal illuminance is used in the standard practice of roadway lighting design and evaluation.

The illuminance level at any point depends on the distance from the light source and luminous intensity of the light source. The value of illuminance can be determined by the inverse square method or using tables and charts developed by the manufacturers of luminaires. Each specific type of luminaire has its own chart and table for roadway lighting design. The inverse square method is often used to calculate the illuminance at definite points. The point must be located at a distance five times greater than the luminaire size. The equation to calculate the illuminance by the inverse square method is presented as Equation 1. Figure 1 shows the elements in Equation 1.

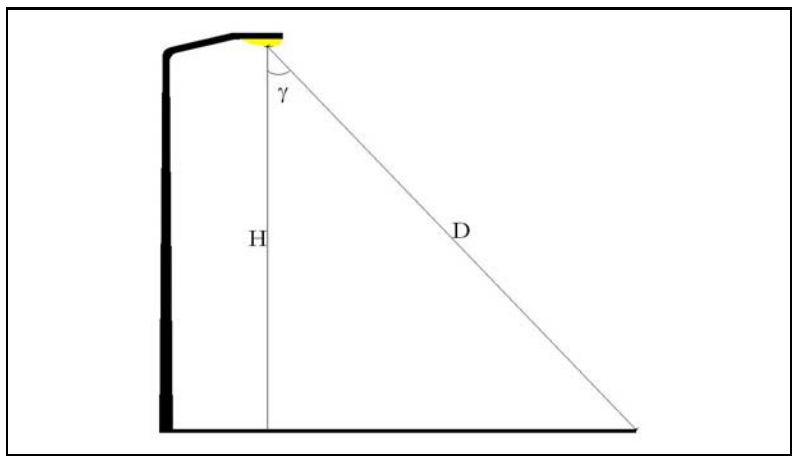

Figure 1. Inverse Square Method Variables.

$$E_h = \frac{I(\varphi,\gamma)\cos\gamma}{D^2} \qquad \text{Equation 1}$$

Where:

$I(\varphi,\gamma)$ = luminous intensity of the source in direction of the point in;
D = actual distance from light source the source in direction of the point in question;
H = vertical mounting height of the light source above horizantal plane;
φ = the angle from the light source reference axis to the point in question; and,
γ = the angle from the nadir of the light source to the point in question.

For horizontal plane, $Cos\,\gamma = H/D$, from which Equation 2 can be derived:

$$E_h = \frac{I(\varphi,\gamma)\cos^3\gamma}{H^2} \qquad \text{Equation 2}$$

Luminance

Luminance is another commonly used measurement of lighting level for the design and evaluation of roadway lighting systems. The American Association of State Highway and Transportation Officials (AASHTO) Roadway Lighting Design Guide *(2002)* defines luminance as a measure of the reflected light from the pavement surface that is visible to the motorist's eye. Determination of luminance requires consideration of reflective characteristics of the pavement. Equation 3 is used to calculate the value of luminance at a desired point. In addition, the luminance calculations and field evaluations are conducted based on two assumptions: (1) The observer is at a distance of 83.07 meters from the point in question; (2) The observer's eye level is 1.45 meters above the pavement. Based on these assumptions, the observers' direction of sight is one degree downward. The observer is located on a parallel line to the centerline of the roadway that passes through the point in question. The luminance value at a point can be calculated with the general Equation 3. The general equation must be modified based on the assumptions described earlier to calculate the luminance value at a desired point on the road surface.

$$L = \frac{1}{\pi} E_h q(\beta, \gamma) \qquad \text{Equation 3}$$

Where:

E_h = illuminance at the point in question, as defined in Equation 2.1 and
$q(\beta,\gamma)$ = the directional reflectance coefficient for angles of incidence β and γ.

Small Target Visibility

Small target visibility is a relatively new approach to improve the safety of drivers. American National Standard Practice for Roadway Lighting of Illuminating Engineering Society of North America *(1999)* (IESNA) included this method in its latest edition. The standard defines small target visibility as the visibility level of an array of targets on the roadway considering the following factors:

- The luminance of the targets
- The luminance of the immediate background
- The adaptation level of the adjacent surroundings
- The disability glare

Illumination Measurement and Safety Impacts

Evaluation of roadway lighting systems is an important task to ensure that the system works at the desired level. Evaluation methodology is usually selected based on the standards required for the lighting system. The timing of the evaluation is another factor to take into consideration. Initial evaluations are often conducted right after installation. The evaluation results will not be affected by some light depreciation factors such as dirt and aging of luminaires. However, evaluation of a system after years of operation will reveal the effects of light depreciation factors. In the literature

review, many guidelines were found for the design of roadway lighting systems. Many commercial software were especially developed for this purpose. However, few guidelines and standards are available for evaluation purposes.

In 1988, Zimmer developed "A Mobile Illumination Evaluation System" at the Texas Transportation Institute. The main purpose of the system was to collect illumination data for high mast lighting systems. The illumination method was selected for data collection. The system was installed in a test vehicle and illuminance measurements are taken by a light meter placed on top of the vehicle. Illumination data were taken on each lane of roadways to compute the system characteristics. The system developed for that study could collect data at reasonable speeds. However, the technology for lighting measurements and computers at that time were not well developed. Currently, the light meters are more accurate and the laptop computers are faster. For high mast lighting systems, luminaires are relatively higher than conventional roadway lighting. The measurements may not be affected by the height of the light meter sensor as in conventional roadway lighting measurements. The study also did not develop a methodology to convert the illuminance on the top of vehicles to six inches above the pavement.

A study conducted by Green et al. *(2003)* at the Kentucky Transportation Center of the University of Kentucky, investigated the relationship between illumination levels and nighttime crashes. Illumination data was collected with handheld light meters at the identified locations. The results of the study indicated that nighttime crashes were reduced by 45 percent after installing street lighting at the intersections. Additionally, the study included a survey of States related to their roadway lighting standards. The survey results showed that most States use the information from either AASHTO "An Informational Guide for Roadway Lighting" or "American Standard Practice for Roadway Lighting" (ANSI/IESNA RP-8-00) as their standards.

Three methods have been used to evaluate roadway lighting level. Illumination method is mostly used in field evaluation and recommended by national and state lighting design guidelines. An early study has indicated that the idea of developing a mobile illuminance measurement system is feasible. In addition, past studies showed that safety can be improved by adding or improving street lighting.

METHODOLOGY

Based on literature review, illuminance method is found to be the most suitable method for field evaluation of roadway lighting systems. Currently, illuminance data are manually collected by the use of handheld light meters. In this project, a mobile lighting measurement system will be developed to eliminate the risk of personnel and reduce the labor costs.

System Development

Before system development, it is essential to understand what kind of data is needed for collection. The results of literature review indicated that the illuminance is one of

the main criteria for evaluation of roadway lighting level. The illuminance method requires measurement of illuminance (lux or foot candle) values at some desired points. Collecting coordinates of desired points and corresponding illuminance data simultaneously and accurately is a challenging task. If both coordinates and illuminance data were collected separately, it would be difficult to match them. Due to the above reasons, it was necessary to develop a mobile measurement system that can collect both distance and illumination data at the same time. After considering safety and speed issues, it was decided that the system should be installed on top of a vehicle. The system installed in vehicle could collect illumination data at a desired distance interval and a reasonable speed of a test vehicle.

After the initial design, the project team determined the necessity of the following elements:

- Light Meter
- Distance Measurement Instrument (DMI)
- Laptop Computer
- Connections between the computer, light meter and DMI
- Software to collect, store and analyze data

DATA COLLECTION AND ANALYSIS

The study corridor is located along U.S. 19 (SR 55) in Pinellas County from River Watch Boulevard in North Pinellas County to 54th Avenue South spanning 32 miles. The U.S. 19 corridor in Pinellas County has more total pedestrian crashes than any other roadway within the county.

Crash Data

The datasets used for the study include: FDOT U.S.19 pedestrian crashes 2000-2005; FDOT District 7 pedestrian crashes 2000-2005; and FDOT district 7 crash data management system.

FDOT crash data includes only crashes occurring along the State Highway System and typically is limited to long form crash data which include the more sever crashes. As such, the crash data for this study do not include most minor “fender-bender’ crashes. Likewise, non-injury pedestrian crashes tend to be underreported. Crashes that occur on frontage roads along U.S. 19 are also included in the data set.

Three years of pedestrian accident data (2003-2005) were collected to adequately identify the corridor’s safety problems and evaluate the relationship between the lighting intensity and crash frequency. The hard copies of pedestrian crash record (2003-2005) were reviewed. There are a total of 199 pedestrian crashes.

Illumination Data

The illumination along the corridor was recorded using a developed mobile lighting measurement system, a combination of a light meter and a Distance Measurement Instrument (DMI). The illumination was recorded at 40 feet intervals on the most right side lane of U.S. 19.

Data Analysis

Along the 32 mile stretch of U.S. 19 in Pinellas County, according to the FDOT crash database, 105 pedestrian crashes of the total 199 pedestrian crashes during the six year period occurred at night. Also, only 18 of these 105 crashes occurred at locations without streetlights, and the remaining 87 crashes occurred at locations where streetlights were present. Therefore, the lighting conditions of the crash site locations were analyzed.

Figure 2 shows the frequency of crashes and lighting level as measured in lux. Illuminance is the amount of light reaching the roadway surface, measured in foot candles (lumens/ft2) or lux (lumens/m2).

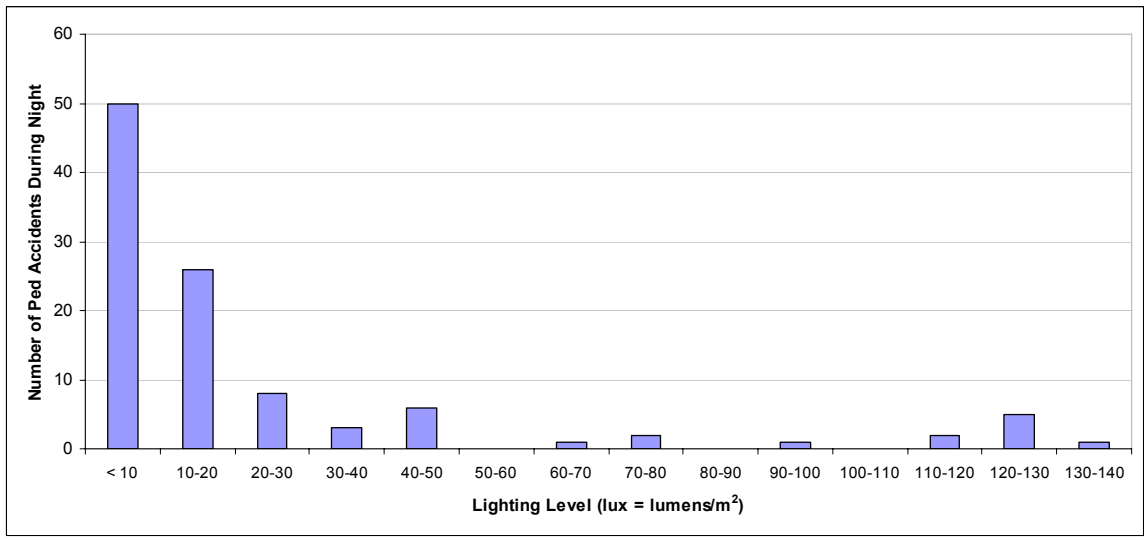

Figure 2. Number of pedestrian accidents at night for different lighting conditions.

The lighting level was measured using a handheld light-meter (EXTECH 401036) fixed to the top of a vehicle (about four feet above the pavement) moving at an average speed of 30 mph. The measurement was taken in the right lane of the roadway. As shown in Figure 8, lighting condition at 50 crash site locations was below 10 lux. According to the preliminary measurement of lighting level on U.S. 19, night time pedestrian crashes occur more often at lower lighting level conditions as compared to higher lighting level conditions.

CONCLUSIONS

The mobile lighting measurement system developed by this research can be used to collect massive light data in short periods of time. The new system will not only reduce the cost of the future data collection efforts, but also improve the safety of the data collection personnel. The preliminary research showed that there is a possible relationship between the night time crashes and roadway lighting level. The next phase of the project will collect the illuminance along 250 miles state highway. And also the crash data will be collected to investigate if there is a direct relationship between the lighting level and night time crashes.

ABSTRACT

We discuss the combining of micropile substructures to produce a new retaining and reinforcement structure for slopes. Each substructure is an element comprising of several separated micropiles connected by a roof plate. The structure has the advantages of small pile length, easy and quick construction, operational safety, and low cost. It can be applied to a moderate or small slope or in landslide control projects. In particular, the structure is very suitable for dealing with project emergencies. According to the general load features of the structure, it is believed that the part of the structure above the slip surface of a landslide may be regarded as a single rigid frame under landslide thrust and that the part under the slip surface may be treated as an elastic axial bar model. In this way, internal forces of the structure and the required length of the anchoring section of the micropiles can be obtained. This information is used directly in practical design. Analysis shows that each micropile in the structure is mainly loaded by an axial force, but the roof plate is principally subject to a bending moment. The new structure and the analysis method proposed in this paper are successfully used in practice for a cutting slope in a Guangyuan–Bazhong expressway project in Sichuan Province, China, and the performance of the structure is verified.

Keywords: combined micropile structure, slope slippage, landslide thrust, rigid frame, internal forces of a structure

INTRODUCTION

This paper examines a structure that prevents slope slippage. The structure comprises of several micropiles connected by a roof plate to endure lateral load.

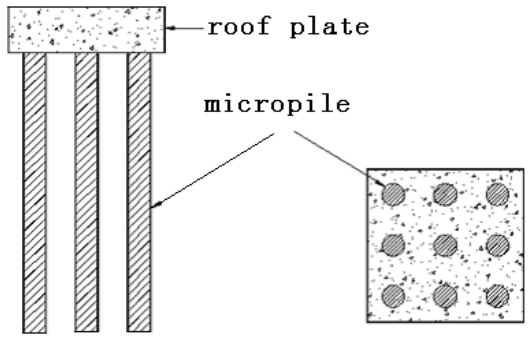
Many of these structures could be arranged along a slope strike with a set separation to resist landslide thrust. Each micropile in the structure has a slenderness ratio greater than 30 and a diameter no greater than 250 mm. Micropiles that are inserted into the ground by boring and pressed grouting usually have a diameter between 110 and 150 mm. The proposed structure has the advantages of small pile diameter, short construction time, high security for constructors, low cost, and flexible arrangement.

The concept of micropiles was first suggested by Fernando Lizzi in the 1950s (Tom et al., 2000). The piles were called root piles at the time and used to reinforce building foundations. The technology of small piles has since then been developed in America, France, Japan and China. Structures of micropiles that endure vertical loads have been widely discussed in previous works. However, there has been little research on structures bearing lateral forces (Duncan and Evans, 1994; Donald et al., 1995; Mokwa and Duncan, 2001; Thomas et al., 2004; Thompson and White, 2006). In China, a micropile structure with a top beam connection has been used for landslide reinforcement in recent years. However, the combining of the aforementioned micropile structures has scarcely been studied (Huang, 2001; Xie et al., 2001; Wang, 2005). Some works have examined the seismic response of micropiles under lateral forces by considering their dynamic characteristics (Kevin et al., 2004; Sung June Lee, 2004). Based on previous works, Chinese researchers preliminarily analyzed the action characteristics of beam-connected micropiles and discussed key points that should be addressed in project design (Ding, 2001; Ding and Wang, 2004). Shi and He (2005) reported a preliminary design approach that uses reticular micropiles connected by a top beam. The composite structure of reticular micropiles and soils is referred to as a reinforced soil wall. They determined the different states of bonding between micropiles and soils using an approximate model: a calculation model of a reinforced concrete beam. Feng et al. (2006) studied calculation methods for multiple micropiles connected by a top beam to reinforce a bedrock slope and proposed a new method for slope reinforcement.

Using existing research results, a new structure comprising of micropiles connected by a roof plate to prevent slope slippage is proposed in this paper. We present analysis of the structure and discuss engineering applications.

NEW MICROPILE STRUCTURE AND ITS RETAINING MECHANISM

New micropile structure. The new structure for preventing slope slippage presented here comprises of a roof plate and micropiles of grouting materials and reinforcements as shown in Figure 1. The grouting materials protect the reinforcements against corrosion. The roof plate assembles all elements and forms an integral system that can sustain pile stresses. The roof plate requires sufficient thickness, strength, rigidity, and durability. To ensure a reliable connection between the plate and piles, reinforcement hooks are fabricated at the top of the piles.



(a) Micropile structure (b) Roof plate profile

Figure 1. The new combined micropile structure.

Prevention of slope slippage and reinforcing mechanism. The ability of the micropile structure to resist sliding of the slope and maintain stability depends on the piles and surrounding rock–soil mass. For efficiency, the base of a micropile needs to be under the most likely to slip surface. The micropile–rock–soil complex, axial forces, and bending and shearing forces need to be considered.

(1) Micropile–rock–soil complex

The micropile structure passes through the potential sliding mass and is anchored in the stable bed below. During the grouting of micropiles under pressure, the micropile bodies push through the rock–soil mass and cement together loose broken grains. This can improve the mechanical properties of the rock–soil mass surrounding the micropiles and form a micropile–rock–soil complex that resists slope slippage. Micropiles act as a complex skeleton with good strength and rigidity. Thus, the micropile–rock–soil complex can constrain the deformation of the rock–soil mass between piles. The micropile structure plays an important role in this system. The micropiles transfer internal component stresses of the rock–soil mass and stabilize the stratum. The transferred stress is less concentrated as it is distributed more widely. This efficiently prevents slipping along the slip surface, and, therefore, the slope is stabilized.

(2) Axial forces

Under landslide thrust, the slender micropiles essentially bear axial forces (axial tension and compression) in anchoring the slope.

(3) Bending and shearing forces

Micropiles are subject to bending moments and shear forces due to the action of landslide thrust. However, these are not the controlling forces for slender pile bodies, i.e., the stability of a micropile is determined mainly by axial forces (tension and compression).

MECHANICAL ANALYSIS MODEL FOR THE MICROPILE STRUCTURE

We considered the simple example of a combined micropile structure having small elements. Each element comprises of nine micropiles (in three rows and three columns). Figure 2 shows that the columns are set along the slope strike direction (perpendicular to the landslide thrust direction). Assuming we are addressing the problem of plane strain, the vertical effects of the slope body on the structure are not considered. Supposing that load is distributed by the landslide thrust, the linear load distribution for one column of micropiles along the axial direction of the micropiles is:

$$q_0(x) = FL / H \tag{1}$$

where F is the landslide thrust per unit width (kN/m) calculated using the transfer coefficient method and physical mechanical parameters of the sliding mass and rock–soil mass, L is the spacing between two adjacent elements in the slope strike direction, and H is the height of sections of the micropiles above the slip surface.

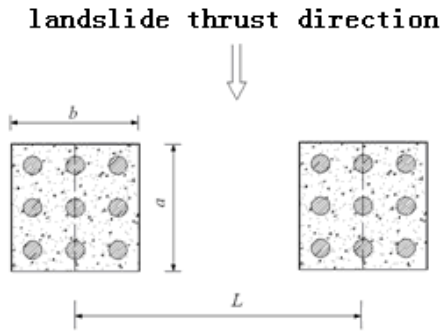


Figure 2. Layout of the combined structure.

The internal forces of the combined structure are determined as shown in Figure 3. The structure above the slip surface is simplified as a plane frame structure by considering the pile–rock–soil complex effect as shown in Figure 3(b). Note that all micropiles except that nearest to the slope top endure lateral force $q(x)$ as well as the extrusion force of the rock–soil mass between micropiles. Because of the complicated interaction between the micropile nearest to the slope top and the rock–soil mass, the extrusion force is neglected simply and conservatively for convenience in practical engineering application. Therefore, the combined structure above the slip surface is a simplified plane frame model as shown in Figure 4.

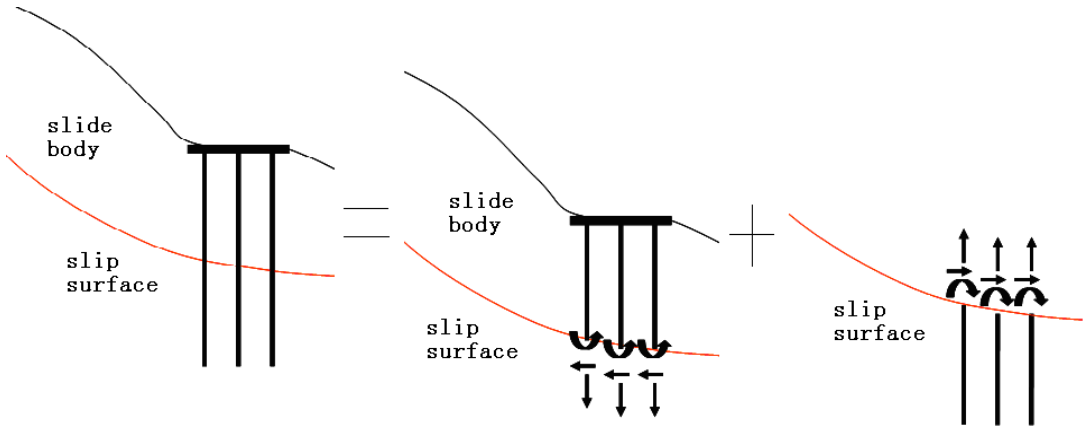

Figure 3. Analytical model of internal forces in the combined structure.

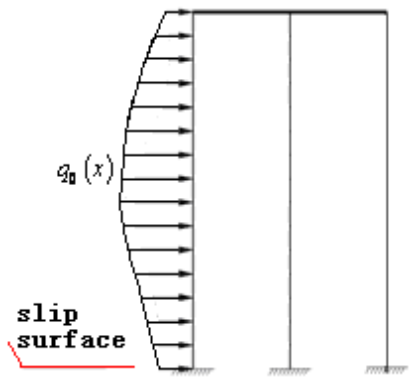

Figure 4. Simplified mechanical model of the upper part of the combined structure.

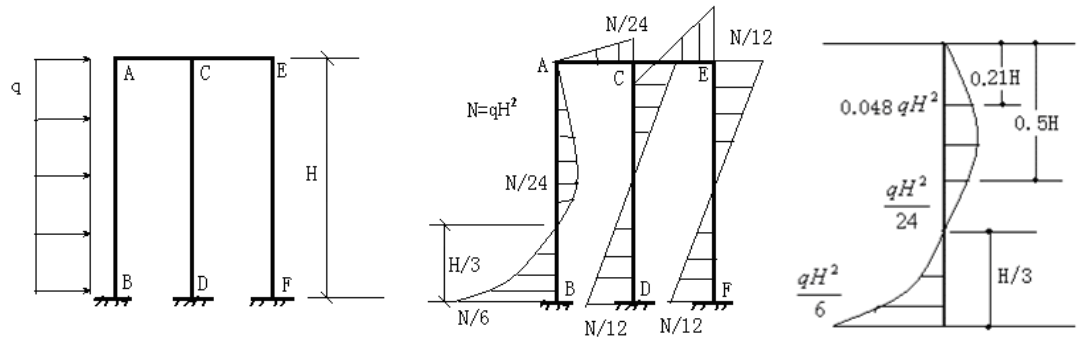
In calculating the load for the lower part of the structure shown in Figure 3(c), we considered an elastic axially loaded member after calculating the load for the upper part of the structure according to the important mechanical characteristics of the micropile and the retaining mechanism of the structure.

ANALYTICAL METHOD

Calculation of internal forces in the micropile body.

(1) Calculation for the upper part of the combined structure

Figure 5(a) is the graphical representation of calculated forces for the upper part of the plane frame structure according to the analysis model discussed above. Structural internal forces and retaining reactions are calculated using structural mechanics; the calculation process is not described here. The results are given in Figures 5(b) and (c).



(a) Calculated graphical representation **(b) Bending moment** **(c) Moment detail for micropile AB**

Figure 5. Internal force calculations for the upper part of the combined structure.

(2) Calculation for the lower part of the combined structure

Internal forces in the lower part of the structure are calculated by considering an elastic axially loaded member. A uniform distribution of friction resistance between the lower pile and rock–soil mass is considered to simplify the calculation. The internal force calculation for the lower pile section is used mainly to determine the required length of the anchoring section. Details are described in the following section.

Determination of the anchoring section length and the full structure length. The method for calculating the anchoring section length is to first calculate the axial force, shear force, and bending moment on the slip surface after internal forces have been calculated for the upper part of the structure. The anchoring depth is determined from the tensile axial force. Whether the length of the free section produces the required compressed micropile stability should then be examined.

The calculation results show that the AB section is subject to the greatest tension. The anchoring section length l_a is determined from the ultimate skin friction of the rock–soil mass around the micropile below the slip surface:

$$l_a = F_{sp} \cdot P_{AB} / (\pi \cdot d \cdot \tau), \tag{2}$$

where F_{sp} is the design safety factor for friction between the injected cement paste and micropile, P_{AB} is the enduring tension for the AB section, d is the micropile diameter, and τ is the magnitude of the ultimate skin friction.

The compression stability of a micropile under pressure (EF section) with a larger slenderness ratio should be theoretically verified. The anchoring section must be longer than both l_a and the minimum anchorage depth for micropiles to work in an elastic state under compression. The anchoring section is usually embedded in stable

rock. Therefore, the compression stability of this section is suitable; however, the length of the anchoring section is generally controlled by tension conditions.

Moreover, soil mass around micropiles (sliding mass) has a smaller restriction effect on the pile body for the upper part of the structure. Therefore, the suitability of its length (i.e., length of the "free section") should be checked in light of stability of compressed bar. A suitable full pile length is then determined. The stability of the free section is calculated using the Euler formula:

$$F \le \frac{F_{cr}}{K} = \frac{\xi \pi^2 EI}{K\left(\mu l_f\right)^2}, \tag{3}$$

where F is the maximum axial force for the compressed micropile, F_{cr} is the critical compressive force according to the Euler formula, K is the design safety factor for the compressed micropile stability, ξ is a correction coefficient between 1.05 and 1.35, EI is the flexural rigidity equivalent, μ is the Euler length coefficient (with a value of 0.5 here), and l_f is the length of the free section.

Determination of the roof plate. The roof plate is a flexible member as shown in Figure 5(b). The upper side of the roof plate endures compression at the third span near the central section. The plate compresses the slope surface, so it is important that the pressure below the plate does not exceed the bearing capacity of the slope surface.

ENGINEERING EXAMPLE

The combined structure proposed in this paper was applied in a cutting slope project for an expressway (Guangyuan–Bazhong line, Sichuan, China). Figure 6 shows the cutting slope site K51 + 175. Table 1 lists the parameters of the slope according to a geological survey. Ultimate skin friction around pile in weakly weathered silt-sandy mudstone is 0.17 MPa, and compressive strength of the rock mass is 7.94 MPa.

The slope comprised of a typical thick layer of clay with a low liquid limit and a crushed stone stratum overlying bedrock. Potential slope failure was typically circular as shown in Figure 6. The design safety factor was taken as 1.25. The design horizontal thrust was calculated using the transfer coefficient method as 324 kN/m.

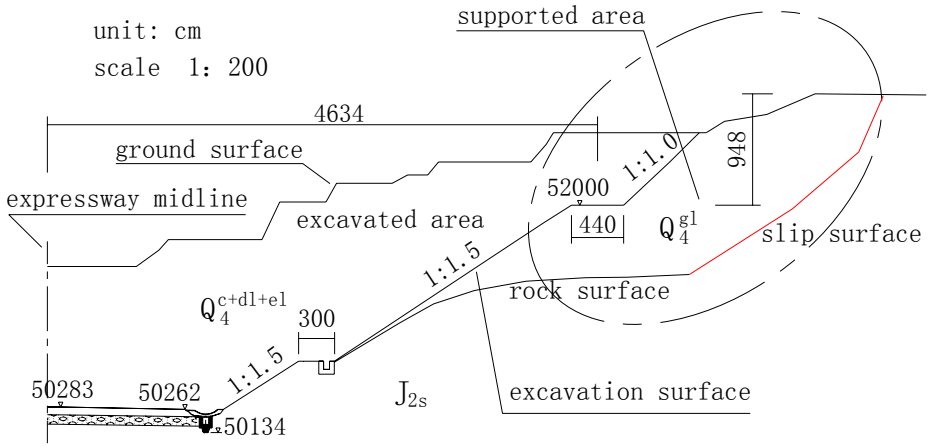


Figure 6. Cross-section of a cutting slope project (Guangyuan–Bazhong expressway, Sichuan, China).

According to characteristics of the slope, we chose a structure element comprising of nine micropiles (in three rows and three columns) connected by a roof plate as shown in Figure 7. The diameter of each micropile hole had a diameter of 130 mm and was injected with M20 cement mortar. Three 32 mm-diameter reinforcing bars were used for each micropile. The distance between two elements was 3 m, and the distance between two micropiles in the same element was 0.6 m in the sliding direction and 0.5 m perpendicular to the sliding direction. The roof plate had an overhang length of 0.2 m. According to the position of the most important potential slip surface, the free section length of the micropile body was determined as 6.6 m.

The used reinforcements had an ultimate tension capacity of 400 MPa and a strength of 320 kN. The equivalent elastic modulus and flexural rigidity of a single micropile were respectively 2.6×10^7 kN/m^2 and 364.5 kNm^2.

Table 1. Mechanical parameters of rock–soil mass in calculations of internal forces.

Stratum number	Rock mass or soil name	State	Bulk density (g/cm^3)	Cohesion (kPa)	Internal friction angle (°)	Allowable bearing capacity (MPa)
$Q_4^{c+dl+el}$	low liquid-limit clay including gravel	soft-hard plastic	2.0	15	10	0.20
Q_4^{gl}	crushed	medium	2.3	20	15	0.25

	stone including soil	density				
J_{2s}	silt-sandy mudstone	strongly weathered	2.36	-	-	0.30
		weakly weathered	2.53	-	-	0.80

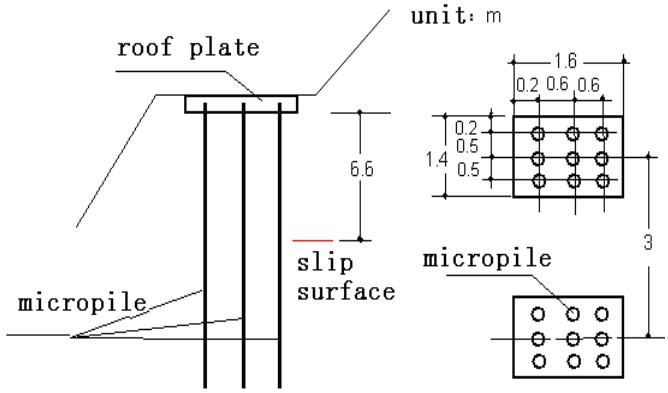

Figure 7. Preliminary design of the combined structure.

(1) Bending moment and axial force

The external load acting on the combined structure was $q = 324 \times 3 / 6.6 = 147.27$ kN/m. From Figure 5(b), the calculated bending moment for the upper part of the structure was $N = 6415.2$ kNm. The axial forces for AB, CD, and EF sections were then calculated as $P_{AB} = 890$ kN (tension), $P_{CD} = 445$ kN (tension), and $P_{EF} = 1335$ kN (compression).

(2) Roof plate calculations

The maximum tension reinforcement of one reinforcement Φ32 was $P_{AB} / 9 = 890 / 9 = 99$ kN < 320 kN. Thus, the reinforcement was suitable.

The admissible shear stress between the anchoring section and rock–soil mass was $\tau = 170$ kPa; F_{sp} was taken as 1.2. Following equation (2), $L_a = 5.2$ m. Therefore, L_a was taken as 5.4 m and the full length of the pile as 12 m.

The critical load of the compression bar for a free section length of 6.6 m was $P_{cr} = 1.2 \times 4\pi^2 EI / H^2 = 4\pi^2 \times 364.5 / 6.6^2 = 396$ kN, where the coefficient 1.2 was determined by considering the restriction effect of the surrounding soil mass on the micropile. Figure 8 is a sketch of the pressure applied to the soil mass and the EF section of the micropile by the CE section of the roof plate. The compressive force $Ps = 250 \times 0.84 = 210$ kN can be supported by the soil mass, while for the EF section, $P = 3 \times 396 + 210 = 1398$ kN > $P_{EF} = 1335$ kN. Thus, the requirement is met.

According to the results in Figure 5(b), the bending moment of the roof plate was $M = qH^2 / 24 = 147.27 \times 6.6^2 / 24 = 267.3$ kNm as shown in Figure 9.

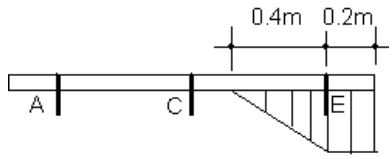

Figure 8. Sketch of pressure under the roof plate.

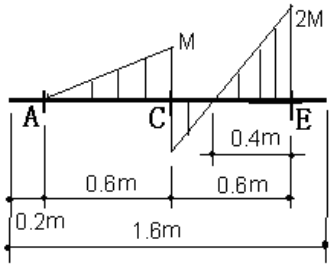

Figure 9. Bending moment of the roof plate.

CONCLUSION

This paper proposes a new type of light retaining structure. The structure is a combination of micropiles with a roof plate and is suitable for situations with small landslide thrust (≤ 500 kN/m). The combined structure brings the rock–soil mass together as one system to resist landslide thrust. Internal forces of the structure are calculated by dividing the structure into two parts. The upper part can be considered a frame structure under lateral landslide thrust, and the lower part can be considered an elastic axially loaded member. The micropiles of the combined structure bear mainly axial forces in contrast to the roof plate, and, thus, principally endure bending moments. The structure can be designed by considering the tension–compression stability of the pile body and the shallow stability of the slope body under the roof plate. The combined structure has been realized in practice for a cutting slope project of an expressway (Guangyuan–Bazhong line, Sichuan, China). The structure promises better application and socioeconomic benefits. To improve the approach, the interaction between micropiles and sliding mass needs to be considered in detail in further studies.

ABSTRACT

In order to study the mechanical characteristics of fly ash soil, fly ash and silty clay were mixed according to the proportions 1:4, 1:2, and 1:1 by dry weight with the water content of 15%, 17%, and 19% to test the static characteristic of fly ash soil. The test results show that the compressive strength of fly ash soil (1:2) slowly decreases with the increase of water content and is greater than 150 MPa when the water content ranges from 15% to 23.5%; the deformation modulus of fly ash soil (1:2) decreases with the increase of water content, while still greater than 3 MPa; the compressive strength of fly ash soil with three kinds of lime soil ratio decrease with the increase of water content, but when lime soil ratio is 1:2, the compressive strength is greater than the others. Through the test of dynamical characteristics, we obtained that the dynamic strength of fly ash soil increases with the increase of confining pressure, and the dynamic strength, dynamic modulus, and shearing strength of the fly ash soil (1:2) are better than the others. The frost heave test shows that the amount of frost heave decreases with the increase of fly ash content, which performs strongly in the early stage of frost heave and is gradually stabilized later.

Key words: mechanical characteristics, fly ash, soil dynamic strength, the modulus of deformation, the amount of frost heave

INTRODUCTION

Northeast China belongs to seasonal frost zone. Subgrade in this area appears to have a moisture accumulation phenomenon in the freezing process under the influence of a negative temperature gradient. After freezing, the volume of accumulated water increases, which causes subgrade uplifting and pavement cracks, namely the frost heave phenomenon. When spring comes, the subgrade soil emerges from the cracks in the pavement caused by frost heave in the form of mud, forming frost boiling. It can be concluded that the water content of subgrade soil makes a great influence on its strength. The current control methods and measures are mainly

the improved reinforcement method and pharmacy method. Fly ash has been widely used in bases and subbases of highway engineering (Feng, 2002). Strength of pavement, especially asphalt pavement, mainly depends on the base, which requires the base material to have sufficient strength to bear the traffic load. According to the current research of home and abroad, there is no systematic analysis on the influence of water content on the nature of the soil engineering (Qi, 2005). The addition of random distribution fiber to fly ash can increase the anti-liquefaction strength of fly ash (A. Soominathan, 2002). Indoor freeze-thaw and freezing stability experiments of fly ash soil have been made to determine if the freeze-thaw resistance of fly ash soil is better than fly ash and soil individually by measuring the value of CBR, and if the freeze-thaw resistance of fly ash and soil is close. The information about the influence of water content on the strength of fly ash soil cannot be found.

Based on the experimental results of fly ash soil with different water content and different lime-soil ratios, this paper analyzes the influence of water content on static properties of fly ash soil, such as compressive strength and deformation modulus, as well as the influence of different lime-soil ratios on the dynamic properties and frost heave of fly ash soil. It can offer a theory to engineering design and the application of fly ash soil.

MATERIALS SELECTION AND SAMPLE PREPARATION

Materials selection. The total content of $SiO_2 + Al_2O_3 + Fe_2O_3$ of the test fly ash is 78.13% ~ 88.64%, and the content of SO_3 is 0.1% ~ 0.72%; the ignition loss of SO_3 is 1.0% ~ 5.26%. The test fly ash is Si-Al-type, with the nature of volcanic ash, appears fine and powdery when dry, feels soft and smooth, and looks like cement dust. Test soil is taken from Changchun city as representation. The physical properties of test materials are listed in Table 1. The mechanical properties of subgrade soil are directly related to water content and soil density. The change of the natural environment will change the water content of subgrade soil. This experiment mixed soil and fly ash with the ratios of 1:4, 1:2, and 1:1 by dry mass; each mixture was tested with water content of 15%, 17%, 19%, and 23.5%.

Table 1. Basic Physical Properties of Specimen.

Materials	Plastic Limit %	Liquid Limit %	Plasticity index %	Optimum water content %	Maximum dry density g/cm^3
Silty clay	22.4	34	11.6	12	1.92
Fly Ash		46.5		36.8	1.09

Sample preparation. The compactness of all samples was controlled by maximum dry density, and the maximum dry density was determined by the standard

compaction test. The preparation process of samples was as follows: mixing the fly ash and soil by dry mass, drying the test soil, crushing and sieving, stirring the mixture of fly ash and soil uniformly, and adding water to the mixture until the predetermined water content. Then the mixtures were maintained in a moist chamber for 24 hours and divided into three layers to be compacted by adopting a standard method.

For the static test, the height of the sample was 50 mm, and the diameter was 50 mm (shown in Figure 1). For the dynamic test, the height was 140 mm, and the diameter was 70 mm. All samples were sealed with plastic film and placed in the conservation box (temperature 20 ± 1°C, relative humidity 96 ± 2%) for 7 days (GB, 1999).

The equipment used in the static test was an YYW-2 strain-controlled, unconfined, compressive instrument produced by Nanjing soil instrument factory; the loading rate was controlled at 2.4 mm/min. The equipment used in the dynamic test was a DTC-306 multi-functional, electro-hydraulic servo dynamic triaxial apparatus made in Japan, shown in Figure 2.

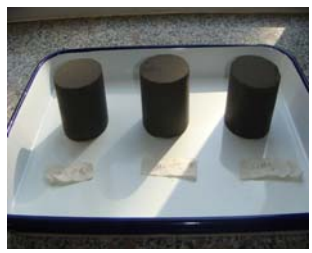

Figure 1. Samples of fly ash soil.

Figure 2. Dynamic triaxial apparatus.

STATIC PROPERTIES TEST OF FLY ASH SOIL AND ANALYSIS

Effect of fly ash content on the characteristics of fly ash soil. With confining pressure equaling 100 kP, 200 kPa, and normal temperature, the dynamic strength of silty clay is slightly higher than fly ash (ash to soil = 1:2). However, with the raising of confining pressure, the increase amplitude of dynamic strength of fly ash soil (ash to soil = 1:2) is greater than silty clay. Under certain conditions, dynamic strength decreases with the increase of destruction cycles, and it increases with the raising of confining pressure (Li, 2007). However, this paper is limited to the research that fly ash to soil = 1:2.

In this paper, plenty of indoor experiments were done to study the effects of different lime-soil ratios on the characteristics of fly ash soil. From Figure 3, it can be obtained that the compressive strength of three kinds of mix ratios with different water content decreases with the increase of water content. When water content is less than the optimum water content, the change of compressive strength with the variation of water content is greater when water content is greater than the optimum water content, the change of compressive strength with the variation of water content is less. However, the compressive strength of fly ash soil with fly ash to soil = 1:2 is greater than the other two cases, which is consistent with literature (Hu, 2002). It can be obtained that the deformation modulus of fly ash soil with water content of ω = 17% and ω = 23.5% decreases with the increase of fly ash content (see Figure 4); when water content reaches the optimum water content, ω = 19%, the deformation modulus of fly ash soil with fly ash to soil = 1:2 is smaller than the other two mix ratios. This shows that the fly ash content greatly influences the deformation modulus of fly ash soil.

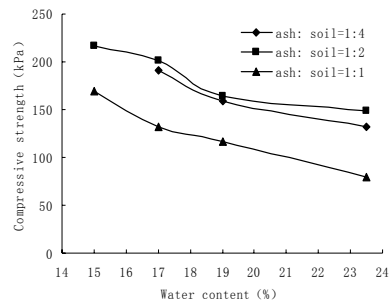

Figure 3. Water content and compressive strength.

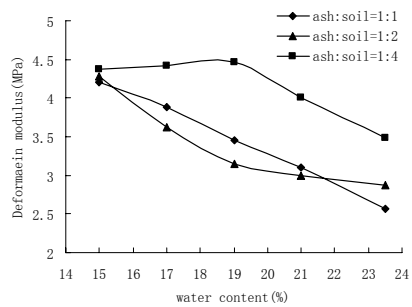

Figure 4. Water content and modulus.

Effect of water content on the strength of fly ash soil (1:2). Subgrade is the foundation of pavement; its wheel load resistance capacity mainly depends on the deformation resistance ability of the top surface of the subgrade under a certain stress level. It can be obtained from Figure 5 that the compressive strength of fly ash soil (1:2), as subgrade materials, changes slightly with the increase of water content. The

compressive strength of the ash soil with a water content within 15% ~ 23.5% is greater than 150 kPa. The optimum water content of the fly ash soil used in this experiment is 19%. From Figure 5, we can see that before the optimum water content the variation degree of the compressive strength of fly ash soil with water content is greater than after the optimum water content, which indicates that fly ash soil has good water stability. When fly ash as a subgrade material is compacted with the optimum water content, the increase of water content caused by other external factors will have less effect on the strength of the subgrade.

Effects of soil water content on the deformation modulus of fly ash (1:2). Based on test data, this paper calculated the deformation modulus corresponding to the limit stress state with different water content. Calculation results are shown in Figure 4. From Figure 4, it can be obtained that the deformation energy of the fly ash soil (1:2) decreases with the increase of water content. When water content changes from 15% to 19%, deformation modulus decreases by 28.67%; when the water content changes from 19% to 23.5%, the curve changes slightly; deformation modulus only decreases by 7.39%. It can be concluded that when water content is greater than the optimum water content, the deformation modulus changes slightly with the variation of water content, and the deformation modulus is greater than 3 Mpa.

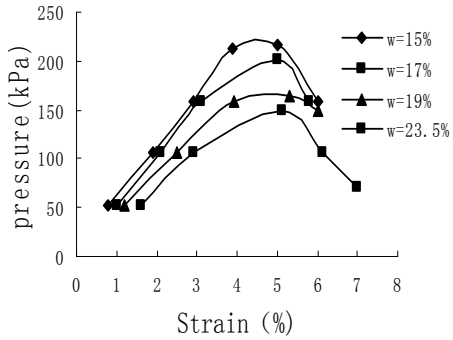

Figure 5. Curves of stress and strains.

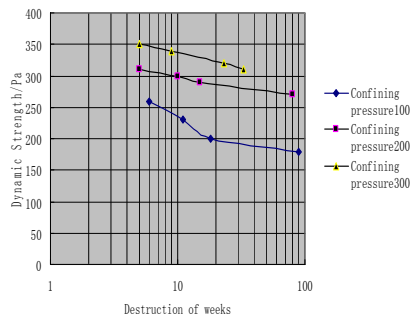

Figure 6. Dynamic shear stress and cycle numbers.

DYNAMIC PROPERTIES TEST OF FLY ASH SOIL AND ANALYSIS

The dynamic properties experiment was carried out with lime-soil ratios of 1:1, 1:2, and 1:4. The test load was applied with frequency f = 1Hz, confining pressure 100 KPa, 200 KPa, 300 KPa, in the form of sine wave. The adopted destruction criterion is ε_d = 5%. In order to draw the $\sigma_d - N_f$ curve, the ideal situation of testing points distribution is that the four points would fall in the range of the $4^{th} \sim 6^{th}$ cycle, $10^{th} \sim 15^{th}$ cycle, $20^{th} \sim 30^{th}$ cycle, and $50^{th} \sim 70^{th}$ cycle. After obtaining the dynamic stress corresponding to N_f = 10 from the $\sigma_d/2$ -lg N_f curve with confining pressure $\sigma_3 = 100$ KPa, 200 KPa and 300 KPa, the pull and push half-cycle stress circle can be drawn by taking consolidation pressure as the vertex and σ_d as the diameter. Then the index of sheer strength, i.e., cohesive force c_d, and internal friction angle φ_d can be obtained by drawing the envelope of failure stress circle. The experimental data are shown in Table 2.

In the dynamic modulus test, the confining pressure of 100 KPa and initial dynamic stress of 100 KPa is applied. After six times of vibration, the next dynamic stress is doubled. Then the dynamic strain (ε_d) in different stress (σ_d) levels are measured. The skeleton curve of $\sigma_d - \varepsilon_d$ is of hyperbola type; it can be described by the hyperbolic model of $\sigma_d = \varepsilon_d / (a + b\varepsilon_d)$. The value of a and b can be derived by the regression statistical analysis. Because the curve of $\sigma_d - \varepsilon_d$ is of hyperbolic curve type, the relationship between ε_d / σ_d and ε_d is linear. The intercept of the vertical axis is $\varepsilon_d / \sigma_d = 1 / E_0$, where E_0 is the initial dynamic elastic modulus. The test data are shown in Table 2.

It can be obtained from Table 2 that the dynamic strength of fly ash soil increases with the increase of the confining pressure. The dynamic strength, dynamic modulus, and shear strength with the lime-soil ratio of 1:2 are better than the other two ratios, which is because the amount of used fly ash increases with the increase of soil clay content and soil plasticity index. But when the amount is over a certain range, too much fly ash exists as free ash in the void of soil, which will lead to the decrease of fly ash soil strength.

ANALYSIS OF FROST HEAVE TEST OF FLY ASH SOIL

To measure the amount of frost heave of fly ash soil, the fly ash and soil were mixed with the ratios of 1:1, 1:2, and 1:4 and stirred with the optimum water content. Then the mixture was compacted and made to cylindrical specimen with the height of 10 cm and a diameter of 5 cm. For imitating the actual lateral force condition of road, the fly ash soil samples were applied with lateral confining pressure. The surrounding samples were kept under constant temperature, so the cold can transfer in the specimen from the top to the bottom. The amount of frost heave is measured by a dial indicator mounted on the top center of the specimen.

Table 2. Results Summary of Fly Ash Soil Dynamic Test.

Ratio of ash and soil	Failure strength of 10 cicles （KPa）			Dynamic modulus (MPa)	Cohesion (kPa)	Internal friction angle （°）
	100 kPa	200 kPa	300 kPa			
1：1	226	283	319	146.26	127.4	18
1：2	234	300	338	171.64	147.5	22
1：4	230	292	326	158.32	134.9	20

The experiment results indicate that the frost heave appears most evident in the early period of cooling (the process of phase transition of water in ash soil) and tends to be stable with the decrease of temperature. Under the same boundary conditions, the amount of the frost heave decreases with the increase of the content of fly ash.

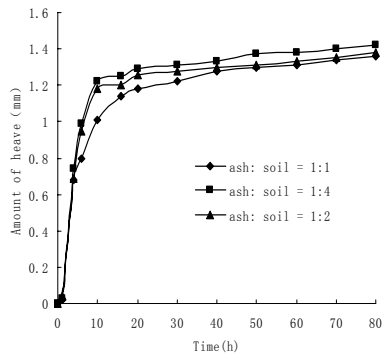

Figure 7. Relationships between the amount of frost heave and time.

CONCLUSION

(1) The compressive strength of the fly ash soil (1:2) changes slightly with the increase of water content. The compressive strength of the ash soil with a water content within 15% ~ 23.5% is greater than 150 kPa. When less than the optimum water content, the variation degree of the compressive strength of the fly ash associated to the change of the water content is greater than when it is over the optimum water content.

(2) When water content is greater than the optimum water content, the deformation modulus changes a little with water content variation; the deformation modulus is greater than 3 Mpa.

(3) The compressive strength with lime-soil ratios of 1:4, 1:2, and 1:1 decreases with the increase of water content. This shows that the fly ash content greatly influences the deformation modulus of fly ash soil.

(4) The dynamic strength of fly ash soil increases with the increase of confining pressure, dynamic strength, and dynamic modulus; the strength index with a lime-soil

ratio of 1:2 is better than the ratio of 1:1 and 1:4.

(5) The amount of frost heave decreases with the increase of fly ash content, which appears stronger in the early time of frost heave and gradually tends to stabilize later.

Abstract: This paper covers a project that conducted methods of self-balanced pile tests with three-dimensional numerical simulation analysis on effects of karst caves on the load capacity of bridge foundations located at hidden caves. Taking Nanpanjiang Bridge in Yunnan as a case study, it carried out static loading tests on No.1 Pier, No.2 pier and No.1 pile which foundations are free from caves. Then it adopted the finite element method to establish a cave-rock-pile foundation three-dimensional analysis model for systematically analyzing effects of top plates with different thickness and caves with different sizes and locations under different working conditions on the loading capacity of bridge foundations. Furthermore, soils having four different conditions surrounding piles under each working condition were also considered and analyzed. It was found that the distance between roof of the cave and pile tip was the main factor affecting the loading capacity of the pile foundation. The research results were successfully applied in evaluating loading the capacity of a pile foundation in Nanpanjiang Bridge in Yunnan. Thus, the research results improved utilization and reliability of roof of karst caves in highway construction.

Key words：*karst; pile; bearing character; numerical simulation*

A large-diameter grouting pile is embedded in the bedrock, whose hole is artificially or mechanically dug. It can fully use the pile strength and rock strength, and because it has good adaptability, high bearing capacity and can substantially reduce the cost, it is widely used around the world. Many experts and scholars at home and abroad have made a lot of work about it, but the bearing characteristics of the pile in karst areas is still lacking (Dengshan et al. 2002; Minghua et al. 2003)..

With Yunnan Nanpanjiang Bridge (Shenggen et al. 2004) as the background, through field tests and numerical analysis, this paper researched the pile bearing character, and on that basis, combining relevant research results at home and abroad, it put forward the evaluation method of pile bearing capacity in karst areas.

1 Nanpanjiang Bridge pile test

1.1 Project Profiles

Nanpanjiang Bridge is a prestressed concrete continuous rigid frame, whose 1#,2# pier is an artificially dug pile foundation, where rock distribution characteristics are as follows: Quaternary loose layer (artificially filled, red clay); cave packed with gravel soils, red clay; strongly weathering siliceous dolomite, loose rock structure; structure and fragmentation quartzite rock fragments, fragments of rock; medially weathering siliceous dolomite and quartzite, joint developed; lightly weathered siliceous dolomite, joint developed.

There is a cave of about 40% of the pile base area 1502.8m below the 2# pile, which extends southeast along of 18.4m, 9m width, and more than 20 meters high, vertical development, clay, gravel soil filled, loose structure, clay-like soft plastic, 1502.8 to 1497.58m without filling. A platform is first filled with gravel, which is grouted layer by layer, and then a masonry wall was built on the platform, pouring concrete to the design elevation.

To determine the pile bearing capacity and analyze the influence of karst on the pile bearing character, the paper selected the 2#pile of 1# pier and the 1#pile of 2# pier for a static load test. The parameters of the test piles are as follows.

Table 1. Test pile parameters.

Pile number	Pile diameter /mm	Pile Length /m	Distance from load box to the end of test pile /m	Estimated value of loading /KN
2# Pile of 1# pier (Test pile Z1)	2500	49.0	12	39800
1# Pile of 2# pier (Test pile Z2)	2500	40.0	15	39000

1.2 Analysis of the bearing capacity

1.2.1 Influence of Karst on pile bearing characteristics

The Q ~ S curve of Z1 pile is obviously steeper than that of Z2. The settlement of Z1 pile is far greater than that of Z2 pile under the same load (Figure 1).

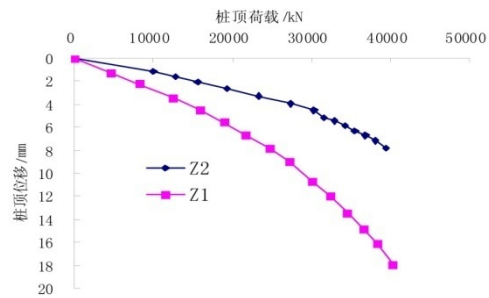

Figure 1. Q～S curve

The tip and the lower-part of the pile were selected for analysis to find the differences between Z1 and Z2. Figure 2 shows the relation between the average friction and relative displacement of Z1 tip, Z2 piles, which is fitted by hyperbola fitting method. From the experimental results, the average friction of Z2 pile is greater than the Z1 pile. From the fitting results, the critical displacement of Z2 pile is 4 mm when it shows maximum friction, and that of Z1 is 8 mm. But they have almost the same maximum friction. And for the lower-part of pile, the box load is supported by the lateral friction and tip resistance. Considering

that the tip resistance is small, especially considering the influence of karst, it is considered that the entire load on the lower-part of pile is taken by friction. The relation curves and the fitted curves are found and the results are as follows. From Figure 3, the measured value and the maximum value of the lower-part of the pile is greater than Z1, and Z1 need greater displacement than Z2 to show maximum friction.

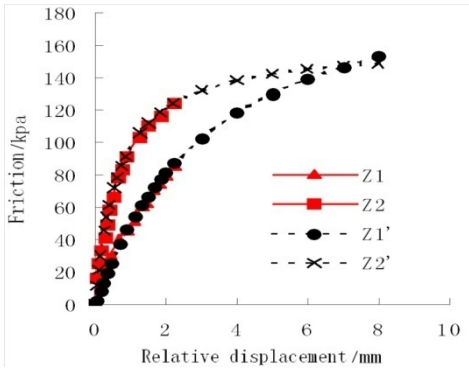

Figure 2. Average friction of pile tip and relative displacement. (The map dotted curve is fitting curve.)

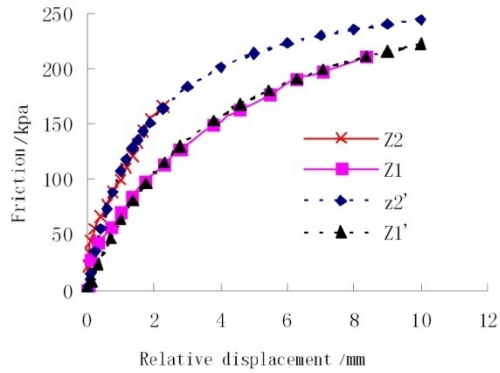

Figure 3. Average friction of the lower-part of pile and relative displacement. (The map dotted curve is fitting curve.)

1.2.2 Analysis of test results

It can be determined from these tests that karst mainly influences the lateral friction of the pile, and the entire pile will be affected. For the pile tip, it mainly affects the lateral friction and for the lower-part of the pile it will affect the entire pile. According to the test and research results, the pile-stress state of the pile end rock-soil friction will have a greater influence on frictional resistance around the pile. When the strength of the rock around the pile tip is low, not only will the lateral strength be reduced, but also the critical pile-soil displacement will increase. The two test piles selected have little difference in the rock around the piles. The main difference lies in that Z1 piles lie on the karst cave, where the filling materials have low strength, resulting in lower strength of the bearing layer, which is not conducive to the friction, and it is more obviously close to the pile tip. In addition, there is a free-face near the end of the pile tip where the rock strength is low compared with the Z2 pile. Pile axis forces gradually diffuse to the rock around the pile through piles of lateral friction, which make the rock more relaxed, deformation increased, and the performance will be more obvious down the pile, causing the low-part friction of Z1 pile to be lower than that of the Z1 pile, so the displacement of maximum friction of Z1 pile is larger than Z2 larger. The Z1 pile tip will be affected little by the cave, because there is a certain distance from the cave, but the displacement of the maximum friction will increase.

2 Influence of karst on pile bearing capacity

Using the finite element method (Shilong et al. 2005), the paper did numerical simulation analysis. First it anti-counted rock with axisymmetric model, concrete and rock characteristics and rock-pile friction contacts, and at the same time did the pile load bearing capacity self-balance experiment with the axisymmetric model. The load-displacement curves can be used to calibrate the model, from which parameters of the numerical model can be found. Secondly, the related axisymmetric model and the three-dimensional model are constructed, and their calculation results were compared, and 3D models were evaluated accordingly. Finally, a three-dimensional model was used to analyze the sensitivity of rock cave location and various rock types, as well as lateral friction and pile resistance.

2.1 Three-dimensional finite element model

In order to analyze the influence of the cave on the pile bearing capacity, based on the 2D axisymmetric model, a 3D finite element model of the pile-rock-cave was established to simulate the interaction, whose scale is similar to the 2D axisymmetric model. The 3D and 2D axisymmetric models have the same contact face, geometric profile, the same material properties, so they have the same load-deformation activity characteristics. Four displacement points were set up along the pile to detect the 3D model.

2.2 Sensitivity analysis of the influence of cave on pile bearing capacity

2.2.1 Calculation of working conditions

Based on the pile-rock-caverns 3D finite element model, having detected it, considering the influence factors of bearing capacity such as the thickness of the tip of the pile, diameter, elevation and eccentricity of the cave, different caves were set up to form various 3D models. Each factor has four models, for a total of 16 models. Meanwhile, in order to analyze the different influence of rock on the pile bearing characteristics, four different rock types were considered in each model.

In order to study and verify the sensitivity analysis conclusion, the cave was considered to be near the pile tip. At the same time the extreme state (where pile is fully embedded in the cave, having no rock supporting it) was also simulated.

A total of 16 working conditions were analyzed, considering the following factors.

(1) The cave lies beneath the pile and they have the same axes. The space from the cave to pile tip is a constant value, which is equal to the pile diameter. Cave diameter changes from where it is one times the pile diameter and its cross section is ten times that of the pile.

(2) The cave lies beneath the pile. The cave center iteration happens with the pile axes. The thickness from pile tip to the cave top changes from five times pile diameter to eight times pile diameter when the cave diameter is equal to five times pile diameter.

(3) The cave eccentric area beneath the pile. The space from the cave top to pile

is constant value, which is equal to the pile diameter. The eccentric distance from pile axes to cave center is one to six times cross-section.

(4) The cave eccentric area beneath the pile. The space from the cave tip to pile is a constant value, which is two times the pile diameter. The eccentric distance from pile axes to cave center is one to four times cross-section.

Cave is considered to lie beneath the pile, whose eccentric distance is equal to 2×D, diameter is equal to 5×D, the thickness from pile tip to the cave top is equal to 1×D, and their calculation models are showed in figure 4.

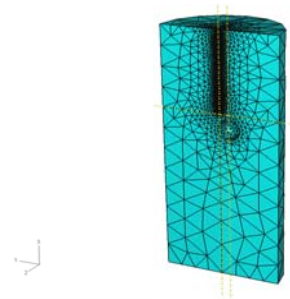

Figure 4. cave diameter of 5×D, thickness of 1×D, eccentric distance of 2×D

2.2.2 Analysis of sensitivity calculation results

Idealistic spherical cave will change the proportion of pile lateral friction and pile bottom bearing capacity to total bearing, When supposing the isotropic of rock pile with D-P plastic flow rules

When the influence factors of the cave on pile bearing capacity increases gradually, for example, the more the cave lies near the pile and the more the cave is big, simulation calculation shows that the load on the pile bottom reduces and the more load is on the interface of rock-concrete. Then, the influence of the roughness of pile-rock, the degree of fragmentation and weathering on the total bearing capacity will be greater than the case that there is no cave beneath pile.

(1) The influence of rock mechanical characteristics on the pile bearing characteristics mainly embodies that the relative changes in the pile carrying capacity and pile lateral friction, the rock pile-stress state of friction will have a greater impact on the lateral friction. When the elastic modulus of the rock around the pile reduce, not only will the pile tip bearing capacity relatively increase, but also the critical displacement of rock-pile will also increase, especially when the cave is located beneath the pile, the impact is more obvious.

(2) When the thickness from the cave to the pile is small (e.g. less than 1D), the ratio of the thickness to the span is less than 0.5, the pile bearing characteristics will be impacted. And with the ratio of the thickness to the span reduce, the proportion of pile tip bearing capacity to total bearing capacity increase, but the proportion of lateral friction to total bearing capacity will be reduced. When the thickness from the cave to the pile increases (e.g. the thickness is equal to 2D) with the same ratio of the thickness to the span, the pile tip bearing capacity in the case of large roof thickness is bigger than that in the case of small roof thickness, but the lateral friction in the case of large roof thickness is less than that in the case of small roof thickness. When the cave center deviates from the pile axes, the influence of cave on pile bearing characteristics will reduce.

(3) Although there is no obvious fact indicating that the bedrock produces

differential deformation, the lateral friction and the pile bearing capacity has changed. It can be seen from the calculation figure that the lateral friction-load slope increases with the diameter increase. Accordingly, the pile bearing capacity decreases. Hasson (1997) pointed out that lateral friction increases when the contact surface stress increases. In the initial loading phase, the displacement is small, as well as the pile - rock surface stress, because most of the load is transferred to the bedrock. When the load increases, displacement increases, the lateral friction plays a more important role in the pile capacity. For small diameter cave, for example, cave diameter is one to five times pile diameter, lateral friction will quickly reach 30% of the total load. Then the lateral friction percentage will be a little lower. The results show that when the lateral friction will achieve the maximum increase with the staggered motion of the rock - piles interface, the incremental load will be supported by bedrock. In the small load loading stage, the main load is supported by bedrock. Then the pile tip carrying capacity–load percentage curve will fall rapidly. Having slow down to the bottom, the pile tip bearing capacity-load percentage will have a some increases. However, the curve rebound increases with the increase of cave diameter. Accordingly, for a super large cave, e.g. 10 times pile diameter, it will delay the lateral friction-load curve peak time. In the sensitivity analysis, four factors the may have influence on the pile bearing capacity were selected. The results indicated that the distance from pile tip to cave top is a key factor of bearing and the diameter and eccentricity have little influence on the bearing.

2.2.3 Analysis when the cave is close to the pile tip

In order to study and verify the conclusions, it was simulated that the cave is close to the pile tip. At the same time the critical state of socketed pile (the distance of pile tip to cave top is equal to zero) is also simulated. The results are shown in Figure 5.

In Figure 5, the distance from the pile tip to cave top is 0D, 0.125D, 0.25D, and 0.375D, respectively, when the ideal spherical cave is close to pile tip.

P-S-curve indicated that the influence of cave-to-pile vertical displacement becomes obviously large when the cave is close to the pile, particularly in the case of one times the pile diameter, the pile bearing capacity becomes smaller, and the vertical displacement is increased under the same load.

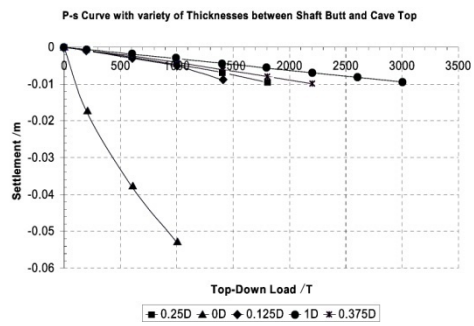

Figure 5. P-S curve of the distance from the pile tip to cave top is equal to 0-1D

3 Conclusions

Through static load tests and numerical analysis, the paper comes to the following conclusions:

(1) Under the same load, the pile settlement in the situation that the cave exists is far larger than that in the situation that the cave doesn't exist. The influence of karst on pile bearing characteristics mainly influences the lateral friction, and has an influence on the whole pile: it will mainly influence the critical displacement of upper pile and both the critical displacement and maximum friction in the lower segment of the pile.

(2) A cave will change the proportion of the lateral friction and pile tip bearing capacity to the total bearing capacity. The load borne by the pile tip will reduce, and the more load will be borne by the interface of rock-concrete when the cave is close to the pile tip and the cave diameter becomes large; Then pile-roughness of the rock, broken rock and weathering has a larger influence on the total capacity than the state that there is no cave.

(3) When the cave is near a pile, particularly in the range of 1D, the influence of the existence of the cave on the pile vertical displacement obviously becomes large. When the cave nears the pile tip, corresponding bearing capacity becomes small and the vertical displacement becomes larger under the same load. There is a close correlation between the displacement and the cave and the load. When the load is small, the differential displacement is also small, otherwise it will increase. In smaller diameter caverns, load - by the displacement is not obvious. When the cave becomes small, it has little influence on the load-displacement.

(4) Four possible influence factors were selected on the pile bearing capacity: thickness from the pile tip to the cave, cave diameter, cave eccentricity, cave depth when there is eccentricity. Analysis showed that the thickness from the pile tip to the cave top is a key factor of bearing capacity and the diameter and eccentricity has little influence on the bearing capacity.

The Analysis of Traffic Landscape from Users' Perspective: The Case of the Zhangjiang Tram

Li Na[1], Chen Xiaohong[2] and Xiong Wen[3]

[123] Room 337, Department of Transportation Engineering, Tongji University, 4800 Cao'an RD., Shanghai, 201804; PH (086)21-69584683;email:linayiqun@163.com

1 Abstract

The conventional studies of traffic landscape mostly focused on the aesthetical requirements from the designers' perspective. However, there has been a lack of concern and research from the users' perspective, which serves as the basis of traffic landscape design and construction. This paper, which is based on the tram construction project in Zhangjiang Area, Shanghai, explores the user's preference to traffic landscape. Users include drivers, passengers, pedestrians, and nearby residents. To explore the preferences for traffic landscape elements among different people in different districts, a survey was conducted to sample users' attitudes towards traffic landscape. The relative importance of various landscape elements can be simultaneously evaluated from this survey.

Keywords: traffic landscape, Zhangjiang tram, preference, landscape elements

2 Introduction

Streets, which serve as our indispensible links to the outside world, are also stages for traffic landscapes and must embody the features of both traffic and landscapes.

When referring to traffic landscape, vegetation or trees typically come to mind. Antupit regards vegetation/trees as the primary element that great streets must include (Antupit S. et al., 1996). But roadside vegetation is not the sole meaning of traffic landscape. Traffic landscape design includes both the design of streets in urban areas and their integration into the surrounding environment, namely comprehensive consideration of the alignment of roads, combination of buildings, public facilities, roadside vegetation and artistic exhibits such as sculptures and flowers (Xue An-shun et al., 2007).

Studies of traffic landscape in China focus mostly on aesthetical analysis from the designers' perspective. However, streets are not only thoroughfares but also community open spaces: public spaces that give shape to the city and provide people with places to meet, gather and transport themselves (Antupit S. et al., 1996). Thus, users' activities are vital constituent parts of roads. Traffic landscape design should meet users' needs. But designers' preference cannot represent the diverse preferences of users, particularly those of pedestrian and drivers. (Yang Liang-liang et al., 2007). It is generally recognized by landscape ecologists, environmental engineers,

environmental economists and sociologists around world that social factors play a very important role in landscape design. Public participation in decision-making and incorporation of human preferences, needs and activities in the management plans safeguard their continuation and success (Pavlikakis G.E. et al., 2006)

Researchers from various countries have investigated differences in preferences between cultural and sub-cultural divisions and ethnic groups. Factors such as personality, environmental orientation and educational background have also been reported to influence preference (Assenna Todorova et al., 2004). However, such studies are rare in China. The basic object of this paper is to explore the domestic landscape preference from users' perspective.

3 Backgrounds and Method

As a transportation mode, the modern tram has advantages of high-speed, low-noise, no exhaust pollution, and low construction and operating costs. It has become a popular construction program in China. The tram network in Pudong area, Shanghai is planned to be 63.0 kilometers in length, covering Lujiazui, Sanlin and Zhangjiang areas. The 8.8 km long section in Zhangjiang area is a test section. It is crucial to solicit and evaluate public opinion with the Zhangjiang Tram project because of the overhead contact system and the tram rail, which are expected to be the most likely elements to disrupt the traffic landscape.

Evaluating the beauty of certain landscape objectively and scientifically is very difficult because, while beauty is partially defined by environmental characteristics, it depends largely on individual judgment. Even when groups of people witness the same scene under the same conditions, they do not have the same impression of the landscape. A landscape is composed not only of what lies before the viewer's eyes but what lies within his head (Meinig D.W., 1976). The methods generally used for evaluating scenic beauty are cartographic representations, simulated assessments and questionnaire surveys (Antupit S. et al., 1996).

The investigation described in this paper was built around the landscape design challenges encountered in the tram construction program in Zhangjiang area, and respondents involved residents, local employees and students. The evaluation utilized questionnaires to obtain categorical information for the respondents, such as age, gender,(无) and occupation. Then, the respondents were shown three groups of simulated photomontages, exhibiting different types of landscape elements. The respondents gave their assessments according to their visual preference after gaining a direct impression of each group of images.

4 Investigation

4.1 General Situation

This survey was carried out on two days in April, 2008. A total of 285 respondents returned the questionnaires, but only 244 respondents provided complete

responses. The questionnaires were distributed in three functional districts in Zhangjiang: Zhangjiang Semiconductor Industry Park, the large Ziwei Road residential community and Zhangjiang university area, through which the planned tram line will pass. A smaller number of questionnaires were distributed outside Zhangjiang area. The number of completed questionnaires in these four sites is showed in Table 1.

Table 1.The amount of the questionnaires in four places.

Place	Frequency	%
Semiconductor Industry Park	62	25.4
University Area	90	36.9
Large residential community	57	23.4
Outside Zhangjiang area	35	14.3
Total	244	100.0

4.2 Basic information

Among all the respondents, 121 were males (49.6%) and 123 (50.4%) were females. A large number of technology- and capital-intensive industries are located in Zhangjiang area, with an employment base of approximately 90,000, which is much more than the area population of 24,000. Meanwhile, Zhangjiang university area includes several respected schools, including Fudan University and Shanghai University of T. C. M., with a combined enrollment of 80,000 students, which is nearly as large as the area employment base. The majority of the people who work and study in Zhangjiang are young or middle-aged. Of the survey respondents, 213 (87.3%) are 18-50 years old and 193 (79.1%) respondents have a college degree or higher. The occupation of respondents is summarized in Table 2 and their ages are summarized in Table 3.

The characteristics of the respondents are representative of the population in Zhangjiang area. Therefore the result of the survey should serve as a proxy for the preference of the people in Zhangjiang area.

Table 2.Occupation of respondents.

Occupation	Frequency	%
Student	109	44.7
Teacher	3	1.2
Factory operator	14	5.7
Office clerk	21	8.6
Technical personnel	48	19.7
Retiree	22	9.0
Other	27	11.1
Total	244	100.0

Table 3.Age of respondents.

Age	Frequency	%
<18	4	1.6
18-30	180	73.8
31-50	33	13.5
51-65	14	5.7
>65	13	5.3
Total	244	100.0

5 Analyses

5 Attention to traffic landscape

The survey includes six aspects of tram construction for respondents to assess the importance according to their own needs, on a ten-point rating scale, from "most important" (10) to "least important" (1). These aspects were improving street landscape, controlling construction cost, increasing travelling speed, improving comfort, reducing fares and preventing pollution. The descriptive statistics of the assessment results are shown in Table 4. Comparing the average scores using an F-test at a significance level of 0.05, the p-value is approximately 0, indicating that respondents' attitudes towards these six aspects differ significantly. The aspect with the highest mean (8.68) and lowest standard deviation (1.97) was "preventing pollution." Its Kurtosis was 4.29, indicating that people are generally very concerned about the issue. For the aspect of "improving street landscape," respondents give an average score of 7.57, in the middle of these six aspects. The results showed that respondents also pay some attention to street landscape, but less than pollution, comfort and fares.

Table 4.The importance of the aspects in tram construction.

Aspects	Mean	Std. deviation	Kurtosis
Preventing pollution	8.68	1.97	4.29
Improving comfort	7.97	2.04	0.53
Reducing fares	7.71	2.48	0.27
Improving street landscape	7.57	2.24	0.61
Increasing traveling speed	7.29	2.39	0.10
Controlling construction cost	5.54	2.73	-0.94

Comparing the scores given by males and females on improving street landscape, the results indicate that there is a difference in opinion between males and females. Female respondents (8.02) paid more attention to street landscape than males (7.11). The comparison of responses by gender is summarized in Table 5. While analyzing respondents of different ages, occupations, education backgrounds and in different survey places, there is no significant difference on their attitudes.

Table 5.T-test for scores of improving street landscape by gender.

Gender	Frequency	Mean	Std. deviation	t	df	Sig. (2-tailed)
Male	121	7.10	2.53	-3.25	217.34	0.001
Female	123	8.02	1.81			

5.2 Importance of street landscape elements

In the questionnaire, several common street landscape elements were listed, including some that have a close relation to tram systems, such as street vegetation,

road surface, and overhead contact system. The respondents were requested to select the most important elements that influence the street landscape from the list and then arrange the elements in importance priority.

Among the completed surveys, 84.4% included select street vegetation as one of the most important elements, which is a much higher frequency than any other elements on the list. This result confirms that quality vegetation is the highest priority for a great street (Antupit S. et al., 1996). Over half of the respondents also selected bus stops and public facilities as the most important elements, which are the two listed elements(删除) most often used by road users in daily life. The percentage selecting overhead contact system and tram rails, the two elements closely related to the tram system, was not very high. Respondents indicated paying little attention to these two elements, possibly because modern tram technology is advanced and less intrusive compared to the conventional tram and the aesthetics have been largely improved. It is also likely that, for many users, landscape elements such as quality vegetation or bus stop facilities can compensate for the disruptive landscape caused by tram construction. The results of the respondents' prioritization are summarized in Table 6.

Table 6.The selection of the elements according to their importance.

Landscape element	Frequency	%
Street vegetation	207	84.8
Bus stops	129	52.9
Public facilities (garbage bins, etc.)	123	50.4
Surrounding buildings	117	48.0
Lamp posts and poles	114	46.7
Road surface	101	41.4
Buses and vehicles	94	38.5
Overhead contact system	93	38.1
Tram rails	91	37.3
Creation of sculptures	69	28.3
Other	5	2.0

Comparing the highest priority element selected by the respondents in each of the four survey distribution sites shown in Table 7, most people still consider street vegetation to be the most important landscape element. In each of the Zhangjiang area sites, respondents identified overhead contact system and bus stop facilities as the next most important elements. This makes sense, since the bus stop is the most commonly used road facility for residents, students and workers in Zhangjiang, so people will pay more attention to this element. However, outside Zhangjiang area, respondents selected tram rail and surrounding buildings respectively, as the next most important, and at a higher rate than the other elements selected by the Zhangjiang sites. This may be caused by the fact that Zhangjiang is a newly-built

community with modern, low density buildings and wide roads. As such, it is likely that being in close proximity to buildings and rail will not bother the Zhangjiang population very much.

Table 7.The highest priority landscape element selected at four survey sites.

Survey Site		Industry Park	University Area	Large Residential Area	Outside Zhangjiang Area
Highest priority landscape element	Street vegetation	58.1%	51.1%	28.1%	60.0%
	Road surface	4.8%	3.3%	5.3%	2.9%
	Lamp posts and poles	1.6%	2.2%	3.5%	2.9%
	Public facilities (garbage bins, etc.)	6.5%	4.4%	7.0%	2.9%
	Overhead contact system	8.1%	10.0%	12.3%	2.9%
	Tram rails	4.8%	7.8%	3.5%	11.4%
	Creation of sculptures	3.2%	1.1%	8.8%	0.0%
	Buses and vehicles	3.2%	4.4%	10.5%	2.9%
	Bus stops	6.5%	8.9%	15.8%	2.9%
	Surrounding buildings	3.2%	6.7%	5.3%	11.4%

5.3 Photomontage simulations

During the survey, respondents were shown three groups of simulated photomontages exhibiting different types of landscape elements: vegetation，artistic exhibits;（删除） and tram components. The respondents gave their assessments on a ten-point rating scale, from “strongly like” (10) to “strongly dislike” (1), according to their visual preference. In order to reduce potential bias from surrounding elements, all three groups of photos were modified with photo software to apply the same backgrounds. The original photos of the vegetation and the sculptures and flowers were taken in Zhangjiang in 2007. Since the tram system in Zhangjiang is still under construction, the original photo of tram components was from a tram system in Spain.

●Vegetation

The first group of photos, shown in Figure 1, displays four types of roadside vegetation. As shown in Table 8, evaluation of the average scores for each type of vegetation using an F-test at a significance level of 0.05 results in a p-value of approximately 0. This indicates that respondents’ attitudes towards these various types of vegetation are significantly different. “Trees with lawn” (8.76) or “Trees

with hedges" (7.94) are strongly favored by respondents, while "no vegetation" ranked lowest among the choices.

Table 8.F-test for various vegetation types.

Vegetation types	Mean	Mean Rank
No vegetation	3.996	1.15
Only trees	4.998	2.00
Trees with hedges	7.945	3.24
Trees with lawn	8.758	3.60

F= 578.18, p=0.000

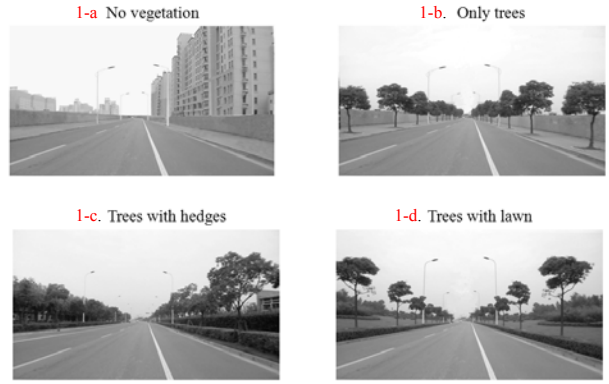

Figure 1.Street Vegetation.

●Artistic exhibits

The second group of photos, shown in Figure 2, displays four types of artistic exhibits. The respondents' attitudes towards these various types of exhibits were significantly different at a significance level of 0.05, as summarized in Table 9. Among them, "display of flowers" (8.615) was the most popular type.

Further comparing the scores of ordinary sculpture and colorful sculpture, respondents' attitudes towards these two exhibits were not significantly different. The Photo2-b of the colorful sculpture exhibit is the actual scene in Zhangjiang Semiconductor Industry Park. Changing the color of the sculpture does not change the preference of the respondents.

Table 9.F-test for various artistic exhibits.

Artistic Exhibit types	Mean	Mean Rank
No artistic exhibit	5.146	1.77
Ordinary sculpture	5.840	2.27
Display of flowers	8.615	3.71
Colorful sculpture	5.824	2.25

F= 331.03, p=0.000

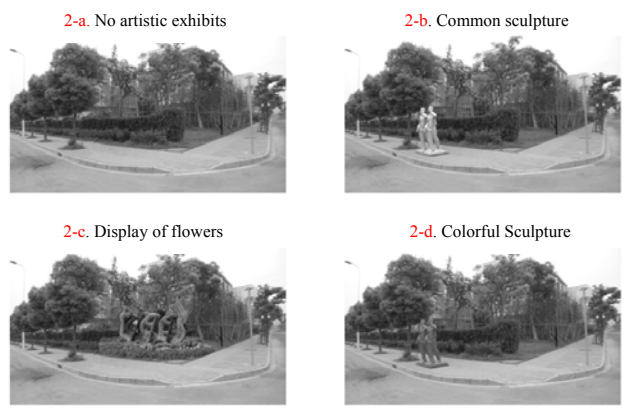

Figure 2.Artistic exhibits of sculpture or flowers

●Tram system components

The third group of photos, shown in Figure 3, displays four combinations of different overhead contact systems and road surfaces. Comparing the average scores using an F-test at a significance level of 0.05, as shown in Table 10, the p-value is approximately 0. This indicates that respondents' attitudes towards these four combinations of components were significantly different. The most preferred combination was grass road surface with no overhead contact system (8.14).

Cluster analysis of the assessment scores splits these four photos into two groups. Photos 3-a and 3-b, which depict a cement road surface, received lower scores than photos 3-c and 3-d, which depict a grass road surface. The results suggest people are more sensitive to road surface than overhead contact system, which is consistent with the results in shown in Table 6.

Table 10.F-test for various tram components.

Components		Mean	Mean Rank
Cement surface	With overhead contact system	4.750	1.55
	No overhead contact system	6.219	2.32
Grass surface	With overhead contact system	6.715	2.68
	No overhead contact system	8.142	3.45

F= 293.06, p=0.000

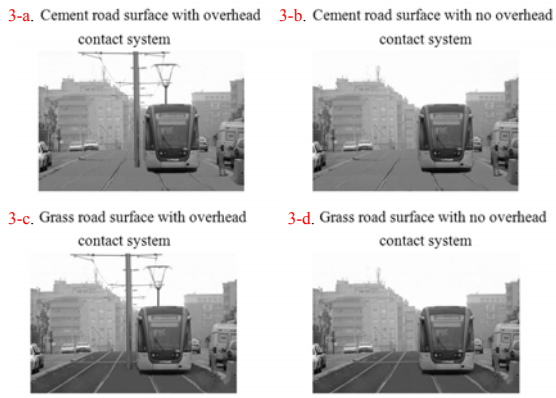

Figure 3.Landscape elements concerning tram.

6 Conclusion

This survey was carried out in three functional districts in Zhangjiang area and one place outside Zhangjiang, soliciting responses from residents, students and employees in Zhangjiang area, and learning the preference of these road users in order to provide some reference to the traffic landscape design in the tram construction program.

Results of the survey indicated that users were most concerned about pollution during construction of the tram project. Users also expressed concern about traffic landscape, but less so than pollution, comfort and fares. There is a notable difference in responses towards traffic landscape between males and females. Responses by females tended to focus more on improving traffic landscape. The findings showed no significant differences among people of different ages, occupation, education backgrounds and fore responses from different survey sites.

For the most important elements in traffic landscape, street vegetation received the largest number of responses, with bus stop and public facilities being the next

most often selected. The percentage of respondents selecting overhead contact system and tram rail, which were considered by the designers as the probable element influencing traffic landscape, was not very high. Comparing the results of the questionnaires of the four survey sites, respondents in Zhangjiang area tended to select street vegetation, bus station and overhead contact system as most important. However, respondents outside Zhangjiang area tended to select street vegetation, tram rail and surrounding buildings. This may be due in part to the fact that Zhangjiang is a newly-built community, with a low building density and wide roads, which lessens the influence of buildings and tram rails.

When comparing preferences for the particular types of street vegetation, trees with lawn or hedges were welcomed by the respondents. Options with only trees or with no vegetation were not popular. The most favored artistic exhibit was displays of flowers. The sculpture placed in Zhangjiang at present did not receive very favorable responses. Comparing the tram system components, the most popular combination was grass road surface with no overhead contact system. Respondents appeared to be more sensitive to the particular road surface than whether or not the overhead contact system was installed. As such, designers could give priority to road surface during planning.

ABSTRACT

Traffic incident automatic detection and recognition play an important role in traffic management and controlling. For the problems of automatic traffic incident detection and recognition, a method is proposed based on wavelet decomposition and support vector machine (SVM) with vehicle acoustic signals. Vehicle acoustic signals are decomposed with the wavelet analysis, and the power in different frequency is regarded as the different incident eigenvectors and also as training samples of SVM traffic incident classifier. By the processing of normal driving, braking and crash incident acoustic signals, the result shows that the proposed method is an effective method for automatic traffic incident detection and recognition.

Keywords: Wavelet decomposition；SVM；Traffic incident；Automatic recognition

INTRODUCTION

The traffic incident detection and identification is a hot research spot in the field of traffic management and controlling. The automatic detection and identification is especially concerned because of its low cost, not subject to weather restrictions, and high detection rate. Automatic incident detection (AID) methods can be divided into indirect and direct method. The indirect detection method determines traffic incident through abnormal traffic flow change, which is characterized by economic convenience. The vast majority of currently used methods belong to the indirect detection method, but its response time is too slow, and has a lag time. The direct detection method finds incident using video image processing technology, this method is "see" the traffic incident in fact, so the detection rate is far more than the indirect detection method, but it is subject to climate conditions, and intensive detection points and large capital are necessary(Jiang, 2001).

The traffic sound has always been looked as traffic noise, so generally people are extent to eliminate these noises. But in fact we can distinct different traffic incidents using special incident sounds. Then could directly "listen to" the incident

happenchance using vehicle sounds as the video image technology to "see" the incident? Harlow (Harlow, 2001) and S.Chen (Chen, 1997) has already begun such studies in this field, Xiong Lieqiang (Xiong, 2005) has proposed to detect traffic incident using vehicle acoustic and road vibration signals, Chen Qiang (2005) has verified the differences of vehicle crash with normal acoustic signals, as well as thunders through the simulation. However, these methods only show the feasibility through vehicle acoustic signals to detect traffic incidents, so the detection method based on vehicle acoustic signals need further study.

In this paper, the AID method is proposed based on wavelet decomposition and SVM using vehicle acoustic signals. The paper is organized as follows: in section 2, the feature extraction is introduced based on the wavelet decomposition, and the SVM method is reviewed. The experiment results are presented in section 3.

BACKGROUND THEORY

Feature extraction based on the wavelet decomposition. The feature selection is an important component on pattern classification since even the best classifier will perform poorly if the features used as inputs are not selected well. Meyer proposed a group of wavelet in1986, and the binary expansion and translation of proposed wavelets constitute standardized orthonormal bases in $L^2(R)$. Mallat (1998) presented the concept of multiresolution analysis in 1988, and gave a fast algorithm of wavelet transform-Mallat tower decomposition algorithm.

In this paper, the vehicle acoustic signal is divided into M bands by the wavelet decomposition, and the energy of each band is $E_i (i = 1, ..., M)$, then the feature vector can be obtained as follow:

$$T = \frac{1}{E_r}[E_1, E_2, \cdots, E_M] \tag{1}$$

Where $E_r = \sqrt{\sum_{i=1}^{M} E_i^2}$ is the root mean square (RMS) of the vehicle acoustic signal.

SVM. For a given training set, while there may exist many hyper-planes that separate the two classes, the SVM classifier is based on the hyper-plane that maximizes the separating margin between the two classes. Mathematically, this hyper-plane can be found by minimizing the following cost function:

$$J(w, \xi) = \frac{1}{2}\|w\|^2 + C\sum_{i=1}^{n} \xi_i \tag{2}$$

Subject to the constraints:

$$y_i[(w \bullet x_i) + b] \geq 1 - \xi_i, i = 1, 2, \cdots, n, \quad (x_i, y_i), i = 1, 2, \cdots, n, x \in R^d, y \in \{+1, -1\} \tag{3}$$

Where C is a user-specified, positive, regularization parameter, and $\xi_i > 0$ are slack variables.

The linear SVM can be readily extended to a nonlinear classifier by first using a nonlinear operator $\Phi(.)$ to map the input pattern into a higher dimensional space. In this condition, the constraints (3) can be written as:

$$y_i(w \bullet \Phi(x_i) + b) \geq 1 - \xi_i \quad i = 1, 2, \cdots n \tag{4}$$

Using the technique of Lagrange multipliers, one can show that a necessary condition for minimizing $J(w, \xi)$ in (2) is that the vector w is formed by a linear combination of the mapped vectors $\Phi(x_i)$, that is:

$$w = \sum_{i=1}^{n} \alpha_i y_i \Phi(x_i) \tag{5}$$

Where $\alpha_i \geq 0, i = 1, 2, \cdots n$, are the Lagrange multipliers associated with the constraints in (4).The SVM approach aims at constructing a classifier of the form:

$$f(x) = sign\{\sum_{i=1}^{n} \alpha_i y_i \Phi^T(x_i)\Phi(x) + b\} = sign\{\sum_{i=1}^{n} \alpha_i y_i K(x_i, x) + b\} \tag{6}$$

Where $K(x_i, x)$ is kernel function. Typical kernel functions have linear, polynomial, RBF and MLP (Hsu 2002, Oliver, 2002, and Millet-Roig, 2000).

EXPERIMENT

The type of the traffic incident is very complex, in this paper three types of acoustic signals of normal, braking and crash are analyzed, and normal driving (it is looked as an incident), braking incident and crash incident are identified truly. The sample frequency of acoustic signals is $11025HZ$. The time-domain waveforms of three different incident acoustic signals are shown in Figure 1, and theirs corresponding spectrum is shown in Figure 2. From Figure 1 and Figure 2, we can see that time-domain characteristics of three incidents have no obvious difference, in the frequency domain the energy of the normal driving is mainly concentrated in the lower frequency bands around $1500HZ$, and the energy distribution is more even in the entire low-frequency (see Figure 2a); the energy of the braking incident is mainly concentrated in about $500 \sim 1000HZ$ and $1500HZ$, and the energy is very small in low frequency band(see Figure 2b);for the crash incident, the energy is mainly concentrated in about $2500HZ$ .The spectral characteristics of three different incidents have obvious difference, so in this paper, the energy in frequency domain is looked as identification features.

Vehicle acoustic signals are divided into 6 layers by wavelet decomposition,

and the energy of various frequency bands is calculated separately. According to (1), 3 group 7-dimensional feature vectors can be obtained. Four samples are used training samples for each traffic incident, respectively. The normal driving incident is looked as one category, labeled as tag 1; the braking incident as a class, labeled as tag 2; the crash incident as a class, labeled as tag 3. A total of 12 sets of 7-dimensional feature vector are obtained, and these feature vectors are used as training samples to identify the traffic incident (see Table 1). Another six samples, which included the above-mentioned three types of incidents, each type has two samples, are used as the test samples for classification and identification. The feature

vectors of these six samples are input to traffic incident classifier set up above, the classification results are shown in Table 2, and the result is exactly the same as known traffic incidents.

CONCLUSION

In this paper, the AID method is proposed based on wavelet decomposition and SVM using vehicle acoustic signals. By the processing of normal driving, braking and crash incident acoustic signals, the result shows that the proposed method has good classification results, the algorithm is simple, and only fewer samples can achieve the classification requirements for automatic traffic incident detection and identification. But the type of traffic incidents is very complex, and the vehicle acoustic signal is prone to suffer from other environment noises, so traffic incident detection and identification need further study with a variety of types of vehicle acoustic signals.

ABSTRACT

Traffic accidents in cold regions have both general trends of change and periodic fluctuation due to the cyclical changes of the climate. Considering that Grey System Prediction Model can reflect the general trends of change visually, and Periodic Extensional Prediction Model mainly reflects the periodic fluctuation, the paper adopts the way of the Gray-Periodic Extensional Combinatorial Model to predict the traffic accidents in cold regions. This model considers both the development trends and periodic fluctuation of the traffic accidents. Finally an example analysis is given to fit and predict the road traffic accidents in cold regions, and the analysis results showed that the Gray-Periodic Extensional Combinatorial Model was suitable for the prediction of road traffic accidents in cold regions, and the fitting and prediction accuracy was much higher, which provides theory reference and practical basis for the traffic accident management and control in cold regions.

INTRODUCTION

Road traffic accidents are very serious under the snow and ice conditions in the cold regions. They are a huge threat to people's life and property. From a theoretical and objective perspective, road traffic accidents are predictable and preventable and have their own laws of development and characteristics. An effective prediction of traffic accidents can master the future development of the situation and rules（Jianming Ma et al. 2008）, and provide an important theoretical basis as well as reference data for road traffic accident mitigation.

At present, the study on the prediction of road traffic accidents is usually aiming at the general trends of change(K. Nikolopoulos et al.

2007；LIU Gang et al. 2007；MingzhiMao, et al. 2006；S.R. Singh 2007）. However, the occurrence of traffic accidents in cold regions has both general trends of change and periodic fluctuations because of the cyclical changes of the climate. Thus it makes the prediction model more uncertain and the prediction accuracy is reduced, and it also reduces the practical value of the prediction results.

Gray prediction of road traffic accidents (MingzhiMao et al. 2006) can discover and master the law of system development through dealing with the original data and building Grey models. The geometric figure of the prediction result is a relatively smooth curve, which can reflect the general trend visually. However, the fitting precision is poor for the data column of road traffic accidents which has greater volatility. While the periodic extensional prediction model can reflect the characteristics of cycle fluctuation commendably, it cannot reflect the characteristic of general trends of change. The more obvious that the general trends of change show, the lower prediction accuracy becomes. In fact, the gray prediction model has strong integration and penetration features for general models, so incorporating GM (1,1) model to the general model can enhance the prediction accuracy sharply. So for the data column of road traffic accidents which have the characteristics of general trends of change and cycle fluctuation, it should build the Gray-Periodic Extensional Combinatorial Model (REN Feng et al. 2007) to combine the two prediction methods. This can make up each other's deficiency and achieve good prediction efficiency.

The paper adopts the Gray-Periodic Extensional Combinatorial Model to predict the traffic accidents in cold regions. That is, building the Residual Periodic Extensional Model on the basis of general Grey Model GM(1,1), and restructuring new data sequence by extracting the dominant period, and stacking the different periodic values at the same time as the residual compensation of GM(1,1).

GARY-PERIODIC EXTENTIONAL COMBINATORIAL MODEL

Assuming that a certain behavioral sequence of the system (nonnegative) is: $X^{(0)} = (x^{(0)}(1), x^{(0)}(2), \cdots, x^{(0)}(n)) \quad x^{(0)}(k) \geq 0; \quad k = 1, 2, \cdots, n$

Build the GM(1,1) model of the $X^{(0)}$ sequence.

1) Calculate the 1-AGO sequence $X^{(1)}$ of $X^{(0)}$. we can get: $X^{(1)} = (x^{(1)}(1), x^{(1)}(2), \cdots, x^{(1)}(n))$, where $x^{(1)}(k) = \sum_{i=1}^{k} x^{(0)}(i), \ k = 1, 2, 3, \cdots, n$.

2) Make the quasi-smoothness test for sequence $X^{(0)}$.

$$\rho(k)=\frac{x^{(0)}(k)}{x^{(1)}(k-1)}$$

If $\rho(k)<0.5$, it will satisfy the smooth condition, and the sequence change is steady.

3) Calculate the mean-value generating sequence $Z^{(1)}$ of $X^{(1)}$.

$Z^{(1)}=(z^{(1)}(2),z^{(1)}(3),\cdots,z^{(1)}(n))\quad z^{(1)}(k)=0.5(x^{(1)}(k)+x^{(1)}(k-1)),\qquad k=2,3,\cdots,n$

Constructing matrix $Y=\begin{bmatrix}x^{(0)}(2)\\x^{(0)}(3)\\\vdots\\x^{(0)}(n)\end{bmatrix}$, $B=\begin{bmatrix}-z^{(1)}(2) & 1\\-z^{(1)}(3) & 1\\\vdots & \vdots\\-z^{(1)}(n) & 1\end{bmatrix}$

4) Make a least-square estimation for the parameters column $\hat{a}=[a,b]^T$.

$$\hat{a}=[a,b]^T=(B^TB)^{-1}B^TY\qquad \alpha=\frac{a}{1+0.5a},\qquad \beta=\frac{b}{1+0.5a}$$

5) Build the model.

$$\hat{x}^{(0)}(k)=(\beta-\alpha x^{(0)}(1))e^{-a(k-2)}$$

6) Calculate the simulated value of $X^{(0)}$.

$$\hat{X}^{(0)}=(\hat{x}^{(0)}(1),\hat{x}^{(0)}(2),\cdots,\hat{x}^{(0)}(n))$$

7) Accuracy test.

Calculate residual series $x'(k)$: $\qquad x'(k)=x^{(0)}(k)-\hat{x}^{(0)}(k)$

Calculate residual sum of squares:

$$s=X'^{T}X'=[x'(2),x'(3),\cdots,x'(n)]\begin{bmatrix}x'(2)\\x'(3)\\\vdots\\x'(n)\end{bmatrix}$$

Calculate average relative error: $\Delta=\frac{1}{n}\sum_{k=1}^{n}\Delta_k$, $\qquad \Delta_k=\frac{|x'(k)|}{x^{(0)}(k)}$

Build the periodic extensional model of residual sequence $x'(k)$.

1) Calculate the mean-generating function of sequence $x'(k)$.

$$\overline{x}_m(i)=(\sum_{j=0}^{n_m-1}x'(i+jm))/n_m;\qquad i=1,2,\cdots,m,\qquad 1\le m\le M$$

Where n is the length of the sample sequences, n_m is the greatest

integer that is smaller than n/m, M is the greatest integer that is smaller than n/2. Then we can get mean-generating function matrix:

$$\begin{bmatrix} \bar{x}_1(1) & \bar{x}_2(1) & \bar{x}_3(1) & \cdots & \bar{x}_M(1) \\ & \bar{x}_2(2) & \bar{x}_3(2) & \cdots & \bar{x}_M(2) \\ & & \bar{x}_3(3) & \vdots & \bar{x}_M(3) \\ & & & & \bar{x}_M(M) \end{bmatrix}$$

Make periodical continuation of mean-generating function $\bar{x}_m(i)$.

$$f_m(k) = \bar{x}_m(i), \quad k = i[\mathrm{mod}(m)], \quad k = 1,2,3,\cdots,n$$

Where mod represents congruence, $f_m(k)$ is the continuation function of the mean-generating function.

2) Extract the advantage period.

(1) Based on the basic principle of variance analysis, we can use the following formula to test whether sequence $x'(k)$ contains the period with the length of m.

$$F^{(m)} = (n-m)S^{(m)}/((m-1)S)$$

It satisfies the F-distribution with the freedom of $(m-1, n-m)$.

where $S^{(m)} = \sum_{i=1}^{m} n_i(\bar{x}_m(i)-\bar{x})^2$, $n_i = n/i, \bar{x} = (\sum_{i=1}^{n} x(i))/n, S = \sum_{i=1}^{m}\sum_{j=1}^{n_m}(x(i+(j-1)m)-\bar{x}_m(i))^2$

For a given confidence level α, if $F^{(m)} > F_\alpha(m-1, n-m)$, we think that $x(k)$ contains the period the length of which is m.

(2) Establish the advantage period with the length of m. That is,

$$S(m)/m = \max S(m)/m, \quad 2 \le m \le M$$

3) Generate the new sequence. Sequence $x'(k)$ subtracts the continuation function which is corresponding to the period m can generate a new sequence. That is,

$$x''(k) = x'(k) - f_m(k)$$

Then, from repeating steps 2 and 3, we can extract the other advantage period.

4) Superposition. $f(k)$ is the superposition value which is the superposition of the value from different cycles at the same time, $f(k) = \sum_{i=1}^{m} f_i(k)$. It is the periodic extensional model which is built by the period-superposition extrapolated method.

Calculate the fitted value of the gray-periodic extensional combinatorial model.

$$\bar{x}(k) = \hat{x}(k) + f(k)$$

EXAMPLE ANALYSES

Table 1 is the statistical result of traffic accident rates of a certain highway in China's northeast area, distributed monthly from 2002 to 2005. The road traffic accident rates show clear signs of the seasonal cycle of change and sustained upward trends, so it is applicable to the gray-periodic extensional combinatorial model.

Table 1. Monthly distribution of road traffic accident rates per 10 thousand vehicles (time/MV) from 2002 to 2005.

Year	Jan.	Feb.	Mar.	Apr.	May	Jun.
2002	0.7970	0.3108	0.8862	0.6636	0.9744	0.8530

2004	1.2058	0.6055	1.1045	0.7436	1.0303	0.9841
2005	1.3293	0.8399	1.3425	0.7924	0.9754	1.1151
Year	Jul.	Aug.	Sep.	Oct.	Nov.	Dec.
2002	0.6485	1.0084	1.1025	0.5345	0.8775	1.0244
2003	0.7159	1.0672	1.2037	0.9399	1.0244	1.2427
2004	0.7355	1.0979	0.9882	0.9542	1.1880	1.0761
2005	0.9197	1.1186	1.4274	0.9745	1.2840	1.2561

Build GM(1,1) model and calculate the residual sequence. Assuming that the sequence of road traffic accident rates per 10 thousand vehicles is: $X^{(0)} = (x^{(0)}(1), x^{(0)}(2), \cdots, x^{(0)}(n)) \quad x^{(0)}(k) \geq 0; \quad k = 1, 2, \cdots, n$

Calculate the parameters column:

$$\hat{a} = [a, b]^T = [-0.0093, 0.7596]^T$$

$$\alpha = \frac{a}{1 + 0.5a} = -0.00934, \qquad \beta = \frac{b}{1 + 0.5a} = 0.763$$

The GM(1,1) model is: $\hat{x}^{(0)}(k) = (\beta - \alpha x^{(0)}(1))e^{-a(k-2)} = 0.771e^{0.0093(k-2)}$

It is an index model and reflects the general trend of change in the sequence. Table 2 shows the residual and fitting error of the GM(1,1) model. The GM(1,1)model reflects an overall upward trend. However, the fitting effect is poor and the model can't meet the prediction requirement because of the accident rate sequence which has cycle fluctuation and large amplitude. Therefore, we should combine the periodic extensional model to correctly reflect the dynamic characteristics of the road traffic accidents in the cold regions.

Build the Periodic Extensional Prediction Model of residual sequence. When m equals to 12，15，13, they are advantage periods,

so $f(k) = f_{12}(k) + f_{15}(k) + f_{13}(k)$ .Then the gray-periodic extensional combinatorial model of the accident rate per 10 thousand vehicles is as follows, $\bar{x}(k) = 0.771e^{0.0093(k-2)} + f(k)$. Table 3 is the fitting result of the model.

Accuracy Test. From table 3 we know that the residual sum of squares equals 0.05 and the average relative error equals 0.0273. Compared to the gray model, the gray-periodic extensional combinatorial model has a better fit precision wise and can satisfy the precision requirement. The fitting results of some individual data in the model are less than desirable, because the original data has large amplitude. If we can carry data transformation processing based on the characteristics of the data to reduce the amplitude at the practical application of the model, the model can get better results.

PREDICTIONS

Suppose k equals to 49,50,51,⋯,60, and substitute the values to the gray-periodic extensional combinatorial model. Table 3 shows the predictive value of road traffic accident rates per 10 thousand vehicles in 2006.

CONCLUSIONS

This study successfully applies the gray-periodic extensional combinatorial model to the dynamic prediction of road traffic accidents in cold regions which have both general trends of change and cyclical change characteristics. The model combines the advantage of Grey prediction and periodic extensional prediction, and develops new information based on the full use of historical data. By the example verification, the Gray-Periodic Extensional Combinatorial Model can reflect the various characteristics of road traffic accidents in the cold regions and have a good fit effect with the historical data. The model expands the application range of the Grey prediction. The prediction accuracy is improved to provide a scientific basis for developing effective road safety countermeasures.

ABSTRACT

The optimization layout of rescue sites is the premise of implementing traffic resources dispatch and improving rescue efficiency. The multi-objective demands for locating rescue sites on roads cannot be easily satisfied with the traditional single-objective rescue facilities. Based on determined objects used for location, the model of multi-objective decision is proposed to provide suitable schemes of location of rescue sites on road. Integrating traditional models of location, such as p-medians, p-centers, maximum covering location and backup covering, the founded model of multi-objective locations satisfy quick response objects by minimizing the maximum rescue time, satisfy service efficiency objects by maximizing the covering demands and minimizing the total weighted time, and satisfy the demand-oriented objects of serious accidental rescue by maximizing the backup covering demands. Combined with analysis, for example, parametric programming is used to analyze the model, which shows that the model is feasible, and can be used as the theoretical basis for locating traffic rescue sites on roads.

0 INTRODUCTIONS

The study of road traffic accident focuses on preventative measures and rescue schemes. The preventative measures mainly include the investigation and renovation of accident black spots, improvement of road conditions, as well as the construction of road safety facilities. The rescue schemes mainly include the rescue association, the resources dispatch, and on-site rescue. Optimizing the location of traffic rescue service sites on roads, which belong to the preventive measures, has not been given enough attention in real works. Location of rescue sites mainly depends on the subjective judgment and experience from decision-makers, a lack of scientific basis. And scholars at home and abroad propose a number of classic models, such as collection covering location model, maximum covering location model, backup covering model, and p-medians and p-centers.

Collection covering location is used to identify the minimum number of facilities which can cover all the requirement sites. If there are limited funds, only P facilities can be chosen, and in this case, the process of maximum covering location is used to identify the location of each facility to maximize the population (or other indicators) of covered requirement sites. As the requirement sites, which are served a by

single facility, can hardly have been served in time under a congested situation, the backup covering model gives the backup covering scheme for requirement sites. Considering the efficiency of location, the p-median model minimizes the total weighted distance from the facilities to the requirement sites. Considering the fairness of location, the p-center model makes the maximum rescue time from the facilities to the requirement sites minimal. The research of reference literature [5, 6] to road-network-zoning essentially belongs to the p-center model. The above models belong to single-objective decision models. Each model extracts only one major factor from the amount of decision factors as the object of the decision of the location. However, for the location of road traffic rescue service sites, the decision-makers should consider the cost of rescue, the response time, the strength of demand, and other factors and integrate all the factors into the final decision. That is to say, the multi-objective location model of decision-making is strongly needed. Therefore, by identifying the objectives of location, this paper proposes the multi-objective model and the method of solution adapting to road traffic rescue service sites location and provides the theoretical basis for traffic rescue sites on roads.

1 THE DECISION OBJECTIVE OF RESCUE SITES LOCATION

For the road network itself, the proportion of serious traffic accidents is relatively small. Therefore, the fairness and efficiency principle should be taken into consideration in the process of location. The fairness principle requires each requirement site can be covered in the rescue time limit. If not all the sites can be covered, we should minimize the maximum rescue time. For different sites, the efficiency requirements are different. For the sites of high strength, the shortest journey time from the rescue service site is required. The fairness principle can be reflected in the collection of covering location and p-centers, and the efficiency principle can be reflected in maximum covering location and p-medians. In addition, due to the serious results of accidents, the rescue service sites should have the ability of backup covering for the requirement sites, so that when grave accidents happen they can be associated and take part in the rescue process, and the damage of the accident can be reduced as much as possible.

The efficiency, as well as fairness, should be reflected in the decision objective of traffic rescue sites location on road. Based on the rapid response or fairness, the first object requires the maximum rescue time from the rescue site to the requirement site minimized. Based on the accessibility and the efficiency of rescue site, the second object requires the amount of requirement of one-time-covering and minimizing the total weighted time from rescue-site to the requirement site. The third object is based on the consideration of backup covering, and it requires maximizing the amount of requirement of backup covering. But the object of the decision does not take the minimized cost into consideration because the fairness and efficiency principle need to identify the number of rescue sites—P beforehand, and the parameter P affects the cost directly.

2 THE MULTI-OBJECTIVE DECISION MODEL OF LOCATION

2.1 The definition of road network

The road network is defined as G= (V, E, A, T), where V is the set of nodes, the amount of nodes |V|=n, E is the set of arcs which connect each nodes, A is the set of weights and the weight of node I is defined as a_i, T is the set of travel times among the sites, t_{ij} is the travel time from rescue-site j to requirement site i. The set of requirement sites I=V, the set of candidate rescue-sites J=V.

2.2 The establishment of the model

We set the maximum rescue time as L, and the objective of minimizing the maximum rescue time requires L being minimized. If node I is covered in limit time T, then y_i=1， otherwise y_i=0. Using the efficiency objective requires the demand quantity of one time covering to reach to $\max \sum_{i\in I} a_i y_i$. If node I is covered by backup resource in limit time T, then u_i=1, otherwise u_i=0. The objective of reducing the damage degree requires the demand quantity of backup covering to reach to $\max \sum_{i\in I} a_i u_i$. Where the requirement site i is severed by the rescue site j, z_{ij}=1, otherwise z_{ij}=0. The quick respond objective requires the total weighted rescue time to reach to $\min \sum_{i\in I} a_i t_{ij} z_{ij}$. The rescue time for reaching the rescue site should be smaller than the maximum rescue time, namely $\sum_{j\in J} t_{ij} z_{ij} < L$. If a rescue service site is established at a candidate site j, then x_j=1 otherwise x_j=0. We set $N_i = \{j \mid t_{ij} \le T\}$ as the set of rescue service sites which could arrive at the requirement site i in the limit time T and p as the number of predefine rescue service sites.

Objective functions:

$$\text{Min } V_1 = L \quad (1) \qquad \text{Max } V_2 = \sum_{i\in I} a_i y_i \quad (2)$$

$$\text{Max } V_3 = \sum_{i\in I} a_i u_i \quad (3) \qquad \text{Min } V_4 = \sum_{i\in I} a_i t_{ij} z_{ij} \quad (4)$$

ST:

$$\sum_{j\in J} x_j = p \quad (5)$$

$$\sum_{j\in N_i} x_j - y_i - u_i \ge 0, \forall i \in I \quad (6)$$

$$u_i \le y_i, \ \forall i \in I \quad (7)$$

$$\sum_{j\in J} z_{ij} = 1, \forall i \in I \quad (8)$$

$$z_{ij} \le x_j, \ \forall i \in I, \forall j \in J \quad (9)$$

$$\sum_{j\in J} t_{ij} y_{ij} \le L, \forall i \in I \quad (10)$$

$$x_i, y_i, u_i, z_{ij} \in \{0,1\}, \ \forall i \in I, \forall j \in J \tag{11}$$

2.3 The explanation of model

The number of rescue sites p is guaranteed by constraint (5). Constraint (6) shows that not every requirement site can be covered within rescue time limit. Constraint (7) guarantees that the requirement site can be covered in second time only when it has been covered one time. Constraint (8) guarantees that every requirement site can be served by relevant rescue service sites. Constraint (9) guarantees that node j can serve requirement sites only when the rescue service site has been established at this node. The maximum rescue time L is defined in Constraint (10). Constraint (11) guarantees the values of variables are 0 or 1. Object (1) and Constraint (5), (9) and (10) guarantee to minimize the maximum rescue time (L) from rescue service site to requirement site. It is namely the p-centers, and incarnates the principle of fairness. Object (2) and Constraint (5) and (6) guarantee to maximize the demand of one time covering. It is namely the maximal covering model, and incarnates the principle of efficiency of system. Object (3) and Constraint (5), (6) and (7) named backup covering model guarantee to maximize the demand of backup covering in term of rescue time limit. Object (4) and Constraint (5), (8) and (9) guarantee to minimize the total weighted time from rescue service sites to requirement sites. It is namely the p-median and incarnates the principle of efficiency.

The above model with 4 objectives is a multi-objective decision model of location. The standard function of multi-objective decision is Min [V_1，$-V_2$，$-V_3$，V_4].

The multi-objective decision model of roads rescue service sites location proposed in this paper integrates the classical location models, such as collection covering location model, maximum covering location model, backup covering model, p-medians and p-centers.

3 THE SOLUTION AND ANALYSIS OF THE MODEL

The methods of solving multi-objective decisions are a flexible approach, in general, including Pareto optimality analysis, objective programming method, fuzzy multi-objective programming method, as well as parameters programming method and so on. Parameters programming method is simple and practical in solving multi-objective programming problems. When using the parameters programming method, multi-objective optimizing model can be converted into a single-objective parameters programming model in two ways: weighted method and constraint method. First, an effective solution is produced in each method. Then, by the way of parameter variation of single-objective linear programming, a group of effective solutions are produced. The constraint method is used to solve the model in this paper.

One of all K objects has been retained and optimized in the constraint method. And the rest K-1 objects, each of which subjects to an acceptable value, have been considered as constraints. By adding these constraints to the original constraint equations, the multi-objective optimization model is converted to a single-objective linear programming problem. By continually changing the acceptable value on the right

side of the constraint equation, a set of effective solutions can be obtained. In the above-mentioned multi-objective decision model, the target V4 is retained, and we make the objective V1, V2 and V3 to be constrained by the acceptable value α, β and γ on the right of each equation. Namely, $L \le \alpha$, $\sum_{i \in I} a_i y_i \ge \beta$ and $\sum_{i \in I} a_i u_i \ge \gamma$. There is a lower limit of α which is the rescue time calculated by p-centers. Both β and γ has an upper limit value. The upper limit value of β is calculated by maximal covering model and the upper limit value of γ is calculated by backup covering model.

A virtual road network of highways is established in Fig 1. The small circles in the network are the candidate rescue service sites and also the requirement sites. The number a_i in each circle is the weight of the requirement site. For example, 2（3） means the weight of Node 2 is 3. The number above each line means the travel time t_{ij} from one site to another. Set limit time of rescue T=7 minutes.

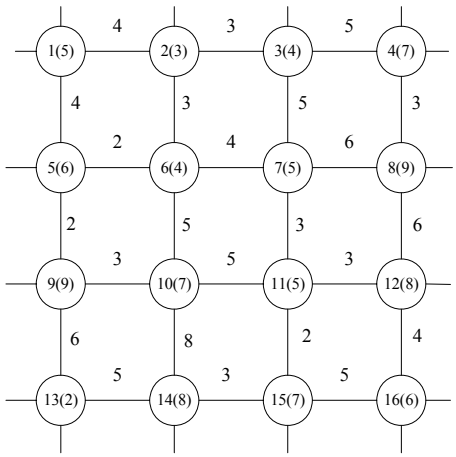

Figure.1 Example of virtual road network.

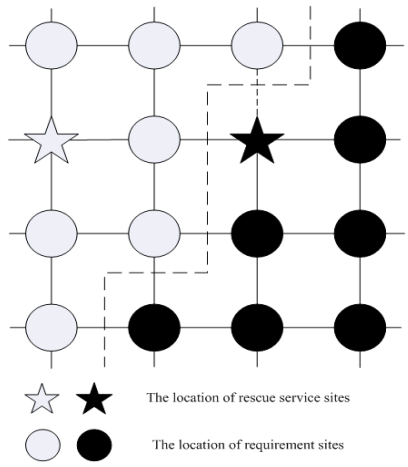

Figure.2 Schematic diagram of constrain method's result.

By calculating, we can see the rescue service sites are established at Node 5 and Node 7. Nodes 1, 3, 8, 10, 11, 12 and 15 can be covered by one time covering and Nodes 2, 5, 6, 7 can be covered by backup covering. The max rescue time is 10 minutes, and the requirement quantity of one time covering is 72, and the requirement quantity of backup covering is 18. The total weighted rescue time of this system is 471 minute. The rescue sites and their service objects are showed in Fig 2. The comparison of multi-objective location and single-objective location are made in Table 1.

It can be inferred from Table 1 that the result of p-centers and p-medians are the same, both of them chose Node 5 and 7 to establish rescue service sites. The total

weighted rescue time and the max rescue time of the system can be minimized simultaneously. In this case, however, the requirement quantity of backup covering is minimal. The maximum covering location realizes the goal that maximize the requirement of one time covering, but the total weighted rescue time and the max rescue time of the system are somewhat extended. The backup covering model makes the requirement quantity of backup covering maximized, but the total weighted rescue time and the max rescue time of the system, as well as the requirement quantity of one time covering are gravely extended. However, the multi-objective model of location is not better than any single-objective model in the performance, but by taking four objectives into consideration, decision-makers can make a reasonable trade-off among them.

Tab.1 The comparison results of multi-objective and single-objective model.

model	*location*	*V1*	*V2*	*V3*	**V4**
multi-object	5，7	10	72	18	471
p-medias	5，12	9	74	5	429
p-centers	5，12	9	74	5	429
maximal covering	6，12	10	78	10	441
backup covering	11，15	13	50	46	590

4 CONCLUSION

Rescue service sites location on roads is a multi-objective optimization problem. In this process of decision-making, both the fairness of location and the efficiency of sites should be considered, and sometimes, the backup covering of sites should also be taken into account. A multi-objective decision model proposed in the paper integrates the classic locating model, such as p-medians, p-centers, maximum covering and backup covering of traffic rescue site location on road. The objective weighted method and constrained method of parametric programming are adopted to solve the model, the solutions of the four classical location schemes are proposed, and an example of calculating the practical value of this multi-objective location model is shown. The multi-objective decision model is a determinate model that is unable to identify the number and the location of rescue vehicles under a crowded situation. Further study using random model and intelligent algorithms is needed to solve these problems.

ABSTRACT

Human, vehicle and road are three essential factors in transport system, the coordination of system may be shown by the road-human, human- vehicle and vehicle-road. The traffic accident has the relations with the coordination of transport system under the condition of normal driving. The speed is the important index which may appropriately show vehicles' operation characteristics, and provide the relationship between human-road and vehicle-road. Each vehicle has an accelerating and decelerating moving speed in the two-dimension, and the speed has the relationship with road geometric, traffic and accident. Based on analyzing the speed and vehicles' operation characteristics, it is developed to use two-dimensional speed difference to show the rule between moving and safety, and then develop the road safety evaluation model and criterion for the horizontal alignment by using theory computing and actual accident investigation method.

INTRODUCTION

There are three important relationships in transportation system: road-human, human-vehicle and vehicle-road. The operating speed is a variable of system operation, which has the relationship with road geometric, transportation environment, driver expectation and vehicle conditions. So it is possible to evaluate the coordination of horizontal and vertical alignments based on vehicles' operating speed characteristic.

At present, the operating speed difference is commonly used to assess the coordination of horizontal and vertical alignments (TRB 1998, NCHRP 2003,FHWA 1999). The advantage of this method is simple and easy to use. The disadvantage is that it neglects the effect that the speed difference per unit time has on the traffic, also neglects the effect that the transition curve has on reducing the vehicles' speed

difference of road section. In addition, it can't show that the curve length has the influence on traffic safety. Therefore, it should be improved.

SAFETY ANALYSIS OF TRANSPORTATION OPERATION SYSTEM

It is important to understand the characteristic indexes of the transportation system in order to assess if the road transportation operation system is coordinated. The transportation operation system has three kinds of characteristic indexes. The first one includes the horizontal and vertical alignments characteristic indexes (slope spot, tangent straight slow spot, transition curve and curve included), the road surface condition changing characteristic indexes(super elevation, roadside width and friction coefficient included), and the apparent distance changing characteristic (distance road section providing, apparent distance changing and so on included). The second one includes some human of actual sensation, such as sigh distance spot, sensation changing spot, human's operation frequency. The third one includes vehicles speed changing path characteristic, vehicles acceleration path characteristic, and vehicles wheel path characteristic.

The practical experience shows that the horizontal and vertical alignments have obvious relations with the operating speed, which may respond the relations on the horizontal and vertical alignments inducing the driver; the driving sensation and operation time may be shown by the driver's most need time; the driving operation difficulty degree and the relations on vehicles conform to the route may be possible to be responded by the vehicles acceleration changing indexes. So it can appraise the system the safety based on operation speed and curve acceleration.

The important indexes and correlational dependence of road, human and vehicle are summarized in Table1.

Table1. Road-Human-Vehicle

Road	Human	Vehicle	Relationships	Indexes
Alignments	Sensation	Speed change	Alignment inducing the drive	Operation speed
Road surfaces	Respond time	Acceleration	Driving operation difficulty degree	Vehicles acceleration changing
Sight distance	Operation difficulty	Wheel	Vehicles conform to the route situation	Vehicles acceleration changing

SAFETY ASSESSING TECHNOLOGY OF CURVE ROAD SECTION BASED ON TWO-DIMENSIONAL SPEED DIFFERENCE

Operating speed model. Speed is one of most obvious index. The operating speed and the curve radius have a very close relationship. Many models have been developed to forecast the operating speed in domestic and other foreign countries (Karen S 2001, NCHRP 2003).

The roadway alignment affects driving speeds. There are some fixed operating speed characteristics at center and entrance of curve. Before analyzing horizontal and

vertical alignment coordination, we need carry on forecasting the operating speeds in the curve center and curve entrance. Considered the curve influence and unifying the former research results, the curve entrance operation speed and the curve center operation speed are shown in Table 2.

Table 2. Operation speeds in the Curve Center and Curve Entrance

Tangent length L (m), from $R_1 \rightarrow R_2$	Speed of vehicle entering curve R_2 （km/h）	Speed in curve R_1 （km/h）
L <100	$V_{85}=108.23-\frac{4508.06}{R_2}$	$V_{85}=108.23-\frac{4508.06}{R_1}$
100≤L≤ 500	$V_{85}=108.23-\frac{4508.06}{R_2}+L-100+(L-100)*0.01$	$V_{85}=108.23-\frac{4508.06}{R_1}$
L >500	108.23	$V_{85}=108.23-\frac{4508.06}{R_1}$

Analysis of two-dimensional speed difference. The speed changing along the curve was shown in Figure 1. While a vehicle goes through the alignment, the driver firstly notices the coming curve, then prepares for deceleration, then starts to decelerate at certain distance spot from the curve. The certain distance includes the part tangent and part curve, when the vehicles go to the curve center point (B), and finish the curve operation simultaneously the moving speed becomes 0 km/h at the curve vertical direction.

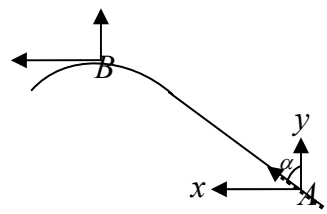

Figure 1. The Speed Changing along the Curve

From recent investigation statistics, it's discovered that vehicles usually decelerate at the 20 m point from the beginning of the curve, the curve length is shown by H(m), the circular curve length is L(m), the circular curve radius is R(m), the speed of starting to decelerate is V_0(m/s), the speed of arriving the mid-point of curve is V_1(m/s), the moving speed is from V_0 to V_1, the speed becomes 0 in the y direction, the corner is a, a is composed by the curve angle a_1 and the transition curve angle a_2, then:

$$\alpha = \alpha_1 + \alpha_2 \tag{1}$$

a_1 is just the curvature of curve:

$$\alpha_1 = \frac{L}{2R} \tag{2}$$

a_2 may be obtained from following:

$$\alpha_2 = \frac{A^2}{2\beta^2} \tag{3}$$

When the vehicle arrives the curve center point, the length is S (m) from A to B, then,

$$S = \frac{L}{2} + H + 20 \tag{4}$$

Supposed the vehicle do an uniform retarded motion from the deceleration spot to the circular curve beginning spot, and then do the uniform motion in the curve section, so the total time is M (s).

$$M = \frac{L}{2V_1} + 2\frac{H+20}{V_0 + V_1} \tag{5}$$

The changing rule that the deceleration difference changes with the time and the radian in the y orientation is:

$$\Delta V_S = \frac{\left|V_1 \sin(\alpha)\right|}{M \bullet \alpha} \tag{6}$$

The changing rule that the vehicle deceleration difference changes with the time and the radian in the circular curve in the y orientation is:

$$\Delta V_d = \frac{\left|2V_1^2 \sin(\alpha_1)\right|}{L\alpha_1} \tag{7}$$

The changing rule with the time and the radian changing rule in $L/2$ curve is the normal state changing rule for the curve, may be seen as a safety state rule. So, it takes the difference between the changing rule with the time and the radian in S and in $L/2$ to show the coordination of horizontal and vertical alignments, the influence and difficulty which the frontal alignments have the influence on the back alignments .The operation difficulty, the safety and the coordination may be expressed with following:

$$\Delta V_{Sd} = \frac{\left|V_0 \sin(\alpha)\right|}{M} - \frac{\left|2V_1^2 \sin(\alpha_1)\right|}{L} \tag{8}$$

Appraisal process and standard. According to above analysis, the connection standards between the curve and the curve, the straight and the curve are realized by:

$0.1 \leq \triangle V_b$. The connection standard between the curve and the curve is not good, it is easy to cause crash occur. The investigation statistics results show that these are the typical l short radius curve, and 152 in 213 accidents.

$0 < \triangle V_b \leq 0.1$. The connection standard between the curve and the curve is fare, it needs to take the traffic engineering measure to reduce the curve enter speed. The investigation statistics results show that these are 43 in 213 accidents.

$\triangle V \leq 0$. The connection standard between the curve and the curve is good, it is fit for driving. The investigation statistics results show that these are 17 in 213 accidents.

CASE STUDY

The above assessment method and the model are applied in a domestic two-level highway, the appraisal results are shown in Table 3.

Table 3. Application Results

Corner		R					Coordination
	6.41.26	1381	950.617	950.687	950.778	950.848	not good
40.45.41		150	951.048	951.098	951.155	951.205	good
	61.39.21	110	951.286	951.336	951.404	951.454	good
8.49.22		630	951.535	951.605	951.632	951.702	not good
	46.5.45	130	951.967	952.037	952.072	952.142	not good
68.7.50		190	953.697	953.122	953.277	953.347	not good
16.29.33		70	953.999	953.797	953.899	953.999	not good
	19.45.44	100	955.341	954.119	954.240	954.360	not good
	62.1.17	120	956.038	954.747	954.888	955.018	not good
17.10.21		130	956.430	955.411	955.485	955.555	not good

From the appraisal results, this method is helpful to design alignments improving the road safety.

CONCLUSIONS

1) A new assessment method and standard was developed to assess the curve coordination. The method overcomes the limitation by the speed difference method, and also makes the appraisal process to conform to the traffic operation.

2) The operating speed model used in the paper is a propositional model. It considers the driving behavior characteristic difference in various places. The operating speed should have the difference, which should fellow the local actual situation.

3) This method may further promote to be applied in highway design and safety evaluation.

Abstract: Risk evaluation models are developed to improve decision making regarding the safety of highway transportation of "toxic gas" hazardous materials. Based on ANN (Artificial Neural Network) theory and the Back Propogation (BP) method, a new risk evaluation model has been established utilizing the assessment indices of the inherent hazard of transported gas, the traffic accident rate of road sections and the population density of roadside areas. 12 road sections whose risk levels have been determined by a fuzzy synthetic evaluation model are used to train the network to an evaluation error less than 10^{-5}. Simulation results show that the proposed model in this paper improves on previous published models and has wide applicability.
Keywords: highway transportation; toxic gas; risk assessment; BP neural network

1 Introduction

Many types of hazardous materials are routinely and necessarily transported on roadway networks. One class of hazardous materials is the "Toxic Gas", which includes materials that are known to be poisonous or are assumed to be poisonous if exposed to human during transportation. Due to their importance in industrial uses, hazardous materials in the "Toxic Gas" category are frequently transported on highways. Analysis on more than 500 hazardous materials transportation accidents show that about 20% of them involves a gaseous hazardous material, and accidents involving the "toxic gas" category often lead to heavy casualty and serious pollution events because of their chemical properties. In order to avoid this kind of accidents and decrease the loss, researchers have studied "toxic gas" hazardous materials transportation and have established practical models for risk assessment, such as the fuzzy synthetic evaluation model, the time-varying risk evaluation model, and risk rank indices method(LIU Haoxue,2006;WEI Hang,2006; REN Changxing,2006). As many factors affect transportation safety and the transportation environment is complex, the methods above cannot always work efficiently because of limitations in the researcher's data availability. After analyzing the advantages and disadvantages

of those methods and considering characteristics and risk factors of road transportation for toxic gas, this paper introduces a new risk assessment model based on a BP neural network to enhance the level of evaluation.

2. Characters of BP Neural Network and Assessment Indexes Choosing

2.1 Characters of BP Neural Network

Assessment based on BP Neural Network (Error Back Propagation Network) has been shown to reduce the difficulties of dynamic optimization for multi-objective and variable-weight problems, and also removes the subjective factors during weight determination. Characteristics of knowledge memory and self-adaptation for a BP Neural Network make the combination of experience and new information possible, making it an effective method for risk assessment. A BP Neural Network is composed of an input layer, a hidden layer and an output layer, and its learning process is composed of signals' positive spread and error's converse spread (ZHU Daqi, 2006; GE Zhexue, 2007). Figure1 shows the structure of a BP neural network

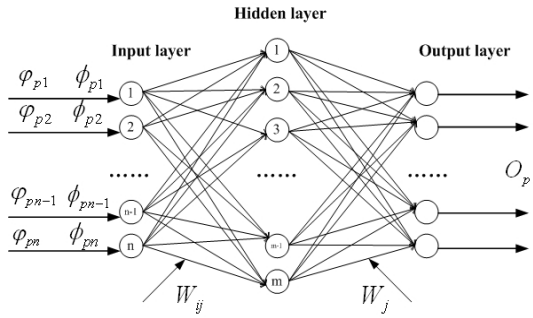

Figure 1. Structure of BP neural network (GE Zhexue, 2007)

Where, $\varphi_{p1},\varphi_{p2},...\varphi_{pn}$ are input values; $\phi_{p1},\phi_{p2},...\phi_{pn}$ are non-dimensional transformed values of training samples; W_{ij} is the connection weight from input node i to hidden node j;W_j is the connection weight from hidden node j to the output layer.

2.2 Choosing Indices

In consideration of the possibility and damage of accidents during transportation, the inherent hazard of the transported gas, the traffic accident rate, and the population density along the routes are defined as assessment indices. Assessment values of indexes are non-dimensional transformed by formula (1) as input vectors of the network. Where, r_i is the non-dimensional value of NO.i index , u_i is assessment value of NO.j index, u_{max} and u_{min} respectively are the highest and the lowest value of NO.i index in its range.

$$r_i = \begin{cases} 1, & u_i \le u_{\min} \\ \dfrac{u_{\max} - u_i}{u_{\max} - u_{\min}}, & u_{\min} < u_i \le u_{\max} \\ 0, & u_i > u_{\max} \end{cases} \quad (1)$$

(1). Traffic Accident Rate of Road Sections

Studies indicate that traffic accidents, vehicle and tank failure, bad condition of the road and weather are main causes for transportation accidents of hazardous materials. The major cause is traffic accidents, accounting for 80% of the cases. Many developed countries have conducted statistical research of hazardous materials transportation accidents. CCPS researched accidents in the USA from the 1980s to early 1990s and obtained authoritative data shown in table.1 which was cited widely. In the absence of pertinent data from China, and considering the present road traffic and infrastructure development in China is similar to the situation of the USA in the 1980s, the traffic accident rate for transport trucks on different road classes in table 1 was used for this model. The evaluated road section's traffic accident rate is determined as the assessment value of this index based on the road section's class and type.

Table1.Traffic accident rate on different highway classes (CCPS, 1995)

Highway type		Traffic accident rate of commercial vehicle(10^6km)
Area	Lane	
Rural	Two-lane	1.36
Rural	Multi-lane(undivided)	2.79
Rural	Multi-lane(divided)	1.34
Rural	Expressway	0.4
Urban	Two-lane	5.38
Urban	Multi-lane(undivided)	8.65
Urban	Multi-lane(divided)	7.75
Urban	Single lane	6.03
Urban	Expressway	1.35

(2). Inherent Hazard

Physical and chemical properties of the subject "toxic gas" material will affect the accumulating time of a toxic cloud or plume, the abreaction, and the severity of consequences, which means that magnitude of risk differs for gases of different properties. A common measure of gas toxicity available for most substances is the Lethal Concentration, or LC50. LC50, gas density and gas odor, are determined as relevant indices for inherent hazard evaluation. According to GB5044-85, the gases are assessed by the above parameters and given assessment values (see table2 and

table 3). The full mark is 50 and the 3 categories are weighed with 50%, 30% and 20% respectively. The inherent hazard evaluation value is the summation of the 3 categories.

Table2.Value of gas toxicity

LC_{50}	Classification			
	Serious toxic	High toxic	Mid toxic	Low toxic
$LC_{50}(mg/m^3)$	<20	20-200	200-2000	>20000
Assessment value	25	20	15	10

(3). Population Density of Roadside

People, livestock, agriculture, waters and nature reserves will be all threatened when leakage of toxic gas occurs (LIU Haoxue, 2006). Life is the first thing that should be considered in risk evaluation of accidents and human casualties directly affect any measurement of accident severity. Therefore, population density of the roadside is chosen to reflect the potential consequences of a given incident.

The model of the roadside should reflect the number of people exposed to a potential gas plume per unit area. The evaluation value is the product of population density of administrative regions where accident occurred and the outdoor exposure rate of those people .In this paper, exposure rate of people is determined as 20%, based on average outdoor working hours.

Table 3. Value of gas density and odor

Toxic gas density /air density	Assessment value	Smell type	Assessment value
>1.3	15	Pungent smelly	3
1.0-1.3	10	Mild	7
0.5-1.0	5	Smell less	10
<0.5	2		

3 Design and Training of the BP Neural Network

3.1 Design of the BP Neural Network

3 assessment indices are determined and vectors of (1,0,0,0),(0,1,0,0), (0,0,1,0) and (0,0,0,1)are used to denote the risk degrees of low, mid, high and highest. A network whose design parameters are shown in table 4 is established, and the amount of hidden units is determined by trials for finding the parameter achieving the smallest error.

Table 4. Designing parameter of BP neural network

Input units	Hidden units	output units	Training function	Learning function	Performance function	Learning error	Learning speed
3	7	4	traingdx	logsig	mse	10^{-5}	0.1

3.2 Training of BP Neural Network

(1). Determination of training samples

12 road sections whose risk levels have been previously identified by fuzzy synthetic evaluation model are used as training samples using non-dimensional transformed assessment values of the indices for each road section as inputs. Input values and expected output values are showed in table 5.

Table 5.Training samples of network

Number	Non-dimensional assessment value				Assessment result	
	Inherent hazard		Traffic accident rate	Population density		
1	CH_3Cl	0.4167	0.8693	0.9533	low	(1,0,0,0)
2	NH_3	1.0000	0.8707	1.0000	low	(1,0,0,0)
3	CO	0.7803	0.8707	0.8533	low	(1,0,0,0)
4	Cl_2	0.3750	0.8693	0.7100	mid	(0,1,0,0)
5	CO	0.7803	0.8693	0.8933	mid	(0,1,0,0)
6	H_2S	0.3750	1.0000	0.8567	mid	(0,1,0,0)
7	F_2	0.2083	0.3224	0.7167	high	(0,0,1,0)
8	Cl_2	0.3750	0.8693	0.8600	high	(0,0,1,0)
9	H_2S	0.4167	0.8693	0.8000	high	(0,0,1,0)
10	Cl_2	0.3750	0.8693	0.3867	highest	(0,0,0,1)
11	NO	0.0833	0.8693	0.0000	highest	(0,0,0,1)
12	N_2O_4	0.0000	0.0000	0.0167	highest	(0,0,0,1)

(2). Training of Network

To achieve better convergence and lower error, the paper takes 0.1 as learning speed, 100,000 as the largest learning time and 0.00001 as learning error. Matlab7.0 is used for training simulation of the network and the required error is achieved after 22502 iterations .Figure.2 is the error curve of training, which indicates that learning error is as low as 9.99885×10^{-6}.

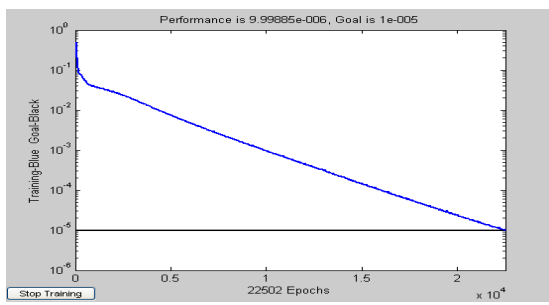

Figure2.error curve of network training

4 Application Case

To validate applicability of the model, 2 representative road sections are

selected for simulation.

NO. 1：An Kang section of 316 national highway is a 3-class two-lane highway in a rural area, the population density of roadside is 20 and the transported gas is SO_2. SO_2 is low-toxicity, pungently odorous, colorless and can be easily detected after leakage. This road section has low population density and serious human casualties can be avoided if protective measures will be taken in time. Considering these factors and accident records, it can be judged that SO_2 transportation on this road section is relatively low in risk but is not the best choice because of low road class.

NO.2: Gao Ling section of BaoTou-MaoMing expressway is a two-lane expressway in a rural area, population density of roadside is 315 and the transported gas is NO. NO will be oxidated to NO_2 in air, NO_2 is high-toxicity, pungent smelly brown gas. Although this road section is in good condition, high traffic volume and high population density make large scale evacuation difficult, with public panic and serious human casualties possible after leakage. So it can be judged that NO transportation on this road section is very high in risk.

Non-dimensional index values of NO.1and NO.2 road section can be calculated and are indicated in table6.

Table6.Evaluating value of road sections

Evaluating index	Index value		Non-dimensional index value	
	NO.1	NO.2	NO.1	NO.2
Inherent hazard	SO_2 33	NO 45	0.5833	0.0833
Traffic accident rate(/10^6km)	1.36	1.35	0.8893	0.8707
Population density(/km^2)	20	315	1.0000	0.0167

Inputting the non-dimensional value (0.5833 , 0.8893 , 1.0000) and (0.0833 , 0.8707 , 0.0167) into the BP Neural network model results in the outputs (0.0000,1.0000, 0.0000,0.0000) and (0.0012,0.0000,0.0013,0.9986)after simulation. This shows that the risk of SO_2 transportation on An Kang section of 316 national highway is medium and the NO transportation on Gao Ling section of BaoTou-MaoMing expressway is highest. The evaluating result output from the model matches the factual risk level of the two road sections.

5 Conclusions

1). This paper presents a risk evaluation model of highway transportation for “toxic gas” hazardous materials based on a BP neural network whose evaluating indices are the inherent hazard of gas, the traffic accident rate of the road section and the population density of the roadside. It improves on previous models that involved complex structures, fussy calculations and influence of subjective factors.

2). A BP network with 3 input units, 7 hidden units and 4 output units is established and its evaluation error reaches 10^{-5} after training. The trained network is used to simulate SO_2 transportation on An Kang section of 316 national highway and NO transportation on Gao Ling section in BaoTou-MaoMing expressway. Simulation results show that the model is short in calculating time, high in accuracy, and broadly applicable.

ABSTRACT

Relative merits of different residuals used in the construction of objective function and weight coefficients in single-objective function for structural model updating are investigated in this paper based on the improved genetic algorithm (IGA). Presently there are three residuals which are used mostly in finite element (FE) model updating: frequency residual, mode shape residual, and modal flexibility residual. Relative merits of the three residuals are analyzed through the simulation of a simply supported beam. Then, model updating is studied comparatively based on IGA. Frequency is the main characteristic parameter of bridge structure, which has high identification precision and should be used with priority. When there are several updating parameters, information should be complemented. If identification error of the mode shape is relatively less, the complement of the mode shape is feasible. In the end, through the analysis of weight coefficients for different residuals in single-objective function, it can be seen that the model updating performance is better when the frequency residual has a larger weight coefficient.

INTRODUCTION

In health monitoring of bridge structure, damage identification based on FE model updating is often used. Simplifying assumptions are widely adopted in FE modeling of a structure and the FE model is constructed based on highly idealized engineering drawings that may not accurately represent all of the physical aspects of an actual structure. When vibration testing is performed to validate the analytical model, inevitably the results, commonly natural frequencies, and mode shapes do not coincide with the expected results from the analytical model. These discrepancies originate from the uncertainties in simplifying assumptions of structural geometry and materials as well as inaccurate boundary conditions. The inaccurate factors mainly come from three aspects: model structure errors, model parameter errors, and model order errors (Mottershead and Friswell 1993). The problem of how to modify the analytical model based on dynamic measurements is the model updating in structural dynamics. That is to say, the purpose of FE model updating is to modify the mass, stiffness, and damping parameters of the analytical model in order to obtain better agreement between analytical and experimental results.

The Iterative method is often used in model updating. Its usual principle is to

quantize the discrepancies between analytical and experimental results through the construction of objective function and minimize objective function through the adjustment of updating parameters. Thus model updating is changed into an optimization problem. Consequently, whether model updating can be carried out successfully mainly depends on the accuracy of the model, quality of vibration testing, definition of the optimization problem, and calculation performance of the optimization algorithm.

In the paper, the relative merits of different residuals used in the construction of objective function and weight coefficients in single-objective function for model updating are investigated. The research results are validated though the simulation of a simply supported beam, it can be seen that model updating performance is better when frequency residual has a larger weight coefficient.

CONSTRUCTION TECHNIQUE OF OBJECTIVE FUNCTION

Model updating is changed into optimization problem as follows

$$\begin{aligned} &Min \quad f = f(x) \qquad R(x) = f_e(x) - f_a(x) \\ &S.t \quad \underline{x_i} \le x_i \le \overline{x_i} \qquad (i = 1, 2, ..., N) \end{aligned} \tag{1}$$

where f is the function of updating parameters which can be the stiffness matrix, mass matrix, mode shape, flexibility, or mode shape correlation, etc... f_e and f_a are the experimental and analytical natural frequencies, respectively. x_i and $R(x)$ represent the updating parameter and residual function, respectively. $\underline{x_i}$ and $\overline{x_i}$ are the lower limit and upper limit of updating parameters, respectively.

Taylor expansion of f at x_0 is as follows

$$f = f(x_0) + \sum_{i=1}^{N} \frac{\partial f}{\partial x_i} \cdot \Delta x_i \tag{2}$$

where N and Δx_i are the number and increment of updating parameters, respectively.

Equation (1) can be rewritten in matrix style

$$G \cdot \Delta x = R \tag{3}$$

where, $\Delta x = [\Delta x_1, \Delta x_2, \ldots, \Delta x_N]^T$, G is the Jacobian matrix, which consists of the partial derivative of modal parameters to updating parameter, and is often named as the sensitivity matrix.

In structural dynamics the eigen equation is as follows

$$(K - \lambda_i M)\phi_i = 0 \tag{4}$$

where K and M are the stiffness matrix and mass matrix, respectively. λ_i and ϕ_i are the eigen value and eigen vector, respectively.

Frequency residual. The most important residual for FE model updating in structural dynamics is the discrepancies between the analytical and experimental undamped eigen frequencies. The eigen frequency residual R_f is formulated as

$$R_f = \sum_{i=1}^{N} \left| \frac{\lambda_{ai} - \lambda_{ei}}{\lambda_{ei}} \right| \quad (i = 1, 2, ..., N), \quad 0 \le \left| \frac{\lambda_{ai} - \lambda_{ei}}{\lambda_{ei}} \right| \le UL \tag{5}$$

where, $\lambda_i = (2 \cdot \pi \cdot f_i)^2$, f_i is the eigen frequency to i-th mode. λ_{ai} and λ_{ei} are the analytical and corresponding experimental eigen values respectively, and UL is upper limit of error between the two eigen values. N refers to the number of identified eigen frequencies which are used in updating process..

Eigen frequencies can be measured and identified during vibration testing, which provide global information of the structure. They are indispensable quantities used in the updating process and have a favorable effect on the condition of the optimization problem. But the high-order natural frequencies are not measured as accurately as the low-order ones. An objective function with only a limited set of eigen frequencies is too poor of a basis for the definition of structural dynamic behavior. So other residuals are also necessary to form the full objective function for FE model updating.

Mode shape residual. Mode shapes contain spatial information about the dynamic behavior of structure. Therefore it is possible to be used as the residual with discrepancies in mode shape in the construction of objective function. Since structures are mostly measured under operational conditions, the in-operation modal testing makes use of the freely available ambient excitation caused by natural excitation sources on or near the test structure. As a result, the identified experimental mode shapes cannot be absolutely scaled, so the scaling and normalization of mode shapes obtained from vibration testing is an important issue, which is not standard in conventional model updating. In model updating, the modal assurance criterion (MAC) is often used in automatic pairing and comparing analytical and experimental mode shapes (Allemang and Brown 1982). The value of MAC is bound between 0 and 1, a value of 1 means a perfect correlation and a value of 0 indicates that the two modes do not show any correlation.

MAC is defined as

$$MAC_i = \frac{(\phi_{ai}^T \cdot \phi_{ei})^2}{(\phi_{ai}^T \cdot \phi_{ai}) \cdot (\phi_{ei}^T \cdot \phi_{ei})} \qquad (i = 1, 2, ..., N) \tag{6}$$

where ϕ_{ai} is the analytical eigen mode which has been paired with the j-th experimental mode ϕ_{ei}.

Mode shape residual is formulated as (Moller and Friberg 1998)

$$R_s = \sum_{i=1}^{N} \frac{(1 - \sqrt{MAC_i})^2}{MAC_i} \qquad (i = 1, 2, ..., N) \tag{7}$$

Modal flexibility residual. The flexibility matrix is defined as the inverse of the stiffness matrix as shown in Equation (8)

$$G = K^{-1} \tag{8}$$

where G and K are the flexibility matrix and stiffness matrix, respectively.

The inverse vibration representation of the flexibility matrix is as follows

$$G = \Phi \Lambda^{-1} \Phi^T = \sum_{i=1}^{n} \frac{1}{\omega_i^2} \phi_i \phi_i^T \tag{9}$$

where, $\Phi = [\phi_1, \phi_2, \cdots, \phi_n]$ is the mode shape matrix, ϕ_i is the mode shape to i-th mode, and $\Lambda = diag(f_i^2)$ is the modal matrix.

A method is developed to accurately estimate structural flexibility considering residual flexibility from forced vibration testing (Doebling 1995), in which the input of the system is known. For the case of known input, there is no problem in calculating the residual flexibility. As to ambient vibration testing, the input of the system is not measured. For the case of unknown input with measurements carried out only in certain locations, the situation is much more different and the calculation of residual flexibility is not so straightforward.

In general, the measured modes are typically those that are lower in frequency. The lower ones contribute the most to the flexibility. Therefore, a good estimate of the flexibility matrix may be obtained from only a few low-order frequencies and mode shapes at measured DOFs. Hence, the flexibility matrix becomes

$$G_{mm} = \Phi_{n_m} \Lambda_n^{-1} \Phi_{n_m}^T \tag{10}$$

where G_{mm} is the measured flexibility matrix, Φ_{n_m} is the measured mode shapes of the structure at measured DOFs, and Λ_n corresponds to the eigen values of measured modes.

In general, the modal flexibility error residual may be given by the expression

$$R_{flex} = \sqrt{\left\| G_{\exp} - G_{ana} \right\|_2} \tag{11}$$

where $G_{\exp}$ and G_{ana} are measured and analytical modal flexibility matrixs respectively at the measured DOFs (Yan *et al* 2004; Zhao and DeWolf 2002) .

IMPROVED GENETIC ALGORITHM (IGA)

Owing to the genetic algorithm (GA) with no restriction on continuous and differential characteristics of the optimization problem and with advantages in robust, global optimization, and capability of parallel processing, GA has become an important method to solve optimization problems. But simple genetic algorithm (SGA), which adopts uniform cross and mutation, tends to appear as the premature phenomenon in the evolutionary process, which could lead the GA to be trapped in the local solution and be unable to find the global optimum solution.

In this paper an improved genetic algorithm (IGA) is presented. Firstly, proportional selection combined with elitist strategy is adopted in selection (Fei *et al* 2006). Secondly, heuristic crossover and non-uniform mutation are taken in crossover and mutation (Tu and Lu, 2008). Finally, adaptive crossover and mutation probability are adopted to ensure the convergence of GA (Srinivas and Patnaik 1996), to make sure genetic iteration evolves to the global optimum solution and guarantee the diversity of population at the same time. The method overcomes the defects of a slow convergence rate and easily becoming stuck at a local optimum when SGA is applied in the health monitoring of bridge structure. It accelerates convergence greatly and ensures the finding of a global optimum solution.

SIMULATED SIMPLY SUPPORTED BEAM

The simply supported beam bridge is adopted in many bridges, so a simulated simply supported beam is studied in this paper. This aims at demonstrating a comparative research on the influence of different possible residuals on objective function for FE model updating. The simulated simply supported beam with a length of 6.4 m is presented (see Figure 1). The mass density and elastic modulus are 2500 Kg/m^3 and 3.2×10^{10} Pa respectively. Similarly, the area and moment of inertia of the

cross section are 0.05 m^2 and 1.66×10^{-4} m^4 respectively.

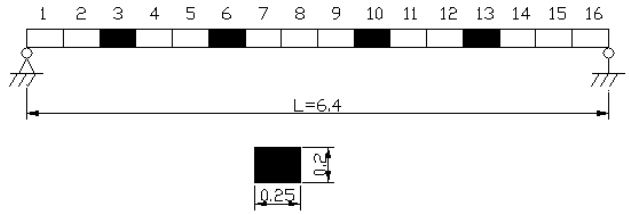

Figure 1. A simulated simply supported beam (m).

Comparative analysis of different residuals. In the paper, IGA is adopted to update the FE model. Evolution is terminated when the generation reaches 1000 or discrepancy between the analytical solution and optimum solution is less than 1e-8. Analytical modal analysis is first carried out to obtain analytical frequencies and mode shapes. To obtain the simulated experimental modal parameters, four damage locations are assumed in the beam (see Figure 1) in which the elastic modulus and moment of inertia of beam elements 3, 6, 10 and 13 are reduced by 30%, 40%, 20% and 30% respectively. The modal analysis is carried out again to obtain the assumed experimental modal parameters. The initial values of frequencies and corresponding errors are shown in Table 1. The maximum error that appeared in frequency is 7.41% and the minimum error is 3.41%.

Model updating of the undamaged beam is to correlate the modal parameters with the damaged beam and to identify the damage severity and location. Elastic modulus of individual elements is chosen as an updating parameter (UP). The number of UP is selected with respect to the numbers of modes considered for which two cases are considered:

Case 1. UP=4, where the elastic modulus of damaged elements 3, 6, 10 and 13 are selected as UP and number of UP is less than the mode number considered. It is the case that structural damaged locations are exactly known.

Case 2. UP=16, where the elastic modulus of all 16 elements are selected as UP and number of UP is equal to the mode number considered. It is the case that structural damaged locations are not known.

Three objective functions consisting of the frequency residual only, mode shape residual only, or modal flexibility residual only are studied independently, of which there are two cases depending upon number of UP.

From the results it can be seen that (see Table 1, Table 2 and Table 3)

1. Based on the frequency residual, IGA can accurately identify the severity of damage when UP=4, but IGA cannot accurately identify the severity and location of damage when UP=16.

2. Based on the mode shape residual, IGA can accurately identify the severity of damage when UP=4. IGA can accurately identify the location of damage when UP=16, but cannot accurately identify the severity of damage.

3. Based on the modal flexibility residual, IGA can accurately identify the severity of damage when UP=4. IGA can approximately identify the location of damage when UP=16, but cannot accurately identify the severity of damage.

Table 1. Results based on frequency residual before and after updating.

Mode	Initial FE model /Hz	Damaged beam /Hz	Error %	Updated value /Hz			
				UP =4	Error %	UP =16	Error %

Overall, the updating performance is not good, so single-objective function based on different residuals and their weight coefficients are studied subsequently.

Weight coefficient for different residuals. There are few research reports on weight coefficient for different residuals in dynamic FE model updating. The

model updating problem is often formulated as an optimization problem in which the objective functions are built up into a single-objective function using weight coefficients. Standard optimization techniques are then used to find the optimum value of the parameters that minimizes the objective function. The results of optimization are influenced by weight coefficients, which are assumed. The choice of weight coefficients depends on model adequacy and uncertainty in the available measured data, which is not known in advance. Hence, the selection of weight coefficients is a very important task since the relative importance among the data is not so obvious, but very specific for each problem.

Different residuals are combined into a singleobjective function by using weight coefficients for each residual. The residuals should be weighted separately according to their importance and accuracy. At the same time engineering insight is needed to provide the correct weight coefficients. There are no strict and quick rules for the selection of weight coefficients since the relative importance in the criterion is not obvious and specific for each optimization problem. Then a method is necessary to solve the problem repeatedly by varying the values of the weight coefficients until a satisfactory solution is obtained (Grandhi and Bharatramv 1993). In this paper, the objective function is as follows

$$R = a \cdot R_f + b \cdot R_s + c \cdot R_{flex} \tag{12}$$

where R_f, R_s and R_{flex} are defined in equation (5), (7) and (11) and a, b and c are weight coefficients for R_f, R_s and R_{flex} respectively.

When FE model updating is carried out, three cases are considered:

Case 1. a=b=c.

Case 2. a=0.1, b=1, c=10.

Case 3. a=10, b=1, c=0.1.

From the results it can be seen that (see Table 4):

1. Objective function value is least in case 3, the maximum is -2.2e-05 and the minimum is -6.42e-06. It is largest in case 1, the maximum is -2.51e-03 and the minimum is -3.72e-03.

2. Frequency error is least in case 3, the maximum is 0.09 and the minimum is 0. It is largest in case 1, the maximum is 2.14 and the minimum is 0.

3. As for MAC error, there is no obvious difference in the three cases.

4. Stiffness reduction error is least in case 3, the maximum is 1.4 and the minimum is 0. It is largest in case 1, the maximum is 29.8 and the minimum is 0.

Table 4. Model updating based on different weighting coefficients.

Weighting coefficient	Objective function value		Frequency error %		*MAC* error %		Stiffness reduction error %	
	Max	Min	Max	Min	Max	Min	Max	Min
a=1,b=1,c=1	-2.73e-04	-8.89e-05	0.57	0	2.17	0.02	9.6	0
a=0.1,b=1,c=10	-2.51e-03	-3.72e-03	2.14	0	1.64	0.01	29.8	0
a=10,b=1,c=0.1	-2.2e-05	-6.42e-06	0.09	0	2.18	0.02	1.4	0

Through the comparative analysis of weight coefficient for different residuals in single-objective function, it can be seen that if the updating method is fixed, when frequency residual is assigned a larger weight coefficient, mode shape residual a

lesser, and modal flexibility residual the least, updating performance is best.

CONCLUSIONS

The following conclusions are drawn:

1. Model updating is carried out using different residuals and the best combination is recognized with the help of simulated case study. It is demonstrated that the combined objective function which consists of three residuals, namely the frequency residual, mode shape residual, and modal flexibility residual, with different weigh coefficient assigned to each of them, is recognized as the best one.

2. Through comparative analysis of weight coefficient for different residuals in single-objective function, it can be seen that if the updating method is fixed, when frequency residual is assigned a larger weight coefficient, mode shape residual a lesser, and modal flexibility residual the least, updating performance is best.

3. Successful updating of the simulated simply supported beam demonstrates that the cost of calculation is not too high. The method in this paper can be used in many applications of bridge structures like damage identification, health monitoring, and structural assessment and is of great theoretical and engineering value.

ABSTRACT

An important consideration in underground expressway plan and design is how to locate passageways providing services. This paper develops a new model to address issues involving demand decay, share rate, and efficiency of passageway simultaneously. The model is built with the objective of maximizing efficiency; and an iterative algorithm using the network equilibrium model is developed to obtain the steady share rate and to determine passageway locations with the maximal efficiency. Finally, an example is presented to illustrate the flexibility and effectiveness of the model and algorithm. The results show that the algorithm can obtain the steady share rate, and get the model convergent. In addition, the passageway locations will be globally optimized.

INTRODUCTION

The academic research of underground expressway presently focuses on traffic capacity, traffic organization, management and control, and the estimation of the environmental influences on underground expressway (Thalheimer, 2004；Hirata et al.，2006). Few quantitative research work has been done on the network planning and passageways locating. This paper analyzes the factors that influence the passageway locations of the underground expressways and proposes a passageway location model. Incorporating the network equilibrium model and space network analysis, a new algorithm is developed with the objective of maximizing efficiency of passageway in the whole network.

ANALYSES ON FACTORS RELATING TO PASSAGEWAY LOCATIONS

In order to ensure the safety and efficiency, connecting the underground expressways with ground road in passageways is preferred at present stage. The passageway location model needs to be achieved by the transport facilities with a rational layout for the purpose of meeting the demand and guiding the spatio-temporal transfer of the demand finally. A demand curve (Hurst, 1972) reflected that the demand is decreasing with the increase of the distance between the demand point and supply location. Farhan and Murray (2006) advanced the location model for the first time, which simultaneously addressed the coverage range, partial regional service, and distance decay.

Comparing with the common location problem, the passageway location of underground expressway has two special aspects: intercommunity and

particularity. The intercommunity is related to decay of the demand caused by the distance; the particularity is the share rate of underground expressway， which is not entirely dependent on the capacity of the underground expressway or the serving capacity of passageway. Thus, the passageway location model of the underground expressway is affected by three major factors: the demand decay, share rate and efficiency of passageway. The objective of the model is to obtain the largest number of vehicles served in per unit time (i.e., achieving the maximal efficiency).

MODEL FORMULATION

For setting up the passageway location model, we have the following assumptions.

1) the road network comprised of the urban expressways and the main roads serve the vehicles within the moderate and long travel distance.

2) the passageway location is assumed to be set up in the intersection.

3) all vehicles on the road concentrate in the middle of the road at a moment; the middle point is the demand point o.

4) the most amount of demands on each road is the largest number of vehicles in the whole day; the demand is N_O.

5) each road in the district is considered to achieve the maximal requirement simultaneously. The extent of travel time and most demand which arisen from the vehicles' passing through from every demand point to the others are neglected here. This assumption is acceptable under the current congested circumstance of the urban network.

To model this problem, we define the notation as follows.

N_o total demand at point o in link a

N_{oj} demand served by passageway point *j* form N_o

A_j share rate of underground expressway in passageway point *j*

A_j^n share rate in passageway point *j* at the *n*th iteration

W_{oj} aggregate of paths of o-j pairs in the network

d_k^{oj} travel distance on the path *k* of *o-j* pairs

$\hat{d}_{oj}$ the shortest distance in all the paths of *o-j* pairs, where $\hat{\mathbf{d}} = (\ldots, \hat{d}_{oj}, \ldots)$

t_k^{oj} travel time (cost) on the path *k* of *o-j* pairs

$\hat{t}_{oj}$ the least travel time (cost) in all the paths of *o-j* pairs

where $\hat{\mathbf{t}} = (\ldots, \hat{t}_{oj}, \ldots)$

$t_a(\cdot)$ Travel time (cost) function on link *a*

x_a Flow of link *a*

$x_{ja'}^n$ Flow of underground expressway *a'* linked to passageway point *j* at the *n*th iteration

C_a Capacity of link *a*

A. Passage Location Model

First, we present two principles to distribute the expressways:

1) the expressway location needs to satisfy the demand of vehicle's middle and long distance travel; and

2) the level of underground expressway needs to be consistent with the ground roads.

The passageway efficiency V is defined as the number of vehicles served in per unit time. Therefore, two conditions need to be fulfilled. The first one is that the more demand of point o, the less travel time (cost) of o-j pairs; and the other one is that the passageway efficiency in one zone is the most in whole. The passageway location function is:

$$\text{Maximize } V = f(N, A, d, t), \tag{1}$$

where the demand decay function is described as $f(d) = e^{-\mu d}$ in the literature (Farhan and Murray, 2006; Hanson and Giuliano, 2004). Furthermore, μ is within the typical range of 0.5 to 2. The value of share rate A will be introduced in section B. Decision variable is defined as:

$$Y_{oj} = \begin{cases} 1 & \text{if } \hat{d}_{oj} \text{ is not less than the shortest distance of } o\text{-}other \text{ pairs,} \\ 0 & \text{otherwise.} \end{cases}$$

Now, the formulation is given as follows:

$$\begin{aligned} \text{Maximize} \quad V &= \max_j \left(\sum_o \frac{N_{oj}}{\hat{t}_{oj}} \times Y_{oj} \right) \\ &= \max_j \left(\sum_o \frac{N_o \times A_j \times e^{-\mu \cdot \hat{d}_{oj}}}{\hat{t}_{oj}} \times Y_{oj} \right), \end{aligned} \tag{2}$$

$$\begin{aligned} \text{subject to} \quad & \hat{t}_{oj} = \min_{k \in W_{oj}} \left\{ t_k^{oj} \right\} \forall o, j, k; \\ & \hat{d}_{oj} = \min_{k \in W_{oj}} \{ d_k^{oj} \} \forall o, j, k; \\ & Y_{oj} \in \{0,1\} \forall o, j; \\ & \sum_j Y_{oj} = p. \end{aligned} \tag{3}$$

t in the model is the sum of the impedances of each link in the path of *o-j* pairs, where the impedances are valued travel time (cost). BRP function is used to gain the travel time (cost) as follow:

$$t_a(x_a) = t_a(0) \left[1 + \alpha \left(\frac{x_a}{C_a} \right)^{\beta} \right] \quad \forall a. \tag{4}$$

The travel time (cost) t_k^{oj} on the path *k* of *o-j* pairs is given by

$$t_k^{oj} = \sum_a t_a \delta_{a,k}^{oj}. \tag{5}$$

The equation $\delta_{a,k}^{oj} = 1$ is feasible if the link *a* is on the path *k* of *o-j* pairs, otherwise,

$$\delta_{a,k}^{oj} = 0.$$

B. Share Rate Model

Function (1) refers to the share rate A of underground expressway. The equilibrium model could offer the distribution flow of link a. Hence, the share rate model is:

$$A_j^n = \frac{\sum_{a'} x_{ja'}^n}{O+D} \quad \forall j, a', n, \tag{6}$$

where a' represents an underground expressway.

A space network comprised of ground roads and underground expressways is constructed using the equilibrium model. Considering the service object, the characteristics, the traffic benefit and non-superposition of underground expressway into consideration, Figure 1 givens an example of constructing a network with underground expressway.

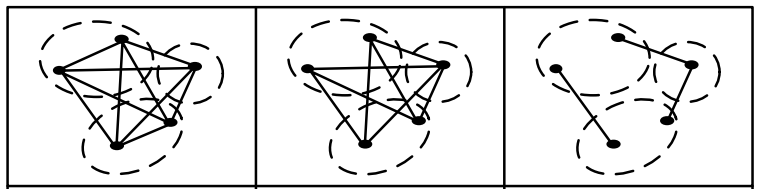

Figure 1. Process of constructing the space network

After several circles of iterative algorithm, the rate is steadied, and the result of passageway location model is optimized.

AN ILLUSTRATIVE NUMERICAL EXAMPLE

The network in Figure 2 is an illustrative numerical example. There are 4 zones and 36 links in this network. Each passageway points' IDs are shown in Figure 3. The demand point *o* is in the middle of each link. Symmetrical distributing randomly produces the amount of demands of points and zones. The shortest distance matrix $\hat{\mathbf{d}} = (\ldots, \hat{d}_{oj}, \ldots)$ and the minimal travel time (cost) matrix $\hat{\mathbf{t}} = (\ldots, \hat{t}_{oj}, \ldots)$ are determined using the Dijkstra algorithm. The application of the second iteration in zone is described as follow:

Input 1) the share rate (A=76.58%) which was the result of first iteration,

2) the demand of each demand point, the shortest distance matrix and the minimal travel time (cost) matrix in zone 1, as listed in Table 1,

3) the parameters μ=1, O_1=D_1=1635, and ε=0.1000.

First, these data is inputted into the model. Then the results show that the maximal efficiency is 644 and the optimized passageway point is No. 8. According to the same method, the maximal efficiencies and the optimized passageway points in other zones can be solved. Then, a new space network is built and its flow is distributed again, up to the new share rate that is obtained. Execute the iterative algorithm again until the result at the fourth iteration shows ε=0.0739, which follows

$\frac{\sqrt{\sum_j \left(A_j^{n+1} - A_j^n\right)^2}}{\sum_j A_j^n} \le \varepsilon,$. The iterative algorithm is finally stopped.

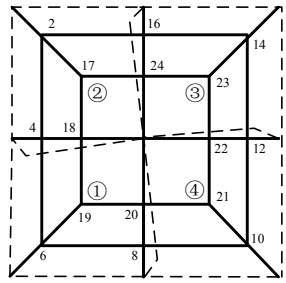

Figure 2. Network

Table 2 presents the results of iterative operations in each zone. Figure 3 illustrates the relationship between value of efficiency and passageway point in each iterative operation. All curves of the four zones are similar, which is explained as follow.

Table 1. Relative Data of Demand Point and Passageway Point

3	1	304	8	58.70%	0.1589
	2	246	4	47.21%	
	3	332	16	56.03%	
	4	391	12	58.25%	
4	1	497	6	66.89%	0.0739
	2	308	4	37.62%	
	3	357	16	65.51%	
	4	388	12	62.25%	

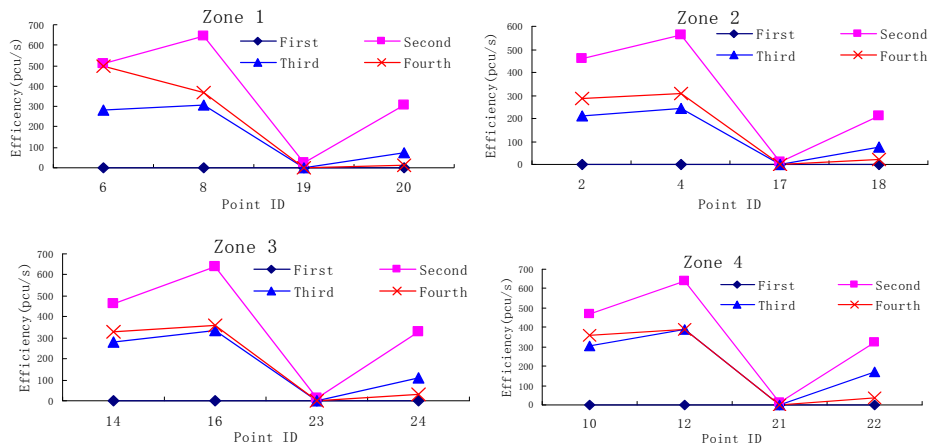

Figure 3. Curves of passageway efficiencies in each zone

1) the values of efficiency in No. 6 and No. 8 zones are larger than those in No. 19 and No. 20 zones in each iterative operation. It reveals that the passageway location model always chooses the optimal point from the points with a high probability. Since the values of efficiency of the points in poor locations are very small, these points are not selected.

2) the four curves tend to tranquilization in the middle level, which means the share rate of underground expressway tends to be steady.

3) the optimized point is No. 8 in the 2nd and 3rd curves, and the value of efficiency in No.6 zone is close to the values of No.8 gradually until it exceeds the No.8 in the fourth iteration. The result shows that the course of the travel time (cost)

tending to be steady has the potential to globally optimize the result of passageway location model.

CONCLUSIONS

This paper presented a new passageway location model of underground expressway. A share rate model and its solution algorithms for forming an underground expressway space network were also developed. In conclusion, firstly, if the number of demand, share rate, and travel time (cost) were known, the locations of passageway can be obtained by using these models. Secondly, since the value of efficiency changed with the steadying of share rate, this iterative algorithm can make the model convergent. Finally, the travel time (cost) also changed continually with the iterative operation. Therefore, the passageway locations of underground expressway are globally optimized.

[1]Department of Civil Engineering, School of Architecture, Science and Technology Institute of Kunming,Kunming,650224 China. Tel:+86-871-3801057;email: ryy64@yahoo.com.cn ; tumu380@yahoo.com.cn

ABSTRACT

According to engineering practice's experience and theoretical research, the evaluation index system of bridge construction organization design is established. Based on entropy theory, the optimum model for the design scheme of construction is set up. This model is established on indices of different schemes to build up a non-fuzzy judgment mathematical matrix and standardize it to calculate entropy, then these indices are applied in calculating entropy weight. Then we can calculate the attribute matrix and seek the ideal point. Finally we can get the best scheme by priority order degree of distance or nearness degree between all schemes and the ideal point. Examples show that the construction management plan selected based on the entropy theory has strong evaluating capability and is simple and effective. This method is instructional in all-around evaluations.

INTRODUCTION

A construction management plan in bridge engineering is a programmatic document of technology and economy for the general layout document of construction engineering (Mao Ze-Hua, 2004). It also plays a very important role in realizing scientific production management, ensuring quality, economizing resources and reducing costs of construction site. There are lots of factors which influence the tendering and bidding of construction management plans in bridge engineering. Often the decision-making scheme concerns a complex system that consists of multiple indices and multiple schemes. Therefore, it is very difficult to evaluate the scheme using merely objective function or the evaluation criterion. The most commonly used method in an evaluation process requires an expert grading method in which the proposal with the highest score wins the bid. The result of this method sometimes can't represent the actual situation of the evaluation object. The process of multi-index assessment method (Mao Ze-Hua,2004;Cai Xue-Feng,2004;Ruan Yong-Fen,2003) depend upon experts to give proper index weights which leads to higher randomicity and the loss of some useful information. Although the analytic hierarchy process (AHP) method is an effective tool for solving a multi-objective decision-making problem and is successfully applied in many fields of decision-making. But its evaluation matrix used a relatively lopsided judgment scale

(Xie Qian-Bo,1998). To deal with this complicated problem, this paper constructs an index system which influences the decision making of plans according to the actual situation, applying this entropy weight theory in the optimum choice evaluation of constructional organization design of bridge engineering and constructs a non-fuzzy judgment matrix based on the result of read and appraisal from the experts to select the best proposal.

PRINCIPLE OF ENTROPY WEIGHT DECISION-MAKING

The word "entropy" originates from the Greek language. Entropy is referred to as a measure of uncertainty. The bigger the information entropy is, the greater the degree of disorder and the smaller the effect; contrariwise, the smaller the information entropy is, the lower degree the extent of disorder and the bigger the effect. As weight, the entropy deducted through calculation using the evaluation matrix is not the important actual index in decision making or evaluation problems. Rather, the evaluation scheme set is given out, then every evaluation index value is confirmed. It is a coefficient with relative vehement extent under the competition condition (Tian Zhen-Qing,2002; Chen Li-Ming,2003; Qiu Yuan-Hua,2002) under situations when each types of evaluation index is confirmed and the evaluation scheme set is given.

Entropy

When entropy H ($p_1,p_2,\ldots,p_m$) satisfies three combinations below and consistency requirement, the entropy has only have one form.

If $$\mathrm{H}(\mathrm{p}_1,\mathrm{p}_2,\ldots,\mathrm{p}_\mathrm{n}) \le \mathrm{H}\left|\frac{1}{n},\frac{1}{n},\ldots,\frac{1}{n}\right| \quad (1)$$

$$H(p_1,p_2,\cdots,p_n) = H(p_1,p_2,\cdots,p_n,0) \quad (2)$$

$$H(S*T) = H(S) + H(S/T) \quad (3)$$

Then, entropy is defined as

$$H_n(X) = H_n(p_1,p_2,\cdots,p_n) = -k\sum_{i=1}^{n} p_i \log_2 p_i \quad (4)$$

Among p_i is the corresponding probability.

Suppose B' is a non-fuzzy judgment matrix.

$$B' = (b_{ij})_{m\times n} \quad (5)$$

Suppose $s_\mathrm{i} = \sum_{j=1}^{n} b_{ij}(i = 1,2\ldots n)$ is the sum of the elements in the k column, $f_{ij} = b_{ij} \big/ S_i$ can represent the probability of occurrence of the j element in the i result. Therefore the results of n types of calculations result of entropy are as follows:

$$H_i = -\sum_{j=1}^{i} f_{ij} \log_2 f_{ij}(i = 1,2,\ldots n) \quad (6)$$

Entropy weight

In evaluation problems which have *m* evaluation indices and *n* evaluation objects, the non-fuzzy judgment matrix B' is shown as follows:

$$B' = (b_{ij})_{m\times n} \tag{7}$$

$$b_{ij} = \frac{b'_{ij} - \min\limits_{j} b'_{ij}}{\max\limits_{j} b'_{ij} - \min\limits_{j} b'_{ij}} \tag{8}$$

After standardizing matrix B', we can get matrix B below

$$B = (b_{ij})_{m\times m} \tag{9}$$

Among it $b_{ij} \in [0,1]$

So the entropy which has m evaluation indices and n evaluation object is defined as:

$$H_i = -k\sum_{j=1}^{n} f_{ij} \ln f_{ij} \qquad i = 1,2,\cdots m \tag{10}$$

Among it $f_{ij} = \dfrac{b_{ij}}{\sum\limits_{j=1}^{n} b_{ij}}, k = \dfrac{1}{\ln n}$.

In order to make $\ln f_{ij}$ valid, it is commonly postulated that when $f_{ij} = 0$, $f_{ij} \ln f_{ij} = 0$.

In the evaluation which has *m* evaluation indices and *n* influence factors, the degree of influence of *i* assessment indices is entropy weight that can be calculated using following formulas.

$$\omega_i = \frac{1 - H_i}{m - \sum\limits_{i=1}^{m} H_i} \tag{11}$$

$$w = (\omega_i)_{m\times 1} \tag{12}$$

Among it, $0 \le \omega_i \le 1$, $\sum\limits_{i=1}^{m} \omega_i = 1$.

Evaluation process of entropy weight

1. Make sure that there are *n* schemes to be evaluated and *m* assessment indices in each of the evaluation scheme.

2. After standardizing the non-fuzzy evaluation, matrix $B' = (b_{ij})_{m\times n}$,

$B = (b_{ij})_{m\times n}$ can be derived.

3. Calculate entropy of every index H_i

4. Calculate attribute matrix $A = (b_{ij} \times \omega_i)_{m\times n} = (a_{ij})$

5. Seek ideal point $p^* = (p_1^*, p_2^*, \ldots, p_m^*)^T$

Among it: $$p_i^* = \max_j \left\{ a_{ij} \,|\, i = 1, 2\ldots, m; j = 1, 2\ldots n \right\} \tag{13}$$

6. Calculate distance

$$d_j^* = \sqrt{\sum_{i=1}^{m} (a_{ij} - p_j^*)^2}, j = 1, 2, \ldots, n \tag{14}$$

7. Calculate nearness degree.

$$T_j = 1 - \frac{\sum_{i=1}^{m} a_{ij} p^*{}_i}{\sum_{i=1}^{m} \left| p^*{}_i \right|} \tag{15}$$

Based on T_j value, the rank of the proposal can be decided and proposals of lower value will be considered first; if T_j is equal, then compare d_j^* value , consider proposal with lower value first.

APPLICATIONS

Its main bridge is a pre-stressed box-section continuous beam bridge. Five construction companies bid for the project. Each construction company produced a construction management plan based on the requirements of the bidding documents, then we have five schemes P_i(i=1,2,3,4,5). And then we used the main factors which influence the outcome to produce the system of evaluation. The index set used to evaluate the project is , C_J= (C_1, C_2, …,Cu_9) = {Construction plan and scheme C_1, measure on construction quality assurance C_2, safety guarantee C_3 , construction preparative working plan C_4,construction schedule and measure C_5, temporary electricity and heat supply C_6, measure on cost reduction C_7, schedule needing resource C_8 , overall construction site plan C_9} (Cai Xue-Feng,2004) nine experts were invited to score evaluation indices of every the construction management plan. Its result is in Table 1.

Table 1. Assessment result of construction planning design schemes

Constructional management plan schemes	1	2	3	4	5
Construction plan and scheme	85.5	93.5	89.5	96.7	82.5
Measure on construction quality assurance	81.5	85.1	84.3	86.5	87.9
Safety guarantee	82	86	85.3	84.3	85.9
Preparative working plan	89	80.4	80.5	80.5	90.8
Construction schedule and measure	90.5	85.7	89	82.7	86
Temporary electricity and heat supply	86.4	80.3	90	85	80.8
Measure on cost reduction	86.1	85.2	82.5	82.5	85
Schedule needing resource	80	82	80.6	80.7	90
Overall construction site plan	78	84	86	80	81.9

Then non-fuzzy assessment matrix is B'. After standardized and specification the matrix is B.

$$B' = \begin{bmatrix} 85.5 & 93.5 & 89.5 & 96.7 & 82.5 \\ 81.5 & 85.1 & 84.3 & 86.5 & 87.9 \\ 82 & 86 & 85.3 & 84.3 & 85.9 \\ 89 & 80.4 & 80.5 & 80.5 & 90.8 \\ 90.5 & 85.7 & 89 & 82.7 & 86 \\ 86.4 & 80.3 & 90 & 85 & 80.8 \\ 86.1 & 85.2 & 82.5 & 82.5 & 85 \\ 80 & 82 & 80.6 & 80.7 & 90 \\ 78 & 84 & 86 & 80 & 81.9 \end{bmatrix} \quad B = \begin{bmatrix} 0.2113 & 0.7746 & 0.4930 & 0 & 0 \\ 0 & 0.5625 & 0.4375 & 0.7812 & 1 \\ 0 & 1 & 0.825 & 0.575 & 0.975 \\ 0.8269 & 0 & 0.0096 & 0.0096 & 1 \\ 1 & 0.3846 & 0.8077 & 0 & 0.4231 \\ 0.6289 & 0 & 1 & 0.4845 & 0.0515 \\ 1 & 0.75 & 0 & 0 & 0.6944 \\ 0 & 0.2 & 0.06 & 0.07 & 1 \\ 0 & 0.75 & 1 & 0.25 & 0.4875 \end{bmatrix}$$

According to formula (10) we can get the entropy value of each evaluation indices in the Table 2.

Table 2. Entropy value for assessment indexes

Assessment indices	Construction plan and scheme	Measure on construction quality assurance	Safety guarantee	Preparative working plan
Entropy/H	0.7834	0.8317	0.8481	0.4638
Construction schedule and measure	Temporary electricity and heat supply	Measure on cost reduction	Schedule needing resource	overall construction site plan
0.8121	0.7083	0.6746	0.4934	0.7942

According to Table 3, use formula (11) to get attribute matrix A.

$$\omega_i = (0.0836,\ 0.065\ ,0.0586\ ,0.2070\ ,0.0725\ ,0.1126\ ,0.1256\ ,0.1956\ ,0.0795)^{\mathrm{T}}$$

$$A = \begin{bmatrix} 0.0177 & 0.0648 & 0.0412 & 0.0836 & 0 \\ 0 & 0.0365 & 0.0284 & 0.6498 & 0.065 \\ 0 & 0.0586 & 0.0484 & 0.0337 & 0.0572 \\ 0.1711 & 0 & 0.0020 & 0.0020 & 0.2070 \\ 0.0725 & 0.0279 & 0.0586 & 0 & 0.0307 \\ 0.0708 & 0 & 0.1126 & 0.0546 & 0.0058 \\ 0.674568 & 0.505926 & 0 & 0 & 0.0872 \\ 0 & 0.0391 & 0.0117 & 0.0137 & 0.1956 \\ 0 & 0.0596 & 0.0795 & 0.0199 & 0.0387 \end{bmatrix}$$

The ideal points

$$p^* = (0.0836,\ 0.065,\ 0.0586,\ 0.2069,\ 0.0725,\ 0.1126,\ 0.1256,\ 0.1956,\ 0.0795)^{\mathrm{T}}$$

The distance, nearness degree and priority order between each scheme and ideal point can be seen from table 3.

Based on the results, Scheme 4 is the best no matter if it is evaluated by priority order degree of distance or nearness degree.

Table 3. Optimums choice order for every scheme

Scheme	1	2	3	4	5
Distance	1.5310	1.6136	1.7726	1.3648	1.9010
Priority order according to distance	2	3	4	1	5
Nearness degree	0.7034	0.6434	0.6449	0.4741	0.8024
Priority order according to nearness degree	4	2	3	1	5

CONCLUSION

The consistency between the predicted values and the literature (Cai Xue-Feng, 2004) demonstrated the feasibility and correctness of the model. The entropy weight decision-making method can standardize different indexes which have different dimensions, physical implications and belong to different types. Its entropy can represent, to the fullest extent, the actual standard of different indexes and consists of the empirical evaluations from the experts; therefore the evaluation result has the combined advantage of subjective assessment and objective assessment. The entropy model of this passage not only consists of a clear concept and a logical theory, but also can be calculated easily using Excel. Meanwhile, it doesn't have disadvantages which include the usually objective way of fixing entropy weight and

the inclination of assessment result towards the average that results in low distinguishing rate. Therefore, due to the above advantages, it can be widely applied in engineering.

ABSTRACT: This paper defined the quantitative relationship between the times of drivers' unauthorized lane changes and the times of traffic conflict by traffic conflict technology, then the influence coefficient of unauthorized lane change behavior. The concept of lane change frequent-degree is also given in this paper, then the influence of traffic safety from the characteristic of frequently changing lanes about taxi is analyzed and calculated.

INTRODUCTION

Lane changing is a behavior which frequently occurs when vehicles are operating, so there are many characteristics of lane changing on our country's urban roads. They influence traffic safety directly or indirectly (Mohamed et al, 2000). Analyzing the influence of these characteristics on traffic safety is useful for us to gain insight of these behaviors generating causes and regularity of outbreak then guide us to make scientific management methods to secure the traffic safety (Ioannis et al, 2002).

THE CONCEPT OF LANE CHANGE BEHAVIOR

Lane change behavior describes the combined course that drivers adjust and finish their drive strategies according to their driving character, the traffic

environment, such as surrounding vehicles' speed, gap and so on (Jerry et al, 2003). In fact, lane change is a kind of behavior that drivers demonstrate their decision by the way they drive vehicles. According to differences of advantage motivation, lane change behavior can be divided into obligatory and arbitrary lane change (Gipps, 1986). The former means there are definite lanes which drivers must change at a given area, such as ramps diverge and merge vehicles, mixed area, etc. The latter means that when the speed of the front vehicle is slow, the driver will change lanes to maintain a higher speed and more driving space.

LANE CHANGE BEHAVIOR CHARACTER ANALYSIS ON URBAN ROADS

In our country, urban roads have many vehicle types, large traffic flow and complex condition, drivers also have different physiological and psychological character, and the traffic environment influence make the drivers' expected speed limited (Wang et al, 2008), so lane change behavior has much character, such as unauthorized lane change, taxis frequently changing lane, forced lane change at ramp exit and entrance, contend for lane change at instable traffic flow and so on. These characteristics, especially unauthorized lane changes and taxis frequently changing lanes, severely influence the traffic safety.

Drivers' unauthorized lane change analysis

In this paper we investigated about 504 hours of traffic flow on 42 roads in various cities including Harbin, Beijing, Dalian, and Xian. We used the methods of video recording, questionnaires, etc. We got the figures by the date, see figure 1.

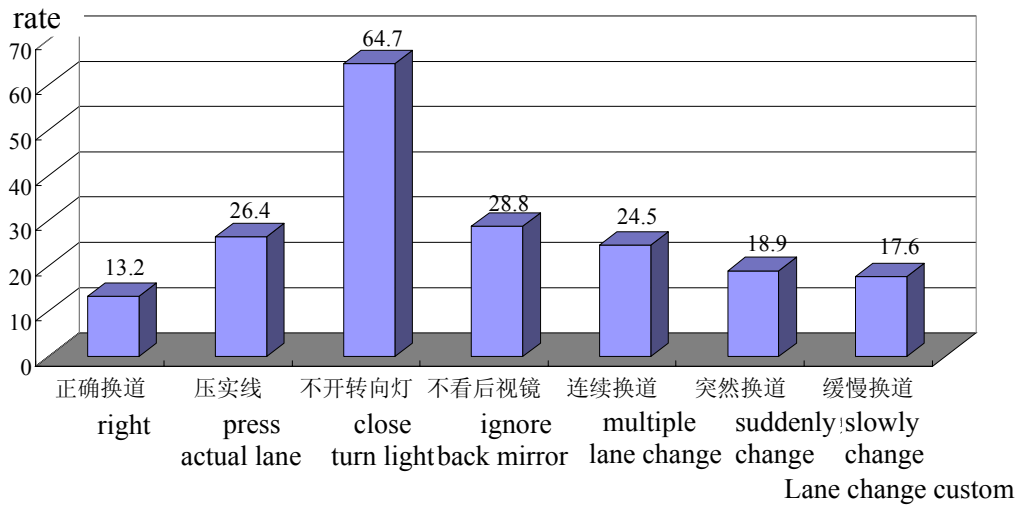

Figure 1 Drivers' lane change custom statistics

From Figure 1 we know that the majority of drivers have unauthorized lane change behavior. We also found that many drivers had several defective lane change customs at the same time. The real cause of unauthorized lane change behavior is that drivers cannot run at their desired speed (Thomas et al, 2005), and they always realize it by violation of regulation, so many drivers perform the defective lane change custom.

Taxis frequently changing lane analysis

In our country, vehicle types are complex, speed contrast is great, taxi drivers often get higher running speed by changing lanes frequently. We define lane change frequency degree K to describe this case, it is the ratio of all the lane change times of one type of vehicle and its traffic flow at specified road sections in one hour time.

$$K = \frac{T_t}{T_v} \tag{1-1}$$

In the formula, T_t means the total lane change times of this type of vehicle in an hour at this road-section, T_v means the traffic flow of this type of vehicle in an hour at this road section. If K is less than 1, several vehicles did not change lanes, if K is more than 1, several vehicles changed not only one lane at a time, the larger the K is the more frequent the lane changes.

There are many taxis on urban roads. The goal of taxis is to serve the passengers with optimum speed in a minimum amount of time, so the taxi drivers often attain higher speeds than the typical driver and always change lanes to attain their aim (Hiroshi, 2001). By calculations based on our investigation, we got the lane change frequency degree average value of several types of vehicles: taxis are 1.45, private vehicles are 1.14 and trucks are 0.86. Consequently, we know that the taxi's lane change frequency degree is larger than other types of vehicles, it agrees with the face.

The influence of drivers' unauthorized lane change to safety

In most cases, the lane changes which violate the regulation did not cause traffic accidents, but it made traffic conflicts(Hoong et al, 2003). We chose the roads which had the same traffic flow and calculated the average value by the investigation data, see table 1.

From this table we know that the more times unauthorized lane changes occur, the more times traffic conflicts with the same traffic flow. Referring to the foreign

calculation method of conflicts and accidents (Nishida, 1999; Sultan et al, 2001), this paper defined the relative value of unauthorized lane changes and got the relative coefficient average value of unauthorized lane change times to traffic safety.

Table 1 Statistic of unauthorized lane change and traffic confliction times (times/hour)

Average traffic flow (veh/h)	1870	2650	3750	4250
Average press real line	5	3	6	7
Average turn light close	24	27	19	23
Average ignore back mirror	7	6	3	4
Average suddenly changing lane	3	5	7	4
Average forced changing lane	8	7	12	10
Unauthorized lane change times	47	48	47	48
Traffic confliction times	39	45	49	54

Table 2 the influence coefficient of unauthorized lane change

Times of unauthorized lane change (time/hour)	<25	25~40	40~55	55~70
Coefficient of traffic safety influence	0.25	0.5	0.75	1.00

The influence of taxis frequently changing lanes for safety

When the taxi changes lanes, it will influence surrounding vehicles' speeds, and frequently changing lanes will influence the vehicles in adjacent lanes (Louid et al, 2005). So many taxies frequently changing lanes will at last influence the speed of the traffic flow, and make it in an unstable state, the unstable traffic flow is the highest traffic accident rate state. We give the condition of taxis frequently changing lanes, see figure 2.

Figure 2 Taxis frequently changing lanes

Taxis changing lanes frequently will make the probability of traffic conflicts grow (Li et al, 2002), this paper obtained the data from classical road-section in Harbin, Beijing, Dalian, Xi'an etc. we got the traffic flow of each road section at three time-intervals every day, and each road section we observed for three days, we recorded the condition of each road section by camera, then threatening the date by professional. By calculation and analysis we found that the conflicting times increased when the taxis changed lanes frequently, so the taxis frequency of changing lanes is an incipient fault which poses traffic safety of urban roads. We cannot give all the data in this paper because of the graphical limitations, so we gave some of data below, see Table 3.

CONCLUSION

Lane changing is a behavior which frequently occurs when vehicles are operating, so there are many characteristics of lane changes on our country's urban roads. They influence the traffic safety directly or indirectly. This paper defined the quantitative relationship between the times of drivers unauthorized lane changes and the times of traffic conflicts by traffic conflict technology, and then determined the influence coefficient of unauthorized lane change behavior. The concept of lane change frequency-degree is also given in this paper, then the influence to traffic safety from the characteristic of frequently changing lanes about taxis is analyzed and calculated. We hope this paper is useful for the theory of developing traffic safety technology and improving traffic safety management, and then improving the traffic environment and protecting traffic safety.

ABSTRACT

Traffic safety is a difficult problem around the world. It is desirable to analyze the crash distribution rules to reduce traffic crashes. However, extensive research is needed to support policy-makers and road safety engineers to make scientific decisions and to take effective measures in China. The objective of the paper is to reveal the distribution rules of crashes in China. Using statistics data, this paper discusses crash frequency and severity distributions by various factors, including temporal dimension, road factors (such as road classes or functions, geometric alignment, etc.), vehicles factors, and drivers' factors in details. The distributions of crash type and crash causes are also examined in the paper. A series of useful and interesting conclusions are available for domestic and overseas traffic policy-makers and road safety engineers.
Keywords: Traffic Safety, Crash Distribution, Crash type, Crash Characteristics

INTRODUCTION

Traffic safety is a serious problem around the world. Crashes have killed 1,462,223 people and injured 5,562,351 people in China since the 1990s (Data from the China Crash Data Annual Report 1990-2007). It is desirable to analyze the crash distribution rules to reduce traffic crashes (Alfonso 2001 and De 2002). However, few researchers，especially in China and some other underdeveloped regions，have performed extensive research to reveal the crash distribution rules (Li 2007, Mao 2007, and Meng 2008). The objective of the paper is to explore the characteristics and the crash distribution rules of crashes in China. First of all, the authors analyzed traffic safety trends then they discussed the rules of crash frequency and severity distributions by various factors, including temporal dimension, road factors (such as road classes or functions, geometric alignment, etc.), vehicles factors, and drivers' factors (such as

driving years). Finally, distributions of crash types and crash causes are examined in detail throughout the paper, followed by the conclusions. A series of useful and interesting rules are available from discussion. The conclusions and suggestions would give reference to domestic and overseas traffic policy-makers and road safety engineers.

CHARACTERISTICS OF CRASHES

Crash tendency and 24-hour distribution

Figure 1 shows the tendency of crash indexes from 1990 to 2007, and Figure 2 shows the characteristics of crash distributions during a 24-hour time period. The crash indexes increased from 1990 to 2003 and decreased from 2003 to 2007. The frequency of crashes was climbing in the daytime (from 7:00 AM to 20:00 PM) while was moving downward in the night (from 20:00 PM to the next day 7:00 AM). The characteristics of crash distributions during the 24-hour time period reflected the characteristics of traffic volume and drivers' physiological changes with time. The conclusion was similar to previous research (Walmman 2001 and Zheng 2006). At peak hours, the volume was larger, and the crash frequency also increased. In the afternoon, the drivers' capacities for work or vigorous activity are general lower than in the morning, and drivers are easily subjected to negative factors, such as fatigue and desertion, which is the reason why more crashes occur in the afternoon. Although there was less traffic volume at night and the crash rate was relative lower, the proportion of fatality crashes was higher due to driver error caused by bad judgment and weak visual nighttime capacities.

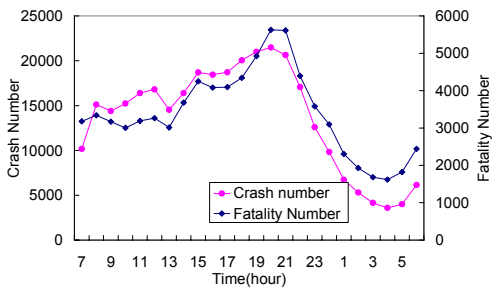

Figure 1. Crash index tendency.

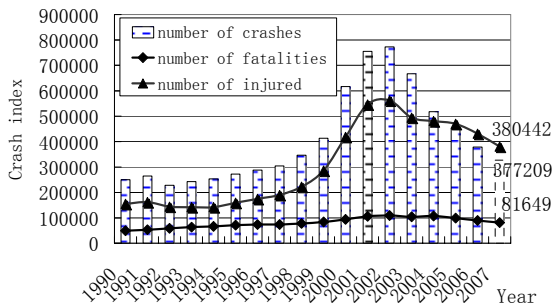

Figure 2. 24-hour crash distribution.

Distribution by roadway

Different safety performances appear on different technical classes and functional Roads (Hauer et al. 2004). Total highway mileage was 3,583,700 kilometers, where 60,271 deaths and 222,420 injuries were caused by 190,825 traffic crashes (accounted for 58.3% of the total number of crashes in 2007). And the city road mileage reached 329,800 kilometers, where 114,433 crashes (accounted for 35.5% of the total number of crashes in 2007) occurred and caused 17,431deaths and 127,271 injuries. In China, highways are divided into five classes: national highway, provincial highway, county

highway, countryside, and village roadway. From the statistical data shown in Table 1, it means that about 14 people would be killed by traffic crashes on an average 100 kilometers of national highway in a year. The average number was nearly nine deaths by crashes every 100 kilometers of provincial highway in a year. About two or three people would be killed by crashes every 100 kilometers of county highway in a year. The crashes that occurred on national highways and provincial highways were two to four times more severe than those that occurred on other roads. There may be two main reasons to explain this phenomenon. First, traffic volume on national highways and provincial highways is much heavier than on other roads. Second, multi-vehicle crashes are more common because of drivers' manipulative errors or illegal behaviors under complicated traffic conditions and deficient road safety facilities.

Compared with the crash frequency of highways, the number of crashes that occurred on city roads was larger than that on the provincial highway but smaller than that on the national highway. Heavy traffic volume and signal lamp would encourage lower speeds, which accounted for the low number of severe crashes. However, roads with mixed traffic volumes will increase the possibilities of crashes on the city roads.

Table 1. Crash distributions on different roads in 2007.

Roadway type	Crash Index in 2007					Crash Index on Average 100 Kilometers			
	No.of crashes	No.of deaths	No.of injuries	Economic losses RMB ($\times 10^4$ Yuan)	Miles (km)	No.of crashes	No.of deaths	No.of injuries	Economic losses RMB ($\times 10^4$ Yuan)
National highway	53039	20033	60841	46336.82	137100	38.69	14.61	44.38	33.80
Provincial highway	62782	20893	72180	2322.77	255200	24.60	8.19	28.28	0.91
County highway	47995	12982	57322	11721.97	514400	9.33	2.52	11.14	2.28
Countryside &Village roadway	20969	4850	25077	3540.44	2619900	0.80	0.19	0.96	0.14
City Expressway	17825	3427	19987	5257	329800	34.70	5.29	38.59	7.97
City Local Road	96608	14004	107284	21028					

Relationship between traffic safety and various traffic mode

Four traffic modes, including passenger cars, buses, trucks, and motorcycles, were the dominant modes involved in traffic crashes. The number of crashes involving cars and buses was twice as high as the number of crashes involving cars and trucks while the severity of crashes related to trucks was more serious than that related to passenger cars because heavy and light trucks with poor brake performance are usually driven while overloaded and with excessive speed. In addition, the number of crashes connected with driving non-motorized vehicles and foot passengers cannot be ignored, since 17,734 crashes resulted, 3,868 people died, and 16,794 people injured.

Distribution by safety performance of vehicle

Crashes often coincide with the dangerous situation of vehicles. But crash data

showed only 5 percent of the total crash number occurred while vehicles operated under suboptimal conditions. Compared with crash severity involving optimal performing vehicles, the severity involved with suboptimal vehicles was more serious, with 5 percent of the total crash number resulting in nearly 10% percent of the total fatalities.

Distribution by driving Years

Crashes are related to driver experience and road user consciousness to obey traffic laws. To some extent, years of driving experience correlates to fewer crashes. Figure 3 illustrates the relationship between driving years and crashes in 2007, which is similar to some researchers' conclusions (Walmman and Hastrom 2001 and Zhong 2007*)*. According to the statistical data in 2007, drivers with less than 3 driving years were involved in 33.72 percent of total crashes number and drivers with less than 5 driving years constituted more than 50 percent of the total number of crashes.

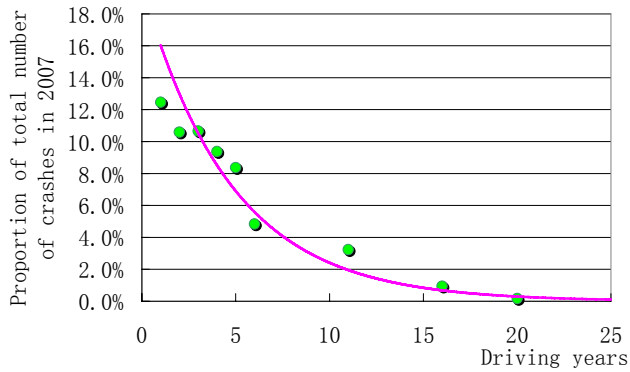

Figure 3. Relationships between the number of crashes and driving years.

As shown in the crash statistics data, a person's occupation may determine the likelihood of involvement in a crash. Peasants were involved in 100,659 crashes because of traffic law violations in 2007, which accounted for 30.76 percent of the total crash number. Individual proprietors answered for 18.71 percent of total crash number and 18.93 percent of total deaths, respectively. Most peasants and individual proprietors are less educated than other people in China. As a whole, crashes reflected the peace-breaker safety consciousness in China.

CRASH TYPE DISTRIBUTION AND CAUSE

Crash type distribution

Crash type was divided into 14 types, including side collision, head-on collisions, and rear-end collisions. Similar to crash types in other countries (Hauer et al. 2004 and Rune 2004), the above mentioned crash types were the most common three types according to the statistical data in 2007(Table 2). Side collisions were the most common and occurred on various types of roads. Head-on collisions usually took place

on Highway Class II and Class III. Rear-end collisions frequently appeared on freeways and highways. The most common three crash types on tangent segments were head-on collisions, side collisions, and rear-end collisions. The number of fatality crashes occurring on tangent segments was 68,231, which was the maximum number of fatalities on various alignments. Most collisions at tangent segments were connected with high speeds. Head-on collisions, overturned vehicles, and side collisions were the three common crash types at curve segments.

Analysis of causes of crashes

Drivers' illegal behaviors were responsible for 89.35 percent of the total crashes in 2007. The 292,343 crashes induced by drivers' illegal behaviors caused 73,510 fatalities and 344,552 injuries, accounting for 90.03 percent and 90.57 percent of total fatalities and total injuries, respectively. The five common drivers' illegal behaviors included: impeding safety driving behavior, disobeying the rule of giving way, speeding, driving with no license, and illegal driving on an opposite lane. The above five reasons caused 199,524 crashes, 48,416 fatalities, and 230,060 injuries, sharing by nearly 60 percent of total crashes number, total fatalities, and total injuries, respectively. The causes of crashes indicated that it takes efficient measures to monitor and administer the drivers' illegal behaviors together with driver education to improve road safety (Zhong and Wang 2006).

Table 2. Crash Type Distribution in 2007

Crash Type	Number of crashes		Number of deaths		Number of injuries		Property loss ($\times 10^4$ RMB Yuan)	
	%of total	Number	%of total	Number	%of total	Number	%of total	Number
Side collision	120547	36.84%	20966	25.68%	139601	36.69%	29617.09	24.71%

CONCLUSIONS

This paper investigated traffic safety, and analyzed the characteristics and distribution of crashes in China. The main findings of the study can be summarized as follows:

1. In China, the general tendency of crash indexes has experienced a slight downward trend from 2004 to 2007. The number of crashes occurred at peak hours and more often in the afternoon.

2. The ratio of number of crashes occurring on highways and city roads was about 6 to 4 in 2007. The situation of traffic safety on national highways and provincial highways was much more serious than on the other roads. Higher priority should be given in treating high crash locations on national highway, provincial highway and city roads.

3. Passenger cars, trucks, and motorcycles were the main types of vehicles involved in crashes, and crashes reflected the peace-breaker safety consciousness in China.

4. The crash ratio declined for drivers with more years of driving experience. Drivers with less than 5 years of driving experience were more likely to be involved in crashes. Passengers, non-motorized vehicle drivers, pedestrians, and motorcycle drivers are all vulnerable to in crashes.

5. There are many reasons for crashes, but drivers' illegal behaviors are responsible for most crashes. Impeding safety driving behavior, disobeying the rule of giving way, speeding, driving with no license, and illegal driving on an opposite lane are the most common reasons for crashes.

ABSTRACT

The tunnel is a permanent construction and the lining is a main part in the tunnel structure. So the quality of lining construction should affect the traffic safety. In order to maintain the existing void between initial lining and surrounding rock or in the secondary lining construction, ground-penetrating radar nondestructive testing technology and polymer grouting technology for maintenance of tunnels has been presented. First use ground penetrating radar to analyze the distress and voids in the tunnel lining. Then use ground penetrating radar to evaluate quality of the whole structure and determine the disease scope of the tunnel, maintain void region with polymer grouting technology. The field test results show that the use of polymer grouting technology can repair the tunnel distress, and provide an ideal manner for tunnel quick maintenance.

KEYWORDS: *Tunnel, Polymer Grouting, Ground-Penetrating Radar, Quick Maintenance*

1 INTRODUCTION

The tunnel is the permanent construction and the lining is a main part in the tunnel structure. So the quality of lining construction would affect traffic safety. At present, the lining manner is mainly the composite lining and the New Austrian Tunneling Method (NATM) is used for tunnel design and construction. The stage of construction can be divided into two partsy the composite lini and secondary lining. The secondary lining can be carried through when the surrounding rock is stabilized. The stressed state of the secondary lining is very complicated and there are many influence factors, such as surrounding rock grade, groundwater, tunnel burying depth, stiffness of initial supporting and construction time. Because of the influence

factors of construction technique, the tunnel lining void may appear in the position between initial supporting and secondary lining. In case of the existence of the asymmetry void in the secondary lining, the loose pressure and deformation pressure of surrounding rock can not be transmitted asymmetrical. The results of the disease are as follows—are as followeg, the loose pressure and deformation pressure of surrounding rock can not be transmin probability of failure, deformation and falling down of the secondary lining that affects traffic safety seriously. So it is very important to do the tunnel lining construction inspection and long-term traffic safety inspection.

Ground-penetrating radar is a new type of nondestructive instrument techniques (Jing et al. 2007). Characteristics of the instrument include handiness, high efficiency, high precision, high differentiate rate and hyper-shallow detection. Ground-penetrating radar can be used in every stage of tunnel building (You et al. 2007). At the operation and acceptance stage, it also can be used for building quality checking, such as the thickness of lining concrete, lining concrete cracks, tunnel lining voids and leakage. At the operation stage, the tunnel lining service condition can be detected with disease style, disease range and disease depth (Wang et al. 2007).

The common methods to deal with tunnel diseases (such as cracks, voids and leakage) are concrete grouting processes and the use of EAA epoxy material. The main shortcoming is poor maintenance results - only maintained for several months and the high cost of maintenance. The polymer grouting technology for quick tunnel maintenance can be used in concrete panel repairing and elevation (Liu et al. 2007). The achievement is remarkable and the application prospects good (Wang 2007).

2 CHARACTERISTICS OF POLYMER GROUTING TECHNOLOGY

Polymer grouting technology was presented for road and infrastructure maintenance in the 20th century. It has been applied popularly all over North America and Europe. In China polymer grouting technology has begun to be used in freeway maintenance. The critical technologies include polymer material and injection technology. Shallow injection technology is mainly used in void maintenance and elevation of concrete panels. Deep injection technology is mainly applied in base stabilization of road foundation courses and infrastructure.

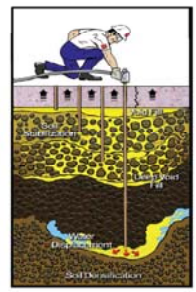

Figure1. Equipment for polymer grouting technology and operating sketch.

Polymer grouting technology has the following characteristics (Liu et al. 2007):

a. Stage of construction is short and less influences the traffic. By the use of polymer grouting maintenance technology, from equipment installation and injection to finishing the whole construction only needs several hours. Traditional methods need at lest several days or several weeks.

b. The polymer material expands rapidly when grouting (its volume is 10-20 times larger than the liquid material). Polymer material fills in the void and crash position automatically.

c. After expansion, the gravity load of the polymer material is only 10% as equivalent volume of grout and it has favorable elasticity.

d. The number of drilling holes is less than in traditional methods and the aperture dimension is also smaller, so it is does not destroy the structure.

e. The performance advantages of polymer material includes good water resistance, non-shrinkage, good durability and non-environmental pollution.

f. The whole injection process is finished under automatic inspection, saving time, saving labor and economy.

3 APPLICATION OF TUNNEL MAINTENANCE WITH POLYMER GROUTING TECHNOLOGY

3.1 Tunnel lining disease inspection with ground penetrating radar

After tunnel construction, besides the lining concrete surface, the inspection of lining quality mainly depends on construction record and experimental data. All these can't reveal the lining thickness and voids behind the lining. But by use of ground penetrating radar, this problem could be effectively solved.

Ground Penetrating Radar (GPR) is an electromagnetic technology that uses radio waves to inspect and scan the underground medium distributing (You et al. 2007), the unseen objective and underground interface. High frequency electromagnetism waves are transmitted with the type of wideband impulse across antenna. By the reflection and transmission of the objective, the waves are received by the receiver antenna. When the electromagnetism wave is transmitted in the medium, its transmission path, electromagnetism field intensity, and wave shape are

affected by the electrical properties and assemble form of the medium. According to the time domain wave collection, treatment and analysis, the underground interface, the spatial position and structural state of the objective can all be ascertained.

With the collection data of ground penetrating radar, the cross section can be obviously divided into three different horizontal layers (Figure 2). The in-phase axis of the reflection wave of the first layer is consentaneous and well-balanced. But the thickness is different which displays the lining thickness. The in-phase axis of most reflection waves of the second layer is inconsistent, the energy of the echo-wave decreases with the reduction of medium density. The disturbing of noise waves shows that there are several reflection waves of voids at grouting tamping section of concrete and surrounding rock.

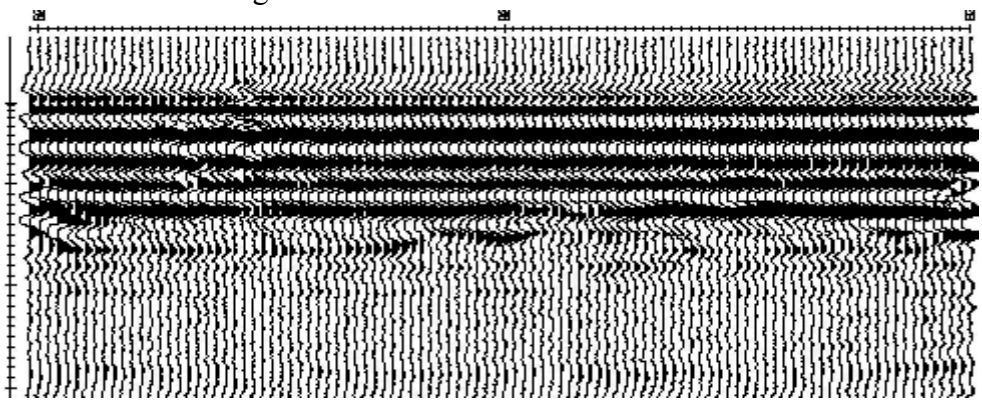

Figure 2. Cross section of ground-penetrating radar image.

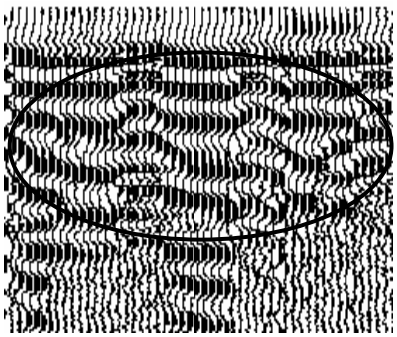
The energy of echo-waves of the third layer is weak and the axis of reflection wave is consentaneous which show the full rock section. The surrounding rock cranny causes the noise waves in some section.

Generally, according to the radar imagines, the interface of the initial lining and the secondary lining, the lining and the surrounding rock could be distinguished. But if the dielectric constant of the initial lining of pneumatically applied concrete and the secondary lining formwork concrete is almost the same, the interface reflection wave of the initial lining and secondary lining isn't obvious. So the initial lining and the secondary lining can be regarded as the same layer.

The tunnel lining diseases are usually the voids and cracks between the initial lining and the secondary lining or between the initial lining and the surrounding rock. With these diseases, the radar imagines are abnormal. Figure 3 and Figure 4 show radar images of tunnel voids in the position of crown of arch and tunnel spandrel, respectively.



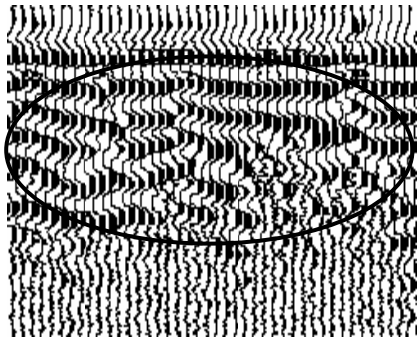


Figure 3. Radar imagine of crown of arch. Figure 4. Radar imagine of spandrel.

The collection GPR images of experimental locations is shown as Fig.5. The result shows that the image along with measure line 5meter-7meter is abnormal and there is a void at the interface of initial lining and surrounding rock. The polymer grouting is suggested to carry through for this section.

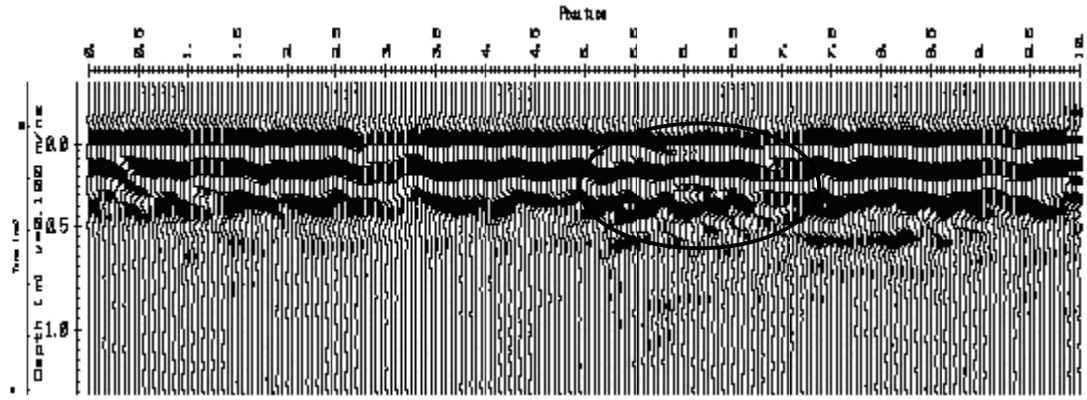

Figure 5. Ground penetrating Radar image of lining before grouting.

3.2 Quick maintenance of tunnel lining with polymer grouting technology

With the polymer grouting technology, a tunnel of a motorway is inspected with ground penetrating radar and polymer grouting maintenance for tunnel lining voids. The core drilling result after polymer grouting is shown as Figure 6. The polymer material overflows from another grouting bore when grouting (Figure 7).

Figure 6. Polymer grouting maintenance Figure 7. After polymer grouting.

After polymer grouting, ground penetrating radar is used to inspect the same section that has voids. A ground penetrating radar image after polymer grouting is shown as Figure 8. Comparing Figure 5 with Figure 8, it can be seen that in the two images the in-phase axis of reflection waves are basically the same. All these indicate that after polymer grouting the void is filled up.

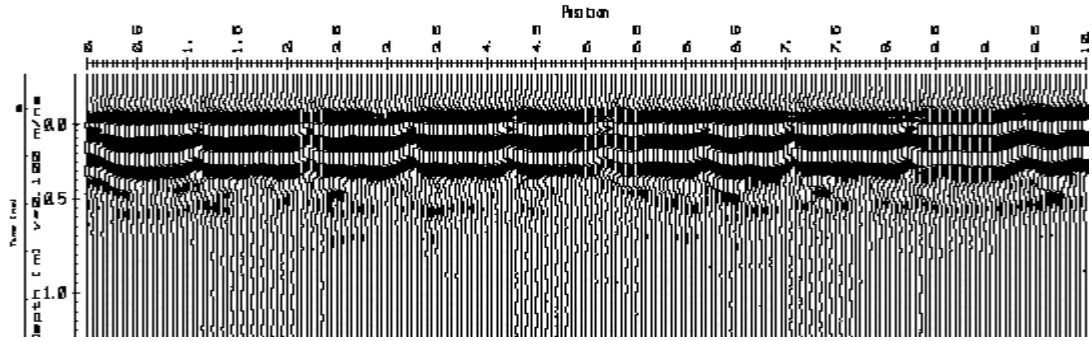

Figure 8. Ground penetrating radar image of lining after polymer grouting.

4 CONCLUSION

The ground-penetrating radar nondestructive testing technology and polymer grouting technology for maintenance of tunnel diseases has been presented. First, ground-penetrating radar is used to inspect the disease and voids in the tunnel lining. Then the void region repaired with polymer grouting repair technology. The test results show that by using polymer grouting technology the tunnel disease can be repaired, and this method is an ideal manner for tunnel quick maintenance.

ABSTRACT

The random disturbance parameter γ is introduced into the cellular automaton (CA) model of traffic flow to simulate the cases of car-stopping, hitting the car ahead, and other vehicular crashes occurring on the freeway. By analyzing the disturbance vehicles in the driving environment of different visibilities of foggy weather, the correlations of limited speed and the safe spacing for optimum visibility are developed. The safe spacing and average safe velocity of the vehicle under different visibilities are simulated and analyzed, thus providing the theoretical gist for freeway administrative departments to establish and implement the management strategies.

Keywords: Cellular Automaton; Visibility; Safe Spacing; Driving Security

INTRODUCTION

The frequency of accidents on the freeway in foggy weather is very high. When visibility is down to a certain critical value, the freeway must be closed. To assure the driving security on the freeway in foggy weather, it's necessary to take some corresponding measures such as road control, meanwhile it's important to keep appropriate velocity and inter-vehicle distance (Tang 2005).

Researcher has been conducted concerning safe driving during foggy weather conditions (Qi 2007). The research on the relationship between speed, inter-vehicle distance, and visibility is also helpful increasing safety on the freeway and reducing the length of closing time of the freeway.

The theory of cellular automaton is widely applied to the research on traffic flow. Its rules can be modified flexibly to consider various real traffic conditions. In this paper, the cellular automata are used to simulate the vehicles. Considering the poor visibility in foggy weather, drivers often slow down to ensure the safety. So the cases of traffic flow on freeway in foggy weather can be better simulated by the FI model of following car slow start (Schadschneider 1997). Through introducing the

random disturbance parameter γ in traffic flow, the paper simulates the unexpected cases of car-stopping, hitting the car ahead, and others in traffic stream. By analyzing the behaviors of disturbing vehicles under the conditions of different visibilities in foggy weather, we have developed the relationships between limited speed and safe spacing to the visibility. It can provide the theoretical gist for the freeway administrative departments to establish corresponding management measures.

THE RANDOM DISTURBANCE MODEL OF A FREEWAY IN FOGGY WEATHER

Cellular automaton is a dynamic system defined on a cellular space that consists of cells with discrete and finite states (Chopard and Droz 1998). The system evolves along the discrete time dimension according to certain partial rules. CA model in traffic flow uses the grids of one dimension lattice chain to simulate the vehicles on the road (Ja et al. 2007). The FI model of following car slow start can be depicted by the following definitions and rules (Benjamin at al. 1996).

A one-lane is expressed by the one-dimensional discrete lattice chain of L cells. Each cell can accommodate only one car traveling with velocity v that takes values ranging from 0 to $v_{\max}$. The car's behavior at the last time step has a great influence on the following car's behavior of speedup at this time step. So the parameter P_1, which is called the slow start probability of following cars in the acceleration rule, is used to describe the diversity of driving behavior of the following car affected by stopping behavior of car ahead. The evolvement rules of the FI model of the following car slow start using the random disturbance parameter γ are described as follows:

(1) The rule of acceleration

If $v_n(t-1)=0$ and $v_n(t)\le v_{\max}$, then with P_2 (random accelerating probability), $v_n(t)\to v_n(t)+1$; with $(1-P_2)$, $v_n(t)\to v_{\max}$. And when the car ahead accelerates, then the following car accelerates with probability P_1.

(2) The rule of deceleration

To avoid colliding with the car ahead, if $v_n(t)>gap$, then $v_n(t+1)\le gap$.

(3) The rule of randomization

Considering the actual driving behavior and the mentality factors of drivers, the cars with maximal velocity change their speeds with the probability P_3 (P_3 is the probability of car braking lingeringly) according to $v_n(t+1) = \max\{v_n(t+1)-1, 0\}$, while the other cars maintain their velocities.

(4) The random disturbance parameter γ

In order to simulate the disturbance of accidents or car stopping in the traffic stream, we choose the vehicles randomly as the disturbance in the simulation and introduce the random disturbance parameter γ as the probability of the disturbance occurrence. Then we simulate each visibility and safe spacing in the condition of various limitative speeds and analyze the states of the following cars whether they are safe under the condition of random disturbance.

(5) The update of vehicle's position

When the velocities of all cars are determined, the position evolving with the time is updated to be: $X_n(t+1) = X_n(t) + v_n(t+1)$

Here in the rules：

$v_{\max}$ ——the limit speed of the car;

$v_n(t)$——the velocity of car n at time t;

$X_n(t)$—— the position of car n at time t;

gap —— the spacing between car n and its preceding car.

In this model, the rule of acceleration reflects the characteristic that the driver wants to drive with the maximal value. The rule of deceleration reflects the behavior taken by the driver for avoiding colliding with the car ahead. The rule of randomization reflects the uncertainty of the driving behavior. The rule of random disturbance simulates the situation of vehicle stream on the freeway in foggy weather.

THE SIMULATION AND ANALYSIS OF SAFE SPACING

By the exertion of the random disturbance parameter in CA model and

analyzing the simulated results in different cases, the relationship between visibility, limitative speed, and safe space are developed.

The determination of parameters of the model

In the CA model, we take the length of the road as L=6.75 km, every cell lattice as c=7.5 m, then the number of lattices is N=900. For the different cases of visibilities, the maximum velocity and safe spacing are chosen crosswise. The process is simulated according to the FI model of following car slow start mentioned above. The number of the time steps that model runs and evolves every time is 10^4. The average velocity values of the last 10^3 steps are used to calculate the average statistic, and the single density point averages the statistic again with the results of 10 times simulation. To obtain the contrastive outcome, we choose 11 groups of data. Every index is listed in Table 1.

Table 1. The indexes of the CA model.

The value of every index of drafted test				The value of every index of test calculated with cell			
Visibility （m）	Drafted maximal speed (km/h）	Inter-vehicle distance a（m）	Inter-vehicle distance b（m）	Visibility （cell）	Drafted maximal speed (cell/s)	Inter-vehicle distance a（cell）	Inter-vehicle distance b（cell）

The analysis of the simulation process

As the FI model of freeway in foggy weather uses the random disturbance

parameter γ to simulate the probability of the traffic accidents or the behavior of car stopping, then the process of simulation introduces the accident rate (Konduri 2002) correspondingly to make the statistical analysis. The indexes are defined in terms of the following rules:

The accident of hitting the car ahead occurs in model when:

$$S_{stop} > S_{safe}$$

That is: when random disturbance appears with a certain probability γ and the braking distance of the following car is bigger than the safe distance, the accident of collision will happen. It's denoted as A_i (i is the frequency of accident). When the number of cars coming into the pileup is k, then we consider it as k-1 times accidents.

The accident rate on a freeway in foggy weather in this model is as follows:

$$P_A = A_n / \left(N_{vehicle} - 1 \right)$$

In the formula: P_A = the accident rate;

$N_{vehicle}$ = the total number of vehicles in car stream.

According to the definition of the accident rate, we analyze the simulated results contrastively. The process of that is as follows:

(1) On the condition of safe spacing, we obtain the values of traffic density or volume when the inter-vehicle distances are *a* and *b*, and calculate values of all indexes according to the values of traffic density and volume.

(2) To simulate with the traffic density ranging from 0 to 1 or the corresponding value of traffic volume, we get the accident rates in the simulation process when the inter-vehicle distances are *a* and *b*, respectively.

(3) Under the condition of unchanged accident rate, we can get the curves of safe spacing in different cases of visibility by varying the safe spacing.

According to the course of simulation, every group of data is analyzed and compared separately. Taking the first group of data for example, when the visibility is 52-cell, we introduce the random disturbance, which is the rate of car stopping. When a car stops or has an accident, the following cars' drivers will have the behavior of decelerating or stopping their cars. Under the conditions of different volumes (densities), we can calculate the possible accident rate according to the visibility of 52-cell and to the safe spacing of 20-cell and 16-cell.

Figure 1 shows the mutative relations of the provided safe spacing and

simulated safe spacing to the density when the visibility is 52-cell, which is 390 meters, and the random disturbance parameter γ is 0.2. From this figure, we can see that when the density is small, the accident rates at the safe spacing of 20-cell and 16-cell are both low, and the difference between them is very small. It indicates that the safe spacing can be shortened further at this density area. At the area of high density, the accident rate at the safe spacing of 20-cell and 16-cell are both very high, and the difference between them is small. But when the density is from 0.22 to 0.78, the accident rates at the safe spacing of 20-cell and 16-cell grow rapidly as density increases. We should formulate the density from 0 to 0.22 to reduce the occurrence of accidents on freeways.

Figure 2 represents the mutative relations of the provided safe spacing and simulated safe spacing to the density when the speeds are limited and the visibility of 52-cell and the disturbance degree γ of 0.2. The figure shows that the influence, which the magnitude of limitative speed has on the accident rate, is small whether it's at the area of low density or high, but the accident rate increases rapidly with the increase of the limitative speed.

Figure 3 shows the changes of the visibility and accident rate simulated under the condition of different disturbance degrees. The changing trends of the curves in the figure show that in the case of low density (k=0.2) the accident rate grows correspondingly to the increase of the disturbance degree, and that the accident rate increases rapidly when the visibility is poor. This shows a fact that the pileup accident occurs frequently in poor visibility areas, in other words, the occurrence rate of very serious accidents is rather high.

THE DETERMINATION OF LIMITATIVE SPEED AND SAFE SPACING

After comparing and analyzing the 11 groups of data and considering the drafted values of different visibilities in foggy weather, we can obtain management and control measures at different cases of visibility on the basis of enhancing the capacity (see Figure 3). Compared with the national standard, it can be seen that the simulated value in control and management scheme is slightly lower than that in the national standard (Yang and Wu 2003). But referring to the capacity, the simulated value of traffic capacity is a little higher than that in the national standard. As seen from the trend of the curves in Figure 4, when the visibility decreases, the velocity and the safe spacing decrease correspondingly; but as the length of the time of the driver's response to the stimulus becomes longer, the needed safe spacing of the

braking distance becomes longer.

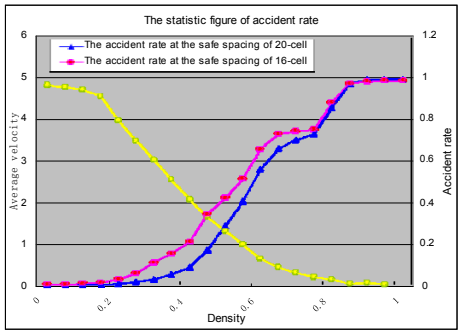

Figure 1. Accident rate with the visibility of 52-cell, γ =0.2 and v_{max} =5.

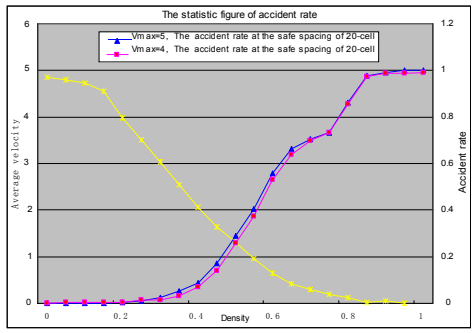

Figure 2. Accident rate when v_{max} =5 and v_{max} =4 at the visibility of 52-cell and γ =0.2.

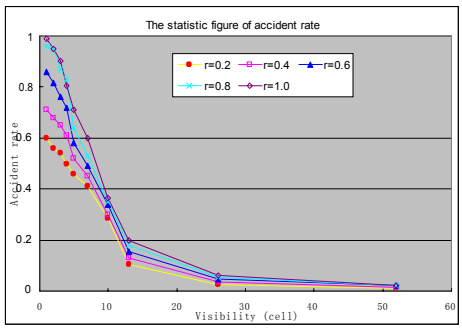

Figure 3. Accident rate when v_{max} =5 and k=0.2.

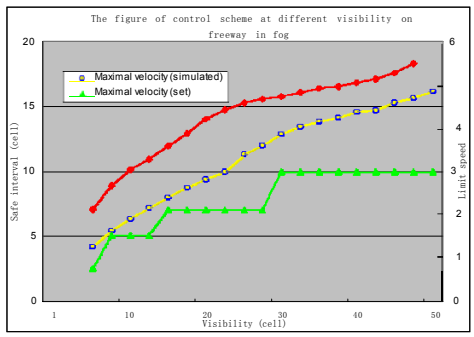

Figure 4. The speed and safe spacing at different visibility in foggy weather.

CONCLUSION

The paper analyzes the relationship between safe spacing, the average safe velocity, and the accident rate synthetically and provides the theoretical general idea of the management control for the traffic management department to enhance the capacity in foggy weather. We can derive the conclusions as follows from the results of the simulation strategies:

(1) To avoid accidents in foggy weather, we should formulate the density from 0 to 0.22.

(2) Under the precondition of maintaining traffic safety, the average safe velocity and the maximal volume at this speed derived from the simulation on the basis of the theory of CA have a great significance on enhancing the transportation

ability of the freeway in foggy weather and thereby enhancing the economic benefit of the freeway.

(3) The result obtained by the simulation scheme is just smaller than that set by the state, but comparing with the actual accident rate on the freeway in foggy weather, the rate in the simulation scheme is smaller. It shows that the incomplete management of opening-up is also the reason causing the accident on the freeway in foggy weather except for the factor of weather. It means that the administrative department should keep the safe spacing by improving their management. So, studying the passing frequency of cars on freeways in foggy weather can help by decreasing the accident rate even further.

Simulation of Turning Stability Control for Two-Motor-Drive Electric Vehicle

Shaobo Xie[1], Cheng Lin[1], Peng Liu[1]and Xiaowei Zhang[1]

[1]National Engineering Laboratory of Electric Vehicle, Beijing Institute of Technology; No.5 Zhongguancun South Street, Haidian District, Beijing city, People's Republic of China, 100081; Email: 2201020133@163.com

Abstract

Two-motor-drive electric vehicles (TMDEVs) have developed significantly in recent years. An important residual problem for this vehicle type is how to coordinate the operation of the driving motors for stable vehicle handling. In order to improve the turning stability of TMDEVs a control scheme, based on the target slip rate of driving wheels, is proposed to distribute the torque of both motors. First a dynamic model of TMDEVs and the tire model are described. Second a control strategy based on the target slip rate using a slide mode control method is specified. Then a dynamic analysis and simulation are conducted. The results show the proposed strategy can make the driving tires achieve the target slip rate and improve the turning stability of this vehicle.

Key words: two-motor-drive, electric vehicle, turning stability control, target slip, dynamic simulation

1. Introduction

With current serious world resource and pollution problems more and more attention is being paid to the electric vehicle. The TMDEV which has no traditional power train and mechanical differential greatly simplifies the structure and enables the accurate controlling of drive motors, due to its characteristic high efficiency and quick response (Shin-ichiro Sakai, 1999). However, the existing problem is how to coordinate the operations of both motors to minimize the abrasion of tires and improve the handling and stability performance, especially when turning the vehicle. This paper proposes a new control scheme and identifies a successful dynamic simulation.

2. Seven degrees of freedom (7-DOF) vehicle model and tire model

The nonlinear vehicle model in the paper with rear wheel drive and front wheel steering includes longitudinal, lateral and yaw dynamics as well as four wheel rotational dynamics.

2.1. Vehicle model

The differential equation of vehicle motion is as follows:

$$m\cdot(\dot{u}-v\cdot\omega_r)=F_{y3}+F_{y4}-F_{y1}\sin\delta_f-F_{y2}\sin\delta_f-\frac{1}{2}C_D A\rho u^2$$

$$m\cdot(\dot{v}+u\cdot\omega_r)=F_{y1}\cos\delta_f+F_{y2}\cos\delta_f+F_{y3}+F_{y4}$$

$$I_z\cdot\dot{\omega}_r=a\cdot(F_{y1}\cos\delta_f+F_{y2}\cos\delta_f)-b\cdot(F_{y3}+F_{y4})+\frac{B}{2}\cdot(F_{y1}\sin\delta_f-F_{y2}\sin\delta_f)+\frac{B}{2}\cdot(F_{x3}-F_{x4})$$

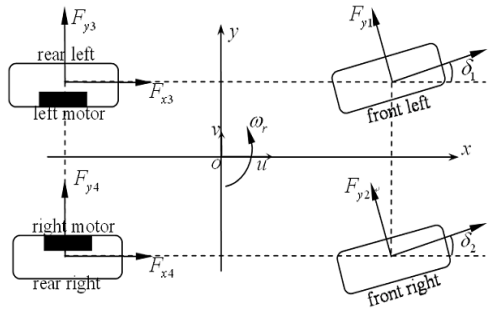

Figure 1. 7-DOF nonlinear vehicle model..

For a front steering vehicle, we assume: $\delta_1 = \delta_2 = \delta_f$, $\delta_3 = \delta_4 = 0$.

For the variation of the tire normal force, which has significant effects on the vehicle handling and stability performance, the tire normal model includes the load transfer due to the longitudinal and lateral accelerations (Farzad Tahami, 2003):

$$F_{z1} = \frac{amg}{2l} - \frac{\mathrm{m}a_x h}{2l} - \frac{ma_y h}{2\mathrm{B}} \qquad F_{z2} = \frac{amg}{2l} - \frac{\mathrm{m}a_x h}{2l} + \frac{ma_y h}{2\mathrm{B}}$$

$$F_{z3} = \frac{bmg}{2l} + \frac{\mathrm{m}a_x h}{2l} - \frac{ma_y h}{2\mathrm{B}} \qquad F_{z4} = \frac{bmg}{2l} + \frac{\mathrm{m}a_x h}{2l} + \frac{ma_y h}{2\mathrm{B}}$$

2.2 Tire model

The tire model has an important influence on the simulation of vehicle dynamics (R. Wade Allen, 2000), especially for large slip angles. The Gim tire model (Gim. G, 1990) was used for the dynamic simulation. This model describes the relationship between longitudinal and lateral forces, which is dependent on normal load F_z, longitudinal slip S_s, slip angle of every wheel α and the friction coefficient of road μ.

The slip angle for each wheel is defined as:

$$\alpha_1 = \delta_f - \arctan\left(\frac{v + a\omega_r}{u - \frac{B}{2}\omega_r}\right) \qquad \alpha_2 = \delta_f + \arctan\left(\frac{v + a\omega_r}{u + \frac{B}{2}\omega_r}\right)$$

$$\alpha_3 = \arctan\left(\frac{v - b\omega_r}{u - \frac{B}{2}\omega_r}\right) \qquad \alpha_4 = \arctan\left(\frac{v - b\omega_r}{u + \frac{B}{2}\omega_r}\right)$$

Longitudinal wheel slip rate can be described as: $s_i = \dfrac{\omega_i r - u_i}{\max(\omega_i r, u_i)}$, $i = (1,2,3,4)$

Lateral wheel slip rate is defined as:
$$\begin{cases} s_\alpha = |\tan\alpha|, & \text{During braking;} \\ s_\alpha = (1 - |s_i|)|\tan\alpha|, & \text{During driving;} \end{cases}$$

The longitudinal force:

$$F_x = C_s S_s l_n^2 + \mu_x F_z \left(1 - 3l_n^2 + 2l_n^3\right) \qquad S_s < S_{sc}$$

$$F_x = \mu_x F_z \qquad S_s \geq S_{sc}$$

The lateral force:

$$F_y = C_\alpha S_\alpha l_n^2 + \mu_y F_z \left(1 - 3l_n^2 + 2l_n^3\right) \qquad S_s < S_{\alpha c}$$

$$F_y = \mu_y F_z \qquad S_s \geq S_{\alpha c}$$

3. The control scheme for turning stability

The TMDEV has no traditional mechanical differential unit. On a straight road with a dry and flat surface, the left and right driving motors can be controlled with the same commands given by the vehicle center controller (Fig. 2). When the vehicle turns , however, the normal load of each wheel will be redistributed because of centrifugal forces and road conditions. Consequently the vehicle controller needs to coordinate the motor operation in order to reduce abrasion of the wheels and keep the vehicle stable for good handling and maneuvering performance. The turning stability control strategy can solve these issues well. Referring to the scheme (Yinghui Ge, 2005), this paper proposes a torque allocation control strategy (Fig. 3), which is based on the target slip rate of the driving wheels. The controluses the sliding mode controller.

The control model can be described as follows: When the vehicle makes a turn in a curve, the slip rate of the rear left wheel s_3^* is chosen as the objective slip rate. At the same time, considering the slip difference $\Delta s = K(Wr - \Delta\varphi)$ between both driving wheels due to the deflection motion, the slip rate of the rear right driving wheel $s_4^* = s_3^* - \Delta s$ can be evaluated. The vehicle controller gives commands to both driving motors, respectively, based on the target slip rate. The real slip rate of both driving wheels are s_3 and s_4, and $\Delta\varphi$ approximately equals to $\frac{\delta}{l}V$.

To eliminate the chattering phenomenon at the boundary layer, the controller structure uses the hyperbolic tangent function (Jalili-Kharaajoo.M, 2003) instead of a saturation function. The increments of the two motors can be shown as: $\Delta T_3 = K_3 \tanh(\Delta s_3)$, $\Delta T_4 = K_4 \tanh(\Delta s_4)$, K_3 and K_4 are the proportional coefficients. So the torque exerted on the motors is $T_3 = T^* + \Delta T_3$ and $T_4 = T^* + \Delta T_4$, T^* is the given torque by the accelerator pedal.

4. Simulation analysis

In this section two different simulations are carried out on the 7-**DOF** nonlinear

vehicle model platform, presented in the Section 2, to analyze and evaluate (Konghui Guo, 1991) the turning stability using a sliding mode control scheme based on the target slip rate. The first is a step maneuver and the second simulation is a single sinusoidal steering input. The initial longitudinal velocity is 20m/s and the initial torque of both motors is 210Nm. The target slip rate of the rear left wheel λ_3^* is 0.05. In all figures, the solid line represents the rear left wheel and the dashed represents the rear right wheel. The values of the vehicle parameter are listed in Table 1.

Table 1. Value of vehicle model parameters in simulation

Symbol	Value	Symbol	Value
m	$1818kg$	J_z	$3885kg.m^2$
a	$1.2m$	I_z	$1.6kg.m^2$
b	$1.5m$	C_f	$-18518N/rad$
L	$2.7m$	C_r	$-20658N/rad$
B	$1.52m$	K	0.05
h	$0.5m$	K_3	12
R	$0.32m$	K_4	15

4.1 Step maneuver

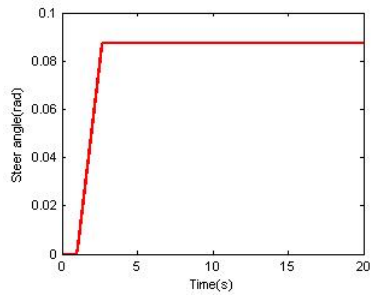

Figure4. The angle of the steering wheel on the step maneuver

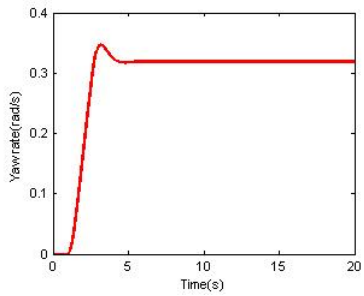

Figure5. Response of yaw rate

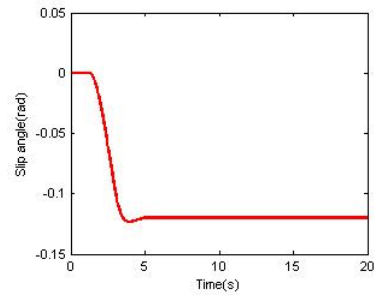

Figure 6. Side slip angle

In this section the steering angle is fixed after 1 sec (Fig. 4). The yaw rate and side slip angle arrive at the desired range in about 1.5 seconds (Fig. 5 and 6) and the vehicle is in a stable condition. The slip rate of both driving wheels fluctuate slightly at the target slip rate of 0.05 (Fig. 7) and the torque is distributed correspondingly (Fig. 8). The figure 9 and 10 show the velocity of the wheel center and the rotation of the right wheel is bigger than that of the left wheel to achieve the target slip rate and decrease the abrasion of the tires.

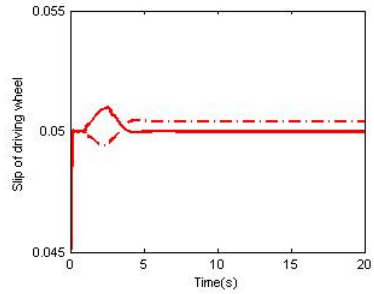

Figure 7. Slip rate of driving wheels

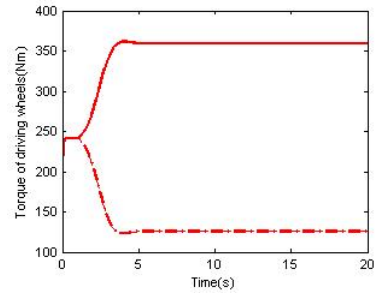

Figure 8. Torque of driving wheels

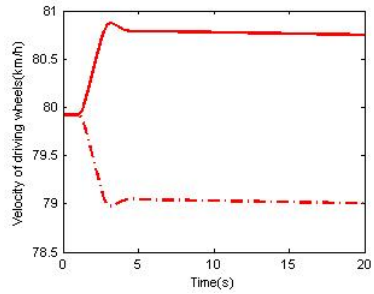

Figure 9. Velocity of driving wheel center

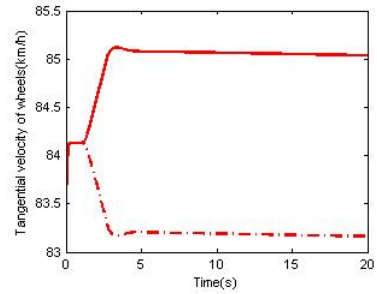

Figure10. Tangential velocity of driving wheel rotation

4.2 Sinusoidal steering input

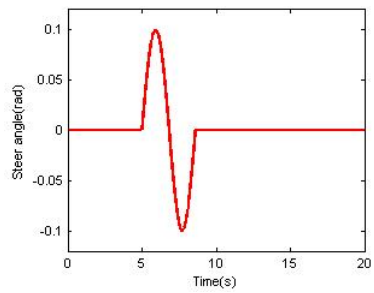

Figure 11. steering angle of single sinusoidal input

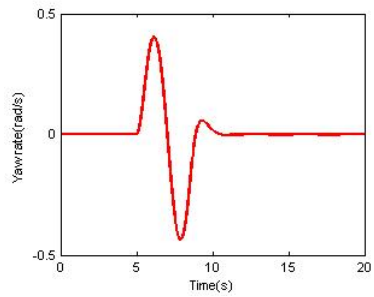

Figure 12. Response of yaw rate

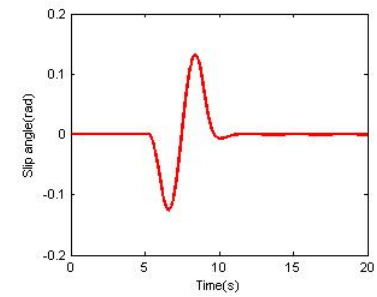

Figure 13. Side slip angle

In this section the steering angle is represented as a single sinusoidal curve with a cycle of 3.6 seconds (Fig. 11). The yaw rate and the side slip angle change correspondingly with the steering angle and the values are controlled within an acceptable range (Fig. 12 and 13). Figure 14 shows both driving wheels reach the demanded slip value of 0.05. It is noted that the tangential and wheel center velocity (Fig. 16 and 17) also act with the sinusoidal steering angle to reduce the abrasion of the tires and improve the turning stability.

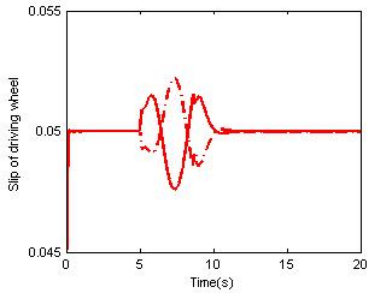

Figure 14. Slip rate of driving wheels

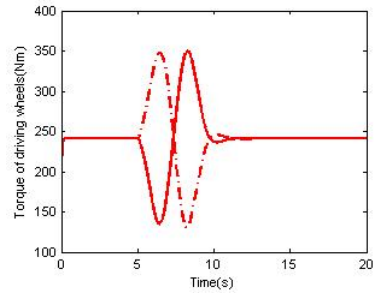

Figure 15. Torque of driving wheels

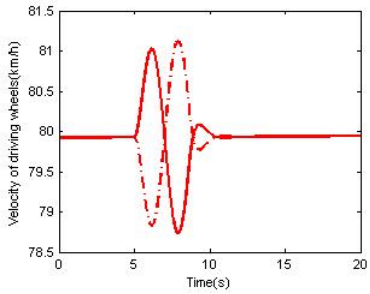

Figure 16. Velocity of driving wheel center

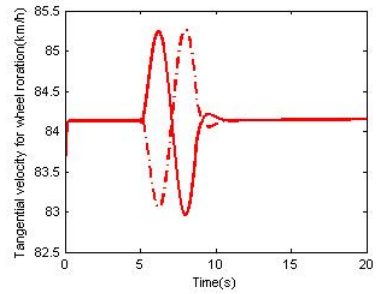

Figure 17. Tangential velocity of driving wheel rotation

5. Conclusion

In this paper, a 7 degrees of freedom nonlinear model of the rear-motored-wheel electric vehicle is demonstrated. The proposed model, based on a target slip rate, is simulated in a step maneuver and with a sinusoidal steering input. The result shows the control strategy can coordinate the torque demands of both wheels and achieve the desired slip rate to improve the turning stability of a two-motor-drive electric vehicle.

ABSTRACT

In Shanghai, the Metro is a major part of a modern urban transit system. Essential to the safe operation of the metro station is the design for emergency evacuations. Based on the comparative study of different simulation theories and methods of group evacuation behavior, Exodus V4.06 and Smartfire V4.1 were employed to simulate the evacuation under different risks in one metro station in Shanghai. The computation result shows that people's distribution in the station has significant influence on the evacuation time and the exits used; the intervention on evacuation route, such as the proper guidance from the working staff, is essential to ensure the right choice of evacuation route, evacuation time saving, and personnel safety.

INTRODUCTION

The Metro, is an essential part of a modern urban transit system. It is a major transportation component because of its high speed, passenger volume, and little influence from the weather. However, due to their inherent properties there exists a great potential risk during metro and metro station operation,

A Metro station is a public facility with high passenger volumes and movement, generally situated underground. A relatively airtight area, there is a large space in the station with a relatively small number of exits which include a few ventilation shafts and several station passageways. Once a fire or other emergencies strike, there could be a considerable number of causalities as well as economic loss without proper evacuation procedures. For instance, in November, 1986, a fire (caused by technical failure) in the Kings Cross Station in London killed 32 and injured more than150 people. Also in March 1995, a poison gas attack in Japan's metro resulted in 12 deaths and about 5500 injuries. (Huang, 2008). The question of how to evacuate a large number of passengers and staff efficiently and safely when fire and other emergencies occur is a topic worth probing.

The evacuation is simulated using Building Exodus V4.0 using one metro station in Shanghai as a prototype. Assuming a fire strikes during the rush hour, the ensuing congestion and confusion during the evacuation is analyzed to determine the key issues, developing corresponding technical measures in an effort to provide references for the design of metro station evacuation and emergency plans.

DESIGN REQUIREMENTS OF EVACUATION IN METRO STATION

Time requirement of evacuation. According to the specification in item 19.1.19 of Code for Design of metro (GB 50157-2003) (NSCGPRC, 2003), and item 26.1.4 of Urban Rail Transit Design Standard (DGJ08-109-2004 (SPCS, 2003), the staircase, escalator and evacuation exits should be sufficient to evacuate all the passengers either on the trains or waiting on the platform as well as the Metro staff in 6 minutes in the event a fire breaks out during the rush hour.

Design requirement of evacuation performance. In fire engineering, the design criteria and specifications require that all people should be evacuated before fire develops fully threatening life. The mathematical description is as follows: (SHI, 2007)

ASET > RSET

ASET (Available Safety Egress/Escape Time) refers to the time from fire breakout to becoming life threatening; RSET (Required Safety Egress/Escape Time) refers to the time used from a fire breakout up to the completion of evacuation.

The evacuation time criterion in common use is shown in Figure 1.

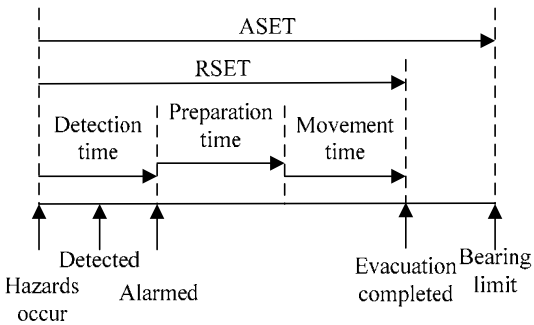

Figure 1 The basis of judgment of safety evacuation

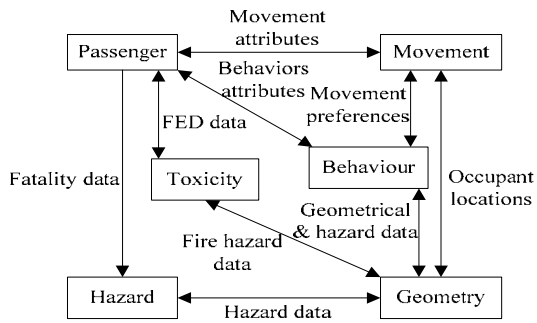

Figure 2 The Interaction of Building EXODUS sub-modules

INTRODUCTION OF BUILDING EXODUS AND SMARTFIRE

The EXODUS software was developed by FSEG (Fire Safety Engineering Group) of Greenwich University in Britain, and is composed of six interrelated sub modules, i.e. the building, people, motion, behavior, risk and toxicity as shown in Figure 2. EXODUS is capable of simulating evacuation in all types of buildings, referencing interpersonal relations in evacuation; the interaction of people and building; the mutual influence of people and the risk environment, thus making it a powerful tool in evacuation design, evaluation and research.

The SMARTFIRE software was also developed by the FSEG. It aims to make Fire Field Modeling techniques accessible to non-Computational Fluid Dynamics (CFD) experts. SMARTFIRE achieves these aims by integrating knowledge-based tools and techniques within many of the modules. SMARTFIRE provides a user friendly environment, together with modest computer requirements, which make Fire Field Modeling a practical and viable reality.

BRIEF INTRODUCTION TO THE METRO STATION IN SHANGHAI

The metro station in the Shanghai simulation covers an area of 10965m^2, with net length 197.36m, net width of standard section 17.10m. It is a two-storied

underground structure and the island style platform is located on the lower floor. The middle part of the platform is the public area, and there are 2 sets of stairs and escalators and one set of cross-zigzag staircase which connects with the station hall. The ends of the platform are the equipment rooms. The planar sketch of the platform is show in Figure 3.

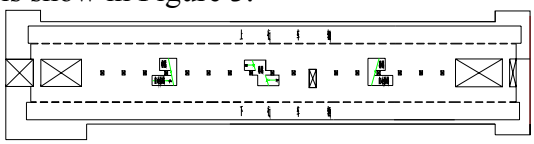

Figure 3 The planar sketch of the platform

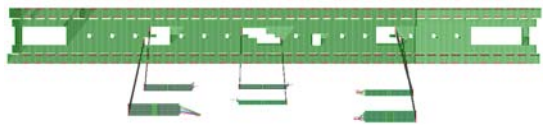

Figure 4 The geometrical model of the platform in the Building Exodus

THE SETTING OF DISASTER ENVIRONMENT

The evacuation under two different kinds of disasters in metro station is simulated and analyzed in this research.

1. Evacuation simulation under general circumstances: It is assumed that there exists an emergency (such as a bomb threat,), and one escalator has stop working; all the people are evacuated with or without the guidance of working staff.

2. Evacuation simulation under disaster: It is assumed that a small scale fire breaks out and all the passengers in the metro station need to be evacuated. According to Congling Shi et ale(SHI, 2006), there are few combustible materials in the station, i.e. 5kg petrol. Thus the simulation in this study is conducted under the assumption that there has been arson with 5kg petrol spilled in the metro station.

THE SELECTION OF PARAMETERS

Walking speed is classified into six scales in Exodus, namely out walk, walk, jump, crawl, going upstairs, going downstairs. The exact speed is listed: 1.2~1.5m/s, 1.08~1.35m/s, 0.96~1.2m/s, 0.24~0.3m/s. The speed of going upstairs and downstairs is quoted from the actual measurement in one metro station in Shanghai by Junchi Ma (MA, 2007), Table 1. In the simulation, the number of people to be evacuated is determined by the passenger flow in long-term period (2034). The worst case scenario would be 200 people on the platform, and 1321 arriving passengers on one train, for a total number of 1521 evacuees.

Table 1 The percentage and walking speed of passengers in the Shanghai metro station in terms of age and gender

Person types	Proportion (%)	Upstairs speed (m/s)	Downstairs speed (m/s)
Male (Aged 15 to 29)	24.5	0.54	0.81
Male (Aged 30 to 50)	25.0	0.50	0.69
Male (Aged 51 to 80)	2.5	0.41	0.54
Female (Aged 15 to 29)	24.0	0.51	0.60
Female (Aged 30 to 50)	22.0	0.47	0.53
Female (Aged 51 to 80)	2.0	0.39	0.39

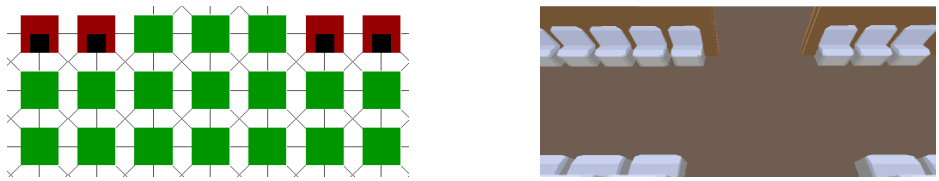

Fig.5 The schematic drawing of chair seat nodes in the model and effect drawing

THE COMPUTATION RESULTS AND ANALYSIS OF THE SIMULATION

A simulated computation geometrical model is set up according to the actual size as in Figure 4. Figure 5 shows the schematic drawing and effect drawing of the nodes of chair seats in the model. Figure 6 is the schematic drawing of the people distribution on the platform and the train before the evacuation.

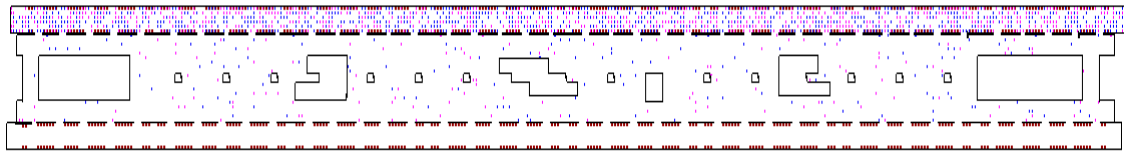

Fig.6 The schematic drawing of the person distribution on the platform

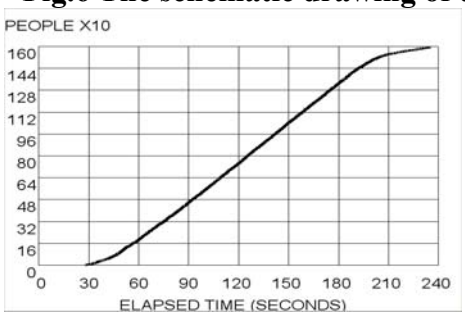

Figure 7 The curve diagram of escaped number against time in the first case under the general circumstances

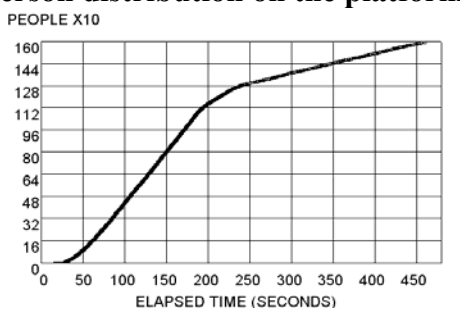

Figure 8 The curve diagram of escaped number against time in the second case under the general circumstances

1. The computation results and analysis of evacuation simulation under general circumstances is classified as follows:

a) In the first case, the 6 staircases in the public area are open to all the people being evacuated who choose the shortest flight route with no external intervention.

The computation results show that it takes 3 minutes and 55 seconds for everyone to be evacuated, as shown in Figure 7. The results are within the code requirements.

b) In the second case, the escalator on the right side of public area is considered closed; the other 5 staircases are open to everyone being evacuated with no external intervention. Item 26.3.3 of Urban Rail Transit Design Standard (DGJ08-109-2004) describes one escalator is likely to be broken down or under maintenance.

The results show that it takes 7 minutes and 30 seconds for everyone to be evacuated, as shown in Figure 8. The results do not meet code requirements. Analysis shows that people tend to choose the shortest flight and the staircase on the right side is heavily congested due to the fact that the escalator on the right side is not available (Figure 9). People using the right staircase are not aware that the middle and left

staircases are not being fully utilized.

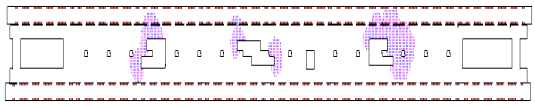

Figure 9 The distribution of people on the platform 2 minutes after the fire breaks out in Case (b) under the general circumstances

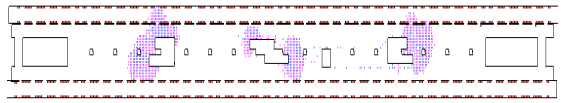

Figure 10 The distribution of people on the platform 2 minutes after the fire breaks out in Case (c) under the general circumstances

c) The third case is similar to the second one. In the third case, when one exit is congested, guidance and intervention is made from the working staff to change some people's flight route to fully use every exit.

Figure 11 shows the people distribution after a 2 minute intervention. The distribution of people in each exit is far more even than that of the second case (Figure 9). The simulation results show that it takes 5 minutes for everyone to evacuate, taking 2 minutes 30 seconds less than in the second case, thus fulfilling the requirement of the code.

2. The computation analysis results of evacuation under disaster is as follows:

In the disaster circumstances, the overall heat release of the fire is 40.3 MW, each second is 1.4MW on average. Assuming that the fire takes place near the pillar (the red part in Figure 11) between the right-side staircase in the middle area and the pillar, and the fire lasts for 1 hour. The fire is simulated by Smartfire 4.1. Figure 11 shows the plan sketch of the computation model. Figure 12 shows the temperature field of the section of Z axis according to the computation results.

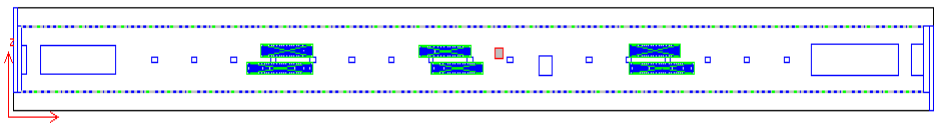

Figure 11 The planar sketch in the Smartfire calculation model

The computation result of Smartfire is introduced in the computation model of Exodus and correlated with the disaster situations in all the modules of Exodus. The computation result shows that the fire risk without heavy fog does not have significant influence on the evacuation result. In this case, with the guidance of working staff and the intervention of flight route, it takes 5 minutes 15 seconds for everyone to evacuate. The simulated result meets the requirements of the codes and no casualties occur in the evacuation.

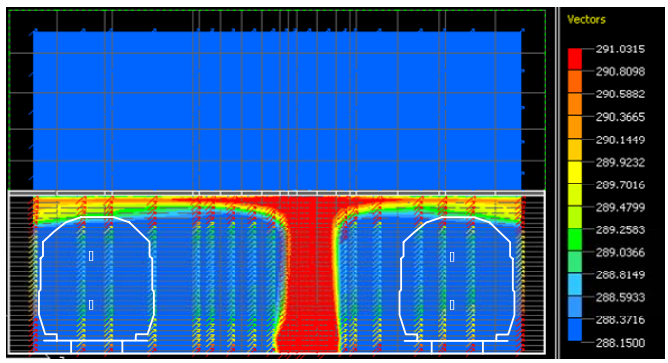

Figure 12 Temperature field in the along z-axis section where the fire breaks up

THE COMPREHENSIVE ANALYSIS OF SIMULATION

According to the analysis of computation results, time needed to evacuate under different circumstances are shown in Table 2.

It is shown from the analysis of different situations that the evacuation time in a metro station meets the requirements of the code. The safe evacuation training of the working staff, regular safety drills, in-time checking and updating of the fire fighting equipment can efficiently prevent major casualty accidents.

CONCLUSION

The conclusion drawn from the computation analysis is listed as follows:

1. Under different risks, people instinctively choose the shortest flight route. Without intervention of people's flight route, the time needed to evacuate is strongly influenced by the use of each exit and distribution of people in the metro station.

Table 2 Time needed to evacuate under different circumstance

Evacuation scene	General scene		Fire scene	
	Immediate evacuation	Immediate evacuation	Immediate evacuation	
Evacuation strategy	All stairs were open; No intervention to evacuation route	One escalator was shut down; No intervention to evacuation route	One escalator was shut down; The evacuation course was intervened	One escalator was shut down; The evacuation course was intervened
Evacuation time	3 minute 55 second	7 minute 30 second	5 minute	5 minute 15 second

2. In evacuation people intuitively choose the shortest route. Some of the exits might not be used at all, while others might be heavily congested. This phenomenon wastes precious time for people to escape. Therefore, intervention must be made to save time, for instance, the rational guidance and intervention from the working staff must be made when one exit is overcrowded.

3. It has been learned from the simulation analysis, that under general circumstances it takes 2 minutes 30 seconds less to evacuate everyone with proper guidance and intervention than without, saving 1/3 of the evacuation time. The result shows the importance of proper guidance.

4. The design of intervention on evacuation route ensures the even use of each exit in evacuation. Proper safety evacuation training of the working staff and rescuers, regular safety drills, in-time checking and updating of the fire fighting equipment can efficiently prevent major casualties.

5. Small scale fire with little fog has little influence on the evacuation. As item 26.5.3 of Urban Rail Transit Design Standard (DGJ08-109-2004) describes, the platform and station hall should be able to resist fire with 1.5MW. In this situation, with proper guidance of the working staff, evacuation can be completed in time.

ABSTRACT

This paper applies the cluster analysis method to categorize the 17 sample companies in a high-tech park in terms of their workshop area. First of all, the annual freight traffic volume per unit workshop area has been used as the index to cluster the 17 sample companies into 4 groups. The results show that each group of companies produces the similar products. Secondly, the workshop area or site area of a company correlates well with its annually generated freight traffic. The regression analysis shows a linear correlation between the workshop area (or site area) of the company and its annual freight traffic volume. These models can be applied to predict the freight traffic volume for the planning high-tech park.

High-tech Park, Freight traffic volume, Regression analysis method, Cluster analysis method

INTRODUCTION

The freight transport constitutes an essential part of the transportation. Together with the passenger transport, the freight transport has become an important component of the urban transportation, which underlies the modern economic and social activities. The research abroad on the freight transport forecasting has started a long time ago. Gregory A. Godfrey and Warren B. Powell proposed the method of the adaptive estimation of the daily demands for the freight transportation using exponential smoothing-based methods (Gregory A. Godfrey, Warren B. Powell, 2000). Then Rodrigo A. Garrido and Hani S. Mahmassani addressed the method of forecasting freight transportation demand with the space–time multinomial probit model in the same year (Rodrigo A. Garrido, Hani S. Mahmassani, 2000). J. Enrique introduced a multi-modal supply–demand equilibrium model for predicting intercity freight flows (J. Enrique Fern_andez L., Joaqu ın de Cea Ch.,Alexandra Soto O., 2003). Peter Nijkamp and his team compared the family of discrete choice models and the neural network model, and the results showed that in general the predictive potential of neural network models is higher than that of discrete analysis (Peter Nijkamp, Aura Reggiani, Wai Fai Tsang, 2004). To meet the demand of recent development in freight transportation industry, Feng Xiao and Hai Yang who work in

Hong Kong University of Science and Technology proposed a game-theoretic model over a freight transportation network (Feng Xiao, Hai Yang, 2007)

The current research in China on the freight transport is relatively insufficient, especially on the freight transport problem of high-tech park. Wang Xiaokun and his team carried out the research on the characteristics and policies of the freight transport in central business district (Wang Xiaokun, Yang Dongyuan, Hu Xiaowen, 2006). Yang Longhai and his team have carried out the research on the forecasting model of freight transportation demand at port free trade zone (Yang Longhai, Zhang Xiqiao, Li Shejiao, Luo Zhaohong, 2007). Liang Chengwen studied the planning method of freight transport in big cities (Liang Chengw, Li Shaoyan, LiuWei, 2008). These above methods and results provide the good reference for this paper.

As we all known, High-tech Park is the cradle of high-tech companies. And the supply and demand goods traffic trips produced by the companies in High-tech Park constitutes a great fraction of the total traffic trips in high-tech park. Normally, there are at least tens of companies, or even more than one hundred companies in a park. And it is unnecessary and impracticable to survey every company in the park in order to find out the patterns of freight traffic trips. From the common sense, the companies whose production categories are similar will have the similar patterns of freight traffic trips. We came out with an idea that we can study the patterns of freight traffic trips in a park by analyzing and investigating the freight traffic trips' related data of some sample companies in the park. Therefore, we randomly picked 17 maturely developed companies as the sample companies for investigating and analyzing the high-tech parks in the city of Changsha in China. This paper establishes the traffic trip prediction model for each category of company after analyzing the freight traffic data of the 17 companies.

1DETERMINATION OF COMPANY ANNUL FREIGHT TRAFFIC VOLUME

The truck is the standard car type among all kinds of freight vehicles to contribute to the traffic volume. Standard parameters of a truck are as following: the normal load of 3~5 ton and the carriage volume of 5~8m^3. From the valid company questionnaires, we can obtain how much a normal-type wagon can load for the various productions and raw materials of the sample companies. So, the annual freight traffic volume of each company can be obtained based on them.

Furthermore, vacant driving can occur during the freight transport. According to the surveys of freight vehicles' load of 17 sample companies, the average vacant driving rate is about 30% among the freight transport in the park. Considering the vacant driving rate, the formula of converted companies' freight traffic volume is:

$$Q = Q_s /(1 - p) \tag{1}$$

Where Q_s represents actual number of car loadings of company's production and raw material; p represents vacant rate of the freight vehicles.

Based on the above analysis, the cruising data of 17 sample companies including their corresponding workshop acre, site acre and production category are shown in Table 1. Each company's annul freight traffic volume is also given by the conversions.

Table 1 annul freight traffic volume on company's unit workshop acre

Company number	Production category	Workshop acre (m^2)	Site acre (m^2)	Annual traffic volume (veh/year)	Annul traffic volume per unit workshop acre (veh/year·100m^2)
1	Cable	5000	12044	22317	446
2	E-apparatus	2183	9392	13759	630
3	Electrical source	2150	10753	4560	212

2 COMPANY ANNUL TRAFFIC VOLUME CLUSTERING ACCORDING TO WORKSHOP ACRE UNIT

2.1 Cluster method and calculation

Usually, the parameters such as "distance" and "similarity coefficient" are used to describe the extent how the samples are similar. In this paper, since there is only one index (variable) in each sample, it's proper to use "distance" to measure the samples' similarity. In the real computing, the formula (2) can be used to compute the distance between samples. That is:

$$d_{ij} = \left| x_i - x_j \right| \tag{2}$$

Where: d_{ij} represents absolute value distance between sample *i* and sample *j*; x_i and x_j are the value of index of sample number *i* and sample number *j*.

After deciding computing model of samples' distance, we still need to choose the method for specific cluster computing. Considering the conditions of the samples and their indexes in the real life, we decide to take the shortest distance cluster method.

This method defines the distance as the shortest distance among all the pairs between the two categories, and that is:

$$D_{KL} = \min_{i \in G_K, j \in G_L} d_{ij} \tag{3}$$

Where: D_{KL} represents the distance between category G_K and category G_L.

From the above cluster analysis and formula, the cluster result of 17 sample companies can be obtained as Figure 1.

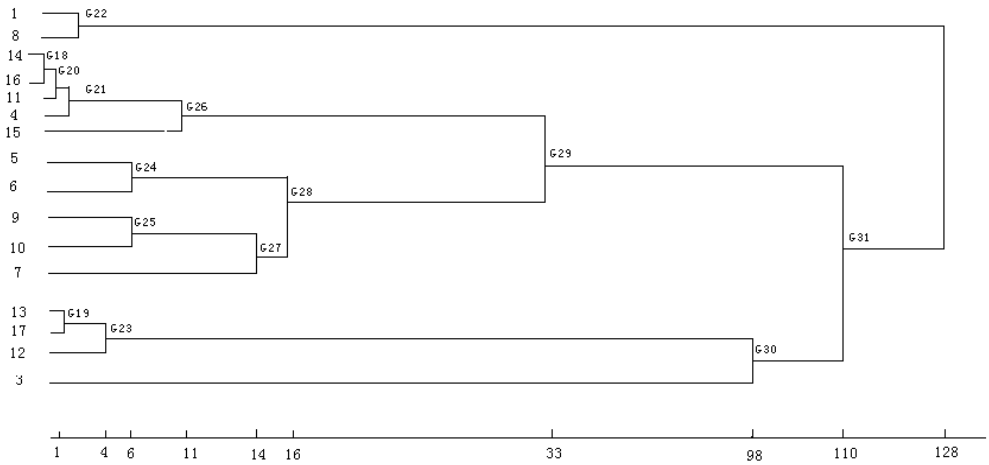

Figure1 Cluster tree figure of 17 sample companies according to freight traffic volume.

Notes: Vertical coordinate represents company number, horizontal coordinates represents the distance between categories.

2.2 The number of category ascertaining

The above cluster result provides how close samples are related to each other, but we still need to determine the number of samples in each category. So the parameter, R^2 statistic in cluster analysis, can be used to decide the number of the cluster category.

In cluster analysis, the expression of R^2 statistic is:

$$R^2 == \frac{\sum_{i=1}^{k} n_i (\bar{x}_i - \bar{x})^2}{\sum_{j=1}^{n} (x_j - \bar{x})^2} \tag{4}$$

Where: n represents the total sample number; k represents k kinds of categories the samples are merged to when clustering; n_i represents the sample number of

category G_i in k categories; $\bar{x}$ represents total gravity of the samples; $\bar{x}_i$ represents gravity of category sample; x_j represents the sample index.

According to formula (4), the value of R^2 corresponding to the cluster at each turn and the number of category can be calculated, as shown in Table 2.

Table 2 Relationship between clustering number and the value of R^2

Clustering	1	2	3	4	5	6	7	8	9	10	11	12
Cluster number	G_{18}	G_{19}	G_{20}	G_{21}	G_{22}	G_{23}	G_{24}	G_{25}	G_{26}	G_{27}	G_{28}	G_{29}
Integrating times	0	1	1	2	3	4	6	6	11	14	16	33
R^2	0.9996	0.9997	0.9997	0.9994	0.9988	0.9988	0.9990	0.9989	0.9982	0.9979	0.9963	0.9779

If we plot the times and the corresponding R^2 in Table 2 on a graph, we can see a turning point of the curve at 11 times, which can be used to decide the number of samples in the clustering category. From Table 2, at 11 clustering times, the cluster distance is 16veh/（year·100m^2)

According to this integrating distance, cluster tree in figure 1 is integrated, and the annul freight traffic volume per unit workshop acre produced by 17 companies in Table 1 can be divided to four categories. They are:G_{26}(4 machine manufacture, 11 machine manufacture, 14 machine manufacture, 15 electromechanical manufacture, 16 battery); G_{28} (5 rubber goods, 6 light car fitting, 7 cash register, 9 chemical fiber, 10 plastic); $G_{23,3}$ (3 electrical resource, 12 medicine, 13 biology, 17 electron); $G_{22,2}$ (1 cable, 2 E-apparatus, 8 material).

3 ESTABLISHMENT OF ANNUL FREIGHT TRAFFIC VOLUME PREDICTION MODEL OF EACH CATEGORY OF COMPANIES

Based on the four categories mentioned above, we can establish the regression model about annul freight traffic volume Q_n and company's workshop acre S_1. Taking the companies in G_{26} as an example: G_{26} consists of 5 companies with the numbers of (4, 11, 14, 15, 16). Table 1-1 already showed the annual freight traffic volume and workshop acre of the 5 companies. If we draw the data on the graph, we can see a linear trend of them and fit them with a linear line. With the mathematical theory of statistic, we can obtain linear regression model about Q_n and S_1. The linear regression models about Q_n and S_1 for other categories of companies can be established in a similar way, as shown in Table 3. Although the site acre is not as closely related to the production and raw material as the workshop acre, the acre of site is more commonly used than the workshop acre. Qualitatively, the company site acre is directly proportional to the workshop acre. So, the regression model about the site acre S_2 and the annual freight traffic volume of each category of companies is also established with the same method, as shown in Table 3.

Table 3 Regression model about company workshop acre, site acre and annul freight traffic volume of each category

Category	$G_{23,3}$	G_{26}	$G_{22,2}$	G_{28}
Regression model about S_1 and Q_n	$Q_n=1.43S_1$ - 1504	$Q_n=0.27S_1$ - 1126	$Q_n=3.29S_1$+ 6419 r=1.00	$Q_n=0.72S_1$ - 368
Regression model about S_2 and Q_n	$Q_n=0.39S_2$+ 100 r=0.90	$Q_n=0.11\ S_2$ - 2104 r=0.92	$Q_n=0.03S_2$+ 17714 r=0.76	$Q_n=0.09\ S_2$ - 1073 r=0.98

Notes: S_1, S_2 represents workshop acre and site acre of each company (m^2)

From Table 3-1, the variables Q_n and S_1, S_2 in most categories are interrelated well with the related coefficient r above 0.90 (r=0.90), except that company site acre and its corresponding annul freight traffic volume in category $G_{22,2}$ doesn't interrelate well. In general, the workshop acre is better interrelated to the annul freight traffic volume than the site acre.

4 APPLICATIONS

4.1 Application instance

We can analyze an application as following. The total area of the industrial estate in a high-tech park in Changsha is 2,985,192m^2. 11.89%(354,857m^2) of the area is $G_{23,3}$, 48.39%(1,444,483m^2) is G_{26}, 29.35%(876,210m^2) is $G_{22,2}$ and 10.37%(309,642 m^2) is G_{28}. According to the formula in Fig. 3-1, the annual freight traffic volume of the present area of every category estate and the total industrial estate can be calculated respectively: 138,494veh, 156,789veh, 44,000veh, 26,795veh and 366,078veh.

Let's assume that the total area of the industrial estate of a planning high-tech park is 6.06km^2. Assuming that the structure of the industrial estate doe not change, each category area can be calculated by the current proportion: the area of $G_{23,3}$ is 721,033.38m^2, the area of G_{26} is 2,934,466.38m^2, the are of $G_{22,2}$ is 1,779,842.7m^2 and the area of G_{28} is 628,857.54m^2. According to the formula in Fig.3-1, the annual freight traffic volume of each category estate and the total industrial estate can be calculated respectively: 281,303veh, 320,687veh, 71,109veh, 55,524veh and 728,623veh.

Based on the above analysis, the freight traffic volume caused by industrial estate in the high-tech park is considerably limited. The current industrial estate area (2.99 km^2) and the planning area (6.06km^2) can only generate the freight traffic volume of 1,003pcu and 1,996pcu respectively. The investigation of the present road network in the high-tech park show that even in the peak hours, the average traffic flow on the road network is only 0.1. And the freight traffic volume (converted to car traffic volume) only constitutes 21% of the total traffic. Therefore, the current road network has enough room for the planning high-tech park. The above analysis will be helpful when planning new high-tech parks.

5 CONCLUSIONS

For the companies whose production category is similar, their annul freight traffic volume produced per unit workshop acre is comparably close; and for the companies whose production category differs, their annul freight traffic volume produced per unit workshop acre also differs.

For the companies whose production category is similar, the workshop acre or site acre of the company correlates well with the annul freight traffic volume produced by the company, so a model can be established to predict the annul freight traffic volume of this category of companies.

After establishing the prediction model of the freight traffic volume, the freight traffic volume of the companies in a planning High-tech Park can be forecasted, and the model can offer the quantitative analysis for the network planning and traffic control in the park.

Bending Vibration Suppression of High Speed Railway Passenger Car Body

Caihong Huang[1], Jing Zeng, and Ren Luo

[1]Traction Power State Key Laboratory, Southwest Jiaotong University, Chengdu, 610031, China; PH (+86)13402834910; email: rainbow.huang@tom.com

ABSTRACT

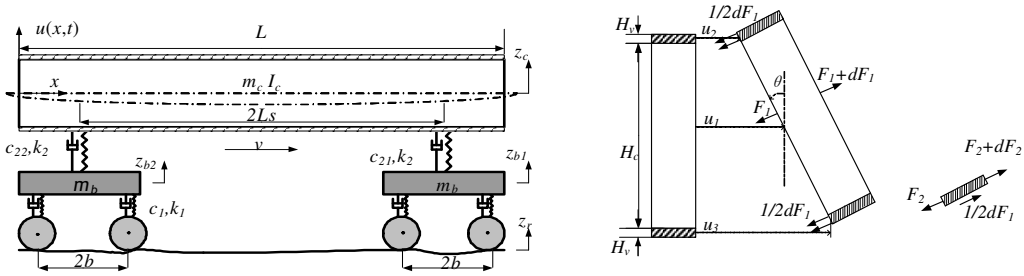
Vertical dynamic response of a high speed passenger car considering elastic vibration has been investigated, in which car body is modeled as a simple uniform elastic Euler-Bernoulli beam with free ends. It is found that vibration in the elastic model is bigger than in the rigid one. In order to reduce the vertical flexural vibration, an effective and practical method is introduced, which is to paste free damping layers on the outside sheathing of the car body. The calculations show that it is a useful measure for improving the riding comfort of the high speed car. The thicker the damping materials attached, the better the ride comfort will be. But considering the weight it may introduce, only 3mm bitumen based damping materials is enough to get a satisfactory result.

INTRODUCTION

To increase train speed, railway vehicles have become increasingly lightweight in recent years. However, it decreases car body stiffness excessively, leading to serious bending vibration in the vertical direction and deteriorating the ride comfort (Takigami and Tomioka 2008). Therefore, it is important to investigate methods to reduce bending vibration with a view to improve riding comfort. Vibration characteristics of the rigid car body and elastic car body are discussed in this paper, the results of which show that first bending mode of vibration has a great influence on the riding comfort of a lightweight car body. To solve this problem, a simple and practical way is suggested which is to increase the structural damping by pasting free damping layers on the outside sheathing of the car body.

MODELING

Vertical model of the high speed car is given in Figure 1(a). It is considered as a rigid-flexible coupling system composed of wheelsets, bogie frames, car body, primary suspension and secondary suspension. The car body is modeled as a simple Euler-Bernoulli beam in consideration of only vertical vibration. The parameter values given in Appendix A are typical for a high speed car.



(a) Passenger car (b) Force and geometric relations

Figure 1. Passenger car model.

Assuming the car body as a uniform elastic beam with free ends (Zeng et al. 2007), equation (1) hold for the vertical displacement of vehicle systems.

$$\begin{cases} m_c\ddot{z}_c + \sum_{i=1}^{N} m_{zi}\ddot{q}_i + c_{21}[\dot{z}_c + \dot{u}(x_1,t) - L_s\dot{\theta}_c - \dot{z}_{b1}] + c_{22}[\dot{z}_c + \dot{u}(x_2,t) - L_s\theta_c - \dot{z}_{b2}] \\ \quad + k_2[2z_c - z_{b1} - z_{b2} + u(x_1,t) + u(x_2,t)] = 0 \\ I_c\ddot{\theta}_c - \sum_{i=1}^{N} m_{\theta i}\ddot{q}_i + c_{21}L_s[L_s\dot{\theta}_c - \dot{u}(x_1,t) + \dot{z}_{b1}] + c_{22}L_s[L_s\dot{\theta}_c + \dot{u}(x_2,t) - \dot{z}_{b2}] \\ \quad + k_2L_s[2L_s\theta_c + z_{b1} - z_{b2} - u(x_1,t) + u(x_2,t)] = 0 \\ m_b\ddot{z}_{b1} + 2c_1\dot{z}_{b1} + c_{21}[\dot{z}_{b1} - \dot{z}_c - \dot{u}(x_1,t) + L_s\dot{\theta}_c] + (2k_1 + k_2)z_{b1} \\ \quad - k_2[z_c + u(x_1,t) + L_s\theta_c] = c_1[\dot{z}_r(t) + \dot{z}_r(t-\tau_1)] + k_1[z_r(t) + z_r(t-\tau_1)] \\ m_b\ddot{z}_{b2} + 2c_1\dot{z}_{b2} + c_{22}[\dot{z}_{b2} - \dot{z}_c - \dot{u}(x_2,t) - L_s\dot{\theta}_c] + (2k_1 + k_2)z_{b2} \\ \quad - k_2[z_c + u(x_2,t) - L_s\theta_c] = c_1[\dot{z}_r(t-\tau_2) + \dot{z}_r(t-\tau_3)] + k_1[z_r(t-\tau_2) + z_r(t-\tau_3) \\ \ddot{q}_i(t) + \eta_i\omega_i\dot{q}_i(t) + \omega_i^2 q_i(t) = -m_{zi}\ddot{z}_c(t) + m_{\theta i}\ddot{\theta}_c(t) + \sum_{i=1}^{2} F_k(t)Y_i(x_k) \end{cases} \tag{1}$$

where:

$$\begin{cases} \omega_i = \dfrac{(2i+1)^2\pi^2}{4L^2}\sqrt{\dfrac{EI}{\rho A}} \\ Y_i(x) = A_iU_i(x) = A_i\left[ch\beta_i x + \cos\beta_i x - \dfrac{ch\beta_i L - \cos\beta_i L}{sh\beta_i L - \sin\beta_i L}(sh\beta_i x - \sin\beta_i x)\right] \\ \beta_i = \dfrac{(2i+1)\pi}{2L},\ \ A_i = 1/\sqrt{\rho A\int_0^L U_i{}^2(x)dx} \\ F_k(t) = -c_2[\dot{z}_c(t) + \dot{u}(x_k,t) + (-1)^k L_s\dot{\theta}_c - \dot{z}_{bk}(t)] - k_2[z_c(t) + u(x_k,t) + (-1)^k L_s\theta_c - z_{bk}(t)] \\ m_{zi} = \rho A\int_0^L Y_i(x)dx\ ,\ \ m_{\theta i} = \rho A\int_0^L (x - \dfrac{L}{2})Y_i(x)dx \\ \tau_1 = 2b/v,\quad \tau_2 = 2L_s/v,\quad \tau_3 = 2(b+L_s)/v \end{cases} \tag{2}$$

where: z_{b1}, z_{b2}, z_c, θ_c represent front frame translation, rear frame translation, carbody translation and pitching. $q_i(t)$ is modal coordinate of the car body flexible

deformation. $x_k=L/2-(-1)^k L_s$, k=1 (Front bogie), k=2 (Rear bogie). η_m is loss factor of car body in the m order modal.

VIBRATION MODE ANALYSIS

In order to investigate which modal is the main modal resulting in the car body elastic vibration, the vibration modal of the car is shown in Figure 2. Considering the track irregularities, amplitude frequency curve in the car body center under various conditions is given in Figure 3. Vibration in the elastic model is bigger than in the rigid one. Moreover, there exists resonance near 9.7Hz which is first bending mode of car body. Because there exists a vibration node of second bending mode in the car body center, it has little influence in the elastic vibration. As to the third vibration mode, it is contrary to the first mode in the center so it also has little influence in the elastic vibration in the center, only has influence in the high frequencies. So the first bending mode is the main mode which needed to be suppressed.

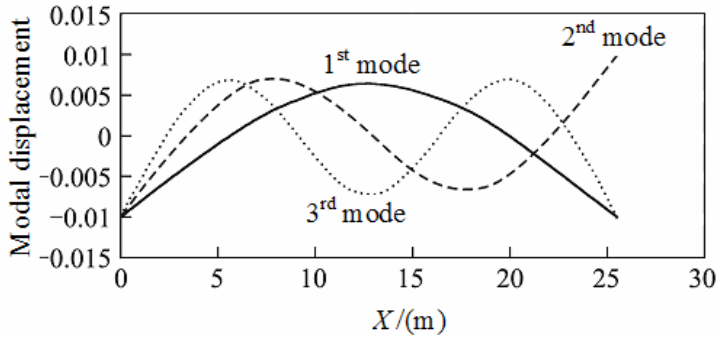


Figure 2. Vibration modal.

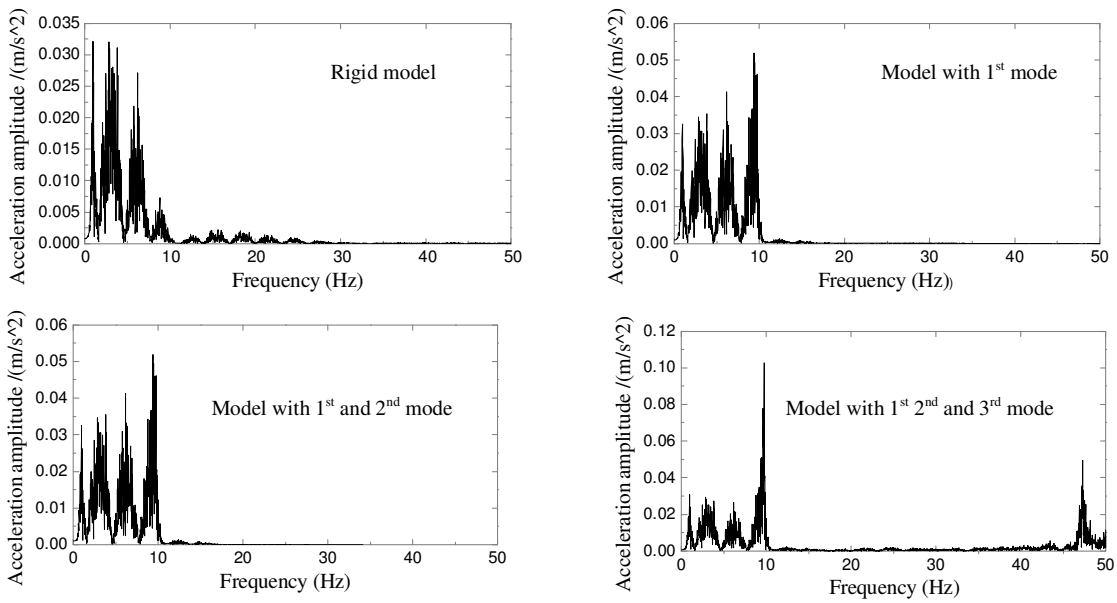

Figure 3. Vertical acceleration of car body center in the frequency domain

Vibration suppression with free damping treatment. As the natural frequency of the first bending mode of car body is the main reason contributing to the elastic vibration, free damping layers can be pasted on the outside sheathing of the car body to increase the internal damping to improving the riding comfort of the high speed car, as is shown in Figure 1.

The displacement field is based on the following hypothesis:

- Flexural vertical displacement field is the same in all parts of the section;
- There is no slip between the different materials;
- Shear stresses are ignored.

Because of the previous hypothesis, the strain energy per length is composed of two terms: traction-compression and flexure of the elastic and viscoelastic parts (Zhao et al. 1990). They have the following expressions:

$$W_{ext}{}^{i} = \frac{1}{2} E_i A_i \left| \frac{du_i}{dx} \right|^2 , \quad W_{fl}{}^{i} = \frac{1}{2} E_i I_i \left| \frac{d^2 y_i}{dx^2} \right|^2 = \frac{1}{2} E_i I_i \left| \frac{d\theta_i}{dx} \right|^2 \tag{3}$$

where, u_i、y_i and θ_i represents the longitudinal displacement、flexural displacement and rotating angle of material i respectively. Under the free damping layers treatment, $\theta_i=\theta$; E_iA_i represents tension stiffness，E_iI_i represents bending stiffness. If the relationship between θ and u_i is given, it is easy to calculate the total strain energy. Assuming θ is harmonic, namely $\theta=\underline{\theta} cos(\beta x)$. If the boundary effects is ignored, $u_i=R_i\theta$ can be got, Where, R_i is called tension effect.

Because the strain energy is different in the full wavelength, strain energy density must be got to calculate the loss factor.

$$W_{extm}{}^{i} = \frac{1}{\lambda} \int_0^{\lambda} W_{ext}\, dx = \frac{\beta}{2\pi} \int_0^{\frac{2\pi}{\beta}} \frac{1}{2} E_i A_i \left| \frac{du_i}{dx} \right|^2 dx = \frac{1}{4} E_i A_i R_i{}^2 \underline{\theta}^2 \beta^2 \tag{4}$$

$$W_{flm}{}^{i} = \frac{1}{\lambda} \int_0^{\lambda} W_{fl}\, dx = \frac{\beta}{2\pi} \int_0^{\frac{2\pi}{\beta}} \frac{1}{2} E_i I_i \left| \frac{d^2 y_i}{dx^2} \right|^2 dx = \frac{1}{4} E_i I_i \underline{\theta}^2 \beta^2 \tag{5}$$

A usual definition of damping is given by the ratio between the dissipated and the strain energies. So, Loss factor of car body with free damping layers is shown in Equation (6):

$$\eta_{\mathrm{m}} = \frac{\sum_{\mathrm{i}=1}^{3} \eta_{mi} (W_{extm}{}^{\mathrm{i}} + W_{flm}{}^{i})}{\sum_{\mathrm{i}=1}^{3} (W_{extm}{}^{\mathrm{i}} + W_{flm}{}^{i})} = \frac{\sum_{\mathrm{i}=1}^{3} \eta_{mi} (E_i A_i R_i{}^2 + E_i I_i)}{\sum_{\mathrm{i}=1}^{3} (E_i A_i R_i{}^2 + E_i I_i)} = \frac{\eta_{m1} (E_1 A_1 R_1{}^2 + E_1 I_1) + 2\eta_{m2} (E_2 A_2 R_2{}^2 + E_2 I_2)}{(E_1 A_1 R_1{}^2 + E_1 I_1) + 2(E_2 A_2 R_2{}^2 + E_2 I_2)} \tag{6}$$

R1 and R2 can be got by the force and geometric relations, as is shown in Figure 1(b).

As self-adhesive type of bitumen-based damping sheet is cheap and

convenient to be used especially to suppress large areas of the shell vibration, it is particularly suitable damping materials in the rolling stocks. Its dynamic characteristics are shown in Figure 5 (Zhang 1994).

To reduce the elastic vibration, two free damping layers are pasted on the outside of the car body. With the damping treatment, the relation between loss factor and thickness is shown in Figure 6.

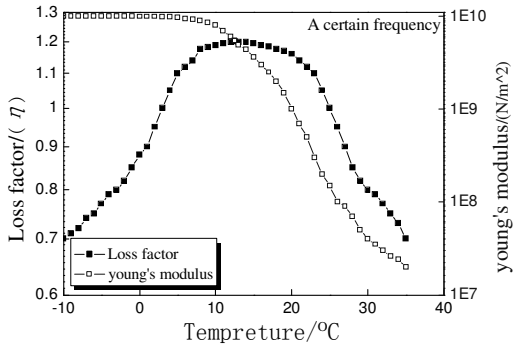

Figure 5. Dynamic characteristics.

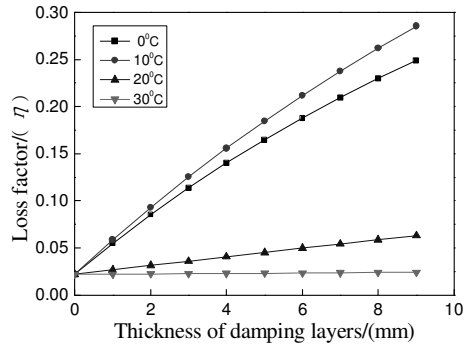

Figure 6. Loss factor and thickness.

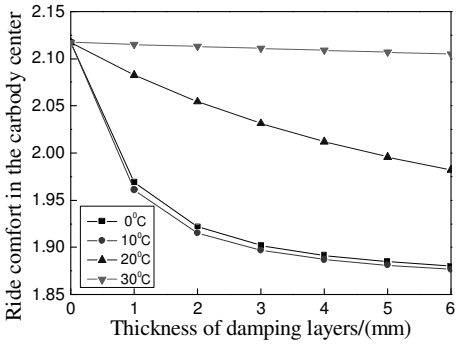
As is shown in the picture, loss factor increases with the increase of the thickness. But considering the weight it may introduce, ride comfort running at the speed of 220km/h is analyzed in Figure 7. As is shown in Figure 7, 3mm is enough, namely, only 700kg is introduced in the weight.

Running at the speed of 220km/h and with a damping thickness of 2mm, the relationship between acceleration amplitude and frequency in the car body center is shown in Figure 8. The first bending vibration near 9.7Hz is suppressed successfully. In the normal temperature, a better result will be got, while in the high temperature it is not so effective.



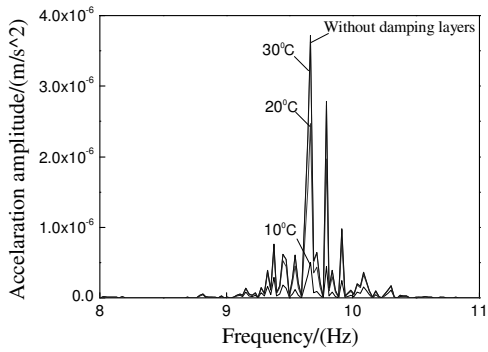


Figure 7. Ride comfort and thickness. Figure 8. Acceleration amplitude.

CONCLUSIONS

After careful analytic analysis and numerical calculating, the conclusions can be drawn as below:

(1) Vibration in the elastic model is bigger than in the rigid one, which is close to the real working condition.
(2) The first bending mode is the main mode which needed to be suppressed.
(3) The first bending vibration is suppressed successfully by the free damping treatment. In the normal temperature, a better result will be got, while in the high temperature it is not so effective.
(4) 3mm is enough, namely, only 700kg is introduced in the weight.

ABSTRACT

Determining deformable location, size, and depth of vehicle is important during the process to reason a road accident. The use of close-range stereo photogrammetry in traffic accident scene investigations is vital for providing such information in more detail comparing with traditional methods. A case study is introduced to verify the method using the paralleling axis stereo vision theory, which provides accurate three-dimensional (3D) coordinates of the deformation-related feature points, and describes the location and the range of the vehicle deformation.

INTRODUCTION

Recording vehicle deformation parameters is important in traffic safety studies, in which the location and range of the vehicle deformation would be obtained for simulating the real accident site and determining the cause of the accident. It is a key element of traffic scene investigations, which involve deformation location, range, and depth. Close-range photogrammetry survey might provide the 3D coordinates of the collision part by recording the deformation location and range.

In related fields, a series of studies on improving traffic scene accident investigations using close range photogrammetry are carried out. One important element discussed in these studies is vehicle deformation measurement. In China, similar research papers are published. For example, Lu (2006) described a method for the reconstruction of vehicle deformation using self calibration, which is a valuable tool for measuring vehicle deformations. The research would continue enriching the theory. The paralleling axis stereo vision theory is adopted to conduct the photogrammetric survey of vehicle deformations. The deformation data are analyzed, the deformation feature locations are obtained, and the deformation depth is calculated.

CLOSE-RANGE PHOTOGRAMMETRIC THEORY

The main concept of close-range photogrammetric theory is to realize the measurement on a small scale model by simulating the eye function in the nature. The

core of close-range photogrammetry is to simulate the stereo vision and discussing the coordination transformation problems among different coordinate systems. Common 3D coordinate systems are revolved during the procedure. These systems are image coordinate system, camera coordinate system, and global coordinate system.

Image coordinate system. The image coordinate system is defined on the image, (u, v) is recorded by pixel unit, (x, y) is recorded by physical unit. O_1 is (x, y) system's origin, and is the intersection point of the camera optic axis and the image flat, x axis and y axis respectively parallels u axis and v axis. If O_1's coordinate is (u_0, v_0) in the (u, v) coordinate system and the relative physical coordinate is (dx, dy), the formula (1) is obtained

$$\begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \begin{bmatrix} \frac{1}{dx} & 0 & u_0 \\ 0 & \frac{1}{dy} & v_0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} \tag{1}$$

Transformation between camera and global coordinate systems. The origin of the camera coordinate system O_1 is at the camera's optic center, X_c axis and Y_c axis respectively parallels x axis and y axis, Z_c axis is the camera's optic axis, which is perpendicular to the image flat, the intersection point of the camera optic axis and the image flat is (x, y) system's origin O_1, OO_1 is the effective camera focus f. The global coordinate system is viewed as the application coordinate system, which shows the location of the real objects.

If (X_w, Y_w, Z_w, 1) is in the global coordinate system and (X_c, Y_c, Z_c, 1) is in the camera coordinate system, then their relationship is given by the formula (2), where R is the rotation matrix (3×3), $R = R_\alpha R_\beta R_\gamma$; T is a position vector, $T = (T_x, T_y, T_z)$

$$\begin{bmatrix} X_C \\ Y_C \\ Z_C \\ 1 \end{bmatrix} = \begin{bmatrix} R & T \\ 0 & 1 \end{bmatrix} \begin{bmatrix} X_W \\ Y_W \\ Z_W \\ 1 \end{bmatrix}, \tag{2}$$

Coordinate calculation using theory of parallel axis stereo vision. As shown in Figure 1, the image flats of C_l, C_r are i_L and i_R, and $I_l(u_l^0, v_l^0)$, $I_r(u_r^0, v_r^0)$ are the centres of i_L and i_R, where I_l is the origin of the coordinate system. The coordinates of P are (X, Y, Z), whose projection in the left image pixel coordinate system is P_l (x_l, y_l), in the right image pixel coordinate system is P_r (x_r, y_r), and baseline length is b.

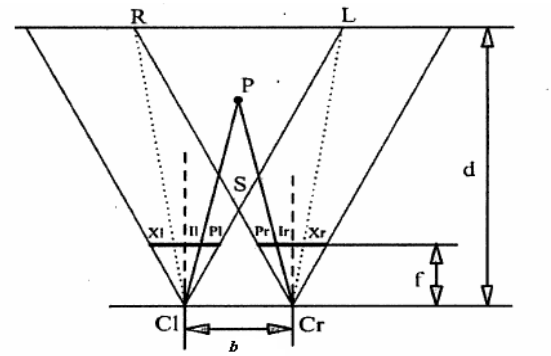

Figure 1. Parallel axis stereocopic vision

According to the perspective projection principle, then

$$\begin{cases} \dfrac{Z-f}{f}=\dfrac{X_l}{x_l}=\dfrac{Y_l}{y_l} \\ \dfrac{Z-f}{f}=\dfrac{X_r}{x_r}=\dfrac{Y_r}{y_r} \end{cases} \tag{3}$$

$$\begin{cases} \begin{pmatrix} x_l \\ y_l \\ z_l \end{pmatrix} = M \begin{pmatrix} X \\ Y \\ Z \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ -f \end{pmatrix} \\ \begin{pmatrix} x_r \\ y_r \\ z_r \end{pmatrix} = M \begin{pmatrix} X \\ Y \\ Z \end{pmatrix} + \begin{pmatrix} b \\ 0 \\ -f \end{pmatrix} \end{cases} \tag{4}$$

Using the formulas (3) and (4), the formula of the parallel axis stereo vision can be obtained as

$$\begin{cases} X = b\dfrac{x_l}{x_l - x_r} \\ Y = b\dfrac{y_l}{x_l - x_r} \\ Z = \dfrac{bf}{x_l - x_r} \end{cases} \tag{5}$$

ELEMENTS OF COLLISION VEHICLE DEFORMATION ANALYSIS

There are many collision forms of road accidents, such as a vehicle hitting a pedestrian, a vehicle hitting a bicycle, a vehicle hitting a fixed object, and multiple vehicle collisions.. While the vehicle collides with another vehicle or object, since the motion inertia is blocked at the moment, vehicle deformation would occur. The location of the vehicle collision can be used to determine the accident cause. After stereo matching of close-range photogrammetry in road accident scene investigations,

the 3D coordinates of the vehicle deformation feature points will be calculated basing on the theory of close-range photogrammetry. Then, deformation analysis could be subsequently performed. The main analysis includes collision location analysis, collision deformation range and shape analysis, and collision deformation depth analysis.

Collision location analysis. The outcome of the collision location analysis may be applied to ascertain the relative touching position and the touching angle of the accident vehicles at the moment that the collision occurs. By choosing some deformation border characteristic points to perform the stereo matching and using the close-range photogrammetric coordinate transformation principle the 3D space coordinates of those points can be calculated. These coordinates are comparatively analyzed with the whole border of the vehicle to determine the collision location on the vehicle body and analyze the vehicle collision parts.

Collision deformation range and shape analysis. The size of accident vehicle deformation range depicts the size of the mutual bumping area where the accident vehicle deformation depth reaches the maximum. The deformable shape demonstrates the space distribution of the impact force at the collision moment. The deformation border characteristic points of the accident vehicle obtained by coordinate calculations can be jointed as a deformation boundary line, which can clearly describe the deformable range and shape of the accident vehicle.

Collision deformation depth analysis. The collision deformation depth of the accident vehicle demonstrates the degree of severity of the collision. It can reflect the degree of the collision action, together with the original stiffness of the collision parts. This has a significant input to the deformation model that determines the collision speed of the accident vehicle on the stiffness—deformation value. But only by measuring and calculating the 3D space coordinates of the deformation characteristic points by the close-range photogrammetry can the accident vehicle collision deformation depth data be determined. To determine these data, the following tasks should be undertaken: (a) choose the deformation characteristic points within the deformation range of the accident vehicle, (b) perform the close-range photogrammetric analysis and calculate the coordinates of the characteristic points using relative transformation, (c) select a fine vehicle that has the same type as the accident vehicle as the contrasting object, abstract the matching feature points, and obtain the corresponding coordinates by the same method, (d) change the two coordinate systems into one coordinate system, and (e) comparatively analyze the coordinates of each pair of characteristic points, and determine the average value of the deformation depths.

CASE STUDY

In a collision on some city road, a black car was crossing the main road of the city from the north to the south, while a red minibus was moving at full speed from the west to the east on the main road. The two vehicles bumped into each other, both drivers not paying enough attention. The black car crashed greatly and the red microbus head was damaged slightly. The black car's deformation is obvious and is representative. Thus, the black car is selected for the deformation analysis. Some stereo images are shot as shown Figure 2.

Figure 2. Stereo images of the black car involved in the accident

The vehicle deformation characteristic analysis process using close-range photogrammetry is as follows. First, the camera model calibration is accomplished (see Table 1), providing the camera model's inner elements. Then, the sign board is put down around the black accident vehicle, which will give the calibrating sizes and provide the self-definition coordinate on the scene. Subsequently, the model's outer elements are obtained at the same time. The stereo images are shot (see Figure 1). Making use of the stereo images, the matching coordinate data are abstracted with the help of the filter procedure and the stereo matching procedure. Finally, the coordinate system is changed into the defined coordinate system using the parallel axis stereo vision with the inner elements and the characteristic points' space coordinates are recomputed by the close-range photogrammetric coordinate calculation methods.

Table 2 is the result of the coordinate calculations, representing the space location of vehicle deformation characteristic point. The 3D data model (shown in Figure 3) demonstrates the space location and the shape of the vehicle deformation characteristic points. The fine vehicle of the same type as the accident vehicle is selected as a contrast. Noting the relative characteristic points in contrast with the accident vehicle deformation characteristic points, it applies the photogrammetric method to calculate the 3D coordinates of those points (see Table 3). Then, MATLAB was used to demonstrate the measurement results (Figure 4 displays the location of the contrasting fine vehicle feature points). Then, different coordinates are transformed into the same system, and every collision point's deformation depth is calculated (see Table 4). Finally, the average deformation depth is determined as 0.143 m.

This case study indicates that using the close-range photogrammetry for analyzing the deformation vehicle in the traffic accident scenes is feasible. This analysis can provide vehicle deformation space location and range description of the accident vehicle. This surveying pattern provides a new look at collision vehicle deformation studies.

CONCLUSIONS

Based on the coordinates of the 3D stereo images of the accident vehicle, it applies the photogrammetric principles to carry out the vehicle deformation characteristic point reconstructions and applies the relevant methods to perform the deformation analysis. This provided a new method to analyze the vehicle deformation that could describe in detail the vehicle deformation information about space position and deformation range.

Abstract: In order to evaluate traffic safety level in the 30 provincial capital cities (except Lhasa) of China, the correlation between the number of traffic accident fatalities and social-economic factors were analyzed. It shows that the number of traffic accident fatalities in the provincial capitals cities of China is markedly correlative with the gross regional product (*GRP*), population, passenger traffic, and freight traffic. According to the correlation, six feasible evaluation indices were put forward, including fatalities per 100000 people population, fatalities per 100 million GRP, passenger traffic fatalness, freight traffic fatalness, fatalities per accident, and mortality of traffic accident. Then they were transformed into four uncorrelated principal components based on principal component analysis. Finally, the four principal components were used to estimate the evaluation score of traffic safety level for the 30 provincial capital cities. The 30 provincial capital cities were ranked by road safety level. The results show that the differences in road safety among the 30 provincial capital cities were comparatively distinct in 2006.

Key words: traffic safety; provincial capital; correlation; comprehensive assessment; principal component Analysis

1 Introduction

Traffic accident has become one of worldwide hazards. The number of traffic accident fatalities in China has ranked No.1 in the world since late 1980s even though it has been declining for 6 years since 2003. The total number of traffic accident fatalities was about 73,484 in 2008 in China. In China, traffic safety has become one attention-getting issue and reducing traffic accident fatalities is still positioned as one of top-ranking national policies. In particular, the provincial capital cities are where traffic safety issues are correspondingly serious in provincial regions. So improving the road traffic safety level for the provincial capital cities is very important in China.

The past experiences have proved that traffic safety evaluation is very important to search for key issues and improve the road safety level. Accordingly, many researchers have dedicated to find new methods for traffic safety evaluation, the remarkable research findings include the synthetic evaluation model (Liu Tao, 2005),

AHP method (Wu Yihu, 2006), evaluation model based on gray theory (Niu Huiyon, 2005), evaluation method based on the theory of fuzziness (Ning Shoude, 2003), evaluation method based on BP artificial network (Yang Tianjun, 2005), and comprehensive method (Peng Junlong, 2005). These models and methods are important for road safety evaluation. However, there are some limitations that restrict their further application. For instance, the correlations between the evaluation indices were neglected; and the weights and classification of evaluation indices were determined by the researcher's subjective experience and preferences.

Principal component analysis (*PCA)* method can transform correlative evaluation indices into uncorrelated principal components that are not confined by the user's subjectivity. This paper attempts to put forward the evaluation indices for the road traffic safety in the 30 provincial capital cities of China, and to evaluate their traffic safety level based on *PCA*. Finally, a precise ranking of the 30 provincial capital cities in 2006 was given based on traffic safety level.

2 Principle of principal component analysis

In general, when evaluation indices are more than two, some of them are likely correlated so that the information of evaluation indices is used repeatedly and the validity of the valuation is impaired. *PCA* can transform such evaluation indices into lesser-uncorrelated composite indices, and utilize the latter to synthetically evaluate road traffic safety without much loss of information.

When setting n evaluation objects and selecting p evaluation indices x_i, $n \times p$ data matrix X is constructed below.

$$X = \begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1p} \\ x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & \vdots & \vdots \\ x_{n1} & x_{n2} & \cdots & x_{np} \end{bmatrix}$$

where x_{ij} is the jth evaluation indices value of the ith objects, i=1,2...,n; and j=1,2...,p.

The matrix X can be transformed into matrix Y, where

$$\begin{cases} y_1 = l_{11}x_1 + l_{12}x_2 + \cdots + l_{1p}x_p \\ y_2 = l_{21}x_1 + l_{22}x_2 + \cdots + l_{2p}x_p \\ \vdots \\ y_m = l_{m1}x_1 + l_{m2}x_2 + \cdots + l_{mp}x_p \end{cases}$$

of which x_i and y_i are the columns of X and Y respectively, the principal components y_1, y_2, ..., y_m ($m \le p$) are those uncorrelated linear combinations whose variances are as large as possible.

The first principal component is the linear combination with maximum variance $Var(y_i)$, the second principal component is the linear combination with second maximum variance, etc. The primary task of *PCA* is to ascertain coefficient l_{ij}, then y_1, y_2, ..., y_m can be used to evaluate the objects as composite indices.

3 Selection of the evaluation indices

3.1 Correlations analysis

The evaluation indices must be measurable, comparable and uncorrelated. Before the selection of the evaluation indices, the correlation between the number of traffic accident fatalities and socio-economic factors is analyzed by the statistical data set over a 17-year period (1990-2006) of China. The Pearson correlation coefficients （R）range from 0.799 to 0.933, and the probabilities of significance (Sig.) are less than the level of significance 0.01 in Tab.1, the number of traffic accident fatalities is significantly correlative with population, *GDP*, passenger traffic, and freight traffic in China. To further validate such correlations, they are analyzed again based on the statistical data set of the 30 provincial capital cities in 2006. Likewise, such correlations as 0.500<R<0.936 and 0.005<Sig.<0.01 in Tab.2 are also significant, i.e. these socio economic factors impacting the traffic safety must be considered when selecting the traffic safety evaluation indices for the 30 provincial capital cities in China.

Tab.1 Correlation between traffic accident fatalities and social economic factors in China，1990-2006

	GDP	Population	Passenger Traffic	Freight Traffic
Pearson Correlation Coefficient（R）	0.821	0.933	0.883	0.799
Sig. (2-tailed)	0.000	0.000	0.000	0.000
Correlation is significant at the 0.01 level (2-tailed).				

Tab.2 Correlation between traffic accident fatalities and social economic factors of the 30 provincial capital cities in China, 2006

	GRP	Population	Passenger Traffic	Freight Traffic	Number of Traffic Accident
Pearson Correlation Coefficient（R）	0.845	0.701	0.500	0.893	0.936
Sig. (2-tailed)	0.000	0.000	0.005	0.000	0.000
Correlation is significant at the 0.01 level (2-tailed).					

3.2 Evaluation indices

Based on the aforementioned correlation analysis, the traffic safety evaluation indices are put forward for the 30 provincial capital cities in Tab.3, where the fatalities per passenger traffic and per freight traffic are used to indicate the average damage level of highway transportation; the fatalities per traffic accident indicates the average danger level of each accident; the mortality is the death proportion in all deaths and injuries of road traffic accidents.

Tab.3 Evaluation indices for traffic safety of the 30 provincial capital cities in China, 2006

Provincial	Fatalities	Fatalities	Fatalities per	Fatalities per	Fatalities per	Mortality

Capitals	per 100000 People	per 100 millions Yuan GRP	Passenger Traffic (persons per 10000 persons)	Freight Traffic (persons per 10000 tons)	Traffic Accident (persons per case)	(%)
Beijing	11.46	0.17	0.55	0.44	0.24	0.17

4 Application of road traffic safety evaluation

(1) Constructing the sample matrix

The six evaluation indices in Tab.3 are regarded orderly as the *j*th evaluation indices for traffic safety of the 30 provincial capital cities in China. As the provincial capital cities, Beijing, Tianjin, Shijiazhuang ...Yinchuan and Urumqi are regarded orderly as the *i*th evaluation objects, i.e. x_{ij} is the *j*th evaluation indices value of the *i*th evaluation objects, the sample matrix $X=[x_{ij}]$ (i=1,2...,30; j=1,2...,6), where the

values of x_{ij} are shown in Tab.3, and x is the columns of X.

(2) Transforming X into standardization matrix $Z=[z_{ij}]$, where

$$z_{i,j}=\frac{x_{i,j}-\bar{x}_j}{s_j},\quad \bar{x}_j=\frac{\sum_{i=1}^{30}x_{i,j}}{30},\quad s_j^2=\frac{\sum_{1=1}^{30}(x_{i,j}-\bar{x}_j)^2}{29},\ i=1,2\ldots30,\text{ and } j=1,2\ldots6.$$

(3) Calculating correlation coefficient matrix R of the matrix Z, where

$$R=\begin{bmatrix} 1.0000 & 0.0474 & 0.2362 & 0.2165 & -0.2674 & -0.2588 \\ 0.0474 & 1.0000 & -0.3195 & 0.5347 & 0.0206 & -0.0404 \\ 0.2362 & -0.3195 & 1.000 & -0.1705 & -0.0721 & -0.0423 \\ 0.2165 & 0.5347 & -0.1705 & 1.0000 & 0.0412 & 0.0053 \\ -0.2674 & 0.0206 & -0.0721 & 0.0412 & 1.0000 & 0.9748 \\ -0.2588 & -0.0404 & -0.0423 & 0.0053 & 0.9748 & 1.0000 \end{bmatrix}$$

and $r_{ij}=\frac{\sum_{k=1}^{30}z_{kj}\cdot z_{kj}}{29}$, of which r_{ij} is the correlation coefficient between the ith and jth evaluation indices, i.e. $r_{ij}=r_{ji}$. R also is the covariance matrix of matrix X.

(4) Calculating the eigenvalues λ_i of R, where $\lambda_1=2.1222$, $\lambda_2=1.7138$, $\lambda_3=1.1310$, $\lambda_4=0.5839$, $\lambda_5=0.4259$, and $\lambda_6=0.0232$, in which $\lambda_1\geq\lambda_2\geq\cdots\geq\lambda_6>0$.

(5) Determining the number of principal components

When $\sum_{j=1}^{m}\lambda_j / \sum_{j=1}^{6}\lambda_j \geq 85\%$, the minimum m is the number of principal components, min(m)=4, and $\sum_{j=1}^{4}\lambda_j / \sum_{j=1}^{6}\lambda_j$ =92.6%>85%.

(6) Calculating the four principal component $y_1, y_2, \ldots, y_4$

$$y_i = z_i \times l_i$$

where l_i is the ith eigenvector of R, z_i is the columns of Z, and y_i is ith principal components.

$$y_1 = -0.3399z_1 + 0.0069z_2 - 0.1384z_3 - 0.0140z_4 + 0.6593z_5 + 0.6560z_6$$

$$y_2 = -0.1067z_1 - 0.6583z_2 + 0.4072z_3 - 0.6231z_4 - 0.0097z_5 + 0.0340z_6$$

$$y_3 = -0.6524z_1 + 0.0152z_2 - 0.6058z_3 - 0.3098z_4 - 0.2297z_5 - 0.2418z_6$$

$$y_4 = -0.6333z_1 - 0.3220z_2 - 0.6625z_3 - 0.1968z_4 + 0.0824z_5 + 0.1047z_6$$

Seen from the first principal component y_1, the weights coefficients of z_5 and z_6 are 0.6593 and 0.6560 respectively, they are bigger than others. This indicates that the fifths and sixth indices (Fatalities per Traffic Accident and Mortality) are more important than others for the 30 provincial capital cities in 2006.

(7) Calculating the evaluation score, the formula is as follows:

$$S = \sum_{i=1}^{4} (y_i \times \frac{\lambda_i}{\sum_{j=1}^{4} \lambda_j})$$

where *S* is the vectors whose *i*th element value is the evaluation score of the *i*th evaluation objects(shown in Fig.1, the 30 provincial capital cities are on the x-coordinate).

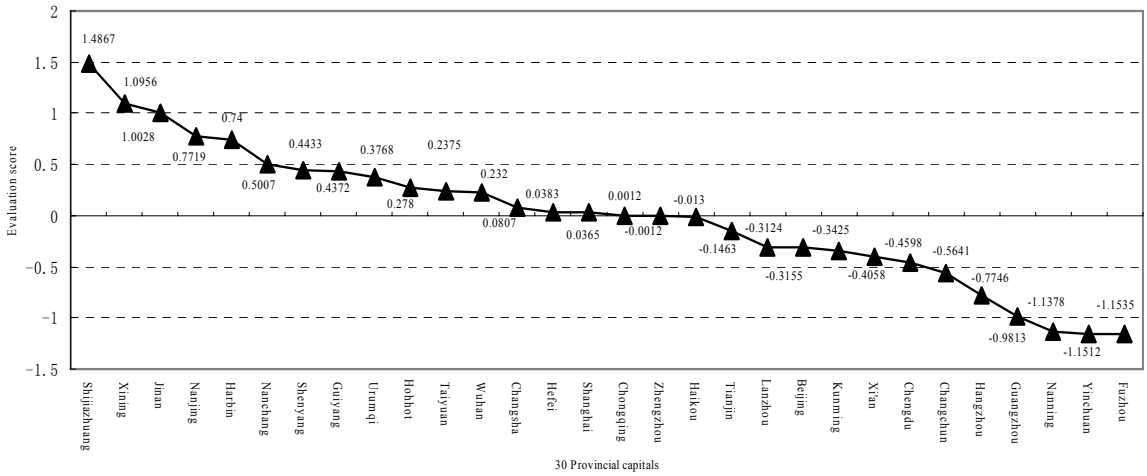

Fig.1 Sequence of traffic safety level for the 30 provincial capital cities in China, 2006.

5. Results analysis

As can be seen from Tab.3, the smaller are the values of theses evaluation indices, the better are the traffic safety level in the provincial capital cities. Thereby, for the 30 provincial capital cities, the larger are their evaluation score in Fig.1, the worse are their traffic safety level. It can also be seen from Fig.1 that the traffic safety levels in the 30 provincial capital cities were markedly discrepant, and the five best provincial capitals of traffic safety were Fuzhou, Yinchuan, Nanning, Guangzhou, and Hangzhou in 2006. The five worst provincial capital cities of road traffic safety were Shijiazhuang, Xining, Jinan, Nanjing, and Harbin in 2006. It indicates that the fatalities per traffic accident and mortality in the five worst provincial capital cities were higher than others, so reducing both is an effectual to improve traffic safety level in the five worst provincial capital cities.

6. Conclusions

Here, the conclusions can be provided as follows:

(1) In China, the traffic safety in the provincial capital cities is evidently correlative with socio-economic factors, expressly such as population, GRP, passenger traffic, and freight traffic, the selection of evaluation indices should focus on them.

(2) The differences in traffic safety level among provincial capital cities in China were comparatively distinct in 2006. The fatalities per traffic accident and mortality were the crucial evaluation indices for road traffic safety of the 30 provincial capital cities in China.

(3) Principal component analysis is one desirable means to evaluate road traffic safety.

ABSTRACT

Space positioning information model and logic model of traffic facilities are established, by studying the internal organizational structure of Geodatabase model. On the basis of the data of Jilin province expressway, the spatial database is designed in detail with seamless integration of database management model, by analyzing the characteristics of spatial database of traffic facilities. The traffic management system is realized by secondary development of GIS, the software of which includes VB.NET, ArcGIS Engine and ArcSDE. The system implementation verifies the superiority of the GIS model, provides a scientific and efficient management tools for traffic facilities management.

INTRODUCTION

The goal of GIS is to provide a spatial framework within which to rationalize the application of the Earth's resources and provide decision support for the sustainable development of the human environment. In this course, the model of geographical objects need be made. Data Modeling, which can transfer the data of real world to useful data sets, plays an important role in the spatial database. Data modeling is applied in the field of GIS, which is spatial data modeling. Spatial data model, which describes the relation of the objects things by datamation of physical model, can simulate and abstract the objective geographic world perfectly on the aspects of spatial semantic and attribute semantic. Space positioning information model and logic model of traffic facilities are established, by studying the internal organizational structure of Geodatabase model. On the basis of the data of Jilin province expressway, the spatial database is designed in detail with seamless integration of database management model, by analyzing the characteristics of spatial database of traffic facilities. The traffic management system is realized by secondary development of GIS.

DESIGN OF SPATIAL DATA MODEL STRUCTURE

The spatial information model of the traffic facilities management system introduces GeoDatabase model, the internal organizational structure is shown in **Figure 1**.

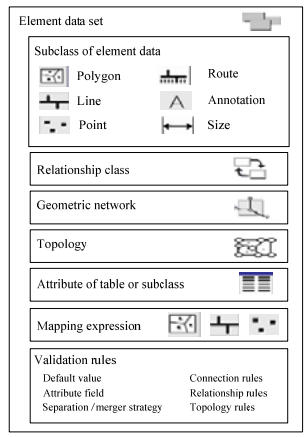

Figure1. Internal organizational structure of geodatabase model

Geometry characteristic, such as point, line and polygon, and the relationship of them are established by using ArcGIS new generation model, that is, GeoDatabase model, in the course of system developing, which is showed in **Figure 2**.

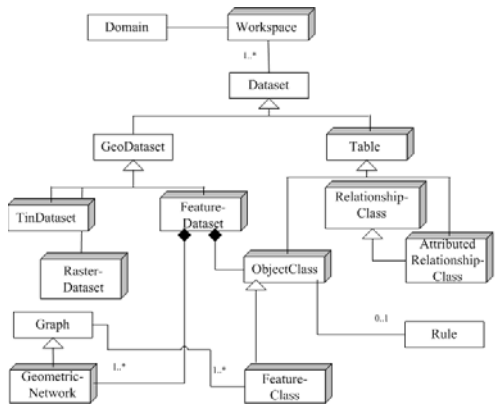

Figure 2 Logic model based on geodatabase

Spatial information model is multidimensional spatiotemporal model including spatial position, time and geographical spatial attribute. The information amount of the model is great, so the information of the model is massive data. The spatial information model, which should be organic dynamical model and satisfy the needs of the different scales, is the basis of GIS application system. On the basis of the main-ramp topology model of expressway, the spatial position information model is established, and the position of point and line, the main design objects of which include infrastructure, such as route, segmentation, toll station, sign, administration office, park plot and service area, and intercommunication ramp position. The spatial positioning model, which is showed in **Figure 3**, is established in the ArcInfo UML System with UML and model provided by ArcGIS. **Figure 4** shows the logic model of point infrastructure of expressway. In this model, the point event can be traffic accident points, facilities distributing points, vehicle position, and so on. The positions of these elements display the statistics and analysis results on the electronic map according to different topic demands, after these elements is positioned by using the corresponding the mileage poles number and the miles percentage of starting and

ending points on topological network being established.

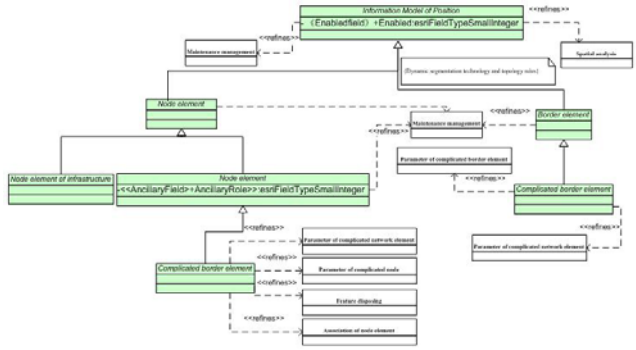

Figure 3. Spatial positioning information model

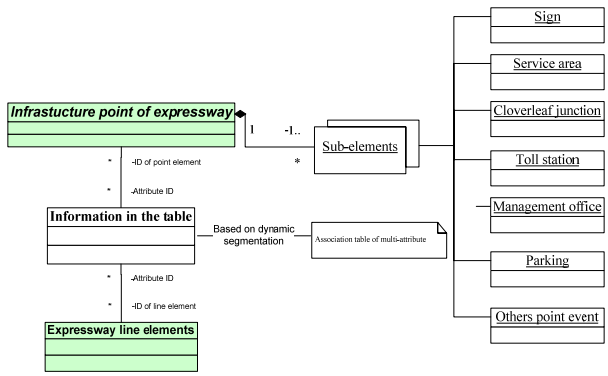

Figure 4 Logic model of traffic facilities

METADATA DESIGN OF SPATIAL DATABASE

Metadata is the data that describes data, that is, the description information about the data and information resource. Geographic metadata helps the users position, evaluate, obtain and use the geographic data by noting the content, quantity, quality, condition and other characters of geographic spatial data.

The system metadata table is design as **Table 1**.

Table 1 Traffic facilities layer information

Filed	Type	Size	Description
ID	Number	Long	serial number
Symbols Index	Number	Long	The index of feature display symbols
Symbol Size	Number	Long	The size of feature display symbols
. . .	. . .	. . .	. . .
Symbol color	Number	Long	The color of feature display symbols

There is a metadata table in every layer. The table of route metadata is shown

in **Table 2**. The table of traffic facilities metadata is shown in **Table 3**.

Table 2 Route metadata

Field	Type	Size	Description
ID	Number	Long	Record Number
Data set encoding	Text	50	Including the information of type
Route Name	Text	50	The name of real world
Name of Attribute Table	Text	50	

Table 3 Traffic facilities metadata

Field	Type	Size	Description
ID	Number	Long	Record Number
Data set encoding	Text	50	Including the information of type
Facility Name	Text	50	The name of real world
Name of Attribute Table	Text	50	

SYSTEM IMPLEMENTATION

Traffic management system calls ArcEngine, the latest research and development kit of ArcGIS, with VB.NET language. The system adopts the C/S architecture, that is, the clients run in 32-bit operating system of Windows XP or windows 2000, the system database is installed on a dedicated server, and the client accesses the system database through ArcSDE database engine. The general framework of system is shown in **Figure 5**.

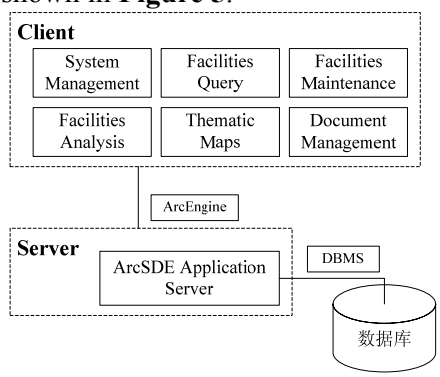

Figure 5. General framework of system

System developing uses the basic functional modules and related application modules of ArcGIS Engine. The basic module, which is a basic function class library, assemblies the ArcGIS Engine interface basically. This module is called by the

application module, after it forms function, on that time, a part of classes are inherited. This module being above of AO, call AO and reference the program set of AxMapControl, AxPageLayoutControl, AxToolbarControl, AxTOCContro, Carto, ControlCommands, DataSourceGDB, DataSourceRaster, Display, Geodatabase, GeoDatabaseDistributed, Geometry, MapControl, Output, PageLayoutControl, System, SystemUI, TOCControl, ToolbarControl, Utility, and so on. The system uses VB.NET language to call the background data through ArcSDE and achieves the query, retrieval and analysis of data. A part of codes are as follows:

```
Dim pPropSet As IPropertySet = New PropertySet
Dim pSdeFact As IWorkspaceFactory = New SdeWorkspaceFactory
With pPropSet
  .SetProperty("SERVER", Server)
  .SetProperty("INSTANCE", Instance)
  .SetProperty("DATABASE", Database)
  .SetProperty("USER", User)
  .SetProperty("PASSWORD", Password)
  .SetProperty("VERSION", version)
End With
openSDEWorkspace = pSdeFact.Open(pPropSet, 0)
```

The system interface is shown in **Figure 6**.

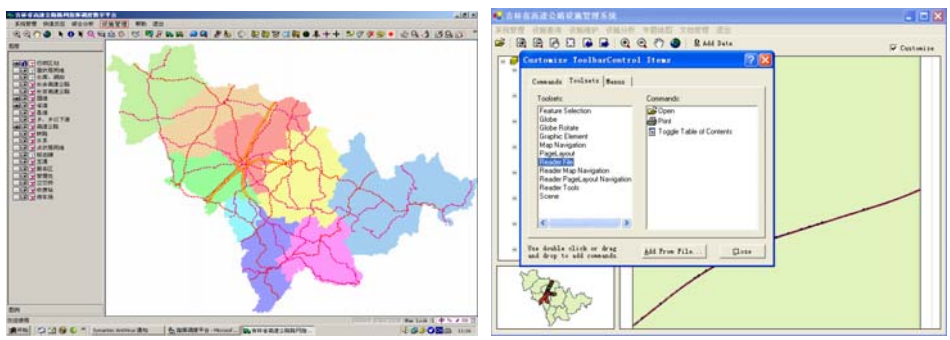

Figure 6. System interface

CONCLUSION

Space positioning information model and logic model of traffic facilities are established by studying the internal organizational structure of Geodatabase model. The spatial database is designed in detail with seamless integration of database management model, by analyzing the characteristics of spatial database of traffic facilities. The traffic management system is realized by secondary development of GIS, the software of which includes VB.NET, ArcGIS Engine and ArcSDE. The system, which provides the effective approach to improve the operating efficiency and service level of freeway for the traffic management departments of Jilin province, and plays an important role in promoting information and sustainable development of Jilin province traffic, is basis of realizing modernization, scientific and intelligent of freeway management. The system implementation verifies the superiority of the GIS model, provides a scientific and efficient management tools for traffic facilities management.

ABSTRACT

Compared with traditional collection methods using detectors or sensors, floating-car data collection has advantages such as a broad coverage area, low cost installation and maintenance costs and little influence from external sources. Therefore, floating-car data is being broadly applied in traffic relative studies. Traffic original data usually contains some random components, which disturb the distinction of traffic status. The original data must be de-noised in order to filter these random components. This paper presents wavelet analysis to de-noise the original data from floating-car data collection. In this paper, the data from RTMS (Remote Traffic Microwave Sensor) collection is treated as true data. Traffic original data, from various ring mainlines of Beijing on various days, are processed through wavelet threshold de-noising. The experiment results show that de-noised data is better than the original data in terms of evaluation indexes. For example, MSE of the de-noised data can drop as low as 6.36% and the correlation coefficient can be increased by more than 1.18%.

INTRODUCTION

Compared with traditional collection methods using detectors or sensors, floating-car data collection has advantages such as a broad coverage area, low cost installation and maintenance costs and little influence from external sources. Consequently, floating-car data is being broadly applied in traffic relative studies (e.g. traffic dynamic forecasts and traffic congestion evaluation). Since data is collected via taxi-mounted GPS (Global Positioning Satellite System) units, the floating-car data is susceptible to drivers' individual behavior, and lane information can be indistinguishable from the floating-car original data. This leads to speed discretization of different lanes on the same road section. Also, the volatility of floating-car data is stronger than that of RTMS (Remote Traffic Microwave Sensor) data. To be sure of data accuracy, floating-car original data needs to be de-noised.

De-noising approaches in common use include MA (Moving Average) algorithm, exponential moving average algorithm, KF (Kalman Filter) algorithm, and etc (JIANG, 2004). They are mostly applied to the stationary and fixed-interval time series. Traffic measurements collected from floating-car systems are primarily spot speed, GPS location and time stamp. The reporting interval of traffic measurements is about 90s and is unsteady, so the traditional de-noising approaches are not effective for floating-car original data. Wavelet analysis, immune algorithms and spectral subtraction algorithms can be applied to de-noise real-time traffic data (CHEN, 2006). In this paper (CHEN, 2006), the decomposition level of wavelet analysis, which has a great effect on de-noising, is

not mentioned.

This paper first introduces the wavelet analysis and wavelet de-noising methods. In contract to wavelet de-noising methods, the acquiescent threshold de-noising is selected and the SNR (Signal-to-Noise Ratio) is used to determine the decomposition level of acquiescent threshold de-noising (FENG, 2005). For the purpose of de-noising effect evaluation, RTMS data is used as the true data and we use MSE (Mean Square Error) and the correlation coefficient as de-noising evaluation indexes. In this paper we use wavelet analysis to de-noise the floating-car original data from various Beijing ring mainlines on various days, and then de-noise the 5-min interval average speed (average speed calculation algorithm is illustrated in the paper HU Z W, 2008). In comparison to the correlation coefficient and MSE of the floating-car and RTMS data, the de-noising effect is significant. Due to the limitation of RTMS detector installation locations, this paper proposes the floating-car data de-noised approach be used only for urban expressways.

AN INTRODUCTION TO WAVELET ANALYSIS

Fourier transformation is usually applied to the non-linear time series. In the case of Fourier analysis, data is either in the time domain or in the frequency domain, but there is no direct relationship between the two. This means that in the frequency domain one can determine which frequencies appeared and how strongly they are present but not where (in the time domain) they appeared. To cope with this problem, a windowed Fourier transformation (WFT) can be used. It splits the input signal into different windows, which are then analyzed individually. The difficulty of this approach lies in the way the window borders must be handled.

The wavelet analysis solves this problem by dealing with the input signal at different scales or resolutions. On a large scale the focus is on rough features, i.e. trends, whereas on a small scale the focus is on minor features, i.e. noise. The general idea is to adopt a wavelet prototype function, called an analyzing wavelet or a mother wavelet. These functions are basics in the function space (Samant, 2000).

By viewing the traffic time series as a signal, wavelet analysis can separate the traffic time series into different resolution levels with different time scales. Thus, wavelet analysis is a technique that enables us to perceive traffic measurements in a third dimension.

THE PRINCIPLE OF WAVELET DE-NOISING

Given a signal x(t), we denote by dx(j, k)=<x, Ψj, k > the wavelet coefficients. The basis of the decomposition is generated from translated and dilated versions of the mother wavelet, Ψ0:

$$\Psi j, k(t)=2\text{-}j/2\,\Psi 0(2\text{-}jt\text{-}k) \qquad j=1\cdots J, \quad k\in Z \qquad (1)$$

The wavelet can be understood as the result of a cascade of quadrature-mirror low-pass and high-pass filters (g(n) and h(n), respectively), in which the output of the high-pass filter (the details of the signal) are wavelet coefficients at each scale j, while the output of the low-pass filter (the approximation of the signal) is filtered again iteratively. The principle of wavelet decomposition is shown in Figure 1.

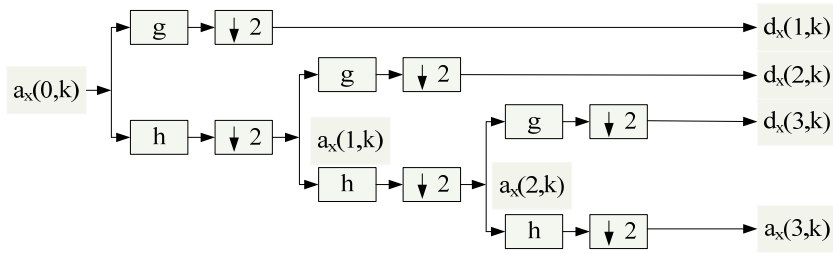

Figure 1. Wavelet de-noising for level 3 decomposition.

METHODS OF WAVELET DE-NOISING

Many de-noising methods based on wavelet analysis have been presented (SUN, 2005). They include the wavelet transform modulus maximum, wavelet correlation, wavelet threshold de-noising and wavelet translation invariant de-noising.

Wavelet threshold de-noising is the most widely used de-noising method among the four, due to its ability to obtain the approximate optimal estimation of original signal, fast computing and extensive adaptation. In the traffic time series, there are some abrupt data points that may be traffic events and jump points of traffic condition. They are essential for traffic prediction and traffic condition analysis. Wavelet threshold de-noising cannot change the traffic measurement characteristics, especially for jump points. When we deal with the real-time traffic time series, the de-noising method must be selected to quickly process data. Based on the above analysis, we apply wavelet threshold de-noising to de-noise the floating-car data.

DE-NOISING PROCEDURES

In floating-car time series, spot speed is an important measurement. Accordingly, floating-car speed time series data is taken for a one-dimension signal. The de-noising procedure of a one-dimension signal includes three parts: decomposition, threshold quantization and reconstruction of signal.

The first step is the decomposition of the one-dimension signal. The goal is to determine the wavelet decomposition level.

The second step is threshold quantization of the high-frequency coefficient dx(J,k). We select one threshold value to quantize the high-pass coefficient dx(j,k)(j=1…J) of each level (from the 1st level to the number N level).

The final step is the reconstruction of the one-dimensional signal according to the ax(J,k) and dx(J,k) (j=1…J).

DETERMINING THE WAVELET DECOMPOSITION LEVEL

SNR is a parameter that illustrates the amount of noise in signal and is defined as the ratio of signal power to the noise power corrupting the signal (HAN, 2007). Given the time series *y(t)* with noise *t*=1, 2,…, N, N is the length of time series. *y(t)=x(t)+w(t),* where *x(t)* is the time series of signal and *w(t)* is the added noise.

SNR is shown as in Equation 2:

$$SNR = 10\log 10\{\sum_{i=1}^{N}[y(t)-\bar{y}]^2 / \sum_{i=1}^{N}[y(t)-x(t)]^2\} \quad (2)$$

Where $\bar{y}$ is the mean of the time series *y(t)*. Generally, greater SNR means more

signal and less noise in the time series. If we select more decomposition levels to de-noise data, the available signal will be lost, leading to the reduction of SNR, more calculations and slower calculating speed. If a lower decomposition level is selected, the de-noising effect is not the best. But SNR of the time series cannot be decreased, so the wavelet decomposition level will have a large effect on the wavelet de-noising.

We applied the wavelet threshold de-noising to the road in the North Third Ring (from LianXiangqiao to Beijing Sports University) on 25 March 2008. We selected different wavelet functions and different decomposition levels to de-noise, and obtained the results shown in Table 1.

Table 1. Correlation coefficient and MSE of floating-car data and different wavelet function under varying decomposition levels.

Wavelet name	Decomposition level	Correlation Coefficient	MSE
db3	1	0.8571	245.770
db3	2	0.8550	247.588
db3	3	0.8607	252.403
db3	4	0.8614	254.339
db2	1	0.8570	247.579
db4	1	0.8532	248.577
db5	1	0.8524	248.164

From the above analysis for the same wavelet function under different decomposition levels, SNR is quickly dropped down by the increase of the decomposition level. For the same decomposition level, SNR is improved little by the increase of wavelet function. Wavelet db3 and decomposition level 1 have achieved the de-noising of original data.

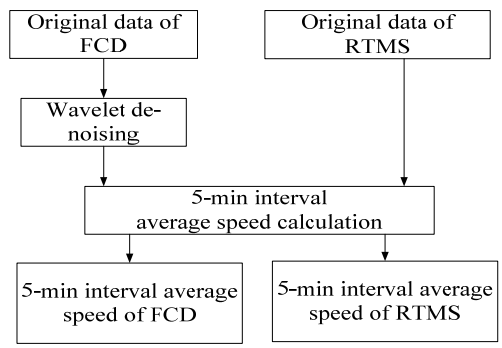

Figure 2. De-noising analysis process.

Process steps are as follows:

1）Floating-car original data is de-noised.

2）The five-minute interval average speed of RTMS data from the same day and road as the floating-car data is calculated.

3）After de-noising the floating-car original data, five-minute interval average speed is calculated and de-noised again.

4）The de-noising effect is evaluated.

This paper selected the correlation coefficient and MSE as the evaluation indexes. The floating-car and RTMS are two different kinds of data collection

technology, so there is inevitably systemic error between them. Still, the whole trend of traffic measurement from the two data collection technologies presents strong correlation. So using RTMS five-minute interval average speed as the true data, we respectively compared the correlation coefficient and MSE of the five-minute interval average speed of floating-car original data and that of the five-minute interval average speed of floating-car de-noised data. We must presuppose that the correlation between the two kinds of data, when collected on the same day, is strong. Otherwise, the data is not de-noised in this way.

EXPERIMENTAL RESULTS

For this paper, we selected mainlines in Beijing as experiment sites. Due to the limited space analyzed, this paper only introduces partial results. The selected road is located in the North Second Ring (from Gulouqiao to Andingmenqiao). First, we compared floating-car original data with floating-car de-noised data. The results are shown in Figure 3 and Figure 4. Most of the noise in the original data was separated. We applied an average speed calculation algorithm to calculate average speed based on the floating-car original data, floating-car de-noised data and RTMS data. We applied MA and wavelet to de-noise the five-minute interval average speed of the floating-car data. We contrasted the correlation coefficient and MSE between the floating-car average speed (data sets were floating-car original average speed, MA average speed and wavelet de-noising average speed) and RTMS average speed. In Figure 5, the correlation of the Wavelet de-noising average speed and RTMS average speed is strongest and the MSE is least. The experiment results show that de-noised data is better than the original data in terms of evaluation indexes, such as MSE, which for de-noised data can drop as low as 6.36% and can achieve a correlation coefficient above 1.18%. The acquiescent wavelet de-noising method can be applicable to the floating-car data so that random components of floating-car data can be filtered.

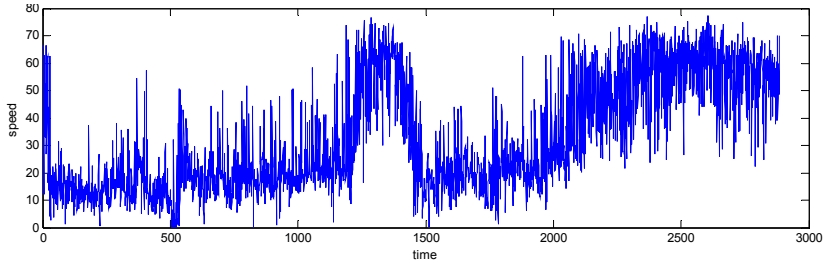

Figure 3. Original speed in North 2nd ring (from Gulouqiao to Andingmenqiao) on July 8, 2008.

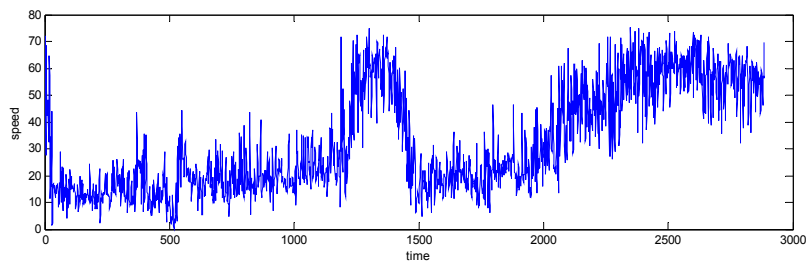

Figure 4. De-noised speed in North 2nd ring (from Gulouqiao to Andingmenqiao) on July 8, 2008.

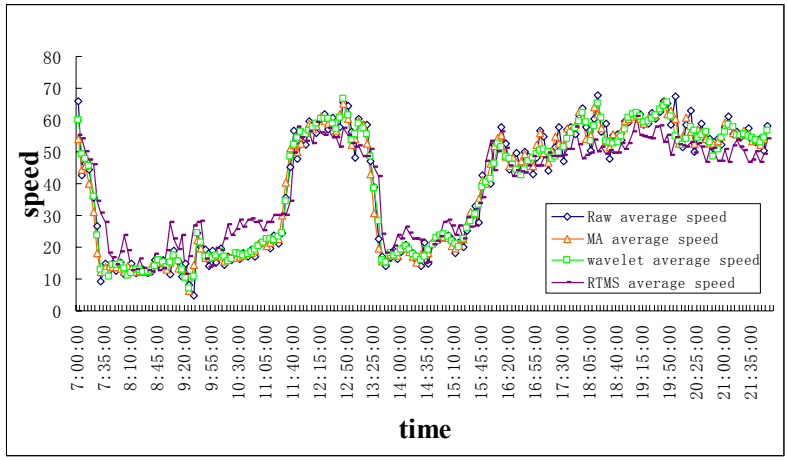

Figure 5. Comparison of average speed in North Second Ring (from Gulouqiao to Andingmenqiao) on July 8, 2008.

FUTURE WORK AND CONCLUSIONS

Floating-car data can cover every class of road in the urban environment. But for now, RTMS can only be installed on urban expressways. Therefore we de-noise the floating-car data on the expressway to contrast with data from RTMS. Through wavelet de-noising, the volatility of floating-car data is decreased and the correlation with RTMS becomes stronger. Thus, wavelet de-noising is applicable to floating-car data. Arterial traffic data is more complicated than expressway traffic data. Due to the limitation of RTMS installation conditions, we cannot obtain arterial traffic data from RTMS. In future work we intend to find an approach to de-noise arterial data.

ABSTRACT

To encourage the use of public transit modes and/or discourage the use of auto for the commuter trip, deep discount policy was provided and implemented in May 2006 in Beijing. To estimate responses of urban travelers to Deep Discount policy, the choice behavior survey was carried out in Beijing, including passengers' individual characters, trip behavior and their choices to railway and bus under certain conditions. And the influence factors of mode split are analyzed. Then traveler mode choice model considering different ticket ratio between railway and bus was established and the mode choice behavior are specified and estimated. The estimation results suggest that ticket cost and ticket cost ratio between bus and railway are the most cited factors in explaining ridership growth and shift. The conclusion will provide an analysis tool for an evaluation of the effectiveness of deep discounts actions. Also the result can provide the Deep Discount policy sustain for the increasing of the trip proportion of public traffic.

INTRODUCTION

As congestion in urban areas continues to worsen and expressway solutions become less effective, many local governments and communities are turning their attentions to public transit systems. To improve the trip proportion of public traffic, deep discount policy was provided and implemented in May 2006 in Beijing. To maximize the return on different improving methods in public transit systems, effective analysis tools are needed to determine transit ridership potential and the benefits of investments.

Foreign scholars paid attention to the relationship between transit ridership and trip fare, such as ticket cost, and did research about it early. Previous research concluded that travelers were more concerned about their travel cost such as ticket cost, trip time and etc(Zong.2005).People are willing to choose the mode which utility is the maximum and the influence of generalized cost on trip is more concerned in those researches (Ben-Akiva et al.1990).Travel cost is divided by the traveler's income to reflect the presumption that a traveler with a high income is less concerned about money cost than a traveler with a low income (Gillen.D.W. 1977). The generalized cost include time cost, currency cost, safety and reliability of the trip

were discussed. Distance ratio between railway and bus and coefficient factors such as rapid and comfort are considered in the design of ticket cost of Shanghai （Liu.2003). Transit Price Elasticity and Cross-Elasticity are provided during the research about the Transportation Elasticity. Several TDM strategies involve transit fare reductions. Commuter Transit Benefit programs，in which employers encourage and sometimes subsidize transit passes，are effective at increasing ridership. Deep Discount transit passes can encourage occasional riders to use transit more frequently. Shaw. J. (1997) in Many Campus Transport Management programs include free or discounted transit fares. Not all increased transit travel that results from fare discounts represents a reduction in automobile travel. A portion represents shifts from walking,cycling and ridesharing,or absolute increases in personal travel.

From the introduction above, we can see domestic and foreign scholars have not done study about ticket ratio between railway and public traffic according to mode choice behaviors. Existing ridership models,either long-range or short-term,are limited by both our understanding of the complicated decision-making processes of individual travelers and a lack of fundamental data. So it lacks a tool to do study about urban deep discount policy.

Public traffic ticket ratio can be divided into three levels: ratio between public traffic ticket and the value level of the society merchandise; ratio between different kinds of public traffic modes' ticket and ratio between bus systems. The two latter ticket ratios have great influence on the passenger proportion which is split by different transportation mode. During the determination of the ticket ratio, to maximum the social benefits, factors which should be considered are listed as the following(Chen Shuhong.2007):(1)Economic bearing capacity of the passenger(2)Competition factor between bus and railway (3)Government Economic policy.

In this paper, based on the choice behavior survey in Beijing, the influence factors of mode split were analyzed. Then traveler mode choice model considering different ticket ratio between railway and bus was established and the mode choice behavior was discussed. The conclusion will provide an analysis tool for an evaluation of the effectiveness of deep discounts actions that encourage the use of public transit modes and/or discourage the use of auto for the commuter trip.

MODEL CHOICE BEHAVIOR SURVEY AND ANALYSIS

Survey Summary

The survey in this paper was conducted in Beijing in October 2005.The subject of this survey was the revealed preference of public traffic users under Deep Discount policy. Consider capacity of the mass transit is invariable whether the value of ticket changes, and there are N identical commuters who can either travel by bus or by railway（Hai-Jun Huang.2002）.

The survey consisted of three parts, of which only two are relevant to this

study. One part concerned respondents' household characteristics such as age, gender, education, occupation, family size, number of family workers, car possession and income level. The other part yielded information about the respondents' potential trip mode choices in different hypothetical choice situations which includes travelers' choice under different ticket ratio such as 1:1, 1.5:1, 2:1and 3:1.

The survey takes the mode of quiz face to face. Railway in route1, 2, 13, Batong and 12 paralleled bus routes with different service level, geographic position the characteristics surrounded were considered. A total of 776 respondents were selected.

In addition, because the trip behavior may be different in weekday and weekend (Guan Hongzhi et al.2003), so the survey for behavior was conducted respectively on weekday and weekend.

Analysis on Survey Results

Trip fare is one of important factors which influence the trip mode choice. The stated preference of users between bus and railway under different ticket ratio were asked in the survey (Yao Liya et al.2003). Using the investigate datum, the proportion of travelers selecting railways and buses were given.

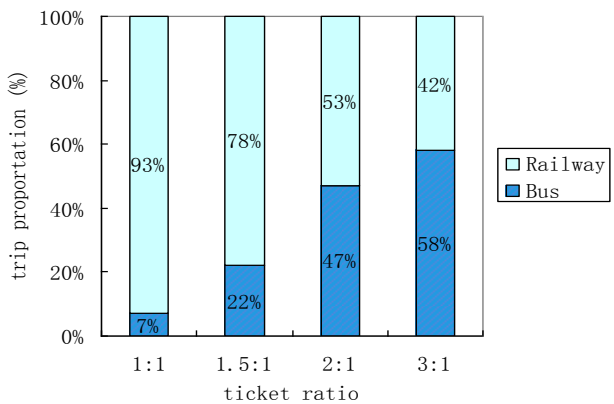

Figure 1. Travel Mode Choice under Different Ticket Ratio

As shown in Figure1 , that the proportion of travelers selecting railways and buses are closely equal which indicates that the traffic volume can be distributed reasonably by adjusting the ticket ratio between railway and bus.

CHOICE MODELS

Model Specifications

Logit model was used as following in this paper （Guan Hongzhi. 2003):

$$P_{in} = \frac{e^{V_{in}}}{\sum_{j \in A_n} e^{V_{jn}}} \qquad (1)$$

where： P_{in} = probability of a traveler n choosing the project i

V_{in} = deterministic component of utility i for user n (fixed item)

A_n= aggregate of the choice project of traveler n

The choice projects aggregate A is supposed as follows:

A= {i=1(bus), i =2(railway)}

Then, the mode choice Logit model can be modeled as:

$$P_{1n} = \frac{1}{1+e^{-(V_{1n}-V_{2n})}} \quad (2)$$

$$P_{2n} = 1 - P_{1n} = \frac{e^{-(V_{1n}-V_{2n})}}{1+e^{-(V_{1n}-V_{2n})}} \quad (3)$$

$$V_{1n} - V_{2n} = \theta_1 + \theta_2 X_{1n2} + \theta_3 X_{1n3} + \theta_4 X_{1n4} + \theta_5 X_{1n5} + \theta_6 X_{1n6} + \theta_7 X_{1n7} + \theta_8 X_{1n8} \quad (4)$$

Where:

V_{1n}=deterministic component of utility for user n from choosing bus (fixed item);

V_{2n} =deterministic component of utility for user n from choosing railway (fixed item);

θ_1=constant;

$\theta_2 \ldots\ldots \theta_8$= parameters to be estimated;

X_{1n2}= traveler n's age1;

X_{1n3}=traveler n's age2;

X_{1n4}=traveler n's income1;

X_{1n5}=traveler n's income 2;

X_{1n6}, X_{1n7} ,X_{1n8}=ticket raito1（1.5:1)、ticket ratio 2（2:1)、ticket ratio 3（3:1)；

X_{1n9}= traveler n's fare.

Variable Filtration and Grouping

Using the survey datum, the influence of the travelers' household characteristics and trip characteristics on trip mode choice are analyzed through crosstabs chi-square test, the result is listed as shown in Table 1.

Table 1. Value of Chi-Square and Correlation of Influencing Factors

Test value	Gender	Age	Occupation	Income	Purpose	Car Possession	Ticket ratio
Chi-squared Value	6.933	18.831	31.405	39.216	18.846	2.518	139.110
Correlation	0.008	0.002	0.000	0.000	0.004	0.113	0.000

As shown in Table 1, gender, age, occupation, income, and trip purpose have marked influences on the results of trip mode split, and the effect of car possession is not significant to choice modes. Variables filtration and grouping were decided as following by correlation analysis:1)Gender is divided into Male and Female;2)Age is divided into three groups: Age1 is between 18 and 35 years old,Age2 is between 35 and 55 years old and age3 is others;3)Occupation is divided into three groups: Occupation1 is official, manager; Occupation2 is engineering and technical personnel, office clerk, workers, professional undergraduate and Occupation3 is others;4)Income

is divided into three groups:Income1 is below 800 RMB/month, Income2 is between 800 and 3000 RMB/month and Income3 is over 3000 RMB/month; 5)Purpose is divided into two groups:Purpose1 is work, business, recreation and Purpose2 is others.

Calibration of Model

Using the logit model and survey datum, mode choice model is proposed as shown in Table 2 and test of the model of mode split is given in Table 3.

According to the statistic analysis, age, income, ticket ratio, and trip fare are chosen as the independent variables of the mode choice model based on ticket ratio. The absolute values of t-statistics of age1, age2 income1, income2, ticket ratio1-3 are all higher than 1.96 at a 5 percent confidence level, which indicates that these seven influential factors are significant for the choice probability.

The coefficients of age1and age2 are positive, meaning that these two factors have positive effect on the mode choice.

The coefficients of income1 and income2 are both negative, which means income has negative effect on the mode choice. The higher the income is, the lower the choice probability of bus is as opposed to railway. The absolute coefficient of income2 is higher than income1, and it can be considered that with the upgrade of the people's income level, the demand of trip such as punctuality, comfortable and convenient performance will become higher than before.

The coefficients of Ticket Ratio1（1.5:1）、Ticket Ratio1（2:1）Ticket Ratio1（3:1）are positive, meaning that these three factors have positive effect on the mode choice. That is to say, the higher the ticket ratio between railway and bus is, the less the travelers are likely to choose the railway as opposed to bus.

And the coefficient of the trip fare is negative, meaning that it has negative effect on the mode choice. The higher the trip fare is, the less the travelers are likely to choose the railway.

The goodness of fit parameter ρ^2 and goodness-of fit index adjusted by freedom $\bar{\rho}^2$ of the model are 0.2595 and 0.2427 respectively, which implies that the forecast veracity of the model is satisfied and the precision of this model is high.

Table 2. Model of Mode Split

	Mode model	Parameter value	t value
	Constant	-4.0407	-4.3445
	Age1（18~35）	1.8523	2.5103
	Age2（35~55）	2.3634	3.0269
Discrete Variables	Income1（￥800-3000/month）	-0.4956	-2.5148
	Income2（>￥3000 / month）	-1.3279	-5.6545
	Ticket Ratio1（1.5:1）	1.4536	4.4146

	Ticket Ratio2（2:1）	2.5817	8.0649
	Ticket Ratio3（3:1）	3.0997	9.5952
Continuous variables	Fare	-0.0706	-1.74

Table 3. Test of Model of Mode Split

Model test	Sample size	L(0)	L($\hat{\theta}$)	-2[L(0)- L($\hat{\theta}$)]	ρ^2	$\bar{\rho}^2$
value	776	-537.882	-500.153	279.14	0.2595	0.2427

According to the calibration result of the model listed in the table 2, the probability of each traveler choosing bus and railway can be given. During the mode split of the traffic planning, if the probability value is larger than 0.5, suppose that traveler is likely to choose the trip mode. The total probability of travelers choosing between railway and bus can be calculated respectively and the passenger volume ratio is also given corresponding to the ticket ratio.

CONCLUSIONS

Based on survey data and BL model, mode choice model corresponding to ticket ratio between railway and bus was established. Conclusions following can be obtained by analyzing the model: Gender, age, income, trip fare and ticket ratio have marked influences on the results of trip mode split, and the effect of car possession is not significant to choice modes. On the basis of combination of variable factors, the variables that should be used in the model were determined and the model of public traffic mode split is presented in this paper. The relationship of trip fare, ticket ratio and mode split can be studied, which provided a base for adjusting the structure of public traffic by using the deep discount policy. The forecast veracity of the model is satisfied and the precision of this model is high.

Abstract

In order to ensure the safety of the bridge operation, Structural Health Monitoring (SHM) or regular tests should be carried out. SHM or regular tests are very important for large structures such as suspension bridges, cable-stayed bridges, cross-ocean bridges, towers, and so on. Much more attention have been paid to some advanced technologies for SHM or regular tests. In order to collect signals wirelessly in civil engineering structure monitoring, a Wireless Dynamic Testing System was designed by modularization and system method, which combines bridge structure detection technique, computer technology, modern sensor technology, wireless communication, and system technology. The wireless testing system consists of a master station and several substations. The master station is composed of a control center subsystem and a data transmission subsystem. The substation is composed of a data transmission subsystem and a gathering subsystem. The software system consists of controlling, data, and Single Chip Microcomputer processing. Finally, the wireless measurement system is tested by a field test of the Sifangtai Cable-stayed Bridge.

Key word: Structural Health Monitoring; Wireless transmission; Bridge detection tests; Data acquisition; Vibration sensor

Bridge structures have to withstand vehicle load, crowd load, wind load, earthquakes, and so on. When any of the loads mentioned above is working on bridges, it would cause effects such as impact and vibration, which is becoming a major issue in the design, computation, construction, operation, repair, maintenance, and management of bridges. Therefore dynamic tests should be carried out on bridges.

Traditional tests use the wired method, which requires a long time to obtain the information needed and is therefore inefficient. To address such problems, a wireless dynamic testing system is proposed which adopts the wireless data transmission method to acquire structural vibration information data and uses software programming to analyze the signals for the intrinsic rules of the bridge vibration. Thus dynamic characteristics of bridge structures can be evaluated.

1 Study and design of the wireless dynamic testing system

The wireless dynamic test system based on the 941B vibration sensor is mainly composed of a master station and some far-end substations. The master station is composed of a control center and a data transmission module subsystem. The far-end substation is composed of a data transmission module subsystem, a data acquisition subsystem, and a vibration sensor. The data acquisition subsystem is composed of a front-end amplification and filtering module, an analog-digital conversion module, a voltage module, and the smallest single-chip system. The structure of the whole wireless dynamic testing system is shown in fig. 1.

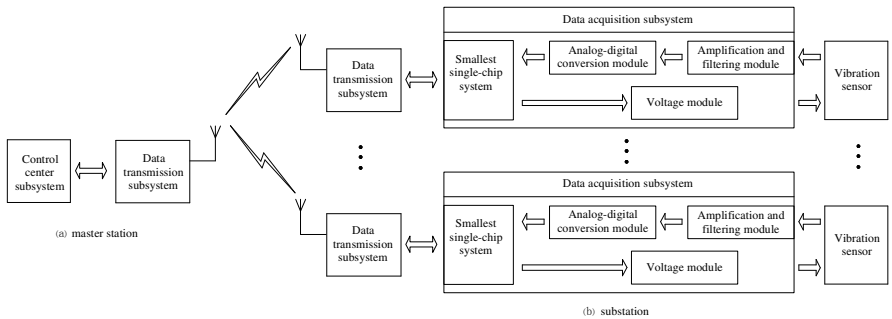

Fig. 1 Structure of Dynamic Wireless measurement system

The dynamic testing system uses a computer as the control center, completing all data acquisition subsystem instruction andsends with data processing. The data transmission module subsystem completes the receiving and dispatching control of the wireless signal from the wireless channel equipments; it may carry on the essential transformation and the pretreatment to the sensor signal. Each data acquisition unit establishes 2 or 3 sensors.

2 Design of collecting subsystem of wireless dynamic measuring system

The data collecting subsystem of the dynamic system which connects sensor units and a single chip computer-controlling module consists of a front filtering amplifying circuit, a single chip computer-controlling module, data collection, and a radio frequency module.

By the controlling orders sent from the master station, it can realize filtering of the simulated signals outputted by the vibration pickup and adjustment of the amplification factor under the control of the single chip microcomputer. This way data is collected and then sent to the radio frequency module for wireless transmission which can enhance the measuring precision of the system and simplify post data processing.

2.1 Design of front filtering amplifying circuit

The amplifying function and filtering function of the front filtering amplifying circuit are performed by a simulation device and integrators. The magnification can be altered by changing the resistance in the simulation amplifying

circuit. As for the simulation integrator circuit, satisfying filtering effects can be obtained through proper change of capacitance and resistance. The selection of filtering and amplifying parameters can be achieved by adding some simulation switches.

2.2 Design of single chip computer controlling module

The single chip computer-controlling module is one of the most important parts of the collection joints in the dynamic testing system. It commands the rest parts of the circuit to work together to guarantee all functions of the data collecting joints are being carried out properly. The single chip computer-controlling module is the smallest system of a single chip computer and consists of a MCS-51 single chip computer, an address latch unit, and an 8255 program general parallel interface chip. The dynamic data collection requires long-time without interruption. Meanwhile, the speed of serial ports between the single chip computer-controlling module and radio frequency module is restricted, which leads to overabundant data and thus great storage depth is required. Therefore each circuit is extended with a data memory device in the design.

Firstly, the address code is applied on the address input terminal of the RAM chip, the corresponding memory unit is chosen, and then the writing operation can be carried out. Then the datum written is put in the datum bus line. The patch selection signal and writing signal are added, which opens the tri-gate to make the transferred datum enter into the input circuit and sent to the bit line of the memory cell in order to be written in the memory unit.

Secondly, the main chain controlling element supplies power, with the voltage between 0 and 5V, but the simulation signal voltage range of the dynamic system is between -5V and +5V, requiring its main chain controlling element to supply a voltage of $\pm$5V. The AD transferred chip used in datum collecting nodes of the dynamic system is the AD7807 produced by the BB Company. By using the internal reference voltage as the working reference voltage, the voltage range of 0 to 5V is determined. Because the voltage of the input simulation signal is between -5V and +5V, the simulation signal must be handled properly before being sent to the AD7807 transferred chip. The treatment methods taken in this system design is: first, a resistor divider is taken to change the voltage range from between $\pm$5V to between $\pm$2.5V; second, let the simulation signals pass thorough a reverse proportion operational circuit with 1 time amplification in turn to render a 180 degrees discrepancy between the output simulation signal and the input simulation signal; third, this signal and a -2.5V voltage signal are applied to the input terminal of a reverse input summation circuit, which would generate a simulation signal with the voltage between 0 to +5V at the output terminal as expressed. By sending this signal to the AD translator, the sample of the input simulation signals could be

finished in the AD7807.

Finally, some addresses and control lines are extended and distributed. Datum memory is added for each circuit signal in the design and an 8255 is added to meet the needs of the data memory for a 19-bit address. The datum bus line is connected with the 8255 datum terminal for a single chip computer to read the data easily.

2.3 Design of data collection and radio frequency module in bridge wireless dynamic testing system

The radio frequency module of the data collection node of the dynamic system requires that acquisition of data and transmission of data be in sync, which means that after each data acquisition, the data acquired needs to be sent to the main station through a wireless channel. This demands the data frame of the communication protocol to be sent in the sampling clearance. In addition, the power amplifier of the data collection node must be kept on open status during the sampling in order to send the data frame, because it needs 5ms to activate the power amplifier. As for the dynamic system, data collection and transmission are alternately appearing, if the power amplifier were turned off after each time of transmission, then it would take 5ms longer each time during the new transmission. This would not only cause too frequent on and off of the power amplifier, but also reduce the using life. Moreover, when the sampling speed is high, activation time would impede the data frame transmission during the sampling interval.

3 Study and design of communication protocol of bridge wireless dynamic testing system

3.1 Study and design of communication protocol of bridge dynamic system

The sampling rate of the dynamic system is 200Hz. The length of data collection is 10 min long each time after receiving the command of data collection. If all the collection data are stored in the SCM and sent to the main station together after the collection is finished, it would render a very large transfer delay and influence the real-time property of the system. Besides, secondary stations need to collect large data memories and this doubtlessly raises the system cost. In order to avoid such problems, every time when finishing a collection, the data collected could be sent to the main station immediately during sampling intervals.

The sampling rate of the dynamic system is 200Hz, namely, the sampling interval is 5ms while the serial rate of SCM is 19.2kbps, which means if all 5ms were used to send data information, only 12 bytes at the most could be transmitted. In addition, the running of the SCM and the delay of the data collection circuit are all time-costly, so the length of the data frame sent during the sampling interval must be less than 12 bytes. Based on the preliminary estimation, the running of the SCM and the delay of the data collection circuit together cost less than 1ms, so

theoretically, as long as the data frame length is less than 10 bytes, the SCM would achieve data collection and transmission in the sampling interval and meanwhile get ready for the next data collection.

In the communication protocol of the dynamic system, the frame length is fixed to 8 bytes, and the serial sending time must be less than 3.4ms. The information frame of the dynamic system is divided into a descending frame and an upstream frame. The descending frame is sent from the main station and used to control the secondary station; the upstream frame is sent from the secondary station and used to send the collection data back to the main station. The details are introduced below:

In this article, we define the communication link from the main station to the secondary station as the descending link while the communication link from the secondary station to the main station is the upstream link. The system adopts a parallel communication style with a rate of 57.5kbps. Both the descending and upstream link use the same uniform frame format and are in support of the ARQ function. The communication flow chart of the system is shown in Fig.2.

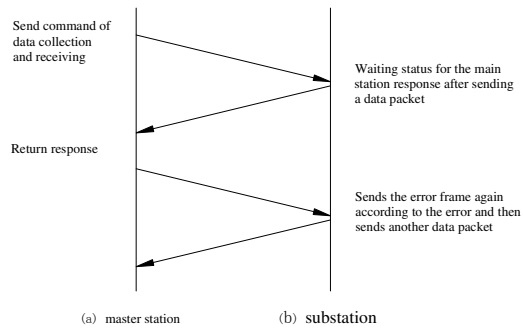

Fig. 2 Communication Process

As soon as the main station gives the command of data collection, the secondary station that receives the command begins to collect the data and sends them back to the main station. To be specific, in the secondary station 4 data and a control dictate compose a data frame, then 8 data frames compose a data packet. After each transmission of the data packet, the secondary station enters into the status of waiting for the main station response. Meanwhile, the main station unpacks the received data packet and checks them, then sends the error drafts back to the secondary station. The secondary station then sends the error frame again according to the error drafts, and then sends another data packet. If the error draft shows no error, the secondary station will send another data packet immediately. In the whole data collection process, the main station could stop the work of the secondary station by sending the stop command.

3.2 communication frame format

The length of the communication frame is 18 bytes and the frame format is

shown in Fig.3.

0x7E	LEN	Dadd	Sadd	TYPE	CONTENT	CHK

Fig. 3 Frame format

0x7E is the first byte, which means the start of the communication frame and is called the frame head.

LEN is the second byte, which is the length of the communication frame. In order to set up radio equipment conveniently, the uplink frame has the same length with the downlink frame. The length of the communication frame is 18 bytes.

Dadd is the third byte, which is the destination address. The master station's address is set to 0x00 while 0xFF is the broadcast address. Each master station could have 254 secondary stations, thus the secondary station address ranges from 0x01 to 0xFE.

Sadd is the forth byte and the source address, which shows the source of the communication frame.

TYPE, the fifth byte, is the type-frame type selection address and its definition is shown in Table 1.

Table 1 TYPE-frame type selection

downlink frame		uplink frame	
The command frame of the first sensor in data Acquisition	0x01	The data-frame of single node	0x01
The command frame of the second sensor in data Acquisition	0x02	The data-frame of multiple nodes	0x02
The command frame of itinerancy between two nodes	0x03	The data-frame of retransmitting ARQ	0x03
The command frame of ending secondary station	0x04	The frame of terminating data Acquisition	0x04
The responsive frame of master station	0x05		
The command frame of being enable to report data	0x06		

CONTENT specifies the content of the communication frame and is part of the frame from the sixth byte to the seventeenth byte. Its length is 12 bytes and a more detailed introduction would be discussed in the following chapters.

CHK is the eighteenth byte and represents the checking byte, adopting the first LEN-1 bytes' summation of all the bytes in the frame except CHK.

4 Field test of Sifangtai Cable-stayed Bridge in Harbin

4. 1 Field test of Sifangtai Cable-stayed Bridge in Harbin

Tests were carried out on the Sifangtai Cable-stayed Bridge in Harbin in May, 2008 by the wireless dynamic testing system. The distance between the master station and secondary station was 100m, and the additional attenuation was 25dB. The testing procedure from the master station to the secondary station was normal and the return time tested is consistent with the estimation, which proved that data acquisition and transmission time of the communication channel are in accordance with design specifications.

4. 2 Results and analysis of the laboratory tests

For the purpose of validating the reliability and accuracy of the system, a comparison of data between the theoretical values and the acquired data obtained by the INV306 dynamic signal acquisition and analysis device, made by the Beijing Oriented Vibration and Noise Research Institute, was carried out.

The fundamental frequency estimated theoretically of the Sifangtai Cable-stayed Bridge is 0.297Hz. Actually measured from the mid-span section in stiffening girder, the vertical fundamental frequency actually measured was 0.352Hz after data processing and analysis by the INV306. The fundamental frequency measured and analyzed by the wireless dynamic testing system was 0.35Hz, which is close to both the result measured by the current equipment and the theoretical value. It proves that the wireless dynamic testing system can be applied to data acquisition from the vibration-pick-up device, and to wireless date transmission. What's more, its accuracy meets engineering requirements and thus it is suitable for application in practical engineering.

Conclusions

Based on vibration sensors, the design of the data transmission module of the wireless dynamic testing system and the corresponding communication protocol realizes reliable and effective data transmission. This system has been successfully applied in strain-gauging of an actual large-scale bridge structure and it has been proven to be theoretically correct and technically feasible with many advantages such as high accuracy, network, high reliability, easy operation, affordability, friendly interface, and so on. It also has positive and initiative consequences on the exploitation of wireless testing in bridge structures

On the whole, the wireless testing system can overcome many insufficiencies of the wired method of data acquisition with obvious efficiency in bridge detection and health monitoring. Thus it has practical significance and application prospects.

ABSTRACT

This paper presents a non-contact method measuring asphalt pavement surface texture based image processing technology and fractal theory to overcome the deficiencies of conventional volumetric method. The pavement surface texture images are acquired using ordinary CCD camera. Then fractal analysis on contour of gray level, which is extracted from binary image by target segmentation at adaptive threshold value and edge detection, is made. A fractal dimension of contour of gray level, scale-independent, is determined.

This study comprises field tests and laboratory tests. A regression equation of FDC and MTD measured by sand patch test is built, and a statistical correlation based on a good coefficient of determination (R^2) for the data is obtained in the preliminary results. It is observed that the FDC decreases with the MTD. At last, the possibility of replacing volumetric by this measurement in the practical application is discussed.

KEY WORDS: Surface texture measurement; Fractal dimension; Digital image processing; Contour of gray level; Mean texture depth.

1. RESEARCH BACKGROUND

It is widely recognized that pavement surface texture influences many different pavement–tire interactions, including friction, interior and exterior noise, splash and spray, rolling resistance, and tire wear (Henry, J. J. 2000). Different texture characteristics have different effects on tire-pavement interactions. As a result, much attention has recently been focused on the measurement and evaluation of surface texture characteristics for transportation safety and ride quality.

There are several different methods for quantifying surface texture. Two commonly used methods are the mean texture depth (MTD) and the mean profile depth (MPD). The MTD is determined using the traditional volumetric method (commonly referred to as the “sand patch test”) whereas the MPD is determined using laser technology at highway speeds. A known volume of sand material is spread properly on a pavement surface to form a circle, and the MTD is then

computed by dividing the known volume of sand by the calculated average of four equally spaced diameters of the circular patch. Even though the reproducibility (40%) of the sand patch test is poor, it is the most common means to measure texture as the reference "ground-truth" standard throughout the world, since there is a great deal of past research (Gerardo, W. F., 2003). The MPD is a statistic computed by analyzing 102 mm segments of the collected profile data that acquired from modern high-speed vehicle-mounted laser-based measuring devices or new portable devices such as the Circular Texture Meter (Jcbarrantes, 2007).

However, even with experienced, skilled operators, the sand patch method takes some time to perform, and is normally done in live traffic conditions with varying levels of traffic control (Gransberg, D.D, 2005, Pidwerbesky. B, 2006). And laser measurements commonly have relatively accurate test results but expensive cost. Moreover, MPD is scale-dependent and the sampling length, the sampling spacing and the instrument resolution, etc. affect the result strongly.

2. RESEARCH OBJECTIVES AND METHODOLOGY

The purpose of this research is to evaluate whether a practical method of pavement surface texture measurement using digital image processing, incorporating fractal theory could be developed. This is accomplished by comparing the results obtained using the sand patch method. The objectives of the research are to develop:

- An accurate, repeatable method of measuring texture to replace the sand patch method;
- A fast, safe method of measuring texture to reduce the operator risk associated with road surface texture measurement and minimize disruption to traffic;
- To find the most effective and scale-independent parameters to estimate texture roughness.

In this regard, it is necessary to determine a parameter to quantify the roughness of surface texture. In surface sciences, the fractal analysis approach is based on concept of self similarity of surface at different scales. Its advantage is that it is insensitive to the structural details, and the structure is characterized by single descriptor, the fractal dimension D. It provides information on the degree of complexity of different surface topographies. Moreover, recent statistical comparison of relevant roughness parameters reveals that the fractal dimension is the most relevant parameter to describe the surface topography (D. Risovi´c, 2008). The objective parameter selected to quantify the surface texture roughness is fractal dimension of contour of gray level (FDC) of each image due to self-similarity of surface texture of asphalt pavements statistically. Here, FDC is defined as roughness of contour of gray level, whose physical meaning is asphalt mixture without voids of pavement surface. In some way, the FDC quantifys the capacity of asphalt mix without voids filling with space of section plane.

Evaluation of surface texture roughness based image analysis by fractal theory is obtained in three main steps:

•Image acquisition: Digital images were taken in the fields and in the lab and sand patch tests are taken in the same location as the images. Pavement surface real texture information was acquired using ordinary charge-coupled device (CCD) camera.

•Image processing and analysis: Some suitable image processing methods are taken to improve primitive image. Then contour of gray level was extracted from binary image by target segmentation at adaptive threshold value and edge detection and FDC, scale-independent, was determined for each 'ring'.

•Regression analysis: The 'ring' FDC is statistically correlated with their corresponding sand patch measurements using some regression techniques and the coefficient of determination (R^2 value) as the objective measure of correlation. The output is a regression equation that describes the best fit of a curve that represents the relationship of the change in FDC with respect to the change in MTD.

3. EXPERIMENTAL PROCEDURES

This study comprises field tests and laboratory tests. Field tests are conducted on the two different types of 6 asphalt pavements existed (coarse-graded HMA&fine-graded HMA) whereas laboratory tests simulated newly constructed SAC type of asphalt pavements. It's necessary to take images before and after the sand patch tests so that the latter determined the size of the former. In the fields, images are taken on the shoulder, wheel path and the area between the wheel-paths. In the lab, 20 standard samples manufactured by wheel rolling method furnished with surface space for both image taking and sand patch tests.

3.1DIGITAL IMAGE ACQUISITION AND PROCESSING

Standardized image acquisition method is carefully designed and carried out. In this regard, the experiment must maintain fixed focal length and fixed tilt of camera. With these constrains met, constant lighting is not needed due to a camera self-adjustment (Stemprok, R., 2000). In this study, each image was taken vertically above the surface texture at a height of about 20cm in the whole experiments.

The acquired images are taken some suitable image processing techniques to improve primitive image quality including resizing, noise reduction, contrast enhance and so on. And the images are converted into black and white images called gray-scale images.

Then images of contour of gray level are extracted from binary image by target segmentation at adaptive threshold values and edge detection. How to choose an adaptive threshold value for target segmentation of each gray image is considered as a key step. Each image has a most adaptive value for target segmentation in the preliminary experiment. There are usually two peaks in the density histogram of a

gray image of pavement surface texture (Mao, L.H., 2005). In a result, the valley between two peaks is considered as the most adaptive value for converting a gray image into a binary image. And the differential edge detection was used for feature extraction from binary images. These images of contour of gray level furnish the input for fractal dimension calculation and the opportunity to relate the roughness analysis of visual output using fractal dimension value with a physical measurement taken at the same location as the images.

3.2 IMAGE FRACTAL DIMENSION ESTIMATION

In the image analysis paradigm, fractal dimension measurements are used to estimate and quantify the complexity of form, shape or texture of objects (Bruno, O. M., 2008). Although various algorithms exist for computing fractal dimension for digital imaging, this study was based on the box-counting. As can be seen, the box-counting method is one of the most popular methods to estimate fractal dimension because of its easily operating.

The box-counting method is based on the number of boxes $N(\varepsilon)$ of size ε required to fill the entire area of an image. To changing the size of ε means that the number of boxes, $N(\varepsilon)$, also changes. In other words, the smaller the size of ε, the greater the number of boxes, while the larger the size of ε, the fewer the number of boxes $N(\varepsilon)$.The box-counting method defines the fractal dimension of an object by the expression below (Voss, R.F., 1988). The procedures of fractal analysis are shown in Figure 1.

$$D = \frac{\log N(\varepsilon)}{\log (1/\varepsilon)}$$

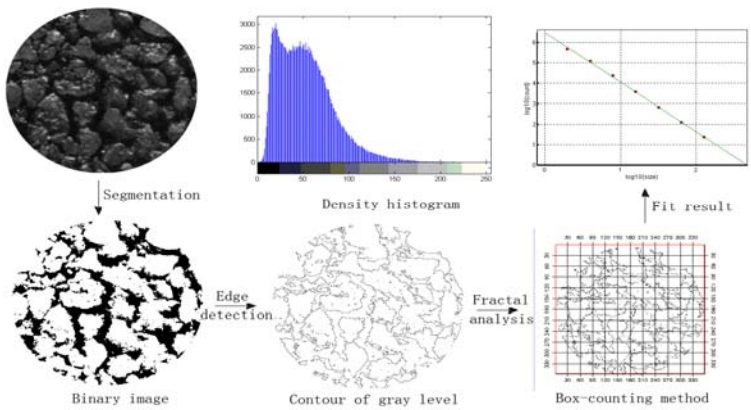

Figure 1. Flowchart of the fractal analysis

4. RESULTS AND DISCUSSION

4.1 CORRELATION BETWEEN FDC AND SAND PATCH TEST RESULTS

The first task is the investigation of the relation between the two indices, i.e. FDC and MTD. A comparison of FDC and MTD on the fine-graded HMA pavement

is shown in Figure 2. One can see that the FDC decrease with the MTD and the satisfactory textures show lower FDCs. Other types of mixture show the same tendency with the fine-graded HMA pavement.

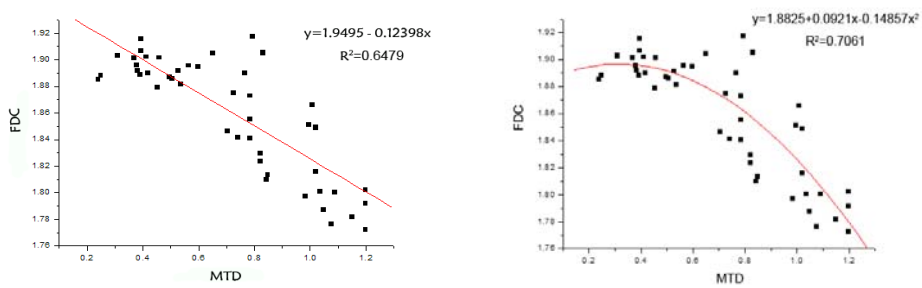

Figure 2. Relationship between MTD and FDC (Fine-graded HMA)

Table 1. Results of Regression Analysis (FDC = f (MTD))

Places	*Mix types*	*Forms*	*Transform equations*	R^2
Field	Coarse-graded HMA	Linear	y= 1.948-0.125x	0.7661
		Polynomial	y= 1.906-8.942x-0.085x^2	0.7869
	Fine-graded HMA	Linear	y=1.949-0.123x	0.6479
		Polynomial	y= 1.882+0.092x-0.148x^2	0.7061
Lab	Stone asphalt concrete (SAC)	Linear	y=2.089-0.235x	0.7232
		Polynomial	y=1.8581+0.257x-0.256x^2	0.7375

Table 1 summarizes the results of the analysis investigated for two forms of regression: linear and polynomial. It also shows the coefficients of determination (R^2) for each of the transforms. The correlation of data between the two indices relies upon the accuracy of position location to ensure that texture as measured with the method corresponds to the exact same spot used for the sand patch results. It is noted that the values obtained are not relative high, but these values could be considered as quite satisfactory since there is an amount of different methods for fractal dimension estimation of images. And it appears that the coefficients of determination (R^2) for polynomial regressions are higher than for linear regressions, which means the FDC deceases not so fiercely when the MTD is small enough(Fine-graded HMA 0.6, Coarse-graded HMA 0.7, SAC 0.8, respectively). According to the results of the applied regression analysis (see table1), the best fit is achieved for the correlation between FDC and MTD.

4.2 EFFECT OF SURCFAE TEXTURE DEPTH ON FRACTAL DIMENSION

In general, the fractal dimension of surface texture is postulated to be proportional to the fracture surface roughness. However, it is observed that the FDC decreased with the MTD. Figure 3 illustrates the reason of this ‘abnormality’.

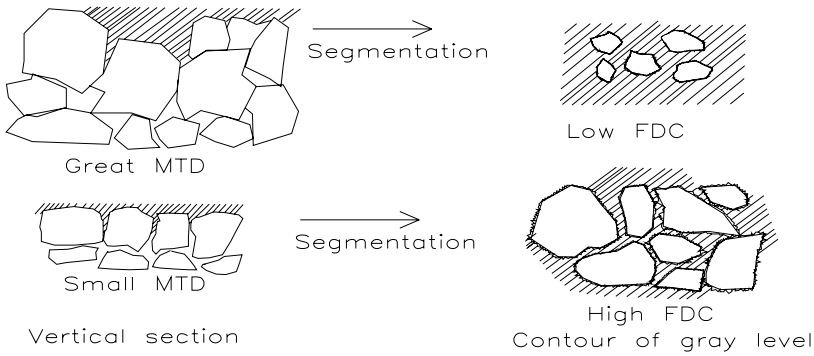

Figure 3. Schematic diagram of result analysis

Segmentation extracted the target (asphalt mixture) from the background (voids) while contour of gray level is gained by edge detection. When MTD of surface texture is great, it's obvious that there are more voids for filling with sand material. As a result, the target is relative less and the FDC was low. In reverse, when MTD is small, the contour of gray level is so complex and irregular that the FDC is high. That's to say, the FDC quantifying the roughness of contour of gray level represented the capacity of asphalt mixture without voids filling with the space of surface plane.

In summary, it can be concluded that surface texture can be measured simply and quickly by using the CCD camera. There is a negative correlation between the FDC and the MTD of surface texture closely and the correlation is proved to be quite good in the aforementioned cases. If image taking methods are standardized and regressions of each type of asphalt pavement between MTDs and FDCs are built, one can predict the MTD of surface texture by images easily based on regression equations rather than obsolete sand patch tests or expensive laser apparatus.

5. CONCLUSIONS

Many useful conclusions can be drawn from the research at this point. First, the literature supports the need for an accurate and reproducible method to measure surface texture. Measuring surface texture by the digital image processing technique and fractal theory can overcome the deficiencies of conventional volumetric method. The main results of the present case study highlighted a number of aspects and findings, which could be summarized in the following:

- The correlation between the FDC determined and the MTD obtained from sand patch test in this study was found to be quite satisfactory.
- Fractal dimension of contour of gray level could quantify the roughness of surface texture in some way. But high fractal dimension of pavement surface textures show low magnitude in depth.
- The results of the trials clearly demonstrated that the merger of digital image processing and fractal theory measurements is possible and the potential to

successfully replace the sand patch test with a camera is high.

However, this study only deals with image-based surface texture analysis in two-dimension (2D) scope, so the real texture (3D images) cannot be reconstructed. Also no correlations with mixture performance are carried out in this study. The next logical stage is to correlate FDC against standard measurements of surface friction. This would then allow this potentially powerful technology to give engineers a fast and inexpensive means to measure surface friction and that information to maintain and ensure the safety of public roads.

6. ACKNOWLEDGEMENT

The authors would like to thank Fujian education department and Fuzhou University (2007-XQ-22) for supporting this research (JA07012, 2007-XQ-22).

Research on Application of Externally Prestressing for Simple-continuous Bridge

Sheng Kejian[1,2], Li Rongda[1], Wang Zonglin[1]

1. School of Transportation Science and Engineering of Harbin Institute of Technology , 150040, harbin

2. Civil Engineering Department of Heilongjiang Institute of Technology , 150050, harbin

ABSTRACT: The joint style of the connecting section is one of the key problems of the simple-continuous system. The cost of bridge structure, the difficult degree of construction, and the performance of application are all determined by its joint style. In this paper, a new joint style, that is, applying externally pre-stressing for the connecting section, has been proposed based on the theories of externally pre-stressing systems and post-continuous technologies at home and abroad. Firstly, by using the finite element analysis software "ANSYS", the nonlinear full-stage simulations on test beams are carried out. The cracking behavior, deflection variation, bending moment redistribution of test beams, and the ultimate loading capacity of continuous beams are investigated emphatically. Secondly, the result of numerical analysis have been verified by corresponding indoor experiments. Finally, some suggestions on structure design are put forward.

Key words: simple-continuous system; externally pre-stressing; nonlinear full-stage simulation; ultimate loading capacity; numerical analysis

INTRODUCTION

Presently, multi-span middle span-length bridges constitute a large proportion of highway bridges. A new construction method, "simple-continuous", was invented based on the integration of the advantages of the simply supported beam in prefabrication production and continuous supported beam in mechanical property. The joint style of the connecting section is one of the key problems of the simple-continuous system. The engineering cost of the bridge, progress, a difficult degree of construction, and the performance of application are all determined by its joint style. The R.C. joint and post-tensioning P.C. joint are the major joint styles in the simple-continuous system bridge presently. However, the usual cracking in bridge decking of the R.C. joint often affects the service performance and durability of structure. At the same time, The post-tensioning P.C. joint has also some obvious defects, such as higher cost, complex construction procedures, a web plate with large size to accommodate pre-stressed tube, a long construction period, especially in a

frozen area, and so on. With the daily increase in the construction of simple-continuous system bridges, the application of this system will be limited in some degree because of high costs, a long interval period, and complex construction caused by singleness of the joint style.

So far, studies on the joint style of simple-continuous system had been done at home and abroad by some researchers. In late the 1990's, as a part of the National Union Highway Research Plan, the Construction Technology Laboratory (CTL) carried out the studies on this joint and achieved a conclusion that the positive moment created by the time effect will lead to the connecting section cracking. In England, Clark and Sugie had a study on the positive and negative moment connecting method of the prefabricated beam in the late 1990's. They suggested that no creep and contraction effects should be considered and the resistance moment of 700kN.m should be designed in joint for the span length of 20~36m. Nebraska University invented two ways to keep prefabricated beams connected, i.e. the reinforced screw bolt joint and pre-tensioned tendons joint. Owing to the simple construction procedure and lower structure cost, the measures had been applied successfully in 10th Street Viaduct in Lincon City in 1993 and had also been applied in other countries.

However, the present design of prefabricated members for simple-continuous structure was carried out fully according to the relative regulations of the simply supported beam and continuous beam, lacking special technical standards and without considering the natural characteristics of this system. Recently, the significant value of the externally pre-stressing structure has been confirmed in China and many kinds of studies have been carried out. Applying externally pre-stressing technology in joint can reduce the size of the web plate, the weight of prefabricated beams, and can eliminate the embedded tube and grouting so as to accelerate the construction process, which will be of significant value to cold regions in Northern China.

DESCRIPTION OF PROBLEM

As we all know, structural system transition is a key procedure of the simple-continuous system construction. The essence of this method is the pouring of connecting concrete and tensioning of externally pre-stressing tendons for negative moment. Under the ultimate state, stress of externally pre-stressing tendons can be written as

$$\sigma_p = \sigma_{pe} + \Delta\sigma_{pu} \tag{1}$$

where σ_{pe} is the effective pre-stressing force, and $\Delta\sigma_{pu}$ is the increment of the pre-stressing force under the ultimate state.

The increment of pre-stressing force will be created due to the deformation of concrete for an externally pre-stressing structure in service. Excessive tensioning

control stress may make the real stress approach to the ultimate strength of the material, eventually, brittle failure taking place. On the other hand, the use of externally pre-stressing tendons for the connecting section will induce the alteration of rigidity and internal force of the structure. However, it is infeasible that the problem mentioned above can be computed by a special equation. Therefore, studying the rules of sectional rigidity alteration, stress increment of pre-stressing tendons, and redistribution of internal force on an externally pre-stressing joint will play an important role in the design and construction of the simple-continuous bridge. Therefore, this paper focuses on the study of applying externally pre-stressed technology in the joints of simple-continuous structures based on the post-continuous technologies and externally pre-stressing theories at home and abroad. The nonlinear analysis on the finite element model of testing beams and experiments are the major contents in this paper.

DESCRIPTION OF ANALYTICAL MODEL

The purposes of numerical analysis are to calculate deflection alteration, stress increment of pre-stressing tendons, and redistribution of internal force on a testing-beam model. The analytical model is designed by means of simulating a testing beam which is 2×3.5m simple-continuous structure, with the span-depth ratio of 11:7. The material of the model adopts the strength design value of "Specifications of Design for Concrete Structure (GB 50010-2002)" and rational concrete constitutive equations.

Cube compressive strength standard value of concrete $f_{cu,k}$=38.5Mpa, singe axle compressive strength f_{cd}=18.4Mpa, singe axle tensile strength f_{td} =1.65Mpa, shear force transition coefficient of open crack β_c=0.3, shear force transition coefficient of closure crack =0.95, Young's modulus E_c= Mpa, Poisson's ratio υ_c= 0.2, and tensile stress release coefficient T_c = 0.6.

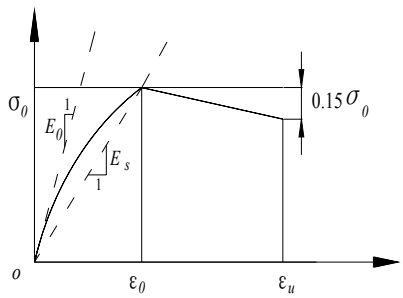
The equation for the ascending branch of a single axle stress-train curve originates from GB 50010-2002, and the equation for the descending branch of the single axle stress-train curve adopts the Hongnestad method. The stress-strain relationship is expressed in the form

$$\sigma_c = f_c[1-(1-\frac{\varepsilon_c}{\varepsilon_0})^n] \qquad (\varepsilon_c \le \varepsilon_0) \qquad (2)$$

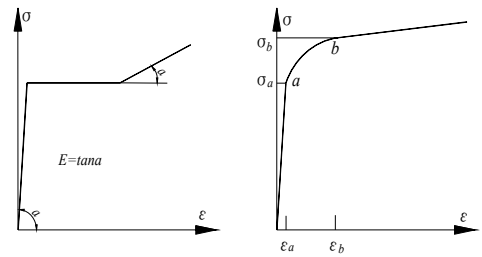
$$\sigma_c = f_c[1-0.15(\frac{\varepsilon_c-\varepsilon_0}{\varepsilon_{cu}-\varepsilon_0})] \qquad (\varepsilon_0 < \varepsilon_c \le \varepsilon_{cu}) \qquad (3)$$

According to GB 50010-2002, the computation results are n=2,ε_0 = 0.002, ε_{cu}=0.0033. The curve mentioned above will be fitted by a series of data points, adopting the multi-linear isocline strengthening model (MISO). The diagram in Fig.1

shows the stress-train curve of concrete, it should be noted that the Young's modulus input is the initial elastic modulus.



(a)



(b)

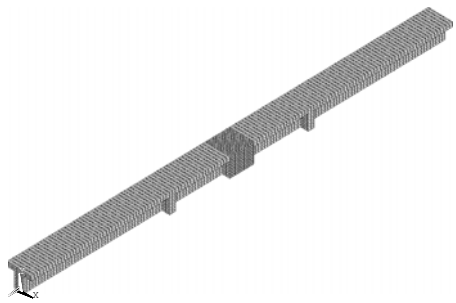
Fig.1. Concrete Stress-Train Curve

Fig.2. Reinforcement Stress-Train Curve

The stress-strain curve of simple reinforcement can be divided into three sections: elastic stage, yield stage, and strengthening stage. Fig.2(a) shows the bilinearity following and strengthening model of simple reinforcement. The stress-strain curve of pre-stressing tendons can also be divided into three sections: elastic stage, softening stage, and succeeding stage. Fig.2(b) shows the multi-linear following and strengthening model of simple reinforcement. The stress-strain curve obtained by testing data is furnished by the following function

$$\sigma = \frac{\sigma_b \varepsilon_b - \sigma_a \varepsilon_a}{\varepsilon_a - \varepsilon_b} + \frac{\varepsilon_a \varepsilon_b (\sigma_a - \sigma_b)}{\varepsilon(\varepsilon_b - \varepsilon_a)} \qquad (4)$$

The separated finite element model applying externally pre-stressing technology with ANSYS is shown in Fig.3., where the SOLID65 element, LINK8 element , and LINK10 element are adopted for concrete, simple reinforcement, and pre-stressing tendons respectively; the bonding and slipping between concrete and reinforcement are neglected.



.

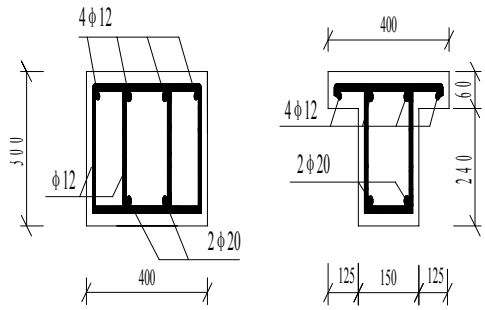


Fig.3. Finite Element Model

Fig.4. Sectional Constitution

The purposes of testing are to research the deflection alteration, stress increment of pre-stressing tendons, and redistribution of internal force on the

testing-beam. The concrete grade of the testing-beam is C40, longitudinal reinforcement adopts Φ20 and Φ16 reinforced bars, hooping reinforcement adopts a ϕ10 plain steel-bar, and externally pre-stressing tendons adopts $\phi^j 15$（7ϕ5）strands. The testing beam is a 2×3.5m simple-continuous structure, its span-depth ratio is 11:7. Fig.4. shows the sectional size and reinforcement layout. Loading layout of the testing beam in a laboratory is shown in Fig.5. Pressure sensors are adapted to measure and adjust bearing opposite force. Straight through pressure sensors are installed at the ends of strands to acquire the stress increment of strands. Using strain gauges to measure the strain of the mid-span and internal bearing and using the dial indicator to measure the displacement of bearings, and beam body, angle of rotation. The step stress scheme is accepted, the gradation of each step is 10kN and persistent time of each step is 20 minutes. When the test is being carried out, the cracking should be observed and the cracking load, bearing opposite force, displacement, and strain are all read carefully. Increasing the load up to the beam failure fully, the crack distribution rule and failure pattern of the beam can be observed.

Fig.5. Experiment Layout of Testing Beam

COMPARATION ANALYSIS OF NUMERICAL COMPUTATION AND TEST RESULTS

Analytical results of Rigidity

By comparing the results of numerical computation and the indoor test, as shown in Fig.6, the load-deflection curve of an externally pre-stressing beam can be divided into three stages: elastic stage before cracking, elastic stage after cracking, and nonlinear ultimate state stage. Approximately, the cracking load is 62.5 kN and the ultimate load is 242.8 kN. Therefore, the “three fold-line rigidity reduction model” applying elastic theory is feasible to compute the deflection of the mid-span for simple-continuous bridge.

Analytical results of stress increment of prestressing force

The relative movement between externally pre-stressing tendons and concrete will take place except for in the anchoring and deflecting areas so that the deformations of them aren’t coordination. The plain deformation analysis method is

also unfit for the computation of the ultimate stress of pre-stressing tendons. Consequently, the stress increment during the test can be acquired only by total deformation of the structure. The diagrams in Fig.7 shows the comparative results of numerical computation and the indoor test. As a result, the stress increment of externally pre-stressing force can be approximately computed by numerical analysis.

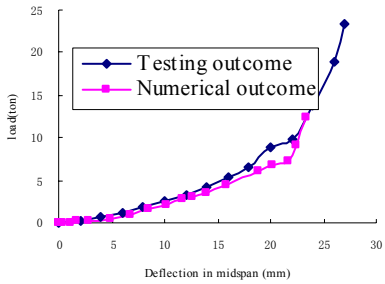

Fig.6.Load-Deflection Curve in Midspan

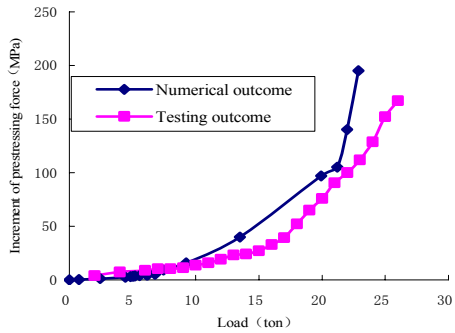

Fig.7. Increment of Prestressing Force-Load Curve

Analytical results of internal force redistribution

After entering into the elastic-plastic stage, the structural rigidity distribution and sectional mass axis are all altered so that the internal force will be also change. The study on internal force redistribution of continuous beams can help analyze the performance under loading, cracking, and deformation rules of continuous beams. Applying the results of internal force redistribution to design continuous beams can make full use of the material strength. Diagrams in Fig.9 report the rule of internal force redistribution of the simple-continuous bridge, where M_2 and M_2' are the internal bearing moments by testing and numerical computation respectively, M_1 and M_1' are the mid-span moments by testing and numerical computation respectively. To make the illustration explicit, viewing the M_2/M_1 as a variable(M_2'/M_1' =1.85) to analyze the moment redistribution rule is performed in Fig.10. With the cracks at the mid-span developing, the rigidity of this section will descend gradually, the moment will also transfer from the mid-span to internal bearing. Thus, M_2/M_1 will rise as the load increases in the Load- M_2/M_1 curve. When cracks in the internal bearing occur, the relative rigidity of this section begins to decrease, and the decreasing speed is higher than that of the mid-span section. Therefore the moment in the internal bearing begin to transfer from the internal bearing to the mid-span. M_2/M_1 will decrease as the load increases in the Load- M_2/M_1 curve.

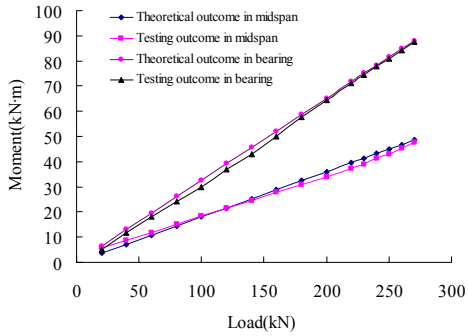

Fig.8. Load－Moment Curve

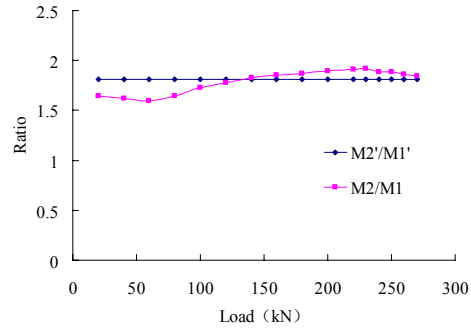

Fig.9. Load－M_2/M_1 Curve

CONCLUSION

This paper proposed the following conclusions by carrying out the theoretical analysis and experimental research on the mechanical performance of the externally pre-stressing force joint for the simple-continuous bridge.

The "Three fold-line rigidity reduction model" can be applied to compute the deflection of the mid-span for simple-continuous bridges according to elastic theory. Therefore, a simple and effective method has been obtained to the further studies on the externally pre-stressing force joint for simple-continuous bridges.

By the comparing and analyzing the results of numerical computation and an indoor test, the hypothesis that the stress increment of externally prestressing force can be approximately computed by numerical analysis has been verified.

The moment redistribution rule after the cracking of he control section was obtained by the comparing and analyzing the results of numerical computation and an indoor test, which will play an important role in reinforcement computation and sectional design of simple-continuous bridge.

Abstract

The restraint failure of airplane wheel chocks is one of the most important reasons for accidental airplane movements and the ground accidents in civil aviation. The calculation formula of wind lift force on airplanes is set up according to the running time-speed-load test data of a B737-800 on the ground. The finite element mechanical radial tire model is set up based on the Mooney-Rivlin constructive model according to the outline deformation test data of airplane tires under different loads. The restraint efficacy and failure modes of statically indeterminate chocks are studied by ANSYS based on the chocks' working conditions, and the new parameter of pushing coefficient is put forward to evaluate the restraint efficacy. In the end, an optimized design scheme is presented for B737-800 metal chocks. The numerical analysis shows that the optimized chock can better match the airplane tires under different loads and can exert more restraint efficacy.

Keywords: *airplane, chock, restraint efficacy, failure mode, structure optimization*

1 Introduction

Wheel chocks are the most common ground support equipment used to restrain airplanes from moving and colliding with other objects such as aerobridges while the airplanes are parked on parking aprons without mooring and engine power (SAE 2002).

However, in recent years the restraint failure of wheel chocks has been blamed for some ground accidents which have led to unexpected huge amounts of property loss. According to our surveys at 12 domestic airports, it was found that those events resulted from the nonstandard design and incorrect usage of wheel chocks (CASTC

2008). This paper aims at providing the solution to the accidental airplane movement and the ground accidents caused by the restraint failure of metal wheel chocks.

2 Radial tire simulation model

Airplane tires are elastomeric and their outlines change in shape and size under different airplane weights. Suppose that the origin is located at the contact point between the parking apron surface and the theoretical tire, the x-axis points to the airplane's tail along the fuselage's length and the y-axis is vertically upward. Table 1 shows the bottom outline deformation test data of B737-800 main wheel tires under airplane basic empty weight (BEW) and takeoff weight (TOW).

Table 1. Deformation test data of tire outlines.

BEW(35140kg)		TOW(46940kg)	
Abscissa(m)	Ordinate(m)	Abscissa(m)	Ordinate(m)
0.000	0.000	0.000	0.000
0.203	0.013	0.218	0.013
0.243	0.026	0.257	0.026
0.270	0.039	0.283	0.039
0.292	0.052	0.300	0.052
0.315	0.064	0.319	0.064
0.352	0.096	0.363	0.096
0.382	0.128	0.391	0.128
0.409	0.160	0.421	0.160
0.430	0.192	0.435	0.192

The finite element mechanical radial tire model can be set up according to the test data of table 1 and the two-term Mooney-Rivlin constructive model which can better simulate the small and middle deformations. The strain energy formula of the Mooney-Rivlin model is as follows (ANSYS 2002):

$$w = c_{10}(\bar{I}_1 - 3) + c_{01}(\bar{I}_2 - 3) + \frac{1}{D}(J-1)^2 \qquad (1)$$

where c_{10} and c_{01} are the material constants characterizing the material deviatoric deformation, $\bar{I}_1$ and $\bar{I}_2$ are the first and second deviatoric strain invariants, J is the determinant of the elastic deformation gradient and D is the material incompressibility parameter. Figure 1 shows the finite element tire model under airplane BEW. It can be seen that the tire bottom is flat due to the airplane weight.

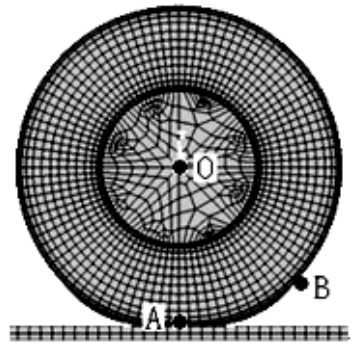

Figure 1. Radial tire model.

3 Wind forces on surface airplane

The wind lift force on an airplane with wing-flap 0 approximately equals the lift force on the same airplane with wing-flap 5 during the early running time. Although the calculated value by this means is a little larger than the actual one, the value is conservative and safe for the analysis of chocks. Figure 2 shows the running time-speed-load test data of B737-800 with wing-flap 5.

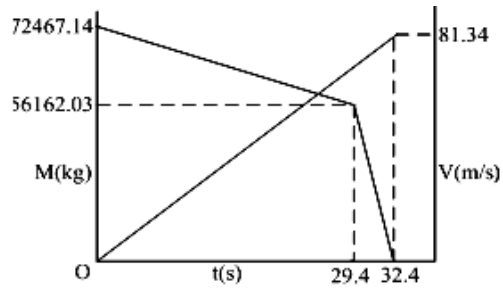

Figure 2. Running time-speed-load test data.

From figure 2 the following equations can be set up,

$$\begin{cases} L = K_L t \\ K_L = \dfrac{\left[\left(M_0 - M_R\right) g\right]}{t_R} t \\ V = K_V t \\ K_V = \dfrac{V_T}{t_T} \\ t_T = t_R + 3 \end{cases} \qquad (2)$$

where L is the wind lift force on an airplane, V is the wind speed, K_L and K_V are the lift force slope and speed slope relative to the running time, respectively, the

subscript labels T and R stand for Takeoff and Rotate, respectively, M_0 and M_R mean the initialization mass and the mass at the Rotate time, respectively.

From equations (2), the following formula used to calculate L can be induced:

$$L = 2164.92V \qquad (3)$$

The wind push force can be calculated by the following formula used to calculate the push force on a plane parked on a ship in high wind conditions (AVIC 1994),

$$P = 6331A\left(\frac{V}{100}\right)^2 \qquad (4)$$

where P is the wind push force, A is the airplane aerodynamic projective area which is vertical to the wind direction. As for the B737-800, A is 38.37 ㎡(CASTC 2008).

The airplanes must be moored when the wind speeds exceed the upper speed limits specified for their stability. The minimum speeds specified for airplanes to be moored in high wind conditions are the maximum speeds under which they can be parked stably and do not move with installed chocks, without parking brakes applied and mooring (Boeing 2005) . Table 2 shows the upper wind speed limits for the B737-800 (Hainan Airlines 2003) and the maximum wind lift and push forces calculated by formulas (3) and (4).

Table 2. Maximum wind lift and push forces on airplanes.

Surface condition	Maximum wind speed(m/s)	Lift force(N)	Push force(N)
Dry	15.43	33404.72	5783.57
Wet	10.29	22277.03	2572.14

4 Restraint efficacy of metal chocks

Metal chocks usually have the structures of linear elements and have two arc-shaped steel tubes pressed by tires, so their mechanical models are statically indeterminate and the restraint efficacy is affected by the spatial positions of those two tubes. A sample of forces on a metal chock is shown in figure 3.

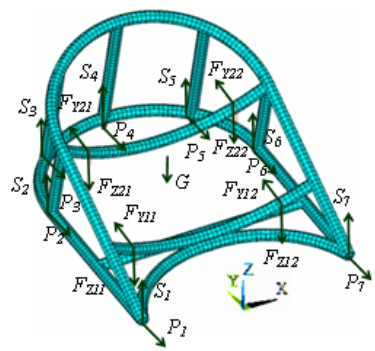

Figure 3. Forces on a metal chock

G is the chock's gravity force. F_{Y11} and F_{Y12} are the push forces on the lower tube, F_{Y21} and F_{Y22} are the push forces on the higher tube from the tire. F_{Z11} and F_{Z12} are the press forces on the lower tube, F_{Z21} and F_{Z22} are the press forces on the higher tube from the tire. F_{Y1} is the resultant force of F_{Y11} and F_{Y12}, F_{Y2} is the resultant force of F_{Y21} and F_{Y22}. F_{Z1} is the resultant force of F_{Z11} and F_{Z12}, F_{Z2} is the resultant force of F_{Z21} and F_{Z22}. F_Y is the resultant force of F_{Y1} and F_{Y2}. F_Z is the resultant force of F_{Z1} and F_{Z2}. S and P stand for the support forces and friction forces on the chock spikes from the ground, respectively.

An airplane usually weighs tens of tons or more, and therefore the lower tubes of metal chocks must be on the parking apron surface to gain the best mechanical conditions for bearing the pressure of the airplane tires. The center point of the tire is defined as point O and its projective point at the surface is defined as point A. The contact point between the tire and the chock is defined as point B. The angle between Line OA and Line OB shown in Figure 1 is defined as the working angle of the lower tube or higher tube. It is known by testing that the smallest working angle of the lower tube is 0.44 rad at which the lower tube locates at the boundary of the contact area between the tire and the parking apron surface. The restraint efficacy of metal chocks can be analyzed when the higher tube's position varies and the pushing coefficient is defined as F_Y divided by F_Z shown in table 3.

Table 3. Pushing coefficient of different move distances.

Move distance(m)	F_{Y1}(N)	F_{Z1}(N)	F_{Y2}(N)	F_{Z2}(N)	F_Y(N)	F_Z(N)	F_Y/F_Z
0.000	99	397	2665	3985	2764	4383	0.63
0.003	269	1363	2360	3641	2629	5004	0.53
0.006	464	2548	1832	3287	2296	5836	0.39

According to the friction self-locking principle, a chock can not be pushed away if the pushing coefficient is smaller than the friction coefficient between the chock and the apron surface. The abscissa represents the higher tube move distance along the radius outwards, the ordinate represents the pushing coefficient shown in Figure 4 when the higher tube's working angle is 0.79 rad and the apron surface is dry.

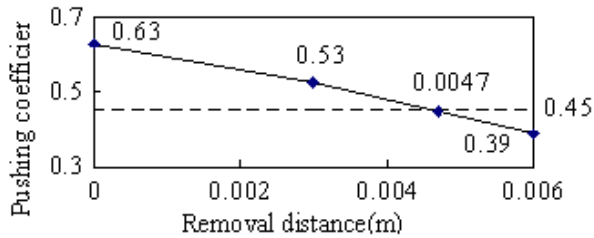

Figure 4. Pushing coefficient of different move distances.

It can be concluded that the pushing coefficient decreases with the increasing move distance of the higher tube. When the higher tube's working angle is 0.79 rad and the distance is 0.006m, the pushing coefficient is 0.39 which is smaller than the friction coefficient of 0.45. In such a case, the chock can not be pushed away by the tire. The intersection abscissa can be calculated and it is 0.0047m. In the same way, the move distances can be calculated when the higher tube's position varies and the apron surface is wet. It can be concluded that the higher tube should locate outside the left boundary of the strip region with shadow lines in Figure 5. However, the lower tube can be pressed and pinched by the tire and the chock can not be removed if the higher tube is too far away from the right boundary. The working region of the higher tube can be worked out based on the above analysis and it is the strip region.

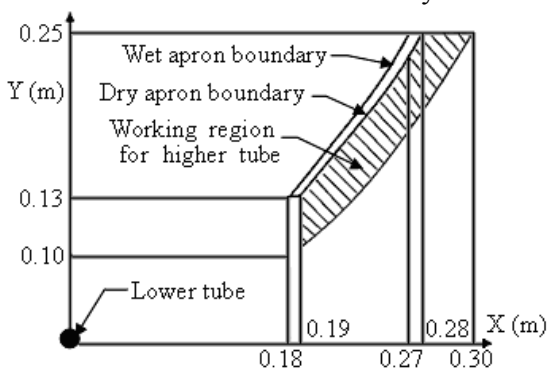

Figure 5. Higher tube working region.

5 Structure optimization design of metal chocks

According to the Figure 5, an optimized design scheme is presented for the B737-800 metal chocks. The finite element mechanical models of a radial tire and a metal chock are shown in Figure 6. The diameter and wall thickness of steel tubes are 0.026m and 0.003m, respectively, and the chock's safety coefficient of the whole structure strength is 1.51 for B737-800 airplanes with the maximum takeoff weight.

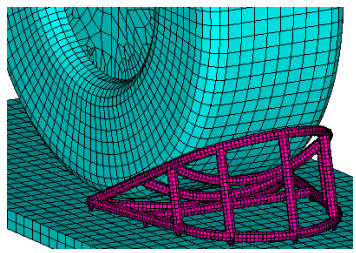

Figure 6. Finite element mechanical models

6 Results discussion

Airplane tires have air-supported membrane structures which are usually more complex than solid ones. The tire model in Figure 1 is set up based on the deformation test data of the tire bottom. The model can be more accurate if it is set up based on the whole tire deformation test data under more different airplane weights.

The working region of the higher tube can also be worked out if the tube moves outwards along the horizontal axis. However, the calculation process is a little more complex because the higher tube's working angle varies.

7 Conclusions

The method for analyzing airplane chocks' restraint efficacy is concise and applicable. So far the research results of this paper have been taken as the basis to draft the technical specification for civil airplane wheel chocks.

ABSTRACT

The paper studies three video detection methods，and present the methods' detection theory. The instantaneous stopping detection method can obtain vehicles' stopping delay. The semiautomatic software detection method can use the video generated from the camera to retrieve vehicles' stopping and accelerating delay. This method however cannot obtain the total delay that includes the accelerating, stopping and decelerating delays. The double section video method sets two areas at a proper situation and obtains the signalized control delay. Using manually collected exact delay, the paper analyses the accuracy of these three video methods. It is proven that the instantaneous stopping detecting method can get about 70% accuracy, the semiautomatic software detecting method 82%, and the double section video detecting method can get more than 90% accuracy.

INTRODUCTION

Delay times at a signal controlled intersection are one of the most important parameters to estimate the control method's effect. It can be defined as the delay time produced by the signal control. For the intersection, the delay time means the extra time that the vehicle spends when passing the intersection. Previous methods for intersection delay include the steady-state theory, fixed number theory, transition function curve method and other classical arithmetic. These methods assume that the arriving vehicle rate and the capacity are not change in a period of time (Quan, 1989). The TRANSYT system just considers the stopping delay. The system assumes that the average arriving traffic flow is known and does not changed in a period of time, which does not consider the vehicle lane's function. In the HCM2000, vehicle dispersing and the upstream intersection's impact is considered in the delay model. The relative research in China focuses on the model parameter's calibration and the relation between delay time and other parameters, such as saturation, lane's function and so on.

The paper describes three video methods to extract the parameters at signal controlled intersections. The video method can get the relative parameters on-line, which does not depend on the model.

VIDEO DETECTOR THEORY

Instant Stopping Delay Method

The instant stopping delay method comes from the gap aviation

photographing method. It records the number of stopped vehicles in per frame and then adds the total number of stopped vehicles in a period of time (Ran, 2007). It is similar to the dot-sample method.

According to the description, at the random time t, every vehicle has the instant stopping delay. If the vehicle is running, the value of $D_i(t)$ is 0, and if the vehicle is stopped, the value is 1. This is shown in equation (1):

$$D_i(t) = \begin{cases} 1 & \text{If the vehicle stopping;} \\ 0 & \text{If the vehicle not stooping;} \end{cases} \quad (1)$$

So, in the period time of T, the total stopping delay can be calculated as:

$$D_{\sum}(T) = \sum_{i=1}^{n} D_i(t) \quad (2)$$

In the formula n is the frame counts in the period time of T.

One of the most difficulties in this method is to judge the vehicle's state. Mitsuru gives three methods to deal with the problem, including the gap method, the moving method, and the manual method. In China, during the red phase, a driver who is on the approach lane will pass the intersection if he/she thinks the space between his/her vehicle and the front vehicle is large enough. Considering that fact, the speed is used to judge the vehicle's state. In SimTraffic, 3.0 m/s is used as the threshold. This choice however does not fit the stopping delay definition. In this research, we choose 0.216km/h as the threshold speed.

Semi-automatic Detection Method Based on the Software

Showing as Fig.1, semi-automatic detection method chooses the stop time effected by the red signal as its first observing time (t_1' in Figure 1) and the time when the vehicle passes the stop line as its second observing time (t_2' in Figure 1).

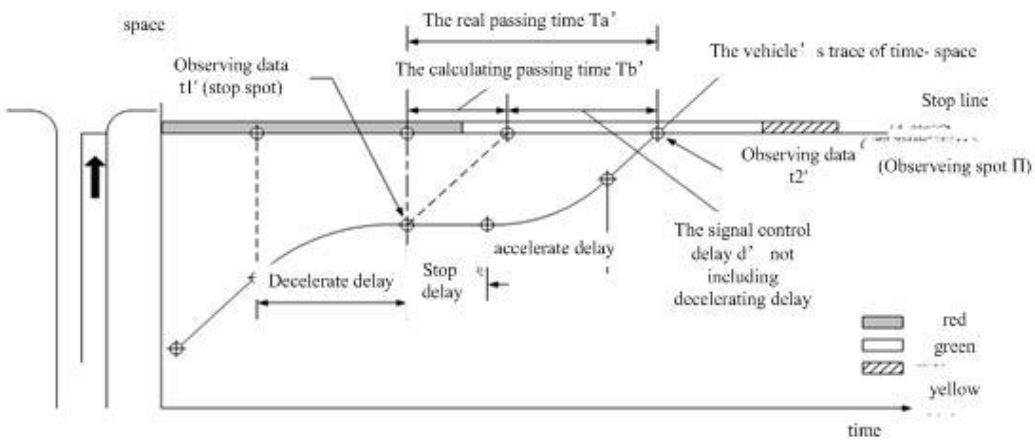

Figure 1 Semi-automatic detection method observe spot sketch map

The signal control delay variable d can be calculated as:

$$d = d' + d_{dc} \quad (3)$$

In equation (3), d' is the delay that the vehicle drives from the stop location to the stop line（s）; and d_{dc} is the vehicle's deceleration delay for blocked (s).

The variable d' can be calculated as:

$$d' = T_a' - T_b' \quad (4)$$

In equation (4), T_a' is the time that the vehicle drives from the stop location to the stop line (s); and T_b' is the calculated value that the vehicle travels from the stop location to the stop line using its normal speed（s）.

The variable T_a' can be calculated by:

$$T_a' = t_2' - t_1' \quad (5)$$

In equation (5), t_1' and t_2' 's meaning are showing in Figure1.

The variable T_b' can be calculated by:

$$T_b' = \frac{D' \times 3.6}{v} \quad (6)$$

In equation (6), D' is the distance between the vehicle's stop location and the observing location II（m）; and v is the vehicle's normal speed.

The deceleration delay variable d_{dc} can be calculated by:

$$d_{dc} = \frac{v}{a \times 3.6} \quad (7)$$

In equation (7), v is the normal average speed（km/h）; and a is the vehicle's average deceleration (m/s^2)，which should be measured in the field.

Double Section Video Detecting

The double section video detection method places two virtual detectors to extract the intersection traffic parameters. The first detector is placed on the stop line to record the vehicle's departure time. The second detector is placed far from the stop line. It aims to record the vehicle's approach time. The distance between the two detectors is 50-100 m. It can vary according to the camera height and the traffic saturation. How cameras can be set up is shown in Figure. 2. In this paper, the detector length is chosen as 15 m. The width can be set according to the number of lanes.

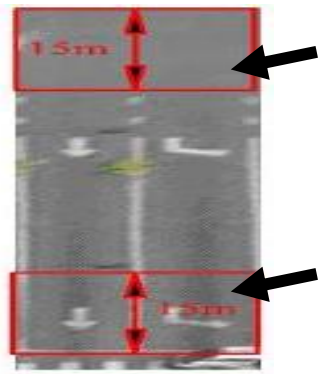

Figure2. The sketch map of the virtual detector setting

Because each vehicle is tracked from entering to leaving, the system can record the entering time and leaving time automatically. So the signal controlled delay time can be easily calculated as shown in Figure 3.

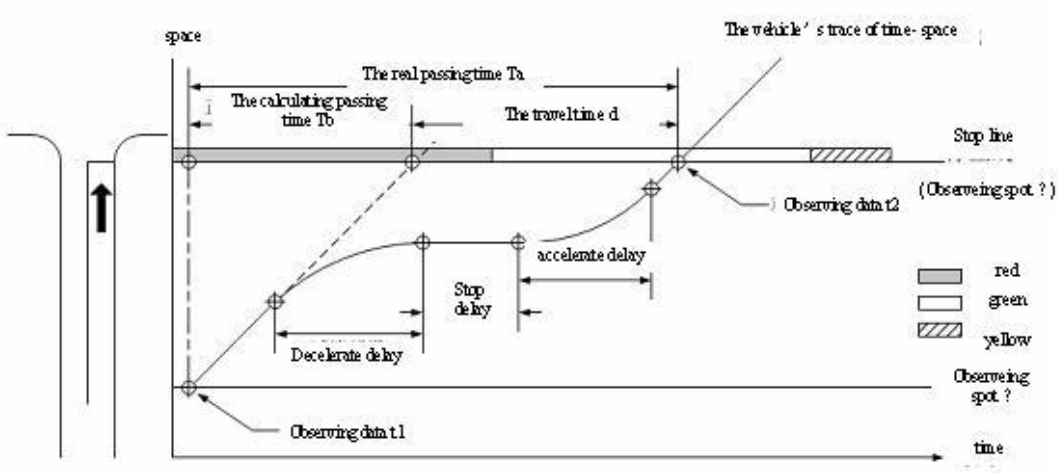

Figure 3. The sketch map of double section method

When the vehicle passes the far stop line detector, the time is recorded automatically (t_1 in Figure 3). Then the vehicle is tracked until it arrives at the stop line detector at , time t_2 in Figure 3. As a result, the actual travel time time that the vehicle spends at the approach road T_a can be calculated by:

$$T_a = t_2 - t_1 \qquad (8)$$

Assume that T_b is the time that the vehicle passing the space between the two detectors using its normal speed. The value of T_b can be calculated by:

$$T_b = \frac{D \times 3.6}{v} \qquad (9)$$

In equation (9), D is the distance between the two virtual detectors（m. Then the signal controlled delay d can be calculated by:

$$d = T_a - T_b \qquad (10)$$

COMPARISON AMONG THE METHODS

For the same video that comes from signal control intersection in Shanghai, the three methods are used for extracting the parameters. The manually collected data are used as the ground-truth. The comparison results are show in Table 1.

Tab le 1. The Comparison Results of the Three Video Detection Methods

cycle	Instant stopping delay method		Semi-automatic detection method		Double section method		Manual stat. data	
	Delay time （s）	Traffic flow(v/c)	Delay time （s）	Traffic flow(v/c)	Delay time （s）	Traffic flow(v/c)	Delay time （s）	Traffic flow(v/c)
1	12.35		25.01	12	24.40	14	22	14
2	7.6		18.49	17	14.53	15	13	15
3	11.67		30.94	7	27.40	9	22.56	9
4	38.5		50.72	8	44.79	6	48.17	6
5	26.75		52.63	11	46.76	11	43.08	12
6	18.88		48.67	8	32.82	9	31	9
7	9.3		84.01	11	58.964	11	62	10
8	38.25		58.67	14	51.71	12	49	12
9	40.92		70.13	9	57.19	8	55	8
10	23.1		52.31	8	43.97	10	39	10
Average error	40.41%		29.44 %	16.18%	9.27%	2%		

*The traffic flow is record as the number of vehicles in per cycle.

From the Table 1, the following conclusions can be made:

(1) The instant stopping delay method can estimate the stopping delay, but cannot estimate the control delay. Also, the method cannot estimate traffic flow.

(2)The semi-automatic detection method can measure the delay that includes the acceleration delay and stopping delay. In the software, the deceleration delay is added through the model to calculate the signal control delay. However this has to be done manually.

(3) The double section video detection method can estimate the signal control delay and traffic flow automatically. However the method requires strict conditions on the height and location of the camera. In addition, the camera has to face down and be placed securely.

(4) As showing in Table 1, for the same video, the instant stopping delay

method can estimate the stopping delay and captures about 60% of the signal control delay. The semi-automatic detection method estimates the signal control delay and other traffic parameters, but it has just 70% accuracy on delay and 83.82% accuracy on traffic flow. The double section video detection method can estimate the parameters as the semi-automatic detection method. The delay error is less than 10% and the traffic flow accuracy is more than 95%.

CONCLUSIONS

The video technology has been widely used in transportation. The paper described three video detection models that are deduced according to their respective detection theories. Using a test example, it is shown that the instant stopping delay method can estimate stopping delay. The semi-automatic detection method has fewer requirements in setting the camera, but it has to be done manually. The double section video detection method can estimate the parameters with high accuracy, but it has strict requirements in setting the camera.

ABSTRACT

Virtual scenes shown on vehicle driving simulator displays are somewhat different from reality, leading to a poor sense of immersion. In order to enhance the immersion techniques of vehicle driving simulators, this paper suggests two ways to make the size of the object shown on the display much more like the real object: by adjusting the parameters of the virtual camera and location of driver's eyes. The paper also analyzes the process of translation from an initial three-dimensional model to a two-dimensional image on the display. The process includes observing, projecting, and scaling the object. We also create a process by which to measure driver vision which entails observing and projecting transformation. Based on the relationship of the analyzed processes, an optimal model is established by adjusting parameters of the virtual camera, including the focus, the visual angle and the image resolution, and by adjusting the location of the driver's eyes. Parameters can be optimized based on the model, which will greatly increase the immersion function of vehicle driving simulators.

Key words: vehicle driving simulator; immersion; parameters of a virtual camera; location of driver's eyes

INTRODUCTION

Vehicle driving simulators are used widely in transportation research and practice. The vehicle driving simulators with arc-shaped channels or multi-channel displays produce much better immersion, interaction, and imagination; however, such simulators are too expensive to be used prevalently, so the simulators used for training are almost always single-channel display. The display size, virtual camera parameters, and location of the driver's eyes in single-channel simulators affect virtual scene immersion and the driver's perception of the scene. If any of these parameters are unreasonable, the displayed image will appear dissimilar to the real object, weakening the simulator's immersion function. Some scholars have researched the relationship between the virtual scene size and the display size, the

location of driver's eyes, and the parameters of virtual camera. Christopher D. Wickens (2002) mentioned in his research about Spatial Awareness Biases that if there is a change in the size of display or the geometric field of view (GFOV), the stand point of virtual camera, or even the location of observer's eyes, it will change both the location and size of the image mapped onto observer's eyes. Woodrow Barfield (1995) studied the relationship of the GFOV and spatial performance, stating that if one reduces the GFOV, the image mapped onto our eyes becomes larger. Ronald R.Mourant (2007) found that the GFOV can affect the driver's judgment about velocity. The GFOV relates to the visual angle of virtual camera: if the angle becomes larger (the focus becomes smaller), the image of the object will be enlarged and the object will appear closer to observer; if the location of driver's eyes is changed, the appearance of the observed object will change too. This leads to a series of changes that include the intersection of the line-of-sight with the display and the image size in driver's eyes. To enhance the sense of immersion, this paper proposes an adjustment in the parameters of the virtual camera and the location of driver's eyes in order to compensate for the fact that immersion is affected by the display size.

APPROACHES TO ENHANCE IMMERSION IN DRIVING SIMULATORS

Foley J D (1987) and Bryson S (1993) mentioned that there are many factors affecting the sense of immersion in virtual reality, such as display size, resolution, focus, etc. Summarizing their points, there are three ways to enhance the immersion of the driving simulator:

(1) Changing the display size. Larger images provide larger fields of view.

(2) Changing virtual camera parameters. The virtual camera parameters include the visual angle of the camera, camera focus, and image resolution.

(3)Changing the location of driver's eyes. Proper location makes the driver feel comfortable.

Since the technology of arc-shaped channels and multi-channel displays has been fully developed, this paper will not discuss the first method, but rather address the other two methods.

THE PROCESS OF SHOWING IMAGES ON THE DISPLAY

There are three steps that transform an original model from the three-dimensional world into a two-dimensional image shown on the display. These are observing transformation, projecting transformation, and scaling transformation (Xiang, 2008).

OBSERVING TRANSFORMATION.

We suppose that there is a world coordinate system (WC) $O-XYZ$, place the object models into the WC, and then establish another coordinate system called the camera coordinate system (or viewing coordinate system, VC for short) $O_c-X_cY_cZ_c$. The origin of the VC is the center of virtual camera $O_c(x_c, y_c, z_c)$, as shown in Figure1.

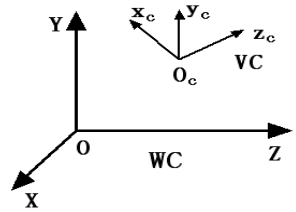

Figure1. Observing transformation

Translation and rotation are two necessary processes when transforming the coordinate of a point from the WC to the VC. Assume there is a point $P_w(x_w, y_w, z_w)$ in the WC, the point located at $P'(x_c, y_c, z_c)$ in the VC, the expression of transformation matrix is shown as follows:

$$\because\ x_c,\ y_c,\ z_c,\ 1)^T = \begin{bmatrix} R_c & t_c \\ 0^T & 1 \end{bmatrix} (\ x_w,\ y_w,\ z_w,\ 1)^T = M_{co}(\ x_w,\ y_w,\ z_w,\ 1)^T \tag{1}$$

Where R_c is a 3-by-3 unit orthogonal matrix, t_c is a three-dimensional translation vector, $0^T = (0\ \ 0\ \ 0)$, M_{co} is a 4-by-4 matrix (Kajita,2007; Zhang, 2008). Since M_{co} is determined by the relative position of the camera to the WC, it is called outside parameters matrix of virtual camera.

PROJECTING TRANSFORMATION. The projecting transformation is quite similar to the imaging process of a virtual camera on a single-channel driving simulator. The camera can be as simplified as a pinhole camera model (Zhang Mao-jun, 2001). Assume $P_i(x_i\ \ y_i)$ is the image coordinate of $P'(x_c, y_c, z_c)$ in the VC, the process of projecting transformation can be written as

$$k_c \begin{bmatrix} x_i \\ y_i \\ 1 \end{bmatrix} = \begin{bmatrix} f_c & 0 & 0 & 0 \\ 0 & f_c & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} x_c \\ y_c \\ z_c \\ 1 \end{bmatrix} = p \begin{bmatrix} x_c \\ y_c \\ z_c \\ 1 \end{bmatrix} \tag{2}$$

Where, k_c is a scale factor, f_c is the focus of the virtual camera optical system, p is called perspective projecting matrix.

The basic unit of the image is a pixel, but the unit of the transformation above is physical, thus we should translate the physical unit to pixel. Suppose that each pixel on X and Y axis occupies dx and dy of length measured by physical unit separately, the origin of the physical coordinate system is (u_0, v_0) in pixel coordinate system (see Figure.2).

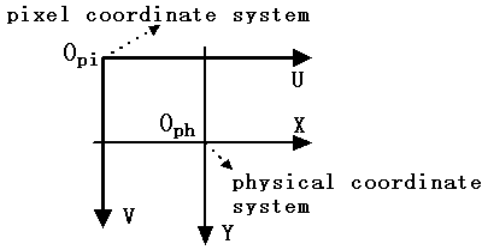

Figure2. Unit transformation

The unit transformation in the image can be expressed as

$$\begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \begin{bmatrix} \frac{1}{dx} & 0 & u_0 \\ 0 & \frac{1}{dy} & v_0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x_i \\ y_i \\ 1 \end{bmatrix} \tag{3}$$

Then the perspective projecting can be deduced as

$$k_c \begin{bmatrix} u_i \\ v_i \\ 1 \end{bmatrix} = \begin{bmatrix} a_x & 0 & u_0 & 0 \\ 0 & a_y & v_0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} x_c \\ y_c \\ z_c \\ 1 \end{bmatrix} = M'_{ci} \begin{bmatrix} x_c \\ y_c \\ z_c \\ 1 \end{bmatrix} \tag{4}$$

Where, $a_x = f_c/dx$, $a_y = f_c/dy$ are measure factors on u , v axis separately, they are called the normalized focus. a_x, a_y, u_0, v_0 are related with inside parameters of virtual camera, so they are called inside parameters of camera.

SCALING TRANSFORMATION. The image in the camera should be scaled to show on the driving simulator display, the process is shown as follows:

$$\begin{bmatrix} u_d \\ v_d \\ 1 \end{bmatrix} = \begin{bmatrix} a(2f_c)^{-1}\cot(\frac{\theta_h}{2}) & 0 & 0 \\ 0 & b(2f_c)^{-1}\cot(\frac{\theta_v}{2}) & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} u_i \\ v_i \\ 1 \end{bmatrix} = M_{c\to d} \begin{bmatrix} u_i \\ v_i \\ 1 \end{bmatrix} \tag{5}$$

Here, we denote a as the length of display, b as the width, and θ_h as the horizontal geometric field of view, θ_v as the vertical geometric field of view., (u_d, v_d) is pixel coordinate of P on the image. The matrix $M_{c\to d}$ can be factored as $M_{c\to d} = M_d M_c$.

Where, $M_d = \begin{bmatrix} a & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & 1 \end{bmatrix}$ and $M_c = \begin{bmatrix} (2f_c)^{-1}\cot(\frac{\theta_h}{2}) & 0 & 0 \\ 0 & (2f_c)^{-1}\cot(\frac{\theta_v}{2}) & 0 \\ 0 & 0 & 1 \end{bmatrix}$

Actually, M_d is related with the size of display and is called the parameters matrix of display; M_c is related with the focus and visual angle of virtual camera.

Since M_c and M'_{ci} are the matrixes that relate to the parameters of virtual cameras, they can be composed to one matrix $M_{ci} = M_c M'_{ci}$, M_{ci} is called as the inside parameters matrix of virtual camera.

The process that translates the point $P_w(x_w, y_w, z_w)$ in the WC to be the point $P_d(u_d, v_d)$ on the display, where the unit is pixel is shown as

$$k_c(u_d, v_d, 1)^{\mathrm{T}} = M_d M_{ci} M_{co} (x_w, y_w, z_w, 1)^{\mathrm{T}} \tag{6}$$

Where, k_c is a scale factor, M_d is parameters matrix of display; M_{ci} is inside parameters matrix of virtual camera; M_{co} is outside parameters matrix of virtual camera.

A SIMPLIFIED IMAGING MODEL FOR DRIVER'S EYES

The process by which an object is mapped onto the eyes is much too complicated, but we can observe the intersection of the line-of-sight with the display when we observe a virtual object as the point that will be crossed with the object imaged in eyes. Likewise, the observing transformation and projecting transformation information are required, but scaling transformation can be neglected in the driver's observation process.

We can designate an eye coordinate system (EC) whose origin is the location of driver's eyes. Similarly, the observing transformation matrix of driver's eyes is $M_{eo} = \begin{bmatrix} \mathrm{R_e} & t_e \\ 0^T & 1 \end{bmatrix}$. It is called the outside parameter matrix of the eyes.

Suppose the coordinate of the object is $P_e(x_e, y_e, z_e)$ in the eye coordinate system; the equation of display surface is $z = z_d$; and the display center is on the z axis. Driver sight intersects the display at $P_d(x_d, y_d, z_d)$. Therefore the parametric equation of the line of sight is

$$x = x_e t, \quad y = y_e t, \quad z = z_e t \tag{7}$$

Since $z_d = z$, so $t = \frac{z_d}{z_e}$, then we can compute that $x_d = \frac{z_d}{z_e} x_e$, $y_d = \frac{z_d}{z_e} y_e$.

If we use an equation to express the imaging process in eyes as

$$k_e \begin{bmatrix} x_d \\ y_d \\ z_d \end{bmatrix} = \begin{bmatrix} z_d & 0 & 0 & 0 \\ 0 & z_d & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} x_e \\ y_e \\ z_e \\ 1 \end{bmatrix} = M_{de} \begin{bmatrix} x_e \\ y_e \\ z_e \\ 1 \end{bmatrix} \tag{8}$$

Here, k_e is a scale factor too.

Similarly, the unit of intersection in the display is physical, it needs to be translated to a point with the pixel unit. The translation matrix is

$$M_d^{'} = \begin{bmatrix} \frac{1}{dx_d} & 0 & u_d \\ 0 & \frac{1}{dy_d} & v_d \\ 0 & 0 & 1 \end{bmatrix} \tag{9}$$

We denote dx_d, dy_d as physical length of each pixel on image that projected to display on X, Y separately. So the whole process is show as

$$k(u_d', v_d', 1)^{\mathrm{T}} = M_d' M_{de} M_{eo} (X_w, Y_w, Z_w, 1)^{\mathrm{T}} \tag{10}$$

CALIBRATING PARAMETERS

Based on the above analyses, the coordinate deviations of the intersection and the point on the display can be expressed by a vector

$$M' = k(u_d, v_d, 1)^{\mathrm{T}} - k(u_d', v_d', 1)^{\mathrm{T}} \tag{11}$$

Since the scale factor k_c is related with depth of the object in the VC, k_e is

related with depth of the object in EC , and usually the origin of the VC approaches the origin of the EC, suppose that $k = k_c \approx k_e$, so (11)can be replaced by

$$M' = k(M_d M_{ci} M_{co} - M_d^{'} M_{de} M_{eo}) \begin{pmatrix} X_w & Y_w & Z_w & 1 \end{pmatrix}^T \quad (12)$$

Define M as : $M = (M_d M_{ci} M_{co} - M_d^{'} M_{de} M_{eo})$

Now the main challenge is to make (12) small enough. Obviously, the factor $k \neq 0$ and $\begin{pmatrix} X_w & Y_w & Z_w & 1 \end{pmatrix}^T$ is variable, so we have to reduce M to achieve this. The problem therefore becomes an inequality-constrained minimization problem. The objective function can be abbreviated as $\min \| M \|$. $\| M \|$ is the normal number of M and the constraints are $\theta_h - \theta_{h\min} \geq 0$, $\theta_v - \theta_{v\min} \geq 0$, $z_d > 0$. Here $\theta_{h\min}$ and $\theta_{v\min}$ are the minimum horizontal and vertical visual angle respectively, its value can be given prior under different conditions, $z_d > 0$ show that the eyes must keep a respectful distance from the display.

So the problem can be written as

$$\begin{aligned} &\min \| M \| \\ &s.t. \theta_h - \theta_{h\min} \geq 0 \\ &\theta_v - \theta_{v\min} \geq 0 \\ &z_d > 0 \end{aligned} \quad (13)$$

Now we can change the inside parameters of camera and the location of driver under the constraints, and the immersion will be enhanced when changing the parameters.

DISCUSSION AND CONCLUSION

To solve the problem that single-channel displays affect the immersion factor in driving simulators, this paper established an optimum model by adjusting the virtual camera's parameters and the location of driver by analyzing computer graphics and the process of imaging in eyes.

Compared to enlarging the display or bending the display to an arc-channel, the method stated in this paper costs much less. If the parameters are optimum, some experiments can be done with simple display that will reduce the cost. Furthermore this method can enhance the immersion factor even if done with a multi-channel or arc-channel display. According to our analysis, the location of driver's eyes is an important factor affecting the immersion process that has been neglected by other literature. However, the method in this paper locates the driver in different experimental environments in order to enhance the immersion.

The model is based on driving simulators with single-channel display. When used on vehicle driving simulators with multi-channel and arc-channel display, it must be modified since the processes by which images are displayed are very complex. This will be addressed in future research, and we will do our best to verify and perfect the method stated in the paper through experimentation.

ABSTRACT

In this paper, we make use of informatics-based methods, establishing a calculation technique to measure the utility of a traffic sign's information for drivers. Additionally, some simple analyses are carried out to determine the usefulness of certain information for drivers who need different types of information.

KEYWORDS

traffic guide sign, information, utility

1 PREFACE

As a traffic management tool, the function of the traffic sign is transmit information to drivers. The relationship between traffic signs and drivers is that of information source to receiver. At present, some achievements have been made in the study of traffic sign information. These studies mainly focus on calculating the volume of information transmitted by traffic signs (Liu Xi, 1999; Cao Peng, 2006), and on evaluating the usability of the signs (Chen Guo-long, 2007), etc. However, it is necessary to improve the utility of traffic signs if we want to ensure that a traffic sign's information is adequately transmitted to the driver. Informatics offer an effective way to measure a traffic guide sign's usefulness.

2 THE CONTROL ROLE OF INFORMATION AND GENERAL INFORMATION MEASURE MATHOD

2.1 THE CONTROL ROLE OF INFORMATION

In the case of traffic systems, information is a statement about the contents of a thing (or system) communicated to the outer world as the system adapts to the external environment. Feeding such adaptations to the external environment, then, this exchanged content makes information an expression set for the specific location of the space in which a thing exists. This information resource reduces driver uncertainty about the status of the thing or system, while differential rule out other uncertainties.

"Control" is an adjustment process meant to overcome any uncertain status in

the system. In such adjustment processes, the system develops so as to move toward a fixed status. “Control” means that system behavior develops in a certain way, while “information” communicates the system's development status as selected by control and information both reflect the system’s increased activity toward negentropy.

2.2 GENERAL CALCULATION METHOD FOR INFORMATION VOLUME

The probabilistic information of a single case removed is the statistical uncertainty of information sink. A formula about the entropy of a discrete source formula proposed by Shannon as shows below (Piao Chang-gen, 2004, *Foundations of Systematology*):

$$H = -K\sum_{i=1}^{n} p_i \log p_i \qquad (2\text{-}1)$$

Where K is a plus constant. H is the measurement about information, choice and uncertainty, termed as the entropy of the probability set $p_1, p_2, \cdots, p_n$. When the logarithmic base is *2*, the K value takes *1*, the units of information amount is *Bit* (abbreviation for *Binary Digit*). This is a general way of representing a method for measuring the amount of an information source.

3 TYPES OF THE INFORMATION OF TRAFFIC GUIDE SIGNS

Generally, the traffic managers need to communicate two types of information: management information and service information, as shown in Figure 1(Shao Hai-peng, 2007). Traffic signs and directions in our study focus on service-oriented information. Their function is to provide travelers with the road network surrounding their current locations and/or urban (or regional) center, landmark buildings, key place names, as well as direction, distance information and so on. This enables drivers to position themselves within the road network, and it provides a reference point so as to assist, travelers in their decision-making.

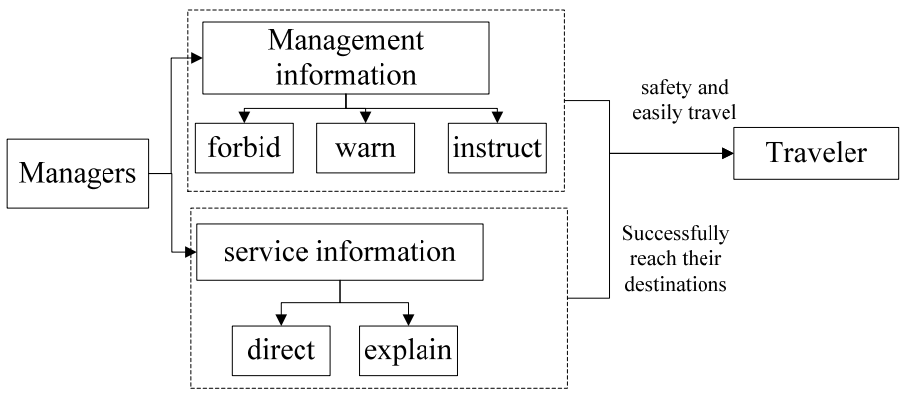

Figure1. Travel information classification and its role

4 CALCULATION METHOD FOR THE INFORMATION UTILITY OF

TRAFFIC GUIDE SIGNS

4.1 ASSUMPTIONS ON THE TARGET OF TRAFFIC GUIDE SIGNS

For the general traffic participants studied in this paper, we made the following assumptions:

a) The drivers are not absolute strangers to the road traffic, but know the basic regional situation (such as it can be found on maps). They are familiar with the surrounding environment, recognizing the important landmarks in the region;

b) For different road signs, drivers know their destinations;

c) Drivers have a basic knowledge of traffic and can understand the content of road signs.

Based on the assumptions above, we calculated the utility of guide information needs for different drivers respectively.

4.2 CALCULATION METHOD FOR THE INFORMATION UTILITY OF TRAFFIC GUIDE SIGNS

With respect to guide signs, the sign is located in a place of discrete probability of source; that is, it communicates self-contained information known as the source self-information. There are *n* types of elements in this source, (Chinese characters, letters, shapes, colors, numbers, images and symbols, etc.). Each element contains its own self-information $H(X_i)$(Zhou Yin-qing, 2006, *Foundations of Information Theory*).

The probability space for element X_i is as follows:

$$\begin{pmatrix} X_i \\ P \end{pmatrix} = \begin{pmatrix} x_1 & x_2 & \dots & x_j & \dots & x_{M_I} \\ p(x_1) & p(x_2) & \dots & p(x_j) & \dots & p(x_{M_i}) \end{pmatrix}$$

So, the self-information of guide sign H can be calculated by formula (4-1):

$$H = \sum_{i=1}^{n} H(X_i) = \sum_{i=1}^{n} \sum_{j=1}^{M_i} - p(x_j) \log p(x_j) \quad (i=1,\ 2, \cdots\cdots\ n,\ j=1,2 \cdots\cdots M_i) \text{(4-1)}$$

Among the information of guide sign, as for element i

$$p(x_1) = p(x_2) = \wedge = p(x_{M_i}) = \frac{1}{M_i},$$

so, formula 4-1 equals to (4-2):

$$H = \sum_{i=1}^{n} H(X_i) = \sum_{i=1}^{n} \log M_i \qquad (i=1,2, \ \cdots\cdots n) \qquad \text{(4-2)}$$

Where: H ——The total information volume of information source;

X_i ——element i in information source;

M_i ——status Number of element i ;

$p(x_j)$ ——the probability of the status j for an element of information source;

n ——types of elements contained in information source, including characters, letters, shapes, colors, numbers, images and symbols.

As for the information volume contained in every element of a traffic guide sign, Yung-Ching Liu (Yung-Ching Liu 2005) has presented a calculation method for each element. For instance, in the case of Arabic numerals, each number transmits 3.3 bits of information; in the case of sign-shape, 8 kinds of shapes can be used in traffic signs (*Road Traffic Signs and Markings GB5768-1999*) and each shape transmits 3bit information In this way, we can calculate the total amount of self-information contained in each guide sign.

For traffic sign users, the amount of information obtained from the sign is limited; they can not make full use of all the information contained in the sign. Here, we divide all the information on the signs into two parts: some elements ($X_a, a \in (0, k \le n)$) can provide users with certain information, and the information contained in these elements can be fully absorbed by users, Other sign elements($X_b, b \in (0 \le k, n)$) only enable users to reduce some uncertainties; they can help somewhat in reaching the destination, but do not provide exact information. Therefore, the information that the sign users get from traffic sign H' is supposed to composed by two parts, as shown in (4-3)：

$$H' = \sum_{a=1}^{k} \log M_a + \left[\sum_{b=k}^{n} \log M_b - \sum_{b=k}^{n} H(Y; X_b) \right] \quad (0<a<k<b<n) \tag{4-3}$$

therein： $H(Y; X_b) = \sum_{j=1}^{M_j} - p(Y; x_j) \log p(Y; x_j)$,

where： H' ——information obtained by sign users;

Y ——the case of get the destination;

$p(Y; x_j)$——determine the probability of case Y after realized the status j of element b ;

$H(Y;x_b)$—— priori information of element *b* for users.

The other symbols keep the same meaning as mentioned above.

Easily approve that $H' \le H$.

Defining η is the utility of traffic guide signs. It equals the ratio of information that the sign users get and self-information of information source, as shown in (4-4):

$$\eta = \frac{H'}{H} \tag{4-4}$$

From the above analysis we can see: $0 \le \eta \le 1$.

4.3 THE UTILITY OF INFORMATION ANALYSIS FOR DIFFERENT TYPES OF DRIVERS

1) Drivers who are completely familiar with the local traffic environment

These drivers do not need the information on the sign at all. The guide sign is superfluous, so they get no information from the guide sign, the utility $\eta = 0$.

2) Drivers who are fairly familiar with the local traffic environment

Such drivers are fairly familiar with the local traffic environment, but could still use the help of outside information to arrive their destination. The information amount they obtain is not 0, the utility $0 < \eta < 1$.

Consider as a point of analysis the driver who only needs directional information to arrive at the destination. According to the rules in *Road Traffic Signs and Markings GB5768-1999*, there are, on average, 4 kinds of direction on signs, the information represented on one sign therefore being $H = \log 4 = 2bit$, After the drivers have obtained the information from the signs, the posterior probability becomes *1/2* for the direction of destination. The information obtained equals $H' = H - \log 2 = 1bit$, so the current utility of guide signs is $\eta = 1/2$. The calculation method for other, more complicated situations is similar.

3) As for those drivers who are completely unaware of the local traffic environment and can receive all the sign information, they can make full use of the information on signs, so, the utility $\eta = 1$.

Up to now, this section describes the calculation method for the information utility of traffic guide signs, and we have analyzed the information utility for different types of drivers.

5 CONCLUSIONS

The value of information utility for traffic guide signs is a key indicator for evaluating the design and usability of road signs. In this paper, made use of some informatics research to create a calculation formula for standardizing the utility of guide sign information, and we have analyzed the information utility for different types of drivers. What should therefore be recognized is that the three main types of drivers have different needs at different locations, so the main information type of guide signs should also be different. Different partial information should be provided for drivers who have different information requirements. In this way can improve the utility of guide signs, thus saving materials and resources used for the production of signs.

ABSTRACT

This article analyzes the characteristics and the applicability of the gray cluster theory, taking the traffic statistics of Jiangsu, Jilin, Beijing, Chongqing and Gansu as examples, and arriving at the conclusions that the road traffic safety levels of Beijing and Chongqing are relatively higher, the level of Jiangsu is ordinary, while the levels of Jilin and Gansu are relatively lower. This paper, aiming at road traffic safety assessment based on the gray cluster theory, explores the analysis thread and research steps, as well as analyzes the reasonableness of the results. What's more, the authors propose their own ideas on the selection of the evaluation indicators, the determination and processing of whitening values of different gray classes. In addition, this paper also carries on the forecast to this theory's application prospect and the trend of development.

Keywords: Traffic safety evaluation; gray cluster theory; evaluation indicators; whitening function

INTRODUCTION

Gray system theory (Niu 2005) takes the uncertainty system as the research objects, mainly withdraws the valuable information from the generation and development of the known information in order to correctly understand and evaluate the system operation behaviors. In the road traffic system, the happening of the accidents may be random and casual, and some traffic data are also inconvenient to be collected and sorted. Therefore, there may be a number of uncertain factors in the road traffic system. Accordingly an area's road traffic system may be regarded as a gray system (Yue et al., 2005). In the safety evaluation process, sometimes there is no need to have access to all statistical indicator data. In accordance with the gray cluster thought, evaluating the overall level of road traffic safety in a certain gray class can be realized through screening, processing, extending, and expanding of part of the available information, with the combination of the qualitative and quantitative analysis.

The gray cluster theory can be used to consider the multi-factor influences of the evaluating indicators, and reflect the road traffic safety conditions accurately through the determination of the primary factors. Else, the evaluation method can carry out a comprehensive analysis from the horizontal or the vertical angle, which means it can assess the road traffic safety situation in the different areas or in the same area during the different periods dynamically. Above all, the gray cluster theory has broad applicability and significant guiding effect in the practical work.

As a result, this article has a research on the road traffic safety evaluation method based on gray cluster theory, with the traffic accidents statistic data of five representative and typical districts: Jiangsu, Jilin, Beijing, Chongqing, and Gansu.

ANALYSIS THREAD

Gray cluster theory is applied to road traffic safety evaluation, while combined with the specific characteristics of road traffic system out of a comprehensive consideration. The analysis and the research may be carried on according to the following steps:

(1) Explicating the objects. Determine the number of the evaluating objects, indicators and the gray classes. In this step, the selection of the evaluating indicators is a key link. The indicators based on the road traffic system should be able to fully reflect the level of the security and the severity of the accidents. In order to fully take the consequences of the accidents and the extent of the impacts relevant to the mobile car retention quantity, highway mileage et al. into account, as well as evaluate the level of road safety reasonably from the aspects of quantity (frequency) and quality (severity), we use the indicators of the relative accidents rate for research: the indicators of mortality per 10 thousand vehicles (persons per 10 thousand vehicles), death/injury ratio (%), the number of serious accidents per 100 thousand kilometers.

(2) Giving out the original sample matrix D. If we calculate and evaluate the actual indicators data directly, it will easily make the concept unclear and the comparison difficult, since each indicator has a different dimension and changing range. Therefore, it's necessary to deal with the data to obtain non-dimension matrix D'. In this article, the non-dimension matrix generates from Equation 1, the values of which are varied between 0 and 1.

$$x = \frac{d - d_{\min}}{d_{\max} - d_{\min}} \tag{1}$$

While the processed values of each evaluating indicator change from low to high, the nature displays from superiorly to poorly.

（3）Determining the whitening values of each gray class. The whitening values of each gray class could be determined through drawing the cumulative frequency curve and then obtaining the characteristic values corresponding to the cumulative frequency of the gray class. However, because this method determines the whitening values of each gray class on basis of the selected sample data, it makes the final

results only comparable among the samples. If we select different sample data when carrying out road safety evaluation, the evaluation criteria established will be different also, which makes the results of the evaluation fail to be comparable. Therefore, some scholars have suggested that the whitening values of each gray class can be obtained from the related normative standards or experts' advices, in order to unify the evaluation standard (Liu Yongqing, Li Wenquan, 2006). Urban Road Traffic Management Evaluation Index System is a set of evaluation indicator systems synthesized, in which the situations of the cities vary from the scale, the development phase, the demand characteristic, and the traffic management points. This article will refer to this system's classification situation and then determine the evaluation standard of different indicators and different gray classes.

(4) Determining the gray whitening function of each gray class. The gray whitening function $f_{jk}(x_{ij})$ describes the "preferred" level of the value in the corresponding range. "i" stands for the evaluation object, "j" stands for the evaluation indicator, and "k" stands for the evaluation gray class.

(5) Calculating the cluster coefficients. It conforms to the Equation 2:

$$\eta_{jk} = \frac{\lambda_{jk}}{\sum_{j=1}^{n} \lambda_{jk}} \tag{2}$$

"η_{jk}" stands for the cluster coefficients while the indicator j belongs to the gray class k, "λ" stands for the characteristic value—corresponding whitening value.

(6) Carrying on the cluster to the object. First, determine the cluster value of each gray class of each indicator using Equation 3:

$$\sigma_{ik} = \sum_{j=1}^{n} f_{jk}(x_{ij}) \bullet \eta_{jk} \tag{3}$$

Secondly, fix the final cluster value according to the Equation 4:

$$\sigma^{*} = \max(\sigma_{ik}) \tag{4}$$

Finally, determine the safety situation hierarchy of each object.

APPLICATION EXAMPLE

Basic data

This article takes Jiangsu, Jilin, Beijing, Chongqing and Gansu as examples, and then evaluates their levels of road traffic safety through gray cluster method. These five representative districts are different from geographical locations, natural conditions, and levels of economic development.

In 2007, the related traffic data of each district are shown in Table 1.

Table 1. Basic data（2007）

District	Mobile Car Retention Quantity（10 thousand cars）	Highway Mileage（km）	Traffic Accidents Death（persons）	Traffic Accident Injury（persons）	Serious Accidents Number（accidents）
Jiangsu	330	133732	5884	18617	12
Jilin	110	85445	1870	8099	10
Beijing	278	20754	1182	6257	0
Chongqing	145	104705	1218	11893	9
Gansu	53	100612	1548	4286	11

(**Note:** The data of Traffic Accidents Death, Traffic Accident Injury and Highway Mileage are obtained from 2008 China Statistical Yearbook. The data of Mobile Car Retention Quantity are referred to National Economy and Social Development Statistical Bulletin of different areas in 2007. The data of Serious Accidents Number are obtained from the Brief on the 2007 National Road Traffic Accidents promulgated by the Ministry of Public Security.)

Application of Gray Cluster Evaluation

(1) Calculate the indicators of mortality per 10 thousand vehicles, death/injury ratio, and the number of serious accidents per 100 thousand kilometers in the five districts according to the basic data listed in Table 1. From these calculations the sample matrix D is obtained as follow (see Matrix 1). Then, deal with the data in the matrix D to obtain the non-dimension matrix D' (see Matrix 2) according to the Equation 1.

(2) The evaluation standard will be classified as grade 1,2,3,4,5 in accordance to the Urban Road Traffic Management Evaluation Index System (2007), which reflects that the safety level changes from high to low. The whitening values of each gray class are listed below (see Matrix 3).

Since the whitening values of each gray class of each evaluating indicator differ a lot, it should be dealt with the equivalent non-dimensional treatment according to the Equation 1 with the sample data, in order to ensure comparability with the sample matrix. The results of the standardization are shown in Matrix 4.

$$\begin{vmatrix} 17.83 & 31.61 & 8.96 \\ 17.00 & 23.09 & 11.76 \\ 4.25 & 18.89 & 0.00 \\ 8.40 & 10.24 & 8.57 \\ 29.21 & 36.12 & 10.89 \end{vmatrix} \quad (1) \qquad \begin{vmatrix} 0.544 & 0.826 & 0.762 \\ 0.511 & 0.497 & 1.000 \\ 0.000 & 0.334 & 0.000 \\ 0.166 & 0.000 & 0.729 \\ 1.000 & 1.000 & 0.926 \end{vmatrix} \quad (2)$$

(**Note:** The rows express in turn: mortality per 10 thousand vehicles, death/injury ratio, the number of serious accidents per 100 thousand kilometers; the lines express in turn: Jiangsu, Jilin, Beijing, Chongqing, Gansu.)

$$\begin{vmatrix} 8 & 12 & 16 & 20 & 32 \\ 9 & 15 & 20 & 25 & 30 \\ 1 & 4 & 8 & 12 & 16 \end{vmatrix} \quad (3) \qquad \begin{vmatrix} 0.150 & 0.310 & 0.471 & 0.631 & 1.112 \\ 0.029 & 0.184 & 0.377 & 0.570 & 0.764 \\ 0.085 & 0.340 & 0.680 & 1.020 & 1.361 \end{vmatrix} \quad (4)$$

(**Note:** The rows express in turn: grade 1,2,3,4,5; the lines express in turn: mortality per 10 thousand vehicles, death/injury ratio, the number of serious accidents per 100 thousand kilometers. The data of The Number of Serious Accidents per 100 Thousand Kilometers are calculated in light of the classification of the number of the serious accidents mentioned in the Urban Road Traffic Management Evaluation Index System and the average highway mileage of different districts.)

If we determine the whitening values of each gray class by drawing the cumulative frequency curve, we can derive the curves shown in Figure 1. By the figure, we can find that except for the limitation mentioned above, this method cannot be effectively used in cluster evaluation to derive the characteristic values precisely through regression analysis, while the amount of the sample is small and the dispersion degree is large.

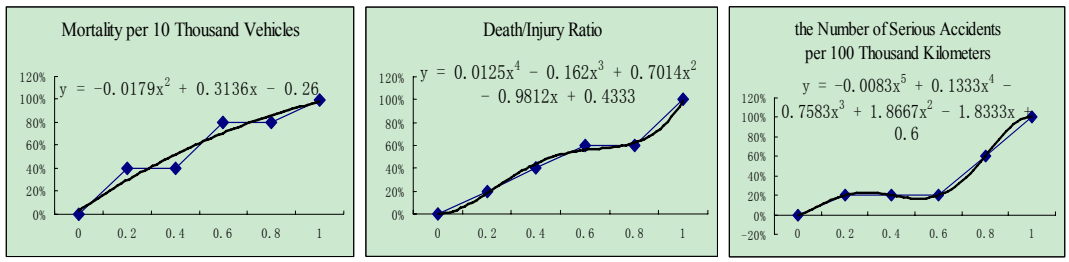

Figure 1. Cumulative frequency curve

(3)The classic gray whitening function is studied in this article. The models are listed below (see Equations 5-9)

$$f_1(x) = \begin{cases} 1 & x > \lambda_1 \\ \dfrac{\lambda_2 - x}{\lambda_2 - \lambda_1} & \lambda_2 \le x \le \lambda_1 \\ 0 & x < \lambda_2 \end{cases} \quad f_2(x) = \begin{cases} 0 & x > \lambda_1 \\ \dfrac{x - \lambda_1}{\lambda_2 - \lambda_1} & \lambda_2 \le x \le \lambda_1 \\ \dfrac{\lambda_3 - x}{\lambda_3 - \lambda_2} & \lambda_3 \le x < \lambda_2 \\ 0 & x < \lambda_3 \end{cases} \quad f_3(x) = \begin{cases} 0 & x > \lambda_2 \\ \dfrac{x - \lambda_2}{\lambda_3 - \lambda_2} & \lambda_3 \le x \le \lambda_2 \\ \dfrac{\lambda_4 - x}{\lambda_4 - \lambda_3} & \lambda_4 \le x < \lambda_3 \\ 0 & x < \lambda_4 \end{cases}$$

$$f_4(x) = \begin{cases} 0 & x > \lambda_4 \\ \dfrac{x - \lambda_3}{\lambda_4 - \lambda_3} & \lambda_4 \le x \le \lambda_3 \\ \dfrac{\lambda_5 - x}{\lambda_5 - \lambda_4} & \lambda_5 \le x < \lambda_4 \\ 0 & x < \lambda_5 \end{cases} \quad f_5(x) = \begin{cases} 0 & x > \lambda_4 \\ \dfrac{x - \lambda_4}{\lambda_5 - \lambda_4} & \lambda_5 \le x \le \lambda_4 \\ 0 & x < \lambda_5 \end{cases}$$

Table 2. The cluster coefficients

	1	2	3	4	5
Mortality per 10 Thousand Vehicles	0.57	0.37	0.31	0.28	0.34
Death/Injury Ratio	0.11	0.22	0.25	0.26	0.24
Number of Serious Accidents per 100 Thousand Kilometers	0.32	0.41	0.45	0.46	0.42

First, calculate the cluster coefficients conforming to the formula (see Table 2).

Then, calculate the cluster values of grade 1 to 5 according to models 5 to 9 in light of the relationships between the sample values and characteristic values (see Table 3).

Table 3. Cluster values of each district

District	1	2	3	4	5
Jiangsu	0	0	0.510	0.239	0
Jilin	0	0	0.354	0.665	0
Beijing	0.890	0.049	0.194	0	0
Chongqing	0.623	0.037	0.385	0.066	0
Gansu	0	0	0.124	0.398	0.261

(4) Calculate the final cluster value according to Equation 4, and then finally determine the safety situation hierarchy of each object. In conclusion, in 2007, Jiangsu: $\sigma^* = 0.510$, the safety level is in grade 3; Jilin: $\sigma^* = 0.665$, grade 4; Beijing: $\sigma^* = 0.890$, grade 1; Chongqing: $\sigma^* = 0.623$, grade 1; Gansu: $\sigma^* = 0.398$, grade 4.

Evaluation Results

On basis of the analysis of the evaluation results, we come to a conclusion: the road traffic safety levels of Beijing and Chongqing are relatively higher, Jiangsu is ordinary, while Jilin and Gansu are relatively lower. It is concluded from the traffic accidents statistical data that the evaluation results in general conform to the reality. The results could support the road safety management departments for decision-making and have a certain reference value.

With the analysis process and evaluation results, we find that: (1) the distribution of the values of the indicators will affect the cluster coefficients. This kind of difference has something to do with the selection of the functions and the indicators. (2) Different indicators should be chosen for different evaluation purposes. In the daily traffic safety management process, we should consider different factors from the humans, vehicles, roads, environment and management, and establish a multi-level evaluation indicator system to make the evaluation results more comprehensive. (3) We should take the timeliness and applicability of the norms into full consideration as there may be some limitations with the development of the society.

PROSPECT

Along with a more widespread application of the gray cluster theory in the road

traffic safety evaluation, some experts and the scholars have made some tentative plans for improvements to the traditional model. For instance, the improvement to the determination method of the whitening values of each gray class which is mentioned in Section 3 changes the pattern of traditional methods. Moreover, several scholars have made some improvement to the whitening function. In theory, the sample values after dealing with the whitening functions should change rapidly as the differences between the sample values and characteristic values of certain gray class increase. However, the classical whitening function value changes stably, which would not obtain the best cluster effect. The function should be improved to be expressed in the form of an exponential function (Tian et al., 2007). Because the exponential function has the characteristic of interval monotonicity and the existence of the limitation, it is quite appropriate to take it as whitening function. In addition, the gray cluster theory is also widely combined with other theories, such as AHP and neural network technology et al. The application fully displays the characteristic of each theory and evaluates the level of the road traffic system more objectively.

CONCLUSION

Referring to the present research situation and improvement opinions of the gray cluster theory, this article chooses the classical cluster steps for the analysis and comparison of the road safety assessment, and proposes its own understandings on how to select and identify the evaluating indicators. For the determination of whitening values of each gray class, the article opts for the classification provided by "Urban Road Traffic Management Evaluation Index System", which could break through the limitations of the sample data to improve the objectivity and the comparability of the assessment. The authors put forward their own ideas on the treatment of obtaining non-dimensional whitening values, using the equivalent approach to the sample indicators' to maintain the consistency of membership and ensure the standardization. What's more, the article analyzes the influencing factors of the results, such as choice of objects, determination of standards, expressions of the function et al., which have certain significance on the safety management work.

Abstract: This study aims to develop a system to manage road traffic control information and analyze traffic resources. In this system road traffic control information is represented as objects, such as points, lines, or regions, in GIS while the specifications of them are stored in the attribute table of the objects. Moreover, GU (Graphic User) interfaces are developed to process, edit, query, display, and print the information. Based on road networks and the relevant traffic control information, a road traffic resource analysis system is developed.

INTRODUCTION

GIS (Geographical Information System) is a computer application system to collect, process, analyze, and display spatial data and transmit data in different systems, locations, and users. GIS is extensively used in many fields, such as transport management, urban planning, and real estate marketing (Zhang *et al*, 2003). GIS-T is a computer system that can collect, store, manage, analyze, and handle spatial and traffic information. It is the extension of GIS in transportation and an integration of GIS technology to analyze and process transportation information.

The rapid urbanization and motorization in China has shortened the cycle time for urban road supply and demand. Since the existing road system cannot meet the demand, the urban road networks are being improved continuously and the traffic control system, including traffic signals, signs and marks, lanes, and one-way roads, is being frequently adjusted. During the construction of new or improved roads, infrastructure construction sites often occupy a portion of an existing road and significantly affect the efficiency of the overall road network. Therefore, how to collect, manage, and update the dynamic information and analyze traffic resources with this information has become a subject of significant interest. Based on a GIS platform, this study develops a system to manage road traffic control information and analyze traffic resources dynamically and visually. It has been implemented and used by the police from the urban traffic branch.

Many applications of GIS in the field of transportation can be found. For example, the road network model system of GuangDong is used to edit, analyze, and

display highway network data of GuangDong province (Wang, *et al*, 2001). The LanZhou urban traffic information system can not only display the locations of video monitors but also analyze congestions and display the congested locations. The GuangDong highway network model system is based on a 1:500,000 map scale. Using the same method, the LanZhou system represents roads and intersections with lines and points, respectively, in GIS. In both systems, the road information is inputted manually and information relating to traffic controls and construction sites cannot be positioned accurately. Moreover, spatial data in the system differs from the actual situation due to the use of small-scale maps (Yang *et al*, 2000).

To overcome the problems, we use a 1:2500 map scale for the spatial information resource and polygon objects of MapInfo to represent roads and intersections. As a result, spatial information such as the width or length of a road or the area of the intersection can be obtained directly. Since traffic control information and construction sites can be recorded into polygons of roads and intersections, traffic resources can be analyzed accurately with the spatial analysis of GIS. However, it is obvious that the traditional line-point network topology method cannot be applied here. In order to analyze traffic resources and release real-time information, a new network topology method that can analyze the spatial relationship between the polygons of intersections, roads, and the direction of roads has been developed.

SYSTEM STRUCTURE

As shown in Figure 1, the system consists of data models and GU interfaces. Data models refer to layers in the MapInfo database. There are several layers, including the road layer, the intersection layer, the traffic mark layer, the traffic sign layer, and the layers of current construction sites, future construction sites, and construction history.

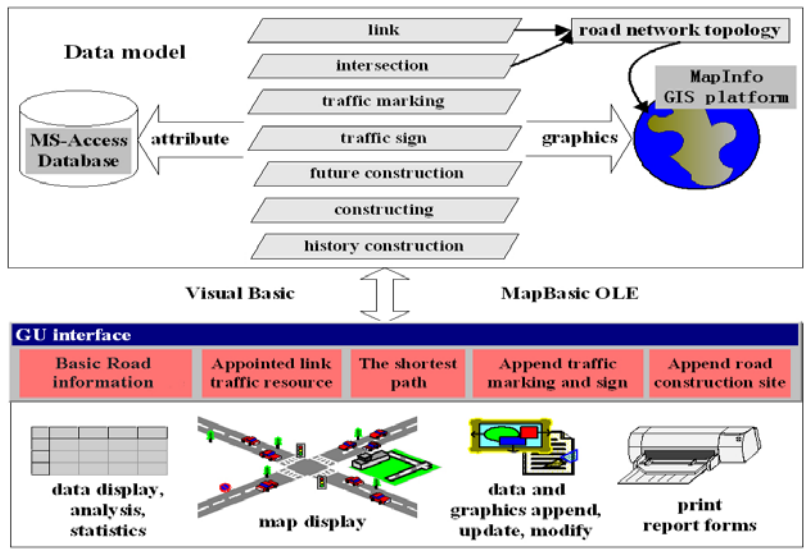

Figure1. System Framework

Layers of roads and intersections are the bases. Polygons here correspond to links or nodes of the road network, but with the same shape as the actual ones. Users can measure the area, width, and length of an intersection or road and can also know its spatial location. The traffic mark layer contains all traffic control marks on the pavement and they have the same shapes and XY-coordinates as the actual ones. The traffic sign layer contains all traffic control signs beside or above the roads. Layers of current and future construction sites and construction history record all construction sites that may affect road traffic based on the dates of establishment of the construction sites and construction activity. GU interfaces are developed with MS-VB that can be used to analyze, display, input, update, and modify attribute and graphic data. It also contains the interfaces of the basic road information, the inquiry, the statistics of traffic control information, the traffic marks and signs, the construction site appending, and the shortest path search and display. With them, users can manage and query various road traffic control information visually.

SYSTEM DESIGN AND REALIZATION

Data Model

As the basic data platform, the road and intersection layers are the first two data models. They are established based on a 1:2000 digitized map. Roads and intersections are polygons in MapInfo. Since the digitized map can vividly reflect the actual urban topography, these polygons completely contain the spatial attributes of the urban road network. In order to establish the network topology structure automatically, a road polygon must start from the adjacent intersection when creating a road in the database. Then, topology analysis of the road network can be carried out with spatial calculations in MapInfo as follows:

Step 0: Number the objects in the road and intersection layers respectively. Put the serial numbers of them into a field of the attribute table (Table 1).

Step 1: Fetch each object in the road layer and find objects in the intersection layer that intersect with each road object. As Figure 2 shows, intersections *i and, j* are two ends of roadway *k*. In terms of network topology, it can be said that roadway *k* starts from (and ends at) intersection *i* and ends at (also starts from) intersection *j*. This is done by judging which intersection the road polygon starts from

Step2: Find one-way roads manually and record them in the attribute table as shown in Table 1 (Ren *et al*, 2003)

Step3: Calculate the coordinate strings of road *k* (k：$(1，x_1,y_1)，\ldots，(n，x_n,y_n)$), and intersection *j*（$j$：$(1，x_1,y_1)，\ldots，(m，x_m,y_m)$）to get the XY-coordinate $(q，x_q,y_q)$ of the first intersecting point between the road and the road ending intersection. Calculate the road length with coordinate string（$\boldsymbol{k}$：$(1，x_1,y_1)，\ldots，(q，x_q,y_q)$）and road width with coordinate string（$\boldsymbol{k}$：$(1，x_1,y_1)$，$(n，x_n,y_n)$）. Record the length and width in the attribute table.

Table 1 Roadway Attribute Table

Link ID	Start point	End point	Direction	Length	Width
K1	***l***	***i***	1（single）	***d1***	***w1***
K2	***i***	***j***	0（two）	***d2***	***w2***

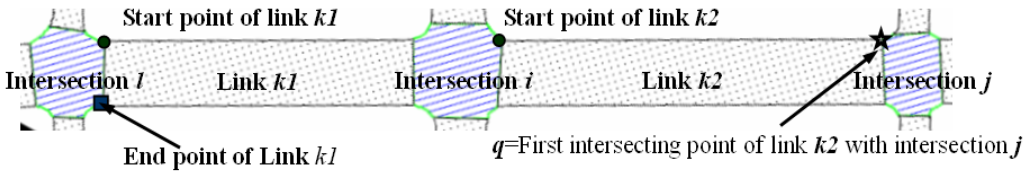

Figure 2. Road Network Topology

The traffic sign layer records the location and attributes of traffic control signs on both sides of the road. The traffic mark layer records the location, shapes, and attributes of traffic control marks painted on the pavement. The attributes include the name, number, type, and installation time. The traffic sign and mark layers are established annually. Thus, at the beginning of each year the system will create new layers and store the old ones automatically. Construction information along a road is stored in three layers, which records current ones, future ones, and the history of the constructions, respectively. A construction site is represented with a polygon and polygons are painted with different colors to display the characteristics of the project. Information about the construction site such as name, nature (water, electricity or gas), starting date, ending date, responsible person, and number of the occupied lanes is stored in the attribute table.

Figure 3 shows a part of the data model in the system. Two construction sites (electricity and gas projects), traffic signs along the roadway, zebra stripes, the lane, center line, and several traffic flow orientation arrows can clearly be seen. All of them are essential to analyzing traffic resources. For example, the shortest path search algorithm cannot find the correct path unless the “left-turn restriction”, a “construction site on the road”, and a “one-way road” are taken into account.

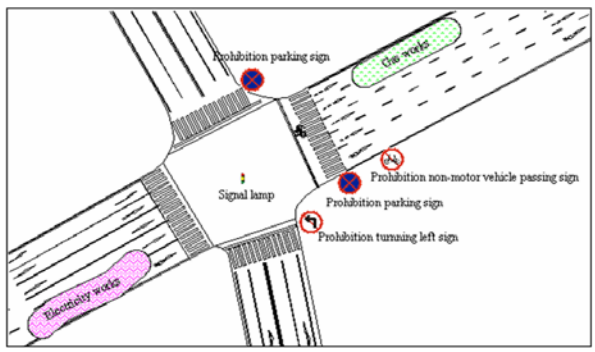

Figure 3. Data Model in the System

Data Model Management System

The data model management system consists of several GU interfaces, which

are supported by MS-VB and MapBasic derived programs. With GU interfaces, users can query, calculate, analyze, display, and print information. In addition, the system also offers tools for users to add new data into the models.

In the basic road information system, simple or complicated inquiries can be done. For example, after the name, width, service level, or direction code is given, the spatial location and detailed descriptions of the corresponding roads can be found. Furthermore, after a road is picked up in GIS, its relevant traffic information will be displayed as shown in Figure 4. A total of 207 traffic signs are available in the traffic sign library. When it is necessary to add a new traffic sign in a data model, the user just needs to point to a site in GIS and select the identification number (ID) of the traffic sign according to the prompt and a new sign will be created automatically. With the same method, the user can add traffic marks in a designated location. A total of 20 kinds of traffic flow orientation arrows, 2 kinds of zebra stripes, 2 kinds of car lanes, and 2 kinds of center lines are available in the marks library.

In the construction site input system, after the user draws a line in a position and inputs the name, starting and ending dates, responsible person, and the width of the area, as shown in Figure 5, a new construction site will be added. The system stores and manages it according to the starting date. If the date is in the past, a buffer of the line will be created in the current construction site layer. Otherwise the buffer will be created in the future construction site layer. Since construction site data changes everyday, the system can update and transfer data among the three layers automatically.

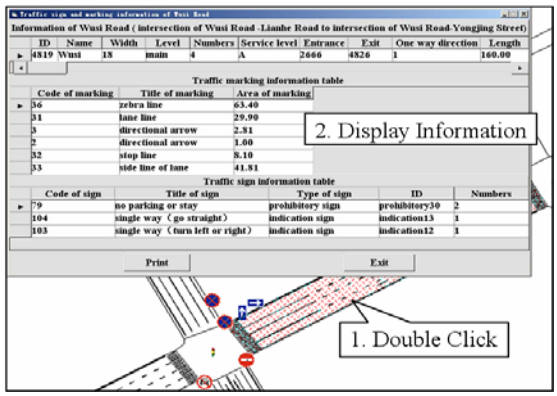

Figure 4. Shows Information for a given Road

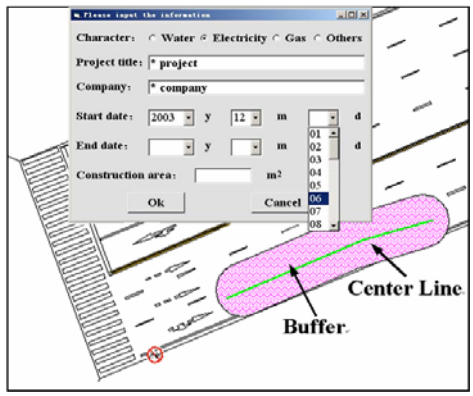

Figure 5. Adding a Construction Site

A tool in GIS is created to do this when the system is started. After the system begins to work, the tool will decide if there are projects in the future construction layer that will start according to the entered dates. If there are projects currently starting, the system moves the data from the future construction layer to the current construction layer. Then the tool will decide if there are projects in the current construction layer that will be finished according to the entered dates. If there are projects currently ending, the system will ask the user to confirm it and move the data from the current construction layer to the construction history layer. If the user

does not confirm the construction ending according to the entered date, the system will ask for an updated ending date.

ROAD TRAFFIC RESOURCE ANALYSIS

Road traffic resource analysis includes road surface condition analysis, the shortest path analysis, vehicle routing, and traffic resource distribution. Since the system stores lots of relevant road traffic information, the accuracy and validity of a traffic resource analysis based on the system can be guaranteed. The shortest path searching method should be the subject of more detailed research to ensure it properly takes into account the many relevant factors. It is reasonable to think that besides signal controls, travel speed and turn restrictions are the main factors affecting the travel time of a path (LU *et al*, 2003). Within a temporary equilibrium, the travel time of each road is stable. For example, the travel time of a road does not change during the rush hour on weekdays. However, if there is a construction site on the road, the travel time will become longer. Therefore, although in a temporary equilibrium, the shortest path does change when there are new construction sites or turn restrictions. Therefore, an indicated shortest path might indeed not be the actual shortest path (ZOU *et al*, 2002). Based on the information about road and traffic control in the database and the Dijsktra algorithm, we developed a method that can take the effects of construction sites and turn restrictions on travel time into account during the shortest path search.

Since a left-turn restriction cannot be considered in the Dijsktra algorithm, it has to be put into the network topology. Traditionally, an intersection with a left-turn restriction is separated into several nodes and then roads are connected to the nodes according to the actual situation as shown in Figure 6. This method increases the number of nodes and links in the network. If the road network is large and there are many left-turn restrictions, it will increase the calculation time greatly. Moreover, since a road network in our system is represented as a polygon, it is difficult to partition an intersection into several polygons. A method, in which the ID of the left-turn exit-link of an approach is recorded in attribute table, was developed.

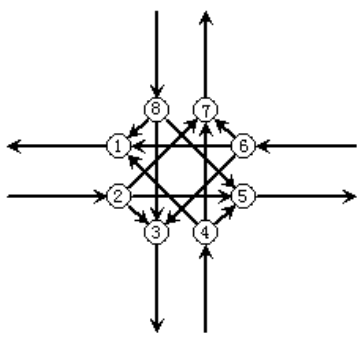

Figure 6. Actual Connection of an Intersection

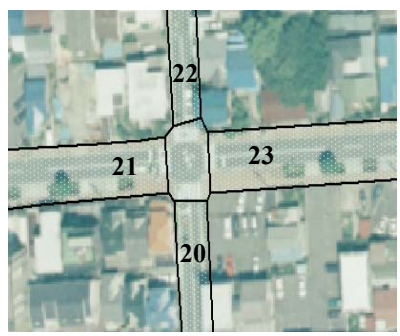

Figure 7. Exits of a Left Turn Restriction Approach

As Figure 7 shows, suppose the left-turn in approach 20 is restricted and its exit-links are roads 21, 22, and 23. In that case, we record 21 in the field of

"Left-Turn Restriction" of record 20. This can be done either by a manual or an automatic method. The automatic process supported by the GIS spatial analysis function is described as follows.

1) As Figure 8 shows, the process is creating a rectangle that is double the size of the minimum bounding rectangle of the intersection polygon and calculating the XY-coordinates of the vertex of the rectangle to get ($1,X_1,Y_1$), ($2,X_1,Y_2$),($3,X_2,Y_2$), ($4,X_2,Y_1$).
2) Next, it creates lines from the CentroID of the intersection to CentroIDs of roads, then judges which side of the rectangle intersects with the line from the CentroID of the intersection to the CentroID of road 20 to obtain point 5 (which is the same as point 1) and point 4, the remaining point with the bigger ID. Here point 1 remains.
3) Finally, it decides which line intersects with side 1-2 to get a line from the CentroID of the intersection to the CentroID of link 21. Then it knows link 21 is the exit link for a left-turn off road 20.

Since not all approaches are left-turn restricted, the program will not be run for all roads in the network. What we should do is to overlay the traffic marks layer onto the road layer to find roads that contain left-turn restriction marks and run the program for these roads. The overlay can also be done by a program and the two programs can be integrated into one tool.

After the above work, in the Dijsktra algorithm, if the field of "Left-Turn Restriction" of the current road is not zero, then the travel time of the forward link with its ID equal to that number will be given a large value such as 100 hours.

Construction on the road may affect road capacity and thus extend the travel time. Since delays happen only when road capacity is under severe traffic flow, traffic flows on roads should be taken into account when analyzing the effects of the construction sites on the shortest path. The traffic flows are the results of traffic assignments in static equilibrium (Lu, 1997). In the condition of a road without a construction site, equilibrium traffic flow q_a on road a can be calculated with the Franc-Wolf algorithm and road capacity C_a can be calculated based on road width. Then road traffic time can be calculated with the BPR (Bureau of Public Road) function while considering the construction sites. As Figure 9 shows, there is a construction site, which is l meters long, W meters wide on road 23 and road 23 has n lanes in one direction which are w meters wide. Therefore, its travel time is as follows.

$$t_{23} = t_{23}(0)\left\{(1+\alpha\left(\frac{q_{23}}{C_{23}}\right)^{\beta})\times\frac{L-l}{L}+(1+\alpha\left(\frac{q_{23}}{C_{23}\times\dfrac{w\times n-W}{w\times n}}\right)^{\beta})\times\frac{l}{L}\right\}$$

Here t_{23}=actual travel time, q_{23}=traffic flow on the road, C_{23}=link capacity,

L=length of the road (meters, obtained from the link layer), α, β=parameter (α=0.045, β=4), $t_{23}(0)$=road travel time for a speed not restricted by the effects of the construction site.

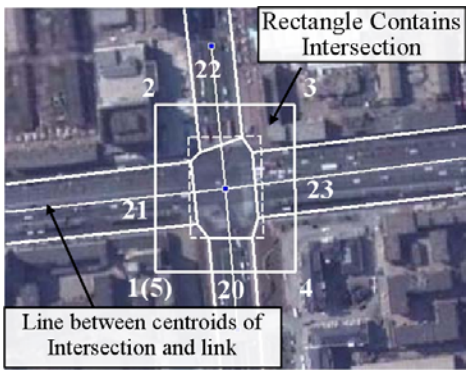

Figure 8. Automatic Judge Exit of Left Turn

Figure 9. Overlap of Link with Construction Site

We compiled programs with C# and MapBasic for the above situation and the Dijsktra algorithm and installed the programs into two front ground interfaces. Users can easily search the shortest path between intersections with these interfaces. This shortest path takes both left-turn restrictions and construction sites in the road network into account.

SUMMARIZATION

With the above method we developed a road traffic control information system based on a MapInfo database. It advanced the standardization, digitalization, and modernization of road traffic information management. The system functioned well and improved the efficiency of the Police Office responsible for traffic management. However, since the system was developed by the GIS technique as a stand-alone terminal application, it is not suitable for an office network and open information sourcing. Our future research will focus on upgrading the system with the Web-GIS technique to give remote clients the ability to visit the system via the Internet.

ABSTRACT

In order to optimize the crashworthiness of curved-road concrete barriers in which the curve-road radius is 400 meters, based on the NJ concrete barrier, a “vehicle-curve road-barrier” integration model is established. The six cross-section parameters of concrete barriers are regard as factors, five levels for each factor. The optimal results are obtained using the orthogonal experimental design methods. The $L_{25}(5^6)$ orthogonal table is used for the simulation test arrangement, the SPSS statistical package is used for the variance analysis of simulation results. Subsequently, using the optimal results, based on the foundation shape of the NJ concrete barrier, a "vehicle-curve road-barrier” integration model including the foundation of concrete barrier is established. Simulation results show that the integrity of the concrete barrier stays intact, and the assumption of "the concrete barrier bottom node fix" used in orthogonal experimental design is practicable and the foundation shape of the NJ concrete barrier can be used directly in curved-road concrete barriers. Finally, the forces and stresses acting on the concrete barrier during the collision between vehicle and barrier is computed. A reinforcement project of curved-road concrete barriers is suggested.

1 INTRODUCTION

China's traffic accident death toll has been the highest in the world for more than 10 years. Most expressways and the highways has had installed various forms of barriers, setting up the appropriate special rails is in response to major traffic accidents, but unfortunately, the existing rails are based on the straight path. Research on the curved-road is scarce. Barriers used on straight roads has been installed on curved roads, whether or not it is right has not been clearly answered,

and there are not related explanations and justifications in the existing curved-road design specifications (Zhang Jing, Bai Shufeng, Shi Hongxing, etc.,2007). In China, the curved-road network of highways substantial occupies a large proportion, less than 100 meters on average one out of corners. Curved roads is the main source of serious accidents, and road condition improvement is a huge project which needs not only putting in a lot of manpower, material and financial resources, but also much time. Obviously, study of the curved-road barrier is more realistic compared to improving road conditions.

2 FINITE ELEMENT MODEL

2.1 THE BASIC SPECIFICATIONS

Collision conditions (Lei Zhengbao, Zhou Pingyan, Yan Haiqi, etc., 2006): crashworthiness level SS, the mass of bus 18 t, the collision velocity 80 km/h, and the collision angle 20°.

Road design using ultra-high 8% with radius curve of 400m. Busses will be handled as a rigid body, and only the outline of the bus, height of mass center, inertia, weight and other parameters are considered. Parameters are shown in Table 1.

In the bus locations outside the front axle are used to establish coordinates: X-axis parallel to the bus longitude, Y-axis parallel to the bus width, Z axis parallel to the direction of the height of the bus. The coordinates of bus mass center: XC = 3250mm, YC = 1250mm, ZC = 1390mm; bus moment of inertia at the center of mass: I_{zz} = 62586000, I_{yy} = 62586000, I_{xx} = 22897200.(Liu Lan, 2008).

Table 1. Specifications

Exterior dimensions(L×W×H)	12×2.5×4m
F / R track base	2/1.8m
F/R Suspension system	1.5/ 4m
wheel base	6.5m
Minimum Groundclearance	0.350m
Tire radius	0.5mm
Curb vehicle weight	9120 kg
Total Weight	18000 kg

Coefficient of friction between bus and ground is set at 0.7, between buses and rails are set at 0.2; bus collision barrier time 1.5s (Lei Zhengbao, Xie Yuhong, Li Haixia, 2005).

2.2 MESH

Rigid material models are used for the bus and road, bus material parameters: density 7.87kg/dm^3, Young's modulus E =2.0×10^{5}MPa, Poisson's ratio 0.27; road material parameters: density 2.5kg/dm^3, Young's modulus E =3.5×10^{4}MPa, Poisson's ratio 0.25; mesh with the thickness of 1 mm, by 2-point-integral Belytschko-Tsay shell element, shell size were admitted to 50mm, the smallest shell size is 30mm, the element warping angle $\leqslant$ 25° ,and element interior angle $\geqslant$25° . the bus model include 115165 quadrilateral elements, 140 triangle elements, 119757 nodes; road

model containing 73500 quadrilateral elements, 9 triangular elements, 74150 nodes.

Constant-stress flexibility elements and Brittle_Damage material models are used for the barrier. Barrier material parameters: mass density 2.5kg/dm^3, Young's modulus E=3.0×10^{4}MPa, Poisson's ratio 0.20, stretching limit 3MPa, shear limit 14.5MPa, fracture toughness 14.9×10^{-3}kg/mm^2, viscous Parametric 0.72MPa/s, yield stress 29MPa. Then we obtain the "vehicle–curve road–barrier" integration vehicle-road system dynamics finite element model. It is clear that as long as the modified section parameters of the barrier are according to the above steps, we can get the corresponding " vehicle–curve road–barrier" integration system dynamics finite element model.

3 BARRIER CROSS-SECTION PARAMETERS OPTIMIZATION

According to orthogonal experimental design, we get the possible combinations of barrier cross-section parameters to set up "vehicle–curve road–barrier" integration dynamics finite element model one by one using the modeling method above. LS-DYNA software is used to simulate the tests, then achieve the optimal results using SPSS software (Lei Zhengbao, Yu Jinxiu, YAN Haiqi, etc., 2007).

3.1 FACTORS AND LEVEL

Barrier cross-section shape control by the six variables (factors) (Figure 1).

Each factors set five levels (table 2), The $L_{25}(5^6)$ orthogonal table is appropriate.

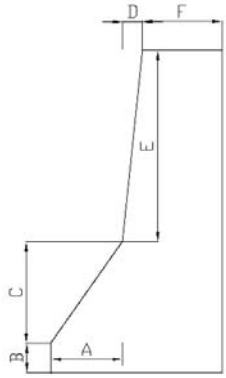

Figure 1. Factors

Table 2. The level of factors (mm).

factor / level	A	B	C	D	E	F
1	125	45	150	50	400	100
2	175	50	200	60	475	150
3	225	65	250	70	550	200
4	275	75	300	80	625	250
5	325	80	350	90	700	300

3.2 THE RESULTS AND ANALYSIS

According to Table 2, based on orthogonal L_{25} (5^6) provided by the combination of tests, and simulation tests carried out 25 times, each factor and test results are shown in Table 3. From Table 3 we know: the 25th test's results are good. Table 4 gives us an orthogonal intuitive analysis results. Table 4 shows that the greater the difference between extreme., the greater the change that the numerical factor in the trial within the scope of change will lead to in tests, so the difference between extremes is the largest one of the factors affecting the level of the test results of the

biggest factors, that is the most important factor. Thus, under the influence of primary and secondary level to arrange the result is: C> B> E> F> A> D.

Tab. 3 experiment result（mm, H.O.RW: height of rear wheel）

Factor / No.	A	B	C	D	E	F	H.O.RW	Barrier height

3	**1215.2**	1239.2	1223.0	**1242.2**	1287.0	1333.3
4	1265.8	1489.8	1227.4	1319.4	1307.8	1457.2
5	1393.8	**957.8**	1878.6	1432.4	1271.0	**1138.8**
D.B.E	282.6	532.0	786.2	190.2	359.8	318.4

Table 4 also shows that various factors, the optimal level for the portfolio: A3B5C1D3E2F5, that is, A=225mm, B=80mm, C=50mm, D=70mm, E=475mm, F=300mm. As this group has no arrangement in Table 3, which shows that orthogonal table lists the 25 groups with not only the best can be seen with the results, but it also can be inferred that the results may be a better match. In order to verify such an inference, it is also necessary with this group of simulation tests.

When significant level α =0.05, the results of variance analysis are shown in Table 5. The paper use the test out of the design methods, so error analysis can only take the relative error, classifying the factors corresponding to the minimum variance as errors.

Table 5 shows that factor C and B are significant factors, should choose their level best, the others can be based on the need to consider their level of choice.

Table 5. Test significance

factor	Error SS	Def	Mean square	F ratio	F	significance
A	298144.640	4	74536.16	2.387	6.390

D.B.E	124908.64	4	31227.16			

4 THE SIMULATION FOR OPTIMAL RESULTS

To prove the above results and identify the optimal solution, it is needed for intuitive analysis of the optimum combination A3B5C1D3E2F5, that is, A=225mm, B=80mm, C=150mm, D=70mm, E=475mm, F=300mm, Fig.2 to Fig.4 for the height change in the bus simulation results.

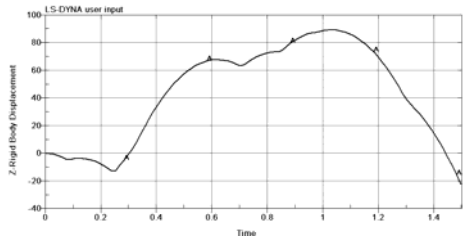

Figure 2. Height of the bus mass center.

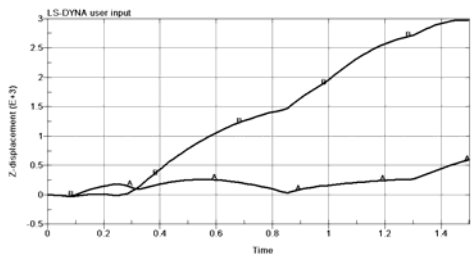

Figure 3. Height of the left and right front wheel.

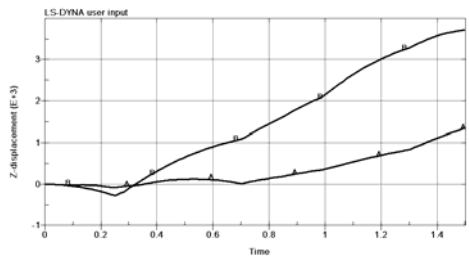

Figure 4. Height of left and right rear wheel.

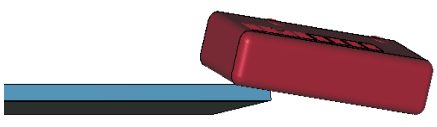
Clearly, the optimal combination A3B5C1D3E2F5 can not stop the bus from running out of barrier. The wheel near the barrier at the end is raised to a height of 1400 mm, significantly more than the maximum height of the barrier. Figure 5 shows that the bus goes out of concrete barrier rails and flies in to the space outside.

By all appearances, the optimal combination A3B5C1D3E2F5 does not lead to optimal results. According to the general principles of orthogonal design, the best simulation test results from 25 groups should be chosen. The 25th group is better compared to simulation results in other groups. The 25th group simulation results are shown in Figure 6 to Figure 9.



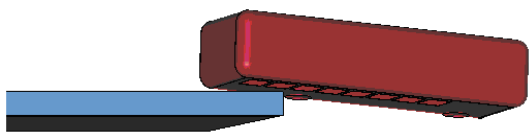


Figure 5. Bus goes out of the barrier. Figure 6. Bus rolls over inside of the barrier.

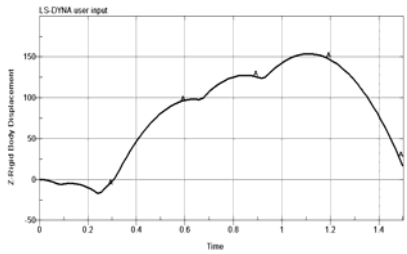

Figure 7. Height of mass center

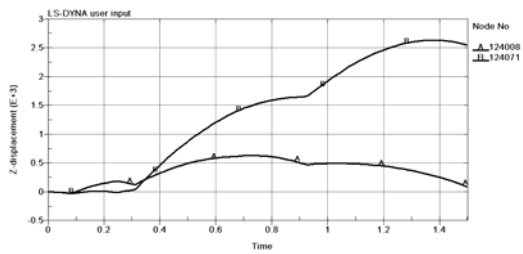

Figure 8. Height of left & right front wheel.

Figure 6 – Figure 9 indicate that the bus has completely rolled over, but did not run out of barrier. Figure 9 shows that the wheel near the barrier rises to a height of 738 mm, while the overall height of the barrier is 855 mm. Thus, the optimal is the 25th group result.

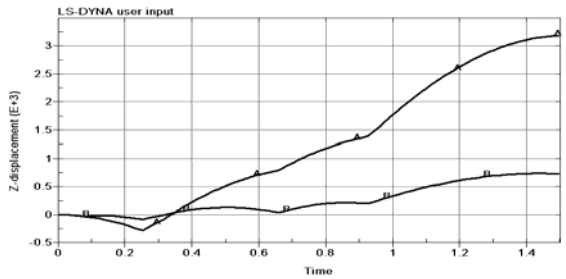

Figure 9. Height of left & right rear wheel.

5 BASE FOR THE DESIGN AND REINFORCEMENT

In the simulation above, the base has not been adopted, an assumption of "barrier at the bottom fixed nodes" is used before it was proved. The reinforcement project in the concrete barrier is also a key question in design.

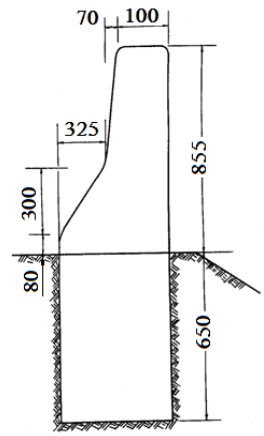

Figure 10. Barrier base

5.1 CURVE-ROAD BARRIERS BASE AND FINITE ELEMENT MODEL

The curved-road barriers finite element model is based on the use of the standardized road side of concrete embedded lock base, in accordance with Figure 10, and the basis for cross-section at the bottom line extends down to 650 mm. This barrier has the section size as follows: 430mm×650mm. Barriers and foundation are poured together locked in embankment road, embedded in the soil.

Road model reference Table 6, taking into account the barrier base width of 495mm, the depth of foundation set for 1500 mm.

Table 6. Material parameters for the road base.

NAME	MAT	Thickness (mm)	Young's modulus(MPa)	Poisson's ratio	Density (t/mm3)
Surface	*MAT_ELASTIC	150	1200	0.25	2.5E-9
Base layer	*MAT_ELASTIC	300	800	0.25	2.4E-9
Pad layer	*MAT_ELASTIC	200	600	0.25	2.3E-9
Ground layer	*MAT_ELASTIC	1500	40	0.40	1.8E-9

5.2 BASE DESIGN

From the simulation results, the barrier is not separated from the foundation, the road embankment is not separated from the soil during vehicle impact, and the base has not been overturned by vehicle. The simulation results show that the base of the straight road is applicable to a curved road (Figure 11 and Figure 12).

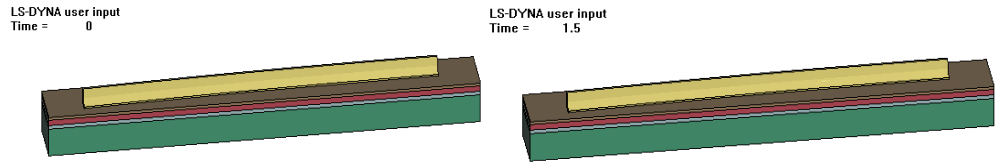

Figure.11 Barrier and its base at t=0s. Figure 12. Barrier and its base at t=1.5s.

Clearly, the barrier integrity intact, the foundation has played its due role for the fixed barrier. In other words, orthogonal experimental designs on the assumption of "barrier at the bottom fixed nodes" are practical.

5.3 REINFORCEMENT PROJECT

From the simulation output, t =0.72s when the rear of the bus collides with the barrier the biggest barrier stress occurred. The maximum stress reached 121.764MPa, as shown in Figure 13. Maximum stress element numbered 204,154, located in the place where barrier and its base connected, is shown in Figure 14.

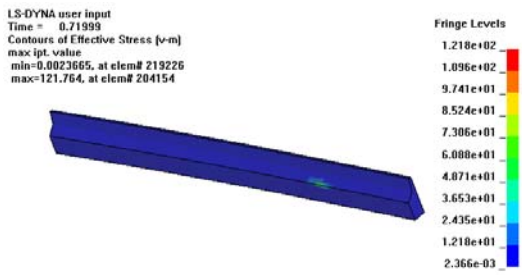

Figure13. Max stress on barrier in simulation.

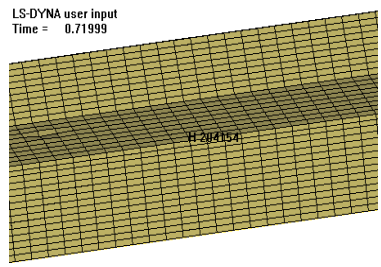

Figure 14. Location of max stress element.

From the entire process of the collision, the stresses are no more than 30MPa, except at t=0.72S when the stress is too large.

The barrier stress analysis finds the weak cross-section in the barrier, the maximum stress, and provides reference for reinforcement. The reinforced steel bars are calculated based on the collision force, then reinforced area and the reinforcement project can be determined. According to the results output the biggest barrier collision force reached 287190 N (see Figure 15).

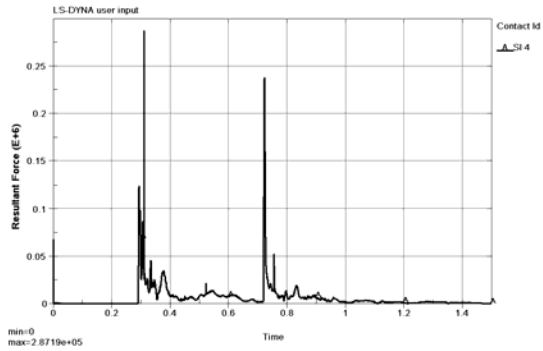

Figure 15. Max force on the barrier.

There have been two kinds of very mature reinforcement options in straight concrete barriers:

Option I, a reinforcement program for general cases: configuration 8 φ12 vertical steel bars and spacing 34cm φ 6 stirrups, in the special position was reinforced.

Option II, an enhanced reinforcement program: Configuration 4 φ 16 & 6 φ12 vertical steel and spacing 34cm φ 8 stirrups, it is also reinforced in a special place.

Concrete is an elastic-plastic material; moreover, force in vehicle collisions is entirely non-linear. In the vehicle collision process, the back wall will have great tensile stress, while the stress in the internal wall is very small, so we must allocation the vertical steel bars along the contour lines.

The steel bars can guarantee that the entire concrete barrier withstands the impact force 287190N, as long as the overall area of the steel bars is more than 1367.6mm^2 which has a tensile strength of 210N/mm^2.

Comparing two types of concrete barrier reinforcement options, we can see that the area of vertical steel bars is only 904.32 mm^2 in the reinforcement program for the general option, less than the requirements of 1367.6mm^2, which does not meet the requirements.

The area of vertical steel bars is 1482.08 mm^2 in the enhanced reinforcement program, more than the required 1367.6mm^2, and so it is able to meet the requirements.

Therefore, the enhanced reinforcement project in straight concrete barrier can be directly used for reinforcement of curved-road concrete barriers, namely: configuration 4 φ16 & 6 φ12 vertical steel and spacing 34cm φ 8 stirrups, as is used for reinforcement in special places.

6 CONCLUSION

(1) Increasing the height of the concrete barrier is an important way to protect busses from going over the barrier, and a reasonable cross-section of the concrete barrier design parameters can control the accident inside the barrier.

(2) the optimal cross-section parameters of curve-road concrete barrier is: A=325mm, B=80mm, C=300mm, D=70mm, E=475mm, F=100mm.

(3) the six cross-section parameters of the curved-road concrete barrier have the following priorities: C> B> E> F> A> D.

(4) when the significant level $\alpha = 0.05$, C and B are significant variables, and should choose their best levels (that is, B=80mm, C=300mm), whereas the other four variables can be considered based on their needs.

(5) the assumption of "barrier at the bottom of fixed nodes" used in orthogonal experimental designs are practical. The NJ-based form of concrete barrier has good stability, and can be used directly in curved-road.

(6) the enhanced reinforcement project in straight concrete barrier can be directly used for reinforced project of curve-road concrete barrier, namely: configuration 4 φ16 & 6 φ12 vertical steel and spacing 34cm φ 8 stirrups, as is used for reinforcement in special places.

ABSTRACT

The total mileage of highways in China has ranked the second in the world and traffic accidents have become a potential safety problem, which threaten people's lives. Panel data model as a new tool is introduced to analyze crashes. Panel data, which combines cross-sectional and time-series characteristics, allows researchers to construct and test realistic behavioral models that cannot be identified using only cross-sectional or time-series data. This paper introduces the modeling process of fixed effects model and random effects model. These models are applied to the Jingjintang Highway. Variables are divided into four categories including roadway variables, traffic variables, indicator for different areas, and accidents variable. The two models' results are compared and the fixed-effects model was chosen to describe the relationship between accidents and other factors after the Hausman test. The fixed effects model was chosen since it could identify unobserved factors and segments with high safety risks. Panel data model as a new statistical tool will be widely used in the transportation analysis field.

Keywords: Traffic Safety; Accidents Analysis; Panel Data Model; Fixed-effects; Random-effects

INTRODUCTION

According to government statistics (Ministry of Communications, 2006), China's highway mileage reached 3,350,000 kilometers in 2006, ranking the second in the world and people travel more conveniently than before. However, road traffic safety situation continues to deteriorate in recent years. Traffic accidents and the associated economic loss are an incredible social and economic burden on the nation.

This paper introduces panel data models to traffic accidents analysis, which can overcome a simple time-series model or data model cross-section. In this paper,

Jingjintang Highway is divided into 64 subsections according to road conditions and each subsection was considered as a panel. Fixed effect and random effect models were developed and the Hausman test results showed that the individual fixed-effects model is more reasonable to describe highway traffic accidents.

LITERATURE REVIEW

The earlier models for crash prediction were developed using ordinary or normal linear regression, such as multiple linear regression, Poisson regression, and negative binomial regression (Montella, 2008). Panel data analysis is a more recent method for analyzing speed limit policy. Greenstone (2002) used linear fixed effects panel models to track yearly fatality rates in all 50 states from 1982 to 1990. He concluded that fatality rates rose by 30% on rural interstates and fell by 17% on urban non-interstates. Noland (2002) examined the traffic safety effects of roadway infrastructure improvements using fixed-effects negative binomial regressions with panel data from over 14 years. Noland concluded that engineering design improvements have not been effective in reducing fatalities and injuries.

PANEL DATA METHODOLOGY

Model description

Panel data refers to two-dimensional data, consisting of a cross-sectional variable and a time-series variable (Xie 2005). Typical structure of panel data is as shown in Figure 1:

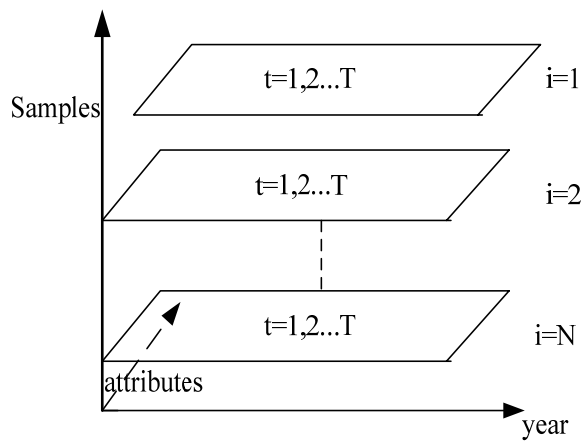

Figure 1. Structure of panel data

Panel data model often contains more data and reduce the co-linearity relationship between explanatory variables. Panel data permits identification of variations across individual roadway segments and over time. Accommodation of observation-specific effects also mitigates omitted variables bias. There are two standard model types that are appropriate for panel data, fixed and random effects models. The specification of fixed effects (FE) linear model is as shown in Equation 1.

$$y_{it} = x_{it}^{'}\beta + \alpha_i + \varepsilon_{it} \quad \text{i=1,2,3...N and t=1,2,...T} \qquad (1)$$

Where ε_{it} is an error that varies across both segments and time periods. α_i is the time-invariant with fixed effect specific to roadway segment i; it can be estimated by the following formula:

$$a_i = \overline{y_i} - \hat{\beta}'_{FE}\,\overline{x_i} \tag{2}$$

Where $\overline{y_i}$ is the number of crashes on segment i over T time periods, $\overline{x_i}$ is the vector of average values of the explanatory variables for segment i over T time periods, and β'_{FE} is the least squares dummy variable (LSDV) estimator.

The specification of a random effects (RE) linear model is as follows:

$$y_{it} = x'_{it}\beta + \mu_i + \varepsilon_{it} \tag{3}$$

Where μ_i is the random effect specific to roadway segment i and ε_{it} is an error that varies across both segments and time periods.

Linear fixed effects models can be estimated using a least squares dummy variable model. Linear random effects models can be estimated using a generalized least squares (GLS) approach, by assuming an appropriate distribution for random effects.

Hausman Test

The choice of specification generally depends more on whether correlations exist between omitted variables and the included explanatory variables. Both FE and RE model forms were estimated here and which estimates should be used in practice are decided after the Hausman test was performed (Alberto M., 2005). The following is the chi-squared statistic:

$$W = \chi^2[\mathrm{K}-1] = [\hat{\beta}'_{FE} - \hat{\beta}_{RE}]'\,\hat{\psi}^{-1}[\hat{\beta}_{FE}' - \hat{\beta}_{RE}] \tag{4}$$

Where $\psi = Var[\hat{\beta}'_{FE} - \hat{\beta}_{RE}] = Var[\hat{\beta}'_{FE}] - Var[\hat{\beta}_{RE}]$, β'_{FE} is the LSDV estimator for the FE panel model, and $\hat{\beta}_{RE}$ is the GLS estimator for the RE panel model.

MODEL DEVELOPMENT

Data preparation

- **Crashes Collection**

Data for this study were collected from different sources. It consists of crashes from January 2002 to December 2005, AADT, passenger cars percentage, large truck percentage and travel speed. There were totally 3784 crashes recorded.

- **Traffic flow data**

There are 23 loop detectors installed underneath pavement to monitor traffic flow for both directions along this freeway. Five traffic flow data items can be extracted from the detectors including speed of large vehicles, speed of small vehicles, volume of large vehicles, volume of small vehicles, and occupation rate. Minimum time interval for original data from detector was one minute. In order to make cluster analysis, the whole freeway was divided into sixty-four subsections according to road characteristics and data was grouped at one-hour interval. The percentage of large vehicles ranged from 21% to 77%. Variables are summarized as shown in Table 1.

Table 1 Traffic data statistics results

Variables	MAX	MIN	MEAN
Crashes per year	109.00	.00	11.0000
AADT	37286.25	4648.37	5616.78
Large vehicles percentage	0.45	0.09	0.24
Section length (km)	10.00	0.50	2.29
Average_angle	56.00	d0.00	24.68
Average_slope	1.62	0.00	0.3563774
Rural or city	City -Rural		

A linear panel data model can be specified as in Equation 5.

$$Accident_{it} = (Segment_length_i)\ \exp(\alpha_{it}\beta_1(X_1)\beta_2(X_2)\beta_n(X_n)\varepsilon_{it}) \quad (5)$$

$$ln(Accident_{it} / Segment_length_{it}) = \alpha_{it} + \beta_1(X_1) + \beta_2(X_2) + ... + \beta_n(X_n) + \varepsilon_{it} \quad (6)$$

Where $Accident_{it}$ is number accidents to occur on section i over the period and the performance of ln(x) makes sure that $Accident_{it}$ is negative integer. $Segment_length_i$ is length of section i. X_i is a $n\times1$ vector containing the values of crash i of p explanatory variables, β_i is a $n\times1$ vector of regression coefficients.

Model process

Fixed model prediction is predicted using least squares dummy variable as Table 2.

Table 2 Least squares regression results

Ln（ACC/Length）	Coef.	Std.Err	t	p
volume	.0001121	9.79e-06	11.44	0.000
Truck_percent	-2.273556	0.5359399	-4.24	0.000
City_rural	0.6786234	0.1302167	5.21	0.000
Cons	0.2274454	0.1717774	1.32	0.187

Prediction results with GLS method is as shown in Table 3.

Table 3 Random effect-model regression result

Accident_ratio	Coef.	Std.Err	T	P vaule
volume	0.0000844	9.91e-06	8.47	0.000
truck_percent	1.4666674	.4986217	3.01	0.003
intercharge	0.7993095	0.1767222	3.41	0.001
City_rural	0.602429	0.1508033	5.88	0.000
Cons	0..24359	0.1568766	1.55	0.12

Hausman test

The Hausman specification test compares the fixed versus random effects under the null hypothesis that the individual effects are uncorrelated with the other variables in the model. Table 4 compares the fixed effect and random effect models.

Table 4 Hausman Test result

	(b)	(B)	(b-B)	sqrt(diag(V_b-V_B)
	fixed		Difference	S.E.
volume	0.000035	0.0000844	-0.0000494	.0000747
Truck_percent	0.2417662	1.4666674	-1.2249012	3.09099
intercharge	0.3777045	0.7993095	-0.421605	
City_rural	0.518205	0.602429	-0.084224	8.636169
Test: Ho: difference in coefficients not systematic			Prob>chi2 =	0.0000

In table 4, P>0 indicates that a random effect model produces biased estimators, violating one of the Gauss-Markov assumptions; so the fixed effect model is preferred. Sigma_u is not significantly greater than sigma_e, so $\theta = \frac{\sigma_\mu^2}{\sigma_\mu^2 + T\sigma_\alpha^2}$ does not approach 1. Estimation with random effect model will produce larger deviations.

Final model explanation

The parameters estimation for fixed model (7) using LSDV are as shown in

Table 5

$$ln(Accident_{it} / \hat{Segment_length_{it}}) = 0.000035 * volume_{it} + 0.2417662 * truck_percent_{it} +$$
$$+0.5158295 * \text{intercharge}_{it} + 0.6324561 * city_rural_{it} + \alpha_i$$
$$\Rightarrow Accident_{it} = Segment_length_{it} * e^{(0.000035 * volume_{it} + 0.2417662 * truck_percent_{it} + 0.581332 * city_rural_{it} + \alpha_i} \quad (7)$$

Table 5 Parameters for panel data model

$\hat{\beta}_1$	$\hat{\beta}_2$	$\hat{\beta}_3$	$\hat{\beta}_4$	$\hat{\alpha} = \sum_{i=1}^{64} \hat{\alpha}_i$
0.00035	0.2417662	0.5158295	0.6324561	1．913
$\hat{\alpha}_1 = 3.889064$	$\hat{\alpha}_2 = 2.406556$	…	$\hat{\alpha}_{63} = 0.7513168$	$\hat{\alpha}_{64} = 0.2509566$

According to the final model, we can see that from 2002 to 2005, increasing traffic volumes, interchange area, percentage of large vehicles and differences of regions are contributing factors for accidents. For highways in plain areas such as Jingjintang, design features are not the main factors for accidents. Meanwhile, we can also find that intercepts of sections with high accidents is more than 2 or 3, while the common road is less than 1. Sections with high accidents can easily be identified by intercepts statistics.

CONCLUSIONS

Although the previous model uses a large number of statistical regressions, they all ignored fixed differences among road subsections. This paper presents panel data application in the highway accident analysis process, which aims to address the inadequate sample size, multi-colinearity problems. Fixed effect model and random effect model were developed respectively using data from Jingjintang Highway. Hausman test results show that individual fixed model is more suitable than random effect model for expressway accidents prediction and analysis. Furthermore, intercepts of different cross-section can help to quickly distinguish between a high accidents sections road and common sections. Panel data model as a new econometric tool is very effective, especially for the existence of regional differences in the traffic analysis.

ACKNOWLEDGEMENT

This project speed limit and control technologies for highways is supported by West Transportation Construction Foundation of China under Grant 2007 318 223 33-01.The author would like to thank supervisor Dr. Sun for advice and Key Lab of Transportation Engineering, Beijing University of Technology for providing data. Also, give thanks to graduate students who collected data.

ABSTRACT

Design speed is generally used as a basis for determining the post speed limits in China. Therefore the fixed value becomes the post speed for the whole road. Because of the big difference in operational characteristics between cars and trucks, this method is clearly inappropriate, considering the effects of Differential Speed Limits (DSL) are controversial. This paper expatiates the advantages and disadvantages of DSL, using hypothesis testing and analysis of variance methods (ANOVA) to analyze the difference of 15th percentile speed, 85th percentile speed, mean speed, speed variance, speed limit compliance between DSL and USL (uniform speed limit). Finally, consider truck mixed rate and traffic volume as variables to establish a linear regression model between speed limit differences and speed statistical indicators.

Keywords: differential speed limits; transportation safety; speed differences; 85th percentile speed

INTRODUCTION

Solomon (1964) conducted a study of more than 10,000 accident-involved drivers and their vehicles speed on a highway of 600km length, and found that the probability of being involved in a crash per vehicle-mile followed a function of vehicle speeds which followed a U-shaped curve. The study found that collision rates was lowest when vehicles travel around average speed, with the increase of speed and mean speed, and the probability of being in a crash increased whenever vehicles traveled at higher or lower than the average speed. Garber and Gadirau (1998) found that collision rates increased with the increasing speed variance. So in order to lower collision rate, speed variance should be decreased. However in recent years, studies have shown that the relationship between accident and speed is not significant. Collision rate relates to variation of vehicle speeds, and vehicles overtaking and

overtaken will be frequent when variation of vehicle speeds is large, which is prone to result in high collision rates. So, speed differences should be dropped as well rather than to only drop speed to lower collision rate.

DSL

Differential speed limit means that according to the operational safety and operation management of different types of vehicles, differential speed limits are imposed on cars and trucks.

There is no consistent recognition of the effect of differential speed limit. Some researchers support DSL, but others object. The supporters of DSL argue that it would increase the probability of crashes between trucks and other types of vehicles if trucks are traveling at a relative high speed. And because of the larger dimension of trucks, the supporters also concern that truck needed more time and a longer distance to decelerate to a complete stop than other types of vehicles if to travel at the same speed. Therefore, a lower speed limit was advised to be imposed on trucks. But the opponents of DSL argued that trucks and other types of vehicles should adopt USL (uniform speed limits), the reason is that, firstly, a truck driver has a greater sight distance than the passenger car driver because of the higher position in a truck, which made truck drivers have enough time to decelerate to complete stop. Secondly, the opponents of DSL also contended that differential speed limit might increase the variation of vehicle speeds and speed differences, and result in higher frequency vehicles overtaking and overtaken which might increase the probability of certain types of crashes.

Many researchers do studies on the effect of DSL (differential speed limit) on mean speed, operating speed, speed variance and other speed statistics indicators, but have not conclude consistent conclusion. Hall and Dickinson (1974) found that the speed variation can be brought about by enforced differential truck speed limits. J.R. Esterlitz and H.M. Baum [4] found that average car speeds were 1.3 mi/h less in states with differential limits and were statistically significantly different, average truck speeds were 2.7 mi/h less in the states with the 10 mi/h differential limit, and this difference was also statistically significant. Harkey, David L and Ruben Mera (1994) stated that mean speed of cars traveling on interstate highway systems was not affected by different speed limits. Other researchers expounded the advantages and disadvantages of DSL (differential speed limit) and also put forward some valuable suggestions.

DATA ANALYSIS

Uniform speed limit scheme is adopted on Yuqian Expressway of Chongqing

province, that cars and trucks have uniform speed limit of 100 km/h. Yusui Expressway of Chongqing province adopts differential speed limit scheme, 100km/h for cars and 80km/h for trucks, this paper collects and analyzes speed data of two different speed limit scheme on linear segment of road section which have similar road geometry conditions.

Classification of vehicle types

MetroCount5600 is used to collect data. MetroCount ARX Classification Schemes divide vehicles into 12 types, but JTG B01-2003 [6] divides vehicles into 3 types, it is obvious that these two classification schemes are not consistent. Convenience for the study, this paper combines two classification schemes, using wheelbase of 3.8 meter as classification criteria, and divide vehicles into cars (wheelbase less than or equal to 3.8 meter) and trucks (wheelbase no less than 3.8 meter).

Speed statistical indicators analysis

This paper using hypothesis testing and analysis of variance methods to comparative analysis the difference of 15^{th} percentile speed, 85^{th} percentile speed, mean speed, speed variance, and speed limit compliance between DSL and USL. The ANOVA results are as follows:

Table 1. ANOVA

	car		truck		total vehicle	
Statistics	F	Sig.	F	Sig.	F	Sig.
15^{th} percentile speed	1.08	0.304	21.477	0	12.461	0.001
85^{th} percentile speed	1.204	0.278	61.456	0	2.737	0.105
mean speed	1.642	0.207	48.027	0	5.676	0.022
Standard deviation	0.284	0.597	35.977	0	0.008	0.931
compliance	2.262	0.14	6.337	0.016		

1）Speed statistical indicators of cars

The results of ANOVA indict that 15^{th} percentile speed , 85^{th} percentile speed, mean speed, speed variance, compliance of speed limit of cars have no statistically significance between roads with DSL and USL. These two different speed limit schema impose the same speed limit on cars, therefore, no significant effect of differential speed limit on cars speed.

2）Speed statistical indicators of trucks

The result of ANOVA indicate that 15^{th} percentile speed, 85^{th} percentile speed,

mean speed, speed variance, and compliance of speed limit of trucks exist difference, and difference is also statistically significant. The trucks speeds over 24 hours (see Figure 1~4) can conclude that 15th percentile speed, 85th percentile speed and speed standard deviation of trucks with DSL are obviously lower, the compliance of speed limit of trucks with DSL are basically lower than those with USL. In other words, imposing lower speed limit on trucks decreases operating speed of trucks, and can also conclude that DSL do not increase the variation of trucks, but make the distribution of trucks more centralized.

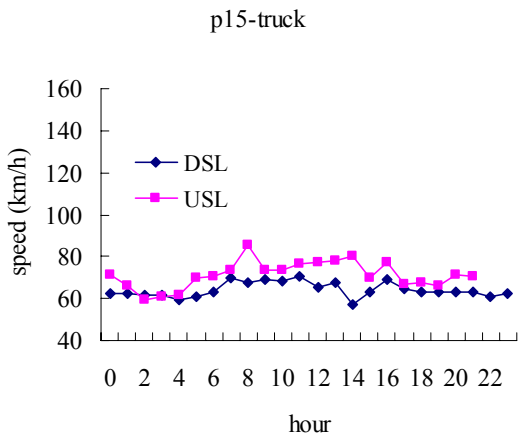

Figure 1. 15th percentile speed

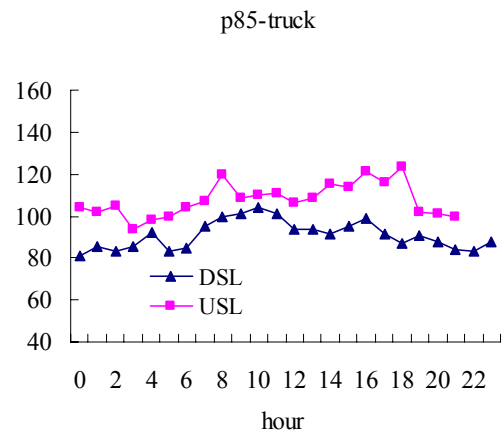

Figure 2. 85th percentile speed

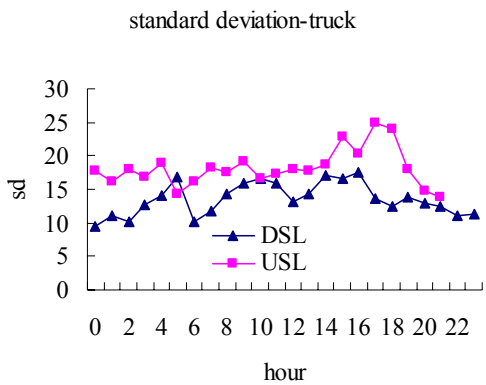

Figure 3. Standard deviation

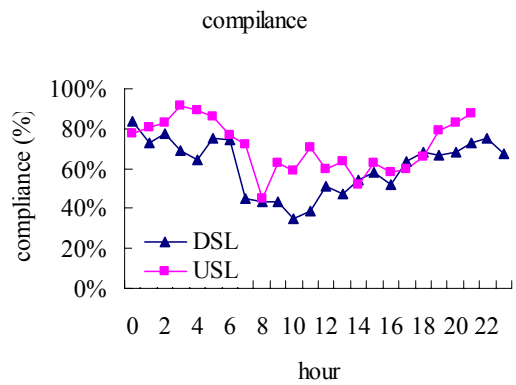

Figure 4. Compliance comparison

3）Speed statistical indicators of total vehicles

The 15th percentile speed, mean speed has significant difference, but 85th percentile speed, speed variance has no significant difference. That is to say differential speed limit affects the total vehicles speed. The effect of DSL on vehicle

speed variance and operating speed is not obvious.

Speed differences analysis

From the analysis, it can conclude that DSL has little effect on cars speed, but has a remarkable effect on truck speed, imposing a lower speed limit on trucks may result in speed statistical indicators of trucks to decrease, and increase speed differences between cars and trucks, it can also affect the variation of vehicle speeds. Correlation analysis (see Table 3) results indicate that speed limit differences resulting from different speed limit schema correlate with operating speed differences between cars and trucks, mean speed differences between cars and trucks, and speed standard deviation, three statistical indicators which increase with speed limit differences. DSL might increase speed differences, and also increase the variation of vehicle speeds, this mostly occurs because imposing a lower speed limit on trucks affect truck speed.

Table 2. Correlation

correlation	dif_p85	dif_mean	Sd
dif_sl	0.865	0.848	0.668

The relationship between speed limit differences and operating speed differences, speed limit differences and mean speed differences, speed limit differences and speed standard deviation need to be further determined. Preliminary study considers truck mixed rate and traffic volume as variables, and use SPSS software Linear Regression-Stepwise method to do regression analysis. Finally, truck mixed rate and traffic volume were excluded because of some reasons. The linear regression results are as follows.

Table 3. Linear regression

linear regression results	R	R^2
dif_p85=0.951dif_sl+24.686	0.865	0.749
dif_mean=0.671dif_sl+21.541	0.848	0.72
sd_total=0.198dif_sl+23.534	0.668	0.446

Where: dif_sl is speed limit difference between cars and trucks; dif_p85 is operating speed differences between cars and trucks; dif_mean is mean speed differences between cars and trucks; sd_total is standard deviation of total vehicles;

CONCLUSIONS AND RECOMMENDATIONS

- There is no consistent conclusion of the relationship between differential speed limit and transportation safety, so more research is needed for further

determination. Differential speed limit considers performance differences of different vehicle types, and might improve the safety operation condition of some type of vehicles. However, vehicle classification is a problem for implement differential speed limit.

- Differential speed limit might increase speed differences between cars and trucks, and might effect the variation of vehicle speeds. It will be very effective if the speed limit method of different vehicle types and lanes is combined. Speed limit by lane is a type of speed management that sets different speed limit value on different lanes. Speed limit signs are always installed on portal framed supports or are located nearby overpasses. The overhead of the speed limit sign indicates the below lane's speed limit. Another method is to paint words or markings on road surface in order to convey speed limit information.

Study on the Influence of Coarse Aggregate on the Pavement Performance of Road Cement Concrete

Shen Ai-qin[1] Xiong Jian-ping[2] He Jun-hui[3] Liu Tai-jun[4]

([123]Key Laboratory for Special Area Highway Engineering of Ministry of Education,Chang'an University,Xi'an 710064,Shanxi,China;[4]Shan'xi Provincial Communication Construction Group,Xi'an 710075,Shan'xi,China)

Abstract:

This paper presents a lab study on the influence of coarse aggregate on the pavement performance of road cement concrete. The result shows that influence degree of every technological property of coarse aggregate affect road concrete differently. The lithology of coarse aggregate will not lead to the obvious fluctuation of the pavement performance of road concrete. The flexural tensile strength of broken pebble stone road concrete is 40% lower than that of crushed stone concrete. The nominal maximum aggregate size of coarse aggregate has significant effect on the pavement performance, and it should be no more than 26.5mm when it's used on high level road. The decreasing amplitude of flake content to the pavement performance of road concrete is bigger than that of needle content. The crashing value of coarse aggregate has very significant effect on the flexural tensile strength of road concrete, so its content should be controlled.

Road Engineering ; Road Cement Concrete ; Coarse Aggregate; Pavement Performance ; Influence Rules

Introduction

Coarse aggregate is an important part of road cement concrete. It forms the backbone structure of the road cement concrete. The technological property and the amount of coarse aggregate have very significant influence on the pavement performance of the road cement concrete (Shen, 2004; Neville, 1983; Mindess et al, 2004).

The climate condition and traffic situation of the areas where the cement concrete pavement is used in our country are very different. Under the different environmental situations and road load levels, the traditional method that chooses coarse aggregate using the strength only is not enough. It's against the performance-based road cement concrete design theory. Therefore this paper systematically analyzes the relation between the technology performance of the coarse aggregate and the pavement performance of road cement concrete. It puts forward the technology index of the road cement concrete which can meet different load levels and climate conditions. It provides scientific basis for improving the related technology standards.

1. Raw Meaterials

The Experiment uses the "Qinling" 425# ordinary Portland cement from Shanxi Yao Country cement plant. Fine aggregate is a river sand with fineness modulus 2.6, belonging to medium sands. Coarse aggregate is a limestone and broken pebble stone.

The main technology performance parameters are shown in table 1.

Table 1 the main technology performance of coarse aggregate

Aggregate spices	Crashing value%	Needle and flake%	Sturdiness %	Mud content %
Limestone	15.6	4.3	4.2	0.4
Broken pebble stone	32.4	8.3	6.1	0.3

2. Experiment Design

Considering the comprehensive influence of coarse aggregate key technology performance parameters and material composition on the pavement performance of road cement concrete simultaneously, and considering the interactive influence of water cement ratio, unit water use and other factors on the experiment ,we developed the detailed mixture ratio of road cement concrete design as shown in table 2.

Table 2 the design of mix proportion for the road cement concrete

Nominal maximum aggregatesize /mm	Water consumption /(kg/m^3)	Water cement ratio			Coarse aggregate /(kg/m^3)	Fine aggregate /(kg/m^3)
		0.40	0.42	0.44		
		cement content/(kg/m^3)				
31.5	145	363	345	330	1350	683
19						
31.5	150	375	357	341		
19						
31.5	155	388	369	352		
19						
31.5	160	400	381	364		
19						

3. Experimental Results and Analysis

The road cement concrete is confected using the designed scheme of mix proportion in table 2. The effect of coarse aggregate on pavement performance of road cement concrete is shown through analyzing the following aspects.

3.1 Variety of Coarse Aggregate (Broken Stone and Broken Pebble Stone)

The workability of fresh concrete and the 28d mechanical strengths of hardened concrete are tested and presented in in table 3.

Table 3 The result of workability and mechanical strength

	Limestone gravel			Broken pebble stone		
Water cement ratio	Slump /mm	Compressive strength/MPa	Flexural tensile strength/MPa	Slump /mm	Compressive strength /MPa	Flexural tensile strength/MPa
0.40	31	44.8	6.28	46	42.2	4.88

	32	48.1	7.05	44	37.4	5.32
	32	43.5	6.25	49	41.8	4.94
	35	42.6	5.89	45	44.0	5.26
0.42	28	45.7	6.08	31	44.4	4.81
	24	45.1	5.94	34	39.0	4.54
	24	46.0	6.33	36	43.6	4.97
	29	39.9	5.86	37	42.5	4.83
0.44	19	42.3	5.32	23	35.0	4.95
	20	42.5	5.35	27	41.7	4.99
	17	42.9	5.34	25	40.6	5.07
	19	37.9	5.12	29	37.0	4.46

(1)The slump of broken pebble stone road cement concrete is 50% greater than that of the broken stone road cement concrete. And when the water cement ratio is certain, as the unit water use increases, the magnitude of increase of slump of broken pebble stone road cement concrete is more than that of broken stone road concrete.

(2) The compressive strength of broken pebble stone concrete is generally lower than that broken stone concrete. And it still can meet the technology demand of road concrete. But under the same mixture proportion, the flexural tensile strength of broken pebble stone road concrete is generally 10~30% lower than that broken stone road concrete. The type of aggregate has great effect on flexural tensile strength of road concrete.

(3) The compressive strength and flexural tensile strength ratio of broken pebble stone concrete is greater than that broken stone concrete. It is disadvantageous to the road cement concrete whose main mechanical control index is flexural tensile strength and anti-fracture ability. Because broken pebble stone has many un-broken natural smooth surface, its bond strength with cement mortar is weaker than broken stone that lead to its flexural tensile strength decrease (Lee, 2002; Du, 1996). Otherwise, the strength of aggregate is so low that it makes the compressive strength and flexural tensile strength ratio of broken pebble stone a little high.

So, the type of coarse aggregate has a significant effect on the workability and flexural tensile strength of road concrete. High grade highway should choose broken stone first.

3.2 Needle and Flacke Particles

Needle and flacke particles of limestone from Shanxi Jingyang are picked out by a standard instrument method, and mixed in the aggregate that doesn't contain needle and flake particles with different proportions. With such aggregate, the road cement's mechanical performance test results are shown in table 4.

Table 4 The mechanical strength of different needle and flake particle content

Flake content/%	Compressive strength/MPa	Flexural tensile strength/MPa	Needle Content /%	Compressive strength/MPa	Flexural tensile strength/MPa

	7d	28d	7d	28d		7d	28d	7d	28d
0	38.3	46.0	5.18	6.34	0	38.3	46.0	5.18	6.34
5	37.2	45.4	5.13	6.22	5	38.0	45.9	5.35	6.37
10	36.0	44.9	4.85	6.08	10	37.6	46.5	5.12	6.20
15	35.4	43.7	4.40	5.45	15	37.9	45.7	4.81	5.86
20	35.0	42.5	3.76	4.52	20	37.4	45.5	4.55	5.12
25	33.9	40.1	3.53	4.07	25	35.4	43.1	4.22	4.73

The test results in table 4 show that, needle and flake particle content on the compressive strength of road concrete has smaller effects. Even if the needle and flake particle content is more than 20%, the compressive strength of concrete decreases only about 4%. Adding needle and/or flake aggregate, the trend of flexural tensile strength of road concrete is decreasing. But it has been noticed that the flake particles of road concrete have more effects on flexural tensile strength than the needle particles. When the particle content is more than 15%, the flexural tensile strength of road concrete decreases as much as 14%. And when flake content is higher, the extent of decreasing is larger.

Above all, it can be seen that if the needle and flake particles are too much, it would reduce the unitary performance of road concrete. For different grades of road, its content should be strictly controlled. The relevant recommended values are shown in table 5.

Table 5 Suggestion on limited values of needle and flake particles content of coarse aggregate

The highway grade		Expressway, first class and second class highway	Third class and forth class highway
Suggested value of this study	Needle content/%	＜9	＜12
	Flake content/%	＜6	＜8

3.3 Nominal maximum aggregate size

Different nominal maximum sizes of coarse aggregate are used to make road concrete, the test results from testing its workability and mechanical strength are shown in table 6.

Table 6 The mechanical strengths of different nominal maximum aggregate size

	31.5			26.5			19.0		
Water cement ratio	Slump /mm	Compressive strength /MPa	Flexural tensile strength /MPa	Slump /mm	Compressive strength /MPa	Flexural tensile strength /MPa	Slump /mm	Compressive strength /MPa	Flexural tensile strength/ MPa
0.40	42	41.5	5.49	34	51.2	6.58	32	48.1	7.05
	47	47.0	5.87	37	45.9	6.48	32	43.5	6.25

	51	50.1	6.25	50	48.2	6.22	48	42.6	5.89
0.42	36	50.3	5.90	28	44.8	6.01	24	42.1	5.94
	39	47.6	5.59	26	42.2	5.73	24	46.0	6.33
	40	45.6	5.41	31	44.7	5.67	29	39.9	5.86
0.44	21	41.1	5.05	20	42.1	5.41	20	42.5	5.35
	25	42.6	4.93	19	40.7	4.92	17	42.9	5.34
	28	40.4	4.65	22	37.5	4.54	19	37.9	5.12

Analyzing the data of table 6, from the perspective of workability we can see that, when the coarse aggregate nominal maximum particle size increases, the slump of new road concrete increases. This shows that increasing the maximum nominal particle size is conducive to improving the road concrete's workability. But it will also make the segregation and bleeding of concrete even more serious. Therefore, choosing nominal maximum particle size still needs comprehensively considering other proportions of concrete. The increase of nominal maximum particle size makes the overall compressive strength of road concrete increase on the overall, but lowering the flexural tensile strength. As can be seen from the experimental data, compared with the largest nominal diameter of 31.5mm, the using of nominal maximum size of the coarse aggregate 19.0mm is easier to prepare a road concrete with higher flexural tensile strength.

The suggested values of road concrete's coarse aggregate nominal maximum size that meet the different highway levels are shown in Table 7.

Table 7 Suggested values of broken stones' nominal maximum size in road concrete

The highway grade		Expressway, first class highway	Second class highway and others
The suggested values of nominal maximum aggregate size/mm	Recommended range	≤26.5(19.0～26.5 are the best)	≤31.5
	Specification regulated data	≤31.5	

3.4 Crushing value

In order to make the test representative, we nation widely selected 10 kinds of different origin prepared gravel road concrete. The test results of their workability and the mechanical strengths are shown in table 8.

Table 8 The mechanical strength of road concrete with different crushing value

Kinds	NO.	Crushing value/%	Slump/mm	Compressive strength/MPa	Flexural tensile strength/MPa	Splitting strength/MPa
Ordinary road concrete	y1-1	12.2	33	49.6	6.42	4.22
	y1-2	14.3	31	50.3	6.61	4.27
	y1-3	15.6	29	43.1	5.37	3.54

	y1-4	15.6	34	47.3	6.22	4.18
	y1-5	18.8	32	45.8	6.01	3.97
	y1-6	21.5	31	46.2	5.89	3.82
	y1-7	23.5	30	44.8	5.7	3.91
	y1-8	25.1	33	44.5	5.65	3.69

(1)When the crushing value of coarse aggregate increases, the compressive strength, the flexural tensile strength and cleavage strength of road concrete will decrease. Linear correlation exists between the two, but the influence of flexural tensile strength is obviously superior to compressive strength.

(2)As can be seen from the data in the table, when the crushing value index is less than 20%, the flexural tensile strength can easily reach 5.5 MPa. It meets the requirements of strength of high-level highway. But when the crushing value index is more than 30% , the flexural tensile strength can hardly reach 5.0 MPa.

(3)Considering the test results in previous sections, the relationship between the crashing value of aggregate and the flexural tensile strength can be referred in table9.

Table 9 The correspondence relation of crushing value and flexural tensile strength

Crushing value（%）	0～20	20～25	25～30	＞30
Flexural tensile strength （MPa）	＞6.0	5.7～6.0	5.1～5.7	＜5.0

4. The suggested technology standard values of coarse aggregate for road concrete

The test analysis above established a correlation between the key technological property of coarse aggregate and pavement performance of road concrete. Ensuring mechanical performance according to different road grades and climate conditions, the suggested values for aggregate are shown in table 10.

Table 10 The suggested values in technical standard of coarse aggregate

The highway grade / Items		Highway, first class highway	The second class highway and the third,fourth highway which has the antifreeze demand	The third,fourth highway and substandard highway
Nominal maximum aggregate size		≤26.5（19.0～26.5optimum）	≤31.5	≤31.5
Crushing value /%	Broken stone	＜20	＜25	＜30
	Broken pebble stone	＜22	＜24	＜26

Needle and flaky particle content	Needle	＜9	＜9	＜12
	Flaky	＜6	＜6	＜8

5. Conclusions

(1)The workability of broken pebble stone concrete is better than that of broken stone concrete. But its flexural tensile strength is 30% less than that of broken stone concrete. Therefore, it is better to use broken stone as coarse aggregate for high level highways.

(2)The influence of needle particle content on road concrete's pavement performance is similar to the influence of flaky particle content, but the influence degree is small . Needle particle content should not exceed 20%.

(3)Flaky particles have significant influence on flexural tensile strength of road concrete. When the flaky particle content is more than 15%, the flexural tensile strength of road concrete may decrease by 14%.

(4)Through the mechanical strength tests of road cement concrete with eleven different crashing values of coarse aggregate nationwide, the crashing value has very significant effect on flexural tensile strength. Its value should be controlled.

ABSTRACT

To understand the actual situation of a port, it should be observed from different perspectives; to evaluate the actual situation of a port, we should use a number of measurement indicators. Take this as a starting point, this paper first introduces the background and reasons for writing. Secondly, it simply describes the competitiveness of our ports and more specifically presents the method of studying the integrated competitiveness of our ports. At the same time, it classifies our ports according to their competitive characteristics, which is the innovation point of the paper. Thirdly, it analyzes the comprehensive competitiveness index ranking of Chinese ports, describes the changes between 2007 and 2006, and identifies a few representative ports on the list, analyzing their various indicators, strengths and weaknesses in detail. Lastly, it sums up the characteristics of Chinese ports based on the previous expressions and gives corresponding policies and recommendations.

1 INTRODUCTION

A nation doesn't have competition ability in all aspects, but it has core competitiveness in a certain aspect, so as to promote the development of other related industries. The competitiveness of our ports directs the competitiveness of our country, and the competitiveness of the country is a source of national strength. The economic development process of China is powerful proof: in the past 30 years of opportunity and development, China has been focusing on building coastal port cities and trying hard to make them hubs of international resources and cradles of technological innovation. It also reveals the law of economic development in light of new economic theory to make the competitive ports take a positive role in promoting the economic development of China. As a result, it is necessary for us to rank the competitiveness of ports of our country. On one hand, this can reflect the present development condition of our ports, and identify their existing problems and constraints; on the other hand, this can also unearth their potential and offer corresponding policies and recommendations, in order to give the ports freer rein to promote China's economic development and further enhance national strength

further in such areas.

2 LITERATURE REVIEW

At present, the domestic and overseas research on port competitiveness is divided into two categories. The first category establishes indexing systems to study port competitiveness. Huang Jianyuan and Yan Yixin (2004) have designed a comprehensive evaluation system of port container transportation competitiveness in China including the indexes such as operational efficiency and cost and expense. Cullinane (2005) has made an analysis of the relative competitiveness of Shanghai and Ningbo, which are the two adjacent container ports. He evaluates the service needs based on the fact that the two ports have the same hinterland, and he analyzes the current supply capacity and future expansion plans at length, ultimately evaluating the relative competitiveness of Shanghai and Ningbo in terms of price and service quality. Li Shitai (2006) establishes an index system that contains four aspects of producing elements: operation and management ability of port, demand condition, and relative supporting industry. There are numerous similar studies in our country, but their selections of index and the methods of quantification are not perfect. They are more limited for contrasting the indexes one by one, and they don't give the overall evaluation and ranking of port competitiveness.

The second category of existing research establishes comprehensive evaluation models to study port competitiveness. The analytic hierarchy process (AHP) is the main method used to determine the weight of index system, and models are constructed to evaluate port competitiveness comprehensively. Scholars such as Ji Yongbo (2005) have established the comprehensive evaluation model of port competitiveness on the basis of a fuzzy optimization model. Expert such as Wang Chunying (2006) have used the method of entropy and weight value to determine the evaluation weight of ports evaluation index to establish the multi-grade fuzzy comprehensive evaluation model. This model helps to analyze the factors of port competitiveness qualitatively, but some indexes are difficult to quantify, and their weights are difficult to determine accurately, which in turn makes it difficult to prove evaluation results.

The common characteristic of these two kinds of research is the lack of application and countermeasures to study ports on the basis of systematic theories. Therefore, they have little reference value for improving the competitiveness of our ports. Based on this, this paper establishes a more scientific index system from five aspects such as the natural conditions of port, the investment trends, the increasing rate of throughput, the assignment capacity of port, and the financial condition of port, which together make up for the shortcomings of comparing a single index other than a comprehensive competitiveness study from the previous research. This paper

establishes the evaluation model of comprehensive competitiveness of port based on the factor analysis method. First, it improves upon the existing theories of AHP and fuzzy evaluation, which have difficulty determining highly accurate evaluation results. Second, it reveals the main factors affecting port competitiveness and it improves the index system and method of evaluating port competitiveness. Finally, it makes an illustrative analysis of the 25 domestic and offers policies to improve the port competitiveness of our country.

3 DETERMINANT OF INDEX SYSTEM OF PORT COMPETITIVENESS

3.1 Definition of port competitiveness

According to the general definition of competitiveness and different, more detailed explanations from academia, and in combination with the characteristics of the port industry, this paper defines port competitiveness as the ability and opportunity that a port enterprise has to provide high-quality and low-price service for relative enterprises and industries in the competitive market environment, so as to achieve the maximum value of port enterprises. The essence of competitiveness is a kind of ability, which at a superficial level is the ability to allocate and utilize the resource advantages that competitors cannot, and at a more fundamental level is the ability to integrate various resources organically, which are the elements of the enterprises. Competitiveness relying solely on natural resources at a certain point in time cannot last long; however, poor resources can also create competitiveness through efficient processes of conversion. Core competitiveness is the organic synthesis of various techniques, skills, and knowledge, the ability to combine internal coordination with overall cooperation comprehensively, and it penetrates the whole organizational process and delivery value. Core competitiveness is the source of creating competitive advantages for enterprise. All world-famous enterprises have unique specialties in product development, technology innovation, management method, marketing, and trademark or customer service. Port competitiveness embodies the following aspects: the first is the customer value, which is a key element of the core benefits that customers care about; the second is the advantage of difference, which highlights their uniqueness in the competition, which is difficult or costly for competitors to imitate; the third is ductility, which exploits new products or services to meet customers' needs and has the vitality of lasting development.

3.2 Definition of index system

According to the above principles, we chose 13 indicators including five aspects: natural conditions, growth rate of throughput, investment trends, operational capacity, and financial status of the port. Natural conditions reflect the geographic location and the channel depth of ports. Growth rate of throughput reflects the

number of goods shipped in and out ports, which are loaded and unloaded. Investment trends reflect the ability to attract capital to ports. Operational ability reflects the efficiency of loading and unloading and the situation of warehousing and storage of ports. The financial situation reflects the solvency, operation, profitability and growth of ports. Table 1 shows the index system in detail:

Table 1. Evaluation Index System of Port Competitiveness.

1st level	2nd level	Name of variables
natural conditions	port draught	X_3
	the number of Bridge Crane	X_2
	Berth	X_1
	location advantage	X_{14}
growth rate of throughput	growth rate of port container throughput	X_5
	growth rate of port cargo throughput	X_6
investment trend	foreign direct investment	X_9
	total investment	X_{10}
operational capacity	routes	X_7
	handling rate	X_4
	utilization of berth	X_{13}
	amounts of berthing	X_8
financial position	total profit	X_{11}
	total asset	X_{12}

The data used in this paper is collected and arranged through surveying "China traffic yearbook in 2007" and the data from questionnaires of various samples of ports.

4 EVALUATION OF PORT COMPETITIVENESS BASED ON FACTOR ANALYSIS

This paper uses factor analysis to evaluate and sort comprehensive competitiveness of ports. We can utilize factor analysis to concentrate with less data and use several practical factors to reflect main information of plenty original data.

4.1 KMO inspection and Bartlett test results of ball degrees

KMO is 0.737 in this study, which is evidence of fitting for factor analysis. The Sig that Bartlett test results of ball degrees gives is 0.000, which demonstrates that the data comes from normal distribution, so it is suitable for factor analysis.

4.2 Evaluating the score and sorting

The score of each factor, the score and the taxis of comprehensive competitiveness are presented in Table 2.

Table 2. List of Monomials and Comprehensive Rank of Ports.

The rank of total score	port	Total score	F1	F2	F3
1	Shanghai	114.38	159.98	-107.67	109.39
2	Tianjin	64.14	86.03	-84.72	110.69
3	Shenzhen	41.18	45.46	6.16	57.08
4	Qingdao	40.06	45.42	-11.79	69.28
5	Ningbo-zhoushan	36.71	39.29	12.28	50.17
6	Yingkou	30.57	32.00	-43.20	107.76
7	Nanjing	26.46	31.88	0.00	25.93
8	Tangshan	24.29	27.00	6.30	29.60
9	Guangzhou	24.19	22.34	2.06	60.41
10	Qinhuangdao	21.60	21.67	-17.81	66.81
11	Suzhou	20.90	19.72	6.96	43.78
12	Xiamen	20.53	17.94	20.23	35.77
13	Yantai	18.73	14.01	10.08	55.89
14	Dalian	18.72	17.66	8.39	36.80
15	Rizhao	18.06	17.90	-12.59	54.43
16	Wuxi	17.06	15.55	17.72	24.96
17	Lianyungang	15.76	9.63	22.96	42.64
18	Dandong	14.01	11.70	-4.78	49.07
19	Zhanjiang	11.18	6.73	10.00	38.12
20	Nantong	10.33	5.70	11.07	36.06
21	Zhongshan	9.50	3.67	9.08	43.43
22	Wuhan	8.81	6.17	0.77	33.28
23	Jinzhou	6.86	-0.15	10.07	43.43
24	Huanghua	6.85	1.77	6.58	36.36
25	Quanzhou	6.52	-0.30	14.90	36.00
26	GroupofFuzhou	6.27	-1.81	16.63	40.72
27	Wuhu	5.57	0.63	8.68	30.33
28	GroupofWenzhou	5.38	-2.38	14.15	39.86
29	Haikou	5.01	0.43	6.51	29.63
30	Shantou	4.58	-0.65	8.31	30.31
31	Zhuhai	3.37	-5.25	12.87	41.87
32	Chongqing	3.35	-3.50	8.99	36.20

Note: Although the scores of competitiveness of many ports are negative, this does not mean the competitiveness of those ports is negative, which is due to the result that the author has standardized the data in the whole process of analysis; it therefore represents the relative competitive level of each port only.

4.3 Result analysis

According to the analysis of the characteristics of the comprehensive competitiveness of China ports, we list separately the most efficient port, the most international port, the most aggressive port, the most innovative port, the most governmental port and the most private port. Such a method of classification analysis is a new event in the industry. It has a profound, extensive and practical significance, coinciding with the purpose of the research. It is good for ports "to understand their own competitive position, dig their own advantages, develop their superiority and avoid their weaknesses, improve themselves, and establish effective investment, financing, innovation and development strategies in competitive market." Next, we will introduce specifically the prior six ports from the China port competitiveness ranking in 2006 and 2007. Their rankings have since changed, but the ports maintain the same competitive characteristics.

(1) The most efficient port: Shenzhen Port

Shenzhen Port depends on the developed Pearl Delta, Macau, and Hong Kong, and it has a vast economic hinterland and advantageous geographical location. Its international shipping capacity is increasing gradually, its infrastructure is improving gradually, its service level continues to improve, and its price advantage is very obvious. Shenzhen Port has become the major hub in the comprehensive transportation system of China, especially its developing container business, which makes it the container hub of south China. In 2007, the container throughput of Shenzhen Port reached to 13.70%, and its cargo throughput reached 13.65%. Because of its excellent benefits, full potential, timely economic growth, and strong ability to provide service to customers, Shenzhen port is worthy of being deemed the most efficient port of China ports in 2007.

(2) The most international port: Shanghai Port

Shanghai Port penetrates the Yangtze River Golden Waterway in the west, and it is located in the main channel of China. A developed economic hinterland, strong support of national policies, and superior conditions of the capital market enable it to accumulate labor, capital, technology, resources, information and technology rapidly, and give it competitive advantages. In 2007, the growth rate of container throughput of Shanghai Port reached 20.41% and the growth rate of cargo throughput reached 4.19%. Although serious environmental pollution of environment, poor capital operation, lack of management levels, and poor earnings potential still restrict its further development, it can make full use of its own advantages to reorder itself, and to realize the transformation from large port to strong port, and to maintain the status of China’s international port.

(3) The most aggressive port: Guangzhou Port

Guangzhou Port is located in the center of the Pearl River Delta whose

export-oriented economy is the most active in China, which has obvious location advantage. Although there are some geographical flaws, the use of Nansha deep-water wharf compensates for these shortcomings, allowing Shenzhen Port to grow over time from river port to harbor port. In 2007, its growth rate of container throughput reached 38.21%, and its average growth rate of container throughput was 41.4% between 2005 and 2007. Guangzhou Port is the Chinese port with the highest berthing rate, the most frequent shipping, the largest batches, the most complex waterways and the most intense competition. Its goods are adequate, its cash flow is abundant, its business is adjusted timely and its port construction is active and steady, so Shenzhen Port is deserved the title of most aggressive port in 2007.

(4) The most innovative port: Qingdao Port

The biggest advantage of Qingdao Port is its natural deepwater waterway; among the other ports its condition is unquestionably superior. It continues to offer the three qualities of "blue sky, clear water, green land" and it has built a wall for wind and dust prevention at an internationally advanced level at present. Relying on scientific and innovative management, the port promotes the "second" era of handling and production strongly. All of the above are its unique aspects. In 2007, the growth rate of container throughput of Qingdao Port reached 22.05%, and the growth rate of cargo throughput reached 17.78%. Because of the urgency consciousness, the port has created an innovative approach to the Chinese "1>2", and it has achieved good results. Therefore, Qingdao Port is worthy of the most innovative port in 2007.

(5) The most governmental port: Tianjin Port

Tianjin Port is located in the intersection of Beijing-Tianjin urban belt and Bohai Sea Rim Economic Circle, which is the nearest port to North and Northwest China among the Bohai Sea Rim Ports, and it is one of the busiest and the fastest developing ports in the northern coastal area of China. Under the support of the government and the guidance of its policies, the complete supporting facilities, the efficient customs clearance process, the positive financial innovation and the plentiful cash flow, this port's core competitiveness has improved greatly, and they will further consolidate as a central logistics hub. In 2007, the growth rate of container throughput of Tianjin Port reached 19.36% and its growth rate of cargo throughput reached 18.02%, so it became known as the most governmental port of China in 2007.

(6) The most private port: NingboZhoushan port

Ningbo–Zhoushan Port boasts the advantage of a joint venture with Sinopec, integrating port resources and improving production efficiency, which makes its oil transit remain very competitive; five kinds of goods structures are increasingly reasonable so that cargo throughput maintains a sustainable growth rate of 12.53

percent; container throughput ranks fourth in terms of coastal ports with the growth rate as high as 31.32 percent. Personalized service makes Ningbo–Zhoushan Port stand among consignors in Europe, Thailand, Malaysia and Singapore, and makes the personality of "taking the Four Seas" of Ningbo's private economy widely known. Ningbo-Zhoushan Port will continue to compete with Shanghai Port in the ship-owner market, and enhance cooperation with the international shipping giant, increasing efforts to develop container routes to attract the world's top 20 largest shipping companies to open routes in Ningbo Port. The "benchmarking strategy" of Ningbo–Zhoushan Port also wins endless business opportunities for itself. Therefore, Ningbo–Zhoushan Port was honored as the Chinese private port in 2007.

5 CONCLUSION

(1) The investment in ports is increasing and the throughput continues to rise

In 2007, the investment in ports continued to increase as it has in recent years, and it appears that the trend of multiple developments, which includes central, local, state-owned enterprises, private enterprises and foreign enterprises namely, and the state-owned enterprises are the leaders of investment. Port investment is mainly distributed in docks, waterways, loading and unloading equipment, information, stack of goods and transportation system, etc. Its strengths are the construction of the infrastructure and information of ports and improvements in loading and uploading and handling ability. It shows that the facilities our ports are improving overall gradually, and their comprehensive ability is strengthening as a whole. In 2007, the cargo throughput of all our ports completed 6410 million tons, which is 15.1 percent larger than in 2006. The domestic trade cargo throughput completed 4561 million tons, which is 15.3 percent larger than in 2006; the growth rate is 1.9 percent faster than in 2006, and it is the first time that the growth rate of domestic trade cargo throughput exceeded foreign trade cargo throughput; The container throughput broke through 100 million cases in 2007. Although the growth of port throughput slowed, the total throughput increased greatly. Coal, oil, minerals and container are still the main contributors to port throughput.

(2) The ports profit overall, but efficiency must improve

The growth of China's economy, the improvement of the management level of ports, and the high efficiency of port productivity contribute to the overall profits of ports in 2007. Compared with the history, the overall profits of ports show great progress. However, compared with the international ports, it is too far behind them. This suggests that the assets of our port enterprises must grow dramatically, but efficiency doesn't grow with the same frequency, which shows that distortions exist in the asset structures of our port enterprises and the structure of port-vicinity industrial zones, which need to be resolved.

(3) Exert the function of port engine, and promote the benefits of regional integration

Port integration is intended to utilize natural port conditions and layout, to integrate port resources according to the economic development of ports and the economy development of their hinterlands, to optimize the port configuration and to exert the function of port engine. When we make port integration among areas, we should consider both the differences of cultural backgrounds of ports and the interest needs of special group of local government. Forever, we could reduce the resistance of integration and achieve the complementary advantages of the regions of ports.

(4) The ports step toward capital market, and their degree of internationalization deepens

In 2007, more and more port enterprises listed in internal and external of China, which demonstrates that the capital consciousness of our port industry is increasing and China's ports are stepping into capital market gradually; it also marks the beginning of modern enterprise management of our ports. Internationalization is the inevitable choice of Chinese ports, which is illustrated by the development process of Shanghai Port. However, acting as the environment is a complete and integrated strategy. At present, it is too early for China's ports internationalize, but we should seize the opportunity of port development, and plan to promote the internationalization of our ports in good time.

(5) The development of ports prompts the development of port-vicinity industrial zone, the differences of regional economics bring the economics characteristics of ports

In 2007, the port engine promoted the further development of port-vicinity industry, which shows that China's economy is becoming more and more mature. Depending on local resources and seizing the opportunity to transform world industries, we have built the port-vicinity industrial chains which adapt international markets in the Pearl River Delta and the Yangtze River Delta, and the industrial areas and city groups around the Bohai region are spreading toward the port-vicinity area. At the same time, the development of regional economies differs, and that brings regional development characteristics to port development. In different areas, the development of ports shows differences. Among each economic belt, the advantage of a port engine appears, and specialization and diversification exist at the same time.

(6) The port construction emerges as an inflection point, port competitiveness confronts with new challenges

The construction of China's ports emerges as an inflection point, and the ports that were once in the secondary position are raised to an important position. The traffic industry is developing with resource-saving and environmentally-friendly

objectives, and it promises new challenges to competitiveness; constructing and improving the comprehensive transportation system puts forward new aims for port layout; building port projects, which mainly rely on continental and marine hinterlands, brings innovative thinking to the forefront. Constructing ports and waterways under complex conditions also poses new challenges to port competitiveness.

ABSTRACT

In the adjacent urban trip modes, car and bus are the most prevalent means of transportation. Based on the practical situation that transport bottlenecks are frequently caused in the urban traffic and working on the premise that both of the two trip modes have access to the same traffic route and intervene with each other, this paper develops a model for transport bottlenecks. The paper analyses the differences of the generalized travel cost between car and bus. It deduces and compares the change of traffic flow and travel costs of car and bus under static and dynamic charge policies. This paper deepens our understanding of the issues on these two competitive systems. Based on the analysis, the paper concludes that from the perspective of sustainable development, the government should guide passengers to change their trip modes and should implement the policy of dynamic fees to promote the sustainable development in urban areas.

KEY WORDS: *model of transport bottlenecks; equilibrium model; transport fees*

INTRODUCTION

Based on the current situation in China, highway trips are more popular for passengers traveling between adjacent cities. In highway trips, cars and buses are usually run by the same route of mixed operations. Thus, it is relatively complicated to establish an equilibrium model of trip modes to be consistent with the practical traffic situation, which also provide the basis for enacting traffic policies from the perspective of sustainable development.

There is extensive research on calculating traffic expenses, pricing, and charges in recent years. After Vickrey presented the mathematical model for endogenesis time election for the first time, some efforts such as Tabuchi (1993) and Arnott (1990, 1995) made contributions on the basis of passengers' traffic time and expenses. Friesz (1983) and Norbert (1994) worked on the pricing issues of various traffic modes in the market economy. Scholars such as Ferrari P. (2002) and Bellei G. (2002) studied the pricing issues of highway trip from many perspectives. Evans (1987, 1990) elaborated the operation condition of public transportation in the competition mechanisms from the perspective of macro economy, but failed to build mathematical models to analyze the operation condition. Other researchers (Huang, 1995 &1998); Si, 2001;, and Chen, 2005) have built relative mathematical models

and worked on the above issues in different ways. However, the above papers have not investigated on how to simulate vehicles' traveling on the highway and how to charge the vehicles especially under the practical circumstances that cars and buses travel by the same route. This turns out to be important to promote the sustainable development of the transportation system.

SETTING UP RESEARCH CONDITIONS

Suppose that two adjacent metropolitan cities are namely a satellite city W and a central city Z respectively; there is no rail traffic between them. Passengers have to choose the highway trip. In the mean time, cars and buses travel by the same route. There is a bottleneck along the highway (Suppose it is a tunnel) with a capacity that m vehicles can pass through it per unit time. There is a toll station on the way from *W* to *Z*. *N* passengers go to work from the satellite city to the central city every morning, among whom N_2 passengers go by car and N_2 passengers go by bus. All the passengers expect to arrive at the central city at a certain time t_D. Normal traveling time of cars from *W* to *Z* is H_c and that of buses is H_b. Furthermore, t_0 is the departure time of cars from *W* to *Z* when cars are expected to arrive at the destination at t_D.

MODEL OF TRANSPORT BOTTLENECKS

Cars' Travel Expenses. When the departure rate of cars from *W* to *Z* exceeds the traffic capacity of the bottleneck m, it is inevitable that cars have to wait in line. Suppose $u(t)$ is the departure rate at a certain time t, and $q(t)$ is the queue length at time t, we can get $dq(t)/d(t) = u(t) - m$.

Traffic expenses of cars which depart at time t may be represented as following:

$$C_{c(t)} = \begin{cases} \alpha_c(H_c + q(t)/m) + \beta_c\left[t_D - (t + H_c + q(t)/m)\right] + F_{c(t)} + R_c & t \le t_0 \\ \alpha_c(H_c + q(t)/m) + \gamma_c\left[(t + H_c + q(t)/m) - t_D\right] + F_{c(t)} + R_c & t > t_0 \end{cases} \quad (1)$$

In the above equation, $C_{c(t)}$ is the generalized travel cost for passengers by car who depart at time t. α_c is the time cost coefficient of passengers. H_c is the normal travel time. β_c is the bonus coefficient （β_c<0） when passengers go to work earlier . $F_{c(t)}$ is the fee for roads and bridges at time t which is imposed by the toll station. R_c is the fee for fuels. γ_c is the punishment coefficient when passengers are late for work. According to the result of Small's investigation (1982) and the research of Smith (1984)，we may have $\gamma_c > \alpha_c > \beta_c$.

Buses'Travel Expenses. Likewise, the generalized travel cost for passengers by bus who depart at time t may be represented as following:

$$C_{b(t)}=\begin{cases}\alpha_b(H_b+q(t)/m)+\beta_b\left[t_D-(t+H_b+q(t)/m)\right]+P_b+R_{(t)} & t\le t_0\\ \alpha_b(H_b+q(t)/m)+\gamma_b\left[(t+H_b+q(t)/m)-t_D\right]+P_b+R_{(t)} & t>t_0\end{cases} \quad (2)$$

In the above equation, $C_{b(t)}$ is the generalized travel cost for passengers by bus who depart at time t. α_b is the time cost coefficient of passengers. β_b is the bonus coefficient （β_b<0）when passengers go to work earlier . P_b is the ticket fare for buses. $R_{(t)}$ is the congestion fee caused by physical contacts when passengers depart at time t. γ_b is the punishment coefficient when passengers are late for work. Likewise, we may have $\gamma_b>\alpha_b>\beta_b$.

Bottleneck Equilibrium Model. When all the passengers can arrive at the destinations at time t by means of the two traffic modes, passengers usually will not change their modes. Suppose that t_c^1 is the departure time of the first passenger who travels by car. and the traffic expenses should be:

$$C_c^1=\alpha_c H_c+\beta_c(t_D-t_c^1)+F_{c(t_c^1)}+R_c \quad (3)$$

Suppose that t_c^z is the departure time of the last passenger, and then the traffic expenses should be:

$$C_c^z=\alpha_c H_c+\gamma_c(t_c^z-t_D)+F_{c(t_c^z)}+R_c \quad (4)$$

Suppose that H is the specified time intervals in which buses commute.

$$t_c^z-t_c^1=\left[N_1+(t_c^z-t_c^1)/H\right]/m \quad (5)$$

When traffic modes are in equilibrium, all the passengers have the same traffic expenses, and we may have

$$\begin{cases}t_c^1=t_D+(F_{c(t_c^1)}-F_{c(t_c^z)})/(\beta_c+\gamma_c)-\gamma_c N_1 H/(mH-1)(\beta_c+\gamma_c)\\ t_c^z=t_D+(F_{c(t_c^1)}-F_{c(t_c^z)})/(\beta_c+\gamma_c)+\beta_c N_1 H/(mH-1)(\beta_c+\gamma_c)\\ \\ C_c^z=\alpha_c H_c+\dfrac{(F_{c(t_c^1)}-F_{c(t_c^z)})\gamma_c}{\beta_c+\gamma_c}+\dfrac{\beta_c\gamma_c HN_1}{(mH-1)(\beta_c+\gamma_c)}+F_{c(t_c^z)}+R_c\end{cases} \quad (6)$$

According to the practical situation in China, the toll stations between cities aim to charge fees for the construction of public highway, and the fixed amount of money they charge depends on different models of cars. Thus, $F_{c(t_c^1)} = F_{c(t_c^z)}$.

So we may have

$$C_b^1 = \alpha_b H_b + \beta_b (t_D - H_b - t_b^1) + P_b + R_{(t)}^1 \quad (7)$$

$$C_b^z = \alpha_b H_b + \gamma_b (t_b^z + H_b - t_D) + P_b + R_{(t)}^z \quad (8)$$

Suppose that the approved passenger load of bus is A, and the bus departs on time. H stands for the specified time intervals in which buses commute. We may have

$$\begin{cases} t_b^1 = t_D - H_b - \dfrac{\gamma_b N_2 H / A}{\beta_b + \gamma_b} \\ t_b^z = t_D - H_b + \dfrac{\beta_b N_2 H / A}{\beta_b + \gamma_b} \\ C_b = \alpha_b H_b + \dfrac{\beta_b \gamma_b N_2 H / A}{\beta_b + \gamma_b} + P_b + R_{(t)} \end{cases} \quad (9)$$

In the above equations, C_b stands for the traffic expenses of passengers by bus.

HIGHWAY TOLLING STRATEGIES

In order to relieve traffic congestions and change the present pricing mechanism, the measures such as increasing the static charges and implementing dynamic charges are the first choices. Suppose the fee F_z is added to reduce passengers by car. Some passengers by car will necessarily change their mode and travel by bus. As a result, the traffic congestions are relieved.

Dynamic pricing aims to optimize the operation of public highways between the two adjacent cities. Thus, no vehicles need to wait in queues. Under this condition, during the period $[t_c^1, t_c^z]$, both of the departure rate and reach rate should be $u(t) = m$. Thus, passengers by car may adopt such a dynamic pricing strategy:

$$F_{c(t)} = \begin{cases} C_c - \beta(t_D - H_c - t) & t \le t_0 \\ C_c - \gamma(t + H_c - t_D) & t > t_0 \end{cases} \quad (10)$$

Based on the analysis of policies of static and dynamic pricing, we may have the conclusion that static pricing may enable passengers to change their travel modes and increase the number of passengers who travel by bus. Dynamic pricing, however,

changes the time distribution of cars, which reduces cars' and buses' waiting times on the road. Thus, from the perspective of sustainable development, the transportation management authority should combine static pricing with dynamic prcing and should enhance buses' departure frequency to promote the sustainable development of the area. The passengers are then advocated to choose public traffic modes and the traffic congestion can be relieved. At this moment the pricing strategy should be:

$$F_{c(t)} = \begin{cases} C_c - \beta(t_D - H_c - t) + F_z & t \le t_0 \\ C_c - \gamma(t + H_c - t_D) + F_z & t > t_0 \end{cases} \qquad (11)$$

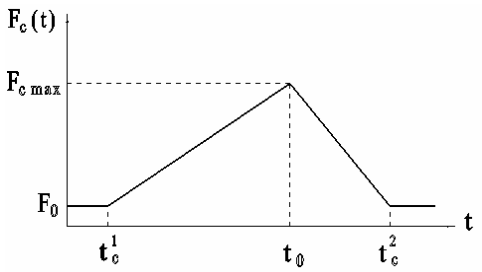

Figure1.The relationship curve of pricing strategies and time

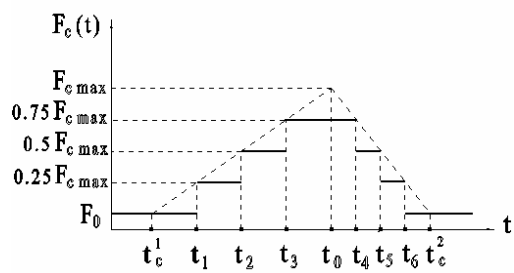

Figure2. The strategy of pricing in different periods

According to Equation（11）, the relationship between the amount of charge and time is shown in Figure 1. As the amount of dynamic charges is a continuous function of time, it requires advanced techniques to implement. However, we may approximate the optimal dynamic strategies by means of adopting staircase pricing strategy. As shown in Figure 2, though it can not eliminate waiting completely, the staircase pricing strategy can relieve traffic congestion and is easy to operate.

CONCLUSION

Trips between adjacent cities in China are very common. The passenger flow to and from work between the satellite city and the central city has already drawn many researchers' attention. This paper simulates the most common traffic modes between adjacent cities and provides basis for developing traffic policies from the perspective of the area's sustainable development. This paper however does not introduce the influence into the model analysis of when passengers who travel by car change their traffic modes. In this case, the number of buses will be greatly increased which may lead to traffic congestion. These issues will be studied in subsequent papers.

ABSTRACT

This paper studies on the emergent incident's influence on expressway network. According to the survey about expressway network of Yangtze River Delta region, the paper defines a basic unit of expressway network. In order to evaluate how the incident influences the expressway, this paper has developed an evaluation indicator, the delay increase. To compare the different influences of different types of incident, this paper addresses several factors which affect evaluation indicator, including flow, duration of incident, and type of the influence. Establish the simulation model of expressway network and do the simulation experiment about the various affecting characteristics of the incident by using traffic simulation software AIMSUN. Use the simulation results to analyze the influence of the incident on the network through specific data. On this basis, study the relationship between flow of vehicle, duration of incident and delay increase and develop a function model about it. This paper also gives the application of the simulation data and function model in practice.

Keywords: Expressway; Incident; Simulation experiment; Delay increase

INTRODUCTION

At present in China, the construction of the highway network of the Yangtze River Delta region has reached a high level. The density of the road network is quite large. However, in the field of expressway management, it still hasn't a complete system either in theory or practice. Especially when the incident happens, it is hard to deal with the case timely and efficiently. Although there are some contingency plans, the plans themselves often have been made by experience. The lack of scientific theories in emergency rescue has become a serious problem. For the management of the expressway, the treatment of the incident is one of the most important parts. In order to treat the incident timely, effectively, and reasonably, the primary mission is to find out how the various emergency incidents influence the expressway. Give the influence an assessment so as to find the better measure of rescue.

The study of this subject both in China and abroad focuses on the expressway emergency response in varies situations (Elvey and John 2003).. The relative research includes detection of the incident, setting up a framework for emergency rescue, and building the system of incident rescue (X. Wang et al.2005). These researches have noted the main features of the incident and the assessment indicators of it on expressway. However, the most current domestic research is based on theoretical analysis and building of framework, lacking the application of specific data. Thus caused few study result to be directly usable in practice. The reason is understandable—it is difficult to obtain the relative data on expressway, especially under emergency. Meanwhile, the study of incident rescue by simulation experiment is hardly seen. Lack of suitable simulation software which can be used to simulate the incident is the main problem. In order to research the influence of incident on expressway while the relative real data can be hardly attained, the use of traffic simulation software is practical and reasonable. The core of the traffic simulation software is its car-following model and lane-changing model. As long as the parameters of these models are defined, the simulation can be completed to find the large number of target data which is used to do the analysis. This paper uses simulation experiment to analyze the influence of incident since the allowed deviation of model parameters will not affect the trend in the experiment result.

THE CHARACTERISTICS OF THE INCIDENT AND EXPRESSWAY NETWORK

According to the investigation of expressway networks in Yangtze River Delta region, the incident on expressway can be divided into two parts, predictable and unpredictable events. The predictable events are usually stipulated in the ordinance and rarely occur. So it has little influence on expressway. This paper will mainly focus on unpredictable events which could also be separated into two parts, traffic accident and inclement weather.

The influence of incident on expressway can be attributed to the influence on section and lanes when doing a simulation experiment. Whether it is a traffic accident or inclement weather, the influence can be attributed to the temporary closure of lanes, sections or section speed limit. The difference only lies in the duration of lane closure, the range of it, etc.

With the development of expressway in the Yangtze River Delta region, the region has been gradually improved into a network. According to the investigation, the incident on expressway will only influence its own section mostly; few times will the cross expressway be affected and there is almost no affect to the parallel expressway. The radiation scope of the incident is not significant. Only large areas of inclement weather will influence the entire expressway network. If there is an incident, police will often use the parallel expressway or ground road nearby to do the traffic diversion. Parallel expressway is more preferred because the use of ground

road diversion will cause greater impact on the road, drivers are often unfamiliar with it, and there also exists some organizational problems. To sum up, this paper gives a definition of basic unit to expressway network. The network is composed by three expressways two of them are parallel and the other crosses them (see Figure 1). All the expressway networks can be divided into a basic unit, and to study the incident influence in a basic unit.

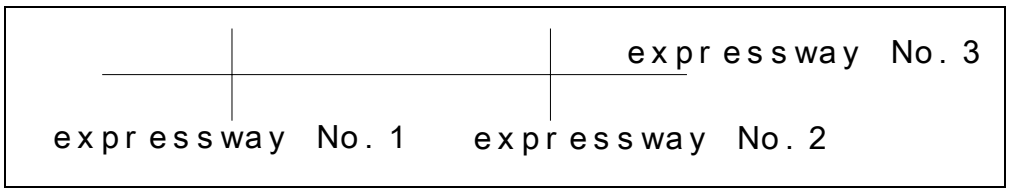

Figure1 Basic unit of expressway network

SIMULATION MODEL

Calibrate the model parameter. Whether the simulation results are meaningful and consistent with the reality is related to the calibration of model parameter. The paper calibrates the parameter on the basis of investigative data. It includes the basic parameters of the expressway network, car type and behavior, etc. It should be noted that the car-following model and lane-changing model in traffic simulation software AIMSUN is the GIPPS model (AIMSUN 6 User's Manual 2008)..

Choose the expressway network for simulation. This paper chooses three expressways named Huhang (No.1), Hangpu (No.2), and Zhajiasu (No.3) in Zhejiang province as the basic unit of expressway network to do the simulation experiment. The general location of these expressway are shown in Figure 1. All the section parameters are calibrated according to them.

SIMULATION EXPERIMENT

Select the evaluation indicator and its influencing factors. This paper develops a new evaluation indicator to evaluate the influence of incident — the total delay increase in expressway network. The delay of a car means the actual time spent to pass the section minus the time needed in free flow condition (the minimum time needed). Then total delay means the sum of delays of all the cars. The evaluation indicator shows the delay increase compared to the normal condition, also means to show the total delay increase caused by the incident.

This paper considers the following three variables as influencing factors on the evaluation indicator.

- Flow in the section: Using 1000~2400veh/h as the scope of simulation. Every 200veh/h as an interval.
- Duration of incident: Using 20~120sec as the scope of simulation.
- Type of influence: Single lane closure, section closure, section speed limit.

The experiment use different combinations of variables to find out its influence

on the evaluation indicator. The experiment has been designed in three parts.

The first part of the experiment: standard test. Since when the traffic flow reaches a certain value, it will not be the free flow anymore. Delay will generate, so delay in the normal condition should be known as the reference of the incident condition.

The second part of the experiment: relationship between flow, duration, and delay increase. This part assumes that there is an incident happening in expressway No.3 and the right lane of its section is closed. Conduct the simulation experiment by only changing the flow in the section and duration of the incident. Since the incident may cause some delay increase in other two cross expressways, sum up the delay increase in all three expressways and get the value of evaluation indicator. The flow changes from 1000 to 2400veh/h, and duration of incident changes from 20 to 110min. There are in total 80 different experiments, part of the results are shown in Table 1.

Table 1 Relationship between flow, duration, and delay increase

Actual Flow （veh/h）	Duration (min)	Delay Increase (min)	Actual Flow （veh/h）	Duration (min)	Delay Increase (min)
1029	20	177	1029	70	487
1029	30	279	1029	80	560
1029	40	333	1029	90	631
1029	50	307	1029	100	662
1029	60	328	1029	110	760

The third part of the experiment: different types of influence in the section. This part assumes that there's an incident in expressway No.3, and section is closed or speed is limited. Do the experiment with different flows and durations, part of the results is shown in Table 2.

Table 2 Experiment data of different type of influence

Actual Flow （veh/h）	Duration (min)	Type of influence	Delay Increase (min)
1029	30	Section closure	11204.93
1029	60	Section closure	42767
1029	60	Speed limit 60km/h	8661
1029	60	Speed limit 80km/h	2150
1029	90	Speed limit 60km/h	12463
1029	90	Speed limit 80km/h	3110

RESULT ANALYSIS

The second part of the simulation experiment assumes that there is an incident happening in the expressway and caused the right lane of its section to close. This kind of incident happens quite typical in the expressway. The relation between flow,

duration of incident and delay increase is shown in Figure 2 according to simulation data.

From the chart, it can be concluded that the delay increase caused by incident and the flow have an exponential relation. When the flow is relatively low, duration of the incident has little contribution to the delay increase. When flow is beyond 1500veh/h, the influence of duration on delay increase becomes more and more obvious. This means that there exists a mutation point of delay increase. Incident duration will have little influence when flow is lower than the value of the mutation point. According to the simulation result, the value of the mutation point is a little bit lower than the half value of the section capacity.

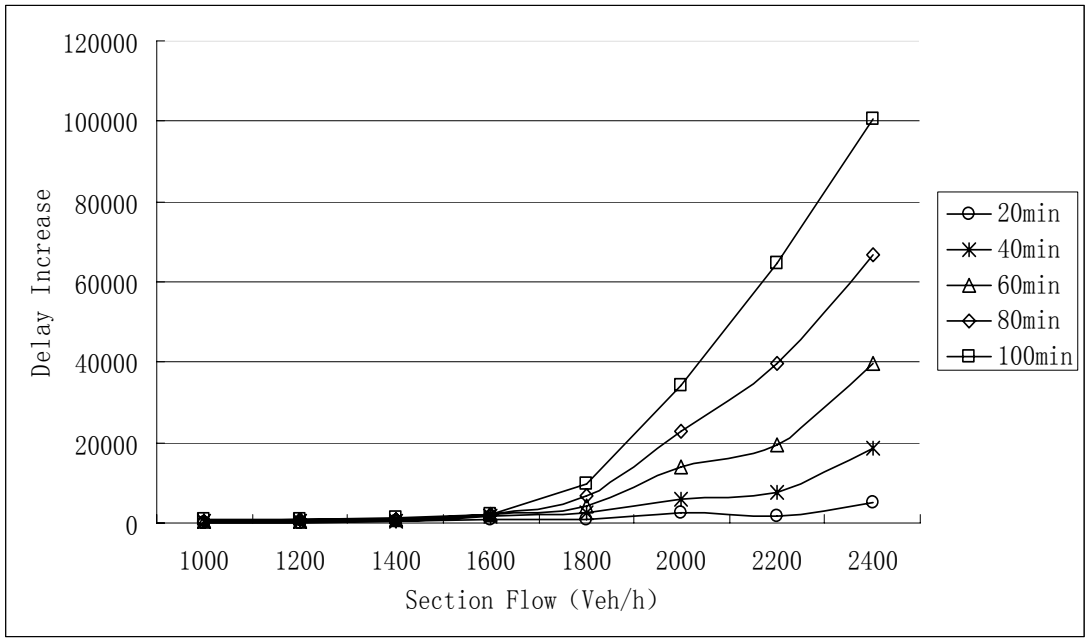

Figure 2 Simulation data about delay increase

In terms of duration, if the flow is kept unchanged, the relationship between duration and delay increase is approximately linear. With the increasing of the duration, the increasing of delay increase became much faster. The reason is that with the increasing of the duration, the influential area in the section expanded. When duration is long, delay will be generated even when the car is still far from the position of the incident.

Analyzing the results of the third part of the simulation experiments, it is obvious that the section closure or speed limit will caused a quite a large delay increase compared to the second part of the simulation experiment.

THE FUNCTION OF DELAY INCREASE

From the second part of the experiment, the relationship between flow, duration and delay increase under the typical incident can be regressed as a function.

According to the analysis above, the function is supposed as in Equation 1.

$$D = e^{aQ + bT + c} \quad (1)$$

Where D is delay increase, Q is flow, T is duration and a, b, c are coefficients in need to be regressed. This paper uses the software SPSS to do the linear regression after using the log function on both sides. The results are shown in Table 3 and Table 4.

Table 3 Model Summary

Model	R	R Square	Adjusted R Square	Std Error of the Estimate	Change Statistics				
					R Square Change	F Change	df1	df2	Sig F Change
1	0.97	0.941	0.94	0.4541	0.941	614.409	2	77	0.000

Table 4 Coefficients

Model		Unstandardized Coefficients		Standardized Coefficients	t	Sig.
		B	Std Error	Beta		
1	c	-0.426	0.247		-1.725	0.089
	a	0.040	0.000	0.888	32.086	0.000
	b	0.250	0.020	0.391	14.117	0.000

From the table, the regression function is calculated as $D = e^{0.004Q + 0.025T - 0.426}$, and the Sig F Change is 0.000. That means the regression model is effective and parameters are obvious. Since the function is regressed, it can be used to calculate the delay increase caused by the typical emergent incident.

CONCLUSION

This paper defined a basic unit of expressway network as the suitable research extent of the influence of incident and a new evaluation indicator to analyze the influence. From the specific simulation data, it can be seen that flow in the section will have the greatest contribution to the delay increase under emergency, especially when the flow is beyond the half value of the section capacity. Since a specific simulation result was found in different types of incident, it can be used to analyze real rescue measures at the indicator of delay increase. When under inclement weather, whether the section should be closed (will cause delay) or just limited in speed (may cause accident and then also cause delay) can be analyzed from specific data so that the better measure can be chosen. The regression model of the delay increase is mainly used to do traffic diversion under emergent incident. When several diversion paths can be chosen, regress each delay model from them and analyze the best diversion measures by calculating the total delay increase under the different

diversion flows.

ABSTRACT

Under the situation of meeting the regional transport needs, we will minimize the social transportation cost to optimize the transport structure, which accords with regional sustainable development. From the perspective of industrial economics, this article analyzes the external costs arising from land use, energy consumption, environmental pollution, traffic safety and other factors of different transport modes. This article also establishes the social cost models which are based on the internalization of external costs. By comparing different modes of economic transport costs, it proposes some recommendations for transport structure optimization to meet the requirements of maximizing social welfare and provides a basis for the transport network planning, adjustment and policy-making.

1 INTRODUCTION

The traditional structural optimization of traffic is mainly based on time efficiency, making the shortest travel time the main objective of optimization. However, if we are only concerned with time efficiency, this will surely give rise to the corresponding energy and resource consumption, and environmental pollution, which will lead to unsustainable development in many regions or countries. Thus scholars have begun to pay attention to the sustainable development of traffic means. Saidur (2007) and Ifue (2007) have studied the relationship between transportation and energy from the perspective of resource control. Barney (1991) and Rumelt (1984, 1987) have discussed energy consumption and control of transportation development from the perspective of energy consumption and land control. The domestic scholar Lu Huapu (2004) has also explored the problem of optimal structure of traffic.

In fact, regardless of the perspective, the key to exploration of traffic optimization is whether it can meet the traffic demand as well as realize the social minimum costs of the entire transportation. If it can reach this requirement, then the traffic structure has reached the goal of optimization. Therefore, the problem of the total social cost is the key to the traffic structural optimization. If we include the external costs such as environmental pollution, resource consumption, and energy consumption in the transport costs as well as minimize the region's overall social

cost, and we accordingly put forward the program of structural optimization of the traffic, then all mentioned above is not only beneficial in terms of sustainable transport development, but also in terms of social sustainable development as a whole.

Economic characteristics of transportation, from the aspect of the transport infrastructure, have more obvious positive externalities due to the property of the quasi-public goods. However, when transport entities (transport companies, private car owners) are providing transport services, society is responsible for pollution, noise, traffic accidents and other external costs. The negative externalities are more obvious, especially with the emergence of congestion. The objective and accurate definition of the economic external characteristics of various transport means is not only the notion of the social costs, but also the realization of the structural optimization of traffic.

2 ANALYSIS OF THE EXTERNAL ECONOMICS OF TRANSPORTATION

2.1 The analysis of the positive externalities about the transportation

The positive externalities of the transport industry are mainly manifested in railways, roads, ports and other transport infrastructure provisions. On one hand, transportation has provided substantial economic and social benefits, which enables the specialization of production, large-scale economic development, economic globalization and the convenience for the mobility of population. As a result, people can enjoy a greater quality of life and more employment opportunities. On the other hand, the traffic transportation increases land values of surrounding real estate and promotes the development of the interrelated industries. It also makes difficult to ask the non-equipment users for return and therefore prevents the outflow of the effects. From a general view, the positive externality of the construction of fundamental transportation facilities always overruns its negative internality. However, its positive externality is limited, as people can turn the external effect into its own income actively and then realize its internality spontaneously.

2.2 The external analysis of transportation

The external analysis of transportation displays its impact on sustainable development, which occurs when providing its service. The negative effects caused by transportation can not be directly measured by money, but they are apparent in the form of external costs, such as traffic jams, pollution, traffic accidents and ecological destroy. In 2001, the direct loss due to traffic accidents reached to 3,088 billion RMB and the loss of pollution reached 1230 million RMB. This kind of analysis also proves that the cost of maintaining transportation is more than the cost people have spent. Among different kinds of transportation activities, the negative external cost of transportation can be divided into: safety costs, environmental costs, and resource costs.

As to the calculation of the external cost, we can make a qualitative evaluation

by way of TELF. We can also make a quantitative evaluation by way of effect-fare. The research of the external cost of transportation in China has been the first step, so we do not have fully comprehensible datum on transportation, and therefore we cannot get the external datum on transportation based on the actual situation of China. Here we can determine something from the outcomes of European countries, which are listed below:

Figure 1. The external cost of different transportation in European countries.

	The transportation of customers			The transportation of goods			
Kinds of Transportation	Highway	Railway	Airline	Highway	Railway	Airline	Water-way
External Cost	50.7	11.6	4.6	57.8	11.5	18.8	14.1

3 THE SOCIAL COSTS MODEL OF TRANSPORT

3.1 The social costs model of various transports

Based on the generalized cost analysis, we can calculate the transportation of various forms of transport social cost. The relationship of social costs, private costs (internal costs), as well as external costs is:

$$C_i = C_i^I + C_i^O \tag{1}$$

In the equation: C_i represents the social costs; C_i^0 represents internal costs; C_i^0 represents external costs (C_i^0 positively expresses the performance of the external income and negatively expresses the performance for the external costs).

Private costs are present in the internal market system. In the transportation industry, private costs include some pre-investment and operation of the process of traffic with the cost of change. It can be expressed as:

$$C_i^I = C_{i0} + K_i^1 Q_i = C_{i0} + K_i^1 NS \tag{2}$$

In the equation : C_{i0} expresses pre-input costs of the i kind traffic mode; K_i^Iexpresses traffic cost correlation coefficient; Q_i expresses traffic volume of the i kind way; N expresses the number of people or things (1000 people or tons); S expresses distance (km).

The calculation of external costs we can derive from Table 1 is:

$$C_i^O = K_i^2 NS \tag{3}$$

The social costs of various modes of transportation:

$$C_i = C_{i0} + K_i^1 NS + K_i^2 NS \tag{4}$$

$$C_i = C_{i0} + (K_i^1 N + K_i^2 N)S \tag{5}$$

3.2 Various modes of transport social cost analysis and comparison

1. Before the external costs are not recorded

Because external costs are not credited to the former, $C_i = C_i^I$, then

$$C_i = C_{i0} + K_i^1 NS \tag{6}$$

According to China's railways, highways, airports and shipping terminals in the corresponding construction standards, as well as the traditional transport standard-price system for railways, highways, aviation, and water transportation, if we make $C_i = C_j$ (i, j representing different transport modes), it can calculate their respective distance of these several modes transportation in the same transportation costs.

2. After credited to the external costs

According to type (5), the same order $C_i^* = C_j^*$, K_i^2, will be substituted for different coefficient from Table 1.It can calculate that their distance at transport costs are equal.

Comparing the costs, we can find that compared with railway transportation, road, water and air transportation, the relative economic distance is shortened. Especially in road transport, the advantages of relative distance are lost. This is because the external costs of rail transport are the smallest and road transport is the largest in this mode of transport.

4 STRUCTURAL OPTIMIZATION OF TRAFFIC STRATEGY

Any product of the existence of external costs can reflect the needs of society, but it also shows the production of producers does not reflect the needs of society, nor can it guide and achieve optimal allocation of social resources through the price mechanism. Therefore, the government should make transportation cost price fully reflect all society and choose the lowest cost of transportation for society according to various transportation characteristics, specifically including the following aspects.

4.1 Through adjustment of taxation to achieve the preparation of market-oriented transportation.

Taxation is an effective means of internalizing external costs. Various modes of transportation cost analysis show that as long as the government can impose tax matching with the external costs in different modes of transport, it will achieve the internalization of external costs of transportation. From the social point of view, there is no loss of social welfare. The social costs have been fully responded to, thereby correcting the market failure, and guiding the social optimal distribution of resources.

4.2 Adjust the composition of the structure of integrated transport systems.

Due to the existence of external costs, current highway transportation and railway transportation are not objective responses to their social costs. In fact, through the analysis of the third part of this article we can see the economics of road

transport are even shorter than imagined. Therefore, the government in the macro transport planning will reduce the cost of railway traffic on society. For long distance transportation of construction, the government should use the rail transit advantages of speed and social costs. For short distance transportation of construction, the government should use the highway advantages of flexibility, considerate and to a certain extent having the smallest social costs. We should support the development of road transport; at the same time, water transport and air transport are beneficial supplements. As far as meeting the traffic demand in the circumstances, it will achieve the smallest social costs.

4.3 Implement different infrastructure investment policies to provide the basis for the traffic structure optimization.

According to different possibilities of the transportation infrastructure internalization of external benefits, we should implement different investment policies. For the expressway, and inter-city railway infrastructure construction, because of their external costs it is relatively easy to internalize and through the appropriate fees ease congestion product characteristics, we can pass to invest financing of civil construction. But for most quasi-public goods belonging to the infrastructure, the government should make an investment. According to the World Bank, the route index for commercial is 2.4; it has a strong commercial infrastructure, but the rural commodity index for highways is 1, basically pure public goods. To the pure public goods by market mechanism is very difficult; it must rely on the government funds. So, for the internalization of external benefit in relatively difficult infrastructures, such as rural, county-level highways, and inland waterways construction, the government should focus on investment, through optimizing infrastructure, in order to realize transportation structure optimization.

4.4 Appropriate support water transportation, optimizing structure of transportation.

Based on the mode of transportation analysis and comparison in external costs, we can find that the external waterway transport costs far less than highway transportation and slightly more than the railway transportation. In a certain range, waterway transport has its advantages, and therefore appropriate development of water transportation is necessary. However, our country's investment in waterway transportation has been fixed at 5% - 7% of the total social costs. This relative share of investment is too small. Therefore, the investment in the inland waterways and shipping docks could increase supplying capacity of water transportation. To a certain extent, it would eliminate or alleviate traffic jams, freight traffic structure, and optimize pressure, reducing traffic and transportation of the total social cost.

5 CONCLUSION

Through the analysis of the characteristics of transportation economy, we can see external economies and diseconomies also exist in transportation. An effective

way of avoiding the external costs of transport like land use, energy cost, pollution is for the government, according to the transportation economic characteristics, to devise accurate traffic development strategies and tax adjustments. Through policies and internalization of external costs, improvements will be made in the reasonable allocation of resources, eliminating market failure, so as to meet traffic requirements, use all the means of transportation to their cost advantage and realize the transportation of lowest total social lowest and traffic structure optimization goals.

Performance Evaluation of Waterproof Bond Layer Materials Based on Grey Target Theory

YU Xin[1]

[1]Transportation College of Hohai University, 1# Xikang Road, Nanjing, China, PH (086)25-83784668; FAX (086) 25-83784668; email:Hhu_yuxin@163.com

ABSTRACT

To compare the performance of Waterproof bond layer materials on concrete bridge deck, combined with Taipu bridge, laboratory tests were carried out to common materials such as hot spray SBS modified asphalt, SBS modified emulsified asphalt, asphalt rubber SAMI and a typical professional waterproof coating. The comprehensive performances of above materials were analyzed based on grey target theory. The results showed that the optimal cost-effective one is asphalt rubber SAMI, followed by hot spray SBS modified asphalt, SBS modified emulsified asphalt. The typical professional waterproof coating are relatively poor.

Key Words: Waterproof bond Layer, Grey Target Theory, Performance Evaluation, Asphalt rubber SAMI

INTRODUCTION

Waterproof bond layer is important to bridge deck pavement . Field investigation showed that the overwhelming majority distresses such as rutting and shoving are related with the shear damage of waterproofing bond layer. Combined with Taipu Bridge on Husuzhe expressway, the paper compared the performance of different materials commonly used in China. Laboratory tests were carried out and results were analyzed based on grey target theory. Last, the paper recommended the optimal cost-effective material. The results provide a reference for selecting waterproof bond layer material.

MATERIAL TECHNOLOGY REQUIREMENTS AND TEST METHODS

Bridge Deck pavement works in harsh temperature conditions, so pavement material should have good high temperature stability and low temperature toughness to prevent the bridge deck pavement from distresses such as flowing, deforming and cracking. Usually, high temperature performance is evaluated with glass specimen surface flowing temperature test and low-temperature tender test is carried out to evaluate low temperature performance.

Studies have shown that shear strength and bond strength are the most important indicators of waterproofing bond layer material. Shear strength is usually evaluated with shear test and the bond strength is evaluated with pull-out test.

In addition, anti-construction damage and watertight are also important performance of waterproofing bond layer materials. They are evaluated with anti-breaking test for the former and high-pressure leakage test for the latter.

Table 1 shows part of the technology requirements and test methods of waterproof bond layer materials in Jiangsu Province of China mainly for the coating and structural materials because the membrane-type material is seldom used.

Table1. Technology requirements and test methods of Coating and structural waterproofing bond layer material

Test type		**Test condition**	**Test** methods
Physical indicators	Flexibility, ℃	-15℃	JC 408-1991 **6.6**
	Heat resistance, ℃	160℃	JC 408-1991 **6.7**
Road Performance	Bond strength （25℃），MPa	0.2	Φ10cm Composite sample 10mm/min Loading speed, electric drawing instrument
	Shear strength （40℃），MPa	0.4	Φ10cm Composite sample，10mm/min，Loading speed, electric shear instrument
	Impermeability	0.3MPa，30min Impermeable	High-pressure leakage test
	anti-construction damage performance	Impermeable in 0.3Mpa water pressure	Anti-breaking test, High-pressure leakage test

INDOOR PERFORMANCE TEST RESULTS

First, different materials were selected. Then, laboratory tests were carried out. The test results are shown in table 2 (Yu et al. 2008).

For asphalt rubber SAMI, the usage amount is 2.0~2.5kg/m^2 with the usage amount of gravel being 7~8kg/m^2.The usage amount of hot spray SBS modified asphalt is 1.8~2.0kg/m^2 with the usage amount of gravel being 7~8kg/m^2 .The usage amount of SBS modified emulsified asphalt is 0.7~0.9kg/m^2 with the usage amount of gravel being 5~7 kg/m^2. For the typical coating material, the usage amount of the bottom material is 0.5～0.52kg/m^2 with the amount of 1# and 2# high viscosity material being 0.95～1.0kg/m^2.

Table 2. Different waterproof bond layer material properties

Material Pilot project	SBS modified asphalt	Asphalt rubber SAMI	coating material	SBS modified emulsified asphalt
High Temperature Performance Test	150℃	150℃	140℃	150℃
Low Temperature Performance Test	-20℃	-20℃	-20℃	-20℃
Shear strength	0.37MPa	0.60MPa	0.37MPa	0MPa
Bond strength	0.88MPa	0.91MPa	0.74MPa	0.89MPa
Anti-aging	77.3%	88.4%	0%	93.0%

performance				
Impermeability	impermeable	impermeable	impermeable	permeable
Cost（rmb/m^2）	11.0	16.5	8.0	5.0

GREY TARGET THEORY

According to test results above, we can see different materials differ in different performance aspects. The paper tried to optimize the best material of comprehensive performance with Grey Target theory. Grey Target analysis method is a kind of grey relation analysis theory that is used on process mode sequence, which selects the more optional unit by comparing the bull's-eye degree (Deng et al. 1998; 2002). The steps of establishing the basic model of Grey Target theory are as follows:

①The establishment of grey mode

Grey mode is a kind of indicator sequence. It is a key factor sequence of a solution about a project.

$$\omega_i = (\omega_i(1), \omega_i(2), \cdots, \omega_i(n)),$$

$$\forall \omega_i(k) \in \omega_i \Rightarrow k \in K = \{1,2,\cdots,n\}, \quad i \in I = \{1,2,\cdots,m\}$$

Among which, ω_i is the sequence of multi-polarity indicators, $\omega_i(k)$ is the data of I mode and k indicator； $K = \{1,2,\cdots,n\}$ is the distribution of indicators;

$\exists k^*, s^* \in K \Rightarrow POL\omega_i(k^*) \neq POL\omega_i(s^*)$， That is, any two indicators do not have the same polarity; $\omega(k) = (\omega_1(k), \omega_2(k), \cdots \omega_m(k))$ is called the K indicator mode sequence, referred to as K-indicator sequence.

②Establishment of the standard mode

For $\omega_i = (\omega_i(1), \omega_i(2), \cdots, \omega_i(n))$

$\forall \omega_i(k) \in \omega_i \Rightarrow k \in K = \{1,2,\cdots,n\}$ $i \in I = \{1,2,\cdots,m\}$

$\omega(k) = (\omega_1(k), \omega_2(k), \cdots \omega_m(k))$， $\forall \omega_i(k) \in \omega(k) \Rightarrow i \in I = \{1,2,\cdots,m\}$；

The $POL(\max), POL(\min), POL(mem)$ are named as the maximum value polarity, the minimum value polarity, moderate value polarity respectively, then

when $POL\omega(k) = POL(\max)$, $\omega_0(k) = \max_i \omega_i(k), \omega_i(k) \in \omega(k)$;

when $POL\omega(k) = POL(\min)$, $\omega_0(k) = \min_i \omega_i(k), \omega_i(k) \in \omega(k)$;

when $POL\omega(k) = POL(mem)$, $\omega_0(k) = u_0$（Specified value）,or $\omega_0(k) = \underset{i}{avg}\, \omega_i(k)$, $\omega_i(k) \in \omega(k)$, then the sequence $\omega_0 = (\omega_0(1), \omega_0(2), \cdots \omega_0(n))$ was the standard model.

③Grey target transformation (Deng Julong et al. 2002)

If $T\omega_i(k) = x_i(k)$， $T\omega_i(k) = \dfrac{\min\{\omega_i(k), \omega_0(k)\}}{\max\{\omega_i(k), \omega_0(k)\}}$ (1)

T is the Grey Target Transformation， $x_i(k)$ is the unified measure Transform value.

④Grey relation factor sets and grey relation differences information space conversion

grey relation factor sets: $@_{GRF} = \{x_i \mid i \in I, x_i = T\omega_i, \omega_i \in @_{INU}\}$

grey relation differences information space: $\Delta_{GR} = (\Delta, \zeta, \Delta_{oi}(\max), \Delta_{oi}(\min))$,

$$\begin{gathered} \Delta = \{\Delta_{oi}(k) \mid i \in I = \{1,2,\cdots,m\}, k \in K = \{1,2,\cdots,n\}, \\ \Delta_{oi}(k) = |x_o(k) - x_i(k)| = |1 - x_i(k)|, x_o(k) \in x_o \Rightarrow x_o = T\omega_o\} \\ \zeta = 0.5, \\ \Delta_{oi}(\max) = \max_i \max_k \Delta_{oi}(k) = \max_i \max_k |1 - x_i(k)| \\ \Delta_{oi}(\min) = \min_i \min_k \Delta_{oi}(k) = \min_i \min_k |1 - x_i(k)| \end{gathered} \tag{2}$$

⑤Calculation of the bull's-eye factor (Deng Julong et al. 1987):

$$\gamma(x_o(k), x_i(k)) = \frac{\min_i \min_k \Delta_{oi}(k) + 0.5 \max_i \max_k \Delta_{oi}(k)}{\Delta_{oi}(k) + 0.5 \max_i \max_k \Delta_{oi}(k)} \tag{3}$$

⑥Calculation of the bull's-eye degrees:

$$\gamma(x_o, x_i) = \frac{1}{n} \sum_{k=1}^{n} \alpha_k \gamma(x_o(k), x_i(k)) \tag{4}$$

α_k is the weight coefficient in the above formula.

MATERIAL SELECTION BASED ON GREY TARGET THEORY

This Grey Target analysis project is named "Bridge Deck Pavement Waterproof Bond Layer Material Evaluation." Four kind materials were used. The test results of these materials are shown in table 2. According to the project type, the paper established a standard mode that included six performances in the list, and took economic value into account. To highlight shear strength and economic value, the weight of the two coefficients were set 1.1 while the weight of the other were set 1.0.

The material optimized should have relatively higher and lower temperature stability. The former target was set 160C and the latter was -20C according to research. The highest test values were elected for the shear strength and bond strength as target. They were 0.60MPa and 0.91MPa respectively. The anti-aging properties were set at 93% as target in the same way. To facilitate analysis, for waterproof performance, impermeable is set as 1 and permeable as 0. For economic value, set the market average cost as target, which is 10.12RMB / m^2. The analysis process is as follows (Li et al. 2008):

①Established original series with the results in table 3.

Table.3 The original series for Grey Target analysis

Material / Comparison factors	$\omega_1(k)$ SBS modified asphalt	$\omega_2(k)$ Asphalt rubber SAMI	$\omega_3(k)$ Coating material	$\omega_4(k)$ SBS modified emulsified asphalt
$\omega_i(1)$ High Temperature	150	150	140	150

$\omega_i(3)$Shear strength（Mpa）	0.37	0.60	0.37	0
$\omega_i(4)$Bond strength（Mpa）	0.88	0.91	0.74	0.89
$\omega_i(5)$Anti-aging performance（%）	77.3	88.4	0	93.0
$\omega_i(6)$ Impermeability	1	1	1	0
$\omega_i(7)$cost（rmb/m^2）	11.0	16.5	8.0	5.0

②Grey Target Transformation

Based on formula 1, transform table 3 to table 4.

standard mode $\omega_o = (160, -20, 0.6, 0.91, 93, 1, 10.12)$， and $T\omega_o = x_o = (1,1,1,1)$

Table.4 The data after Grey Target transformation

	$T\omega_1(k)$	$T\omega_2(k)$	$T\omega_3(k)$	$T\omega_4(k)$
$T\omega_i(1)$	0.937	0.937	0.875	0.937
$T\omega_i(2)$	1.00	1.00	1.00	1.00
$T\omega_i(3)$	0.62	1.00	0.62	0.00
$T\omega_i(4)$	0.97	1.00	0.81	0.98
$T\omega_i(5)$	0.83	0.95	0.00	1.00
$T\omega_i(6)$	1.00	1.00	1.00	0.00
$T\omega_i(7)$	0.92	0.61	0.79	0.49

⑶Grey relational difference information space

First, identify differences information collection Δ, then transform table 4 to table 5 based on formula 2.

Table.5 Differences information collection

	$\Delta_{o1}(k)$	$\Delta_{o2}(k)$	$\Delta_{o3}(k)$	$\Delta_{o4}(k)$
$\Delta_{0i}(1)$	0.063	0.063	0.125	0.063
$\Delta_{0i}(2)$	0.00	0.00	0.00	0.00
$\Delta_{0i}(3)$	0.38	0.00	0.38	1.00
$\Delta_{0i}(4)$	0.03	0.00	0.19	0.02
$\Delta_{0i}(5)$	0.17	0.05	1.00	0.00
$\Delta_{0i}(6)$	0.00	0.00	0.00	1.00
$\Delta_{0i}(7)$	0.08	0.39	0.21	0.51

According to Table 6, the grey relational difference information space is as follows:

$$\Delta_{GR} = (\Delta, \zeta, \Delta_{oi}(\max), \Delta_{oi}(\min))$$

$$\Delta = \{\Delta_{o1}, \Delta_{o2}, \Delta_{o3}, \Delta_{o4}, \Delta_{o5}, \Delta_{o6}\}, \zeta = 0.5$$

For the test material: $\Delta_{oi}(\max) = 1$, $\Delta_{oi}(\min) = 0$

④Calculated bull's-eye factor with formula 3 with the results in table 6.

Table.6 Bull's-eye factor value

	$\gamma(x_o(k), x_1(k))$	$\gamma(x_o(k), x_2(k))$	$\gamma(x_o(k), x_3(k))$	$\gamma(x_o(k), x_4(k))$
$\gamma(x_o(1), x_i(1))$	0.89	0.89	0.80	0.89
$\gamma(x_o(2), x_i(2))$	1.00	1.00	1.00	1.00
$\gamma(x_o(3), x_i(3))$	0.57	1.00	0.57	0.33
$\gamma(x_o(4), x_i(4))$	0.94	1.00	0.73	0.96
$\gamma(x_o(5), x_i(5))$	0.75	0.91	0.33	1.00
$\gamma(x_o(6), x_i(6))$	1.00	1.00	1.00	0.33
$\gamma(x_o(7), x_i(7))$	0.86	0.56	0.70	0.50

⑤Calculated bull's-eye degrees with formula 4 with the results in table 7.

Table.7 Bull's-eye degrees

Material	SBS modified asphalt	Asphalt rubber SAMI	Coating material	SBS modified emulsified asphalt
Bull's-eye degrees	0.88	0.93	0.75	0.73

According to the analysis results, among the test materials, rubber asphalt SAMI has the highest bull's-eye coefficient. In other words, in accordance with the analysis value, asphalt rubber SAMI has the most optimal performance, followed by hot spray SBS modified asphalt, the SBS modified emulsified asphalt and coating material is fairly.

CONCLUSION

During the Taipu bridge Deck construction, four materials for waterproof bond layer commonly used in China were tested. According to the test data, the paper evaluated the comprehensive performance of the materials based on grey target theory. The conclusion showed that, taking economic and performance value into account, the most optimal cost-effective material is asphalt rubber SAMI, followed by hot spray SBS modified asphalt, and SBS modified emulsified asphalt. The typical professional waterproof coating is relatively poor.

Probabilistic Pedestrian-Vehicle Conflict Micro-Model in Non-Signal Controlled Multi-Lane Segments

S. Lu, S. Fang, and S. Zheng

Key Laboratory of Road and Traffic Engineering of the Ministry of Education, School of Transportation Engineering, Tongji University, Shanghai, China; PH (021) 69584649; email: lusiwenwinner@163.com

ABSTRACT

To analyze the safety problem of a pedestrian crossing the street in a non-signal controlled multi-lane segment, the traffic conflict probabilistic micro-models of multiple lanes are developed under conditions of entirely unsafe gap perception in accordance with traffic conflict technology. The model considers the effect of multiple lanes, vehicle volume, and width of lane on the pattern to pedestrians crossing. The numerical results of two-way four-lane traffic conflict probabilistic micro-models are calculated by means of Monte Carlo method. According to the delay level of pedestrians, the evaluation index based on the 90% confidence interval of conflict probability is set up in order to assess the safety of pedestrian crossing streets and optimally establish the pedestrian crossing facilities in segment.

INTRODUCTION

In recent years, the pedestrian traffic accident rates on urban roads have been generally increasing, and the safety of these pedestrians' lives have been seriously threatened when they cross the streets. Especially, the problem caused by pedestrians crossing no-signal controlled multi-lane segment gets more and more prominent. According to the theory of traffic conflict, accidents between pedestrians and vehicles usually result from traffic conflict. Therefore, many researchers hope to analyze the safety problem in pedestrians crossing the street in terms of traffic conflict theory. Based on regression analysis, Javid (2004) has developed the model that describes the relationship between the number of pedestrian-vehicle conflicts and the volume of vehicles and pedestrians; PEI Yu-long (2007) has chosen braking distance for vehicles as the standard of judging conflict severity in order to define the hazard degree of pedestrian crossing streets. However, these researches could not explain the principle of pedestrian-vehicle conflict such as the physical movement characteristic of pedestrian-vehicle conflict. Furthermore, they did not consider the psychological response of crossing pedestrian too much and ignore the influence of the randomness of traffic conflict and the numbers of lanes on the safety level of pedestrian crossing

streets.

Consequently, considering the pedestrians crossing characteristic, this paper develops the theoretic micro-model of multi-lane pedestrian-vehicle conflict probability and the evaluation index of risk for pedestrians crossing a no-signal controlled multi-lane segment in order to evaluate the safety level of pedestrians crossing the street in this segment.

DEFINITION OF PEDESTRIAN-VEHICLE CONFLICT

Based on the contradiction caused by movement of pedestrian and vehicle in a time and space resource aspect, the pedestrian-vehicle conflict is defined as the occurrence of collision between pedestrians and vehicles in a multi-lane road segment when they approach to a certain degree in the range of time and space without any trend to change their initial movement state. The affected area of the conflict is the whole lane width where vehicles run.

DEFINITION OF PEDESTRIAN'S SAFE GAP PERCEPTION

When crossing street in no-signal controlled segment, the pedestrian usually judges the running status of vehicle flow. If the arrival time headway of an approaching vehicle is a less than safe gap, the pedestrian may think it not safe enough and decide to wait aside instead of going across. While the arrival time headway of approaching vehicle is more than the safe gap, he will think it safe and go across. This process is defined as safe gap perception. But if a pedestrian still goes across the street, ignoring the danger when the arrival time headway is less than safe gap, it is considered that he has not perceived safe gap. According to this definition, the value of safe gap for pedestrian crossing the different lanes including the non-motorized lane is put forward.

$$T_i^c = t_r^p + t_{i+1}^p = t_r^p + \frac{i \bullet D + W_{nv}}{V^p} \qquad (1)$$

Where T_i^c indicates the value of safe gap for the pedestrian crossing the vehicle flow in lane i; t_r^p indicates the response time needed for a pedestrian crossing the vehicle flow; D indicates the width of the vehicle lane; V^p indicates the pedestrian crossing speed; t_{i+1}^p indicates the time taken to cross the lane i by the pedestrian; W_{nv} is the width of non-motorized lane.

DEVELOPMENT OF PEDESTRIAN-VEHICLE CONFLICT PROBABILISTIC MODEL IN TWO-WAY MULTI-LANE SEGMENT

According to the definition of safe gap for pedestrians, once a pedestrian goes across a street after safe perception, it does not happen that he conflicts with the approaching vehicle because the arrival time needed for the approaching vehicle is more than that needed for the pedestrian crossing this lane. Once a pedestrian goes

across the street without safe perception, the conflict will probably occur in the process of crossing. It indicates that in fact the pedestrian-vehicle conflict is mainly caused by pedestrians crossing without any safe perception. Meanwhile, the principle of pedestrian-vehicle conflict in one-direction close lanes is the same to that in the opposing far lanes. Accordingly, this paper has mainly researched the situation that pedestrian conflicts occur with one-way approaching vehicle flow (see Figure 1).

When pedestrian who wants to go across the non-signal controlled multi-lane segment has waited longer than what he could endure most or he has something emergent to do, he often directly goes across the street even if the arrival time headway is less than the value of safe gap. Therefore, entirely unsafe gap perception can be defined as that in the process of a pedestrian crossing, the arrival time headway of approaching vehicle in every lane is less than the value of the safe gap.

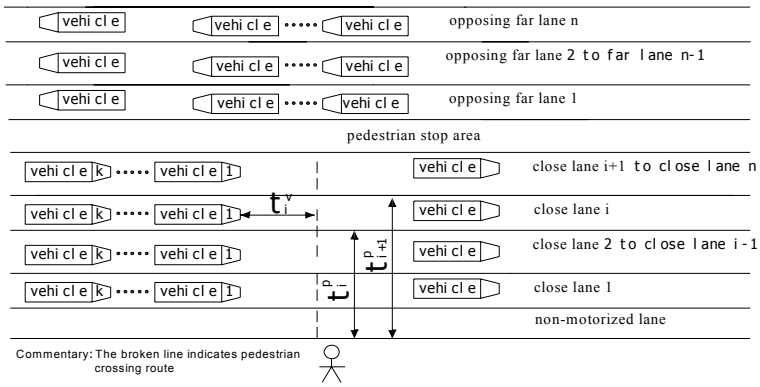

Figure 1. Process of pedestrian-vehicle conflict in lane i.

It is the most dangerous for pedestrians to cross the street in this situation. Meanwhile, no matter how the arrival time headway of a non-motorized vehicle is, the pedestrian always goes across the street. Therefore, the influence of the non-motorized vehicle on pedestrian-vehicle conflict can be ignored. The pedestrian-vehicle conflict probabilistic model is obtained under condition of entirely unsafe gap perception. The details are as follows:

The conditional probability of conflict between the pedestrian and the first approaching vehicle in lane i entirely without any safe gap perception is

$$P_i(C_1|B)=\frac{P[(\bigcap_{g=1}^{n} t_g^{v1}<T_g^c)\bigcap(t_i^p<t_i^{v1}<t_{i+1}^p)]}{P(\bigcap_{g=1}^{n} t_g^{v1}<T_g^c)}=\frac{P(t_i^{v1}<T_i^c\bigcap t_i^p<t_i^{v1}<t_{i+1}^p)}{P(t_i^{v1}<T_i^c)} \quad (2)$$

Where t_g^{v1} indicates the arrival time headway of the first approaching vehicle in lane g when pedestrian starts to cross the street (see Figure 1); n indicates the total number

of one-way lanes; $B=\left\{\bigcap_{g=1}^{n} t_g^{v1} < T_g^c\right\}$ indicates that the arrival time headway of the first approaching vehicle in every lane is less than the value of safe gap; $C_1=\left\{t_i^p < t_i^{v1} < t_{i+1}^p\right\}$ indicates that the pedestrian-vehicle conflict occurs when the first vehicle approaches to the conflict spot.

At the same time, when the arrival time headway of first approaching vehicle is $t_i^{v1} < t_i^p$ in lane i, the pedestrian will probably conflict with the certain following vehicle. Since at first the pedestrian begins to pass through the time headway of the first vehicle that is less than safe gap, it can be considered reasonably that he could choose to go across any arrival time headway of the following vehicle in lane i. In this situation, if the pedestrian walking to the edge line of lane i conflicts with the certain following vehicle, the time and space of both sides absolutely satisfy the condition of $\left\{0 < t_v^{'} < t_{i+1}^p - t_i^p\right\}$. Therefore, $C_2=\left\{0 < t_v^{'} < t_{i+1}^p - t_i^p \bigcap t_i^{v1} < t_i^p\right\}$ indicates that after the first vehicle has passed, the pedestrian conflicts with the certain following one in lane i. Thus, at the moment, the conditional probability of conflict is:

$$P_i(C_2|B)=\frac{P[(0 < t_v^{'} < t_{i+1}^p - t_i^p \bigcap t_i^{v1} < t_i^p)\bigcap_{g=1}^{n} t_g^{v1} < T_g^c]}{P(\bigcap_{g=1}^{n} t_g^{v1} < T_g^c)}=\frac{P(0 < t_v^{'} < t_{i+1}^p - t_i^p \bigcap t_i^{v1} < t_i^p)}{P(t_i^{v1} < T_i^c)} \quad (3)$$

where $t_v^{'}$ indicates the time needed for the certain following vehicle to reach the conflict spot after the first one has passed in the same lane.

Thus, under the situation of pedestrian's entirely unsafe gap perception, the conditional probability of conflict in lane i is:

$$P_i(C|B)=P_i(C_1|B)+P_i(C_2|B) \quad (4)$$

Meanwhile, the non-conditional probability of pedestrian-vehicle conflict in lane i is:

$$\begin{aligned} &P_i(C\bigcap B)=P_i(C_1\bigcap B)+P_i(C_2\bigcap B) \\ &=P[(\bigcap_{g=1}^{n} t_g^{v1} < T_g^c)\bigcap(t_i^p < t_i^{v1} < t_{i+1}^p)]+P[(0 < t_v^{'} < t_{i+1}^p - t_i^p \bigcap t_i^{v1} < t_i^p)\bigcap_{g=1}^{n} t_g^{v1} < T_g^c] \end{aligned} \quad (5)$$

In the process of pedestrian crossing streets, the total conditional probability and total non-conditional probability in one-direction close lanes are respectively:

$$NCP_{total}=1-\prod_{i=1}^{n}[1-P_i(C\bigcap B)] \quad (6) \quad \text{and} \quad CP_{total}=1-\prod_{i=1}^{n}[1-P_i(C|B)] \quad (7)$$

Where NCP_{total} is the total non-conditional probability; CP_{total} is the total conditional probability.

CASE ANALYSIS

Identification of model parameter. According to relevant research results from home and abroad (ZHOU,1987; LU, 2007;) . The model parameters are decided as follows: width of vehicle lane is valued as 3.75 meters; width of non-motorized lane is valued as 2 meters; width of marginal strip is valued as 0.25 meters; speed of pedestrian crossing conforms to parameters $N(1.5, 1)$ normal distribution, $V_{pmin} = 0.5m/s$, $V_{pmax} = 4.5m/s$; In most cases, the arrival time headway of vehicle t_v conforms to parameters λ negative exponential distribution, and response time of pedestrian t_r^p conforms to LN（0.17, 0.194）lognormal distribution, the unit is second.

Calculating method. The probabilistic value of pedestrian-vehicle conflict is difficult to achieve through common integration formula because the model contains many random variables. Therefore, the Monte Carlo method widely applied in the engineering field is used to calculate the probabilistic value of conflict through the production of a random number to meet the conditions of above variables.

Conflict probability in two-way four-lane segment. According to the model of pedestrian-vehicle traffic conflict probability in multi-lane segment developed as above, the probability of pedestrian-vehicle conflict in an urban two-way four-lane segment has been taken as an example to explain the application of model above.

Assuming that the vehicle volume in every close lane at the same direction is equal in terms of factual situation, the numerical calculation results of pedestrian-vehicle conflict probability in **two-way four-lane segment** have been listed in Table 1. It can be found that traffic non-conditional conflict probability increases with vehicle volume under condition of entirely unsafe gap perception. But the total conditional probability increases slowly with vehicle volume, especially in one-way two opposing far lanes because the width of the non-motorized lane has not effect on the pedestrian-vehicle conflict in the opposing far lanes. Furthermore, the conflict probability value is on a higher level. It almost accords with the actual situation. Consequently, it is proved that the main reason causing pedestrian-vehicle traffic conflict is that the pedestrian crosses the street without any safe gap perception (including the error of safe gap perception) by means of theoretical method.

Table 1. Conflict probability in Two-Way Four-Lane Segment

Vehicle volume in one lane（vehicles/h）	200	300	400	500	600	700
Total conditional probability in close lane（%）	69.55	73.23	74.12	76.92	78.56	80.85
Total non-conditional probability in close lane（%）	8.35	14.39	19.94	26.61	32.55	38.99
Total conditional probability in close lane（%）	84.38	86.05	87.12	87.94	88.89	89.86
Total non-conditional probability in close lane（%）	6.74	13.10	19.95	27.23	34.48	41.49

EVALUATION OF SAFETY LEVEL OF PEDESTRIAN CROSSING IN NON-SIGNAL CONTROLLED SEGMENT

In the actual situation where the pedestrian is not willing to wait for a long time under condition of the large traffic volume in a no-signal controlled segment, pedestrian usually tends to make a compromised choice that he can make safe perception in some lanes and doing nothing in other lanes. At the same time, based on the above theoretical analysis, it can be affirmed that when pedestrian is crossing the multi-lane segment, the occurrence of pedestrian-vehicle conflict is not influenced by other lanes but only relates with the arrival time headway of the vehicle in this current lane. The conflict probability corresponds to conditional probability. Consequently, half of total conditional conflict probability under condition of entirely unsafe gap perception $p=CP_{total}/2$ can be used to indicate the total conditional conflict probability on condition that pedestrian crosses the street with safe gap perception for just a part of all the lanes. In the situation, this kind of total conditional conflict probability between pedestrians and vehicles is more likely to reflect the actual safety level of a pedestrian crossing in this segment.

According to the characteristic of traffic conflict in road segment, it can be considered that the number of conflicts between pedestrians and vehicles in this segment conforms to binomial distribution just as $C\sim B(m, p)$. where m indicates the number of pedestrian crossing times in one direction within a given period of time (two people and more crossing together is defined as one time), $p=CP_{total}/2$； m is regarded as the number of pedestrian crossing time with safe gap perception for only a part of all the lanes, and can be written as $m=\alpha M$. Where M indicates the actual total number of times that pedestrians crosses the street, and α indicates the control proportion of total pedestrian crossing times in this way , which is related with the delay in the process of pedestrian crossing. The more the delay time is, the more the proportion of the way that pedestrian forces to cross the unsafe gap will be (YANG, 2007). The details of the method are as follows:

$$\bar{t}=\int_0^{T_{\max}^c} t\lambda_v \mathrm{e}^{-\lambda_v t}\,dt \tag{8}$$

$$d_p=\frac{1-f}{f}\bar{t}=\frac{1-e^{-\lambda_v T_{\max}^c}}{e^{-\lambda_v T_{\max}^c}}\bar{t} \tag{9}$$

$$\alpha=\begin{cases}0.6 & d_p>40s\\ 0.5 & d_p\in(20,40]s\\ 0.4 & d_p\le 20s\end{cases} \tag{10}$$

Where d_p indicates the pedestrian's average delay time corresponding to different volumes; T^c_{max} indicates the maximum safe gap corresponding to average pedestrian crossing speed in one direction; λ_v indicates the total average arrival

rates of vehicle flow in one direction; $\bar{t}$ indicates the average pedestrian waiting time when the arrival time headway is less than maximum safe gap; *f* indicates the probability that the arrival time headway is more than maximum safe gap.

However, when the value of m is large enough, the random variable can be obtained according to the central limit theorem of binomial distribution:

$$Z \approx \frac{C - mp}{\sqrt{mp(1-p)}} \qquad (11)$$

It nearly conforms to standard normal distribution $N(0, 1)$ (when $m \to \infty$).

Based on the assumption and discursion as above, the 90% fractile of total conditional conflict probability under condition of making safe gap perception for only a part of lanes can be used as the control standard of danger level in the process of pedestrian crossing. The detail critical values are as follows (ZHOU, 2001):

$$C_{\text{upper}} = mp + u_{1-\frac{\partial}{2}}\sqrt{mp(1-p)} \quad \text{and} \quad C_{\text{lower}} = mp - u_{1-\frac{\partial}{2}}\sqrt{mp(1-p)} \qquad (12)$$

Thus, Equation 12 has shown that once the actual number of pedestrian-vehicle conflict is more than the critical value, the proportion of the way that the pedestrian forces to cross the unsafe gap can overpass the control rate α given by the delay level of pedestrian. Therefore, according to highway black-spot qualitative control method (GUO, 2002), the danger level is high in this segment and the reasons should be analyzed immediately and relevant measures should be taken when the number of pedestrian-vehicle conflicts is more than C_{upper}; when the number of conflicts is in the range of [C_{lower} , C_{upper}], the danger level is normal and a tracking observation should be taken and some measures should be adopted according to the fact; when the number of conflicts is lower than C_{lower}, the danger level is low and the safety level in this segment is high enough.

According to the method above, the specific case analysis in this paper is as follows: assuming that when pedestrians cross the street during rush hours in two-way four-lane no-signal controlled road segment, the relevant data are: when the total vehicle volume of one-way two close lanes is 1100 vehicles/h and the number of times of a pedestrian crossing is 120 times in an hour and the number of conflicts in close lanes is 36. According to Table 1 and the formula as above, it can be calculated out that $\alpha = 0.5$, and in one-direction close lanes, the critical number of conflicts are respectively C_{upper}=30 and C_{lower}=17. Therefore, it can be judged that the dangerous status of a pedestrian crossing the close lanes is high and relevant measures should be taken; as to the evaluation of safety level for pedestrian crossing the opposing far lanes, the same method could be used.

CONCLUSIONS

Based on the principle of pedestrian-vehicle traffic conflict and pedestrian's

perception of safe gap, the micro-model of multi-lane pedestrian-vehicle conflict probability has been developed, which contains the influence factors such as the lane number, vehicle volume, width of lane. Meanwhile, combined with the delay level in the process of pedestrian crossing and based on the 90% of pedestrian-vehicle conflict probability, the evaluation index of risk level has been put forward in order to provide theoretic foundation for the evaluation of pedestrian crossing safety level in a no-signal controlled segment.

ABSTRACT

This paper analyzes the system structure and technical character of the Communication Based Train Control (CBCT), and introduces the prototype of train tracing operation simulation in CBTC. The control model of train tracing operation in CBTC is established by analyzing the process of train operation, the logical control and the principle of moving block. There is a simulating algorithm of train tracing operation control, which is based on the concept of Moving Block (MB) and the technology of computer simulation. This simulation system is realized to trace several trains through VC++.

INTRODUCTION

The train control technology based track circuit was adopted in the traditional railway transportation signal system. The development of the modern train control system followed the trend of CBTC, which represents direction of the development of the modern railway signal system. The CBTC system realizes many functions, such as real time bi-communication between trains and the wayside with fast speed and sufficient capability, Automatic Train Protection (ATP), Automatic Train Operation (ATO), Automatic Train Supervision (ATS), and so on. The CBTC strongly ties with the MB, which has no fixed block. However, the CBTC can modify the section length according to the train operation status and can move with the train operation. The MB has improved railway transportation efficiency by making train operation more secure and by enabling short tracing intervals between trains. Due to limited time and funding, it is not possible to conduct field experiments of all combinations of parameters. Establishing a CBTC system enables simulation of train tracing operations. Simulation is particularly useful for understanding extreme cases which are very difficult to simulate through field experimentation. Additional parameters that can be tested through simulation include tracing intervals between trains, calculating the least distance of the train tracing, optimizing train organizing in CBTC lines, increasing density of train operation, and strengthening

transportation capability of the lines.

THE STRUCTURE OF THE CBTC SYSTEM

The CBTC system is a wireless signal system used to locate trains. The train operation control takes advantage of the concept of MB. In The CBTC system, the vehicle on-board controller detects and calculates the train position and reports to the wayside system by bi-directional communication. The wayside system sends a "moving authorize" signal to the train according to the train's speed, position and other factors.

The CBTC system consists of ATS, DSU, ZC, VOBC, and DCS, etc. The structure of the CBTC system is illustrated in Figure1.

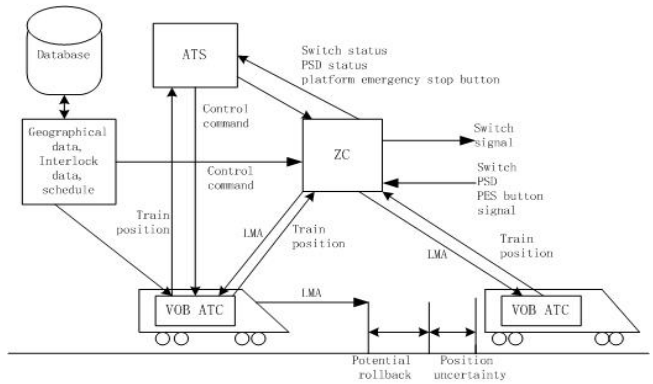

Figure 1. The Structure of the CBTC.

The principle of the train operation. The ZC timer makes judgments that authorize the moving train (speed or distance) according to geographical data, train position, route status, emergency stop button, PFD status, and other factors. This authorization to move signal is sent to the designated train.

The train is controlled by the authorization to move signal. Information, such as the train position and other factors is sent to ZC and ATS.

Wayside equipment supervising. The ATS can offer an MMI (Man Machine Interface) and send operation control commands to the ZC. The ATS gets the information, such as switch status, signal status, PSD status, platform emergency closing, etc., from each centralized station and displays it on the MMI.

The ZC receives the control command and sends a logical judgment to the control switch, the signal, and other equipment in the wayside control unit.

Train supervising. The concerned parameter is input into the ATS MMI and sends the operation command to the designated train. When the train information is changed, the information is automatically sent to the ATS. The information covers train number, train position, and others. The ATS information is displayed in the MMI when it is received. Then, the vehicle on-board ATC will process the command and judge whether the command should be implemented or not. If the command is to be implemented, the train operation control is started.

Vehicle on-board controller. The vehicle on-board controller will use database information to locate the train position by detecting the wayside response.

The vehicle on-board controller communicates between the ATS and the ZC through the DCS to report the train position and status. Then, the control command is sent to the controller.

The principle of MB. The CBTC system can control the train tracing interval by MB. In the traditional track circuit system, the moving authorize signal is limited by the unit of the track circuit section. In the CBTC system, the moving authorize signal is determined in a more precise way. The safe distance between two trains is determined by the current speed of the two trains, train positions, the capability of the train's brakes, obstacle characters, and other dynamic data. The main purpose of the MB system is to reduce the distance between running trains and improve the overall transportation capability. This can be achieved by improving the precision of the trains' positional locations and by increasing the frequency of sending moving authorize signals. Of course, ensuring safe operation to avoid injury is the foundation for all of these improvements and methods.

When the train is running, the train's speed status, position status and other information is sent to the wayside system by a communication network. The wayside system calculates the longest train braking distance and assures that there is no compromise of the safe protection distance. This is the MB section. The principle of MB is illustrated as Figure 2.

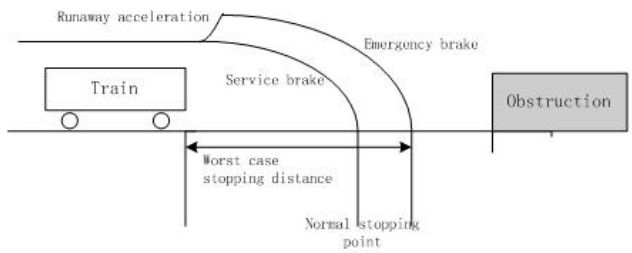

Figure 2. The principle diagram of Moving Block.

THE SIMULATING MODEL OF TRAIN OPERATION CONTROL

The prototype of the CBTC simulation train tracing system is established on the structure of the CBTC system and the principle of the MB.

The ATS's main function is to create the lines and depots illustration and create the operation control function. It can also be used to supervise and control wayside equipment and trains.

Vehicle on-board ATC includes TOD and train data. The TOD is the display system of the driver operating unit. It displays information, such as the current speed, permitted speed, maximum speed, train position status and others. The TOD is used to show the current operation status of the train, provide drivers with the control interface for braking, opening doors, and to perform other operations. It can also be used to send train control commands. The train data consists of train status data and train control command, which includes the operations of the TOD and the ATS. The train dynamic data is sent to the corresponding modules of trains to create the function of the train operation simulation.

The function of the ZC consists of station control, interlock control, and computer moving authorization. The station control includes station hold, station skip, emergency close, and so on. The interlock includes route setting, interlock logic to cancel, and other operations. The moving authorization can calculate the current speed and distance according to ATP protection logic.

The data from the lines and the wayside equipment includes: signal proportion, such as switch, signal, section, emergency station close, PSD, and so on. The line topology includes the relationship between the system platform management parts and depot data.

The train simulation operation is the function of the VOBC. The train simulation operation can simulate train operation, such as, depot leaving, section entry, station entry, station stop, station exit, turning back, depot entry and so on. Train simulation operation generates the information and sends it to the ZC. The information is used to calculate the next moving authorization signal and to display on the interface of the TOD and the ATS.

The simulating model of train operation control is established on the foundation of the prototype of the CBTC system. The distance of train tracing is determined by the distance of moving section, the maximum speed of train running, and the braking performance in the worst instance.

$$L=V^2/(2B) \qquad (1)$$

In the above formula: V is the maximum speed of the train; B is the train braking rate.

The initialization is conducted in the train operation simulation. First, the initial position of the train is determined. This position is the beginning of the section. Each section on the lines is separated into ΔS=25m. When the train is virtually running within ΔS, the time that train takes on each ΔS will be measured.

When all the trains overpass all the ΔS within the current section, this represents that the train head has moved into the next section. Using the same method, we separate the next section into ΔS as the current section; the train runs on the ΔS virtually repeating the above process until the train stops. The process of train operation is described in Figure 3.

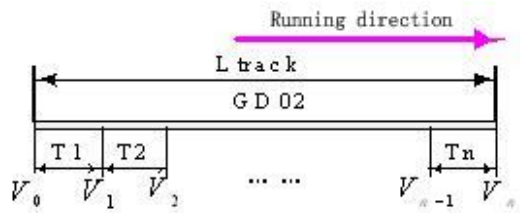

Figure 3. The simulating of the CBTC train operation process.

The process of a train running on the ΔS and the time, T, of a train staying on the ΔS is calculated per the following formula.

$$\Delta S_i = V_{i-1} T + \frac{a_i T^2}{2} \qquad (2)$$

In the above formula: ΔSi is the No.i ΔS of the current section; Vi-1 is

entrance speed of the train running on the No.i ΔS of the current section; a_i is the acceleration of the train running on the No.i ΔS of the current section.

When the train starts up, the entrance speed is V0 = 0 m/s on the current ΔS. The time of the train running on the ΔS can be calculated using Equation (2). The entrance speed on the ΔS can be calculated according to the following formula. It is the entrance speed on the next ΔS.

$$Vi = V_{i-1} + a_i T_i \qquad (3)$$

In the above formula: V_i is the exit speed of the train running on the No.i ΔS of the section; V_{i-1} is the entrance speed of the train running on the No.i ΔS of the current section; a_i is the acceleration of the train running on the No.i ΔS of the current section; T is the time of the train running on the No.i ΔS of the section.

The total distance of the train running on the No.i ΔS of the current section is calculated using the following formula.

$$S_{run} = \sum_{i=1}^{n} \Delta S_i \qquad (4)$$

In the formula: ΔS_i is the No.i ΔS of the current section.

SIMULATION OF TRAIN TRACING OPERATION

In the simulation system, several trains can be simulated in the tracing operation mode at the same time. The simulation control clock is set; the thread is started; and one train is dispatched from the list of trains by rank. Then, the simulating train operation will be processed in the thread. The arithmetic and the flow of the train operation simulation are illustrated in Figure 4.

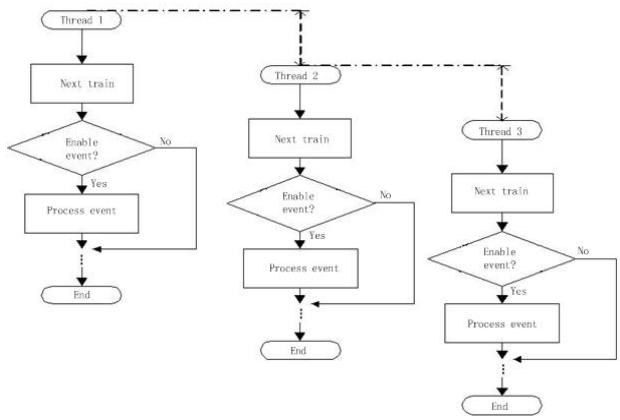

Figure 4. The arithmetic and flow of the train operation simulation.

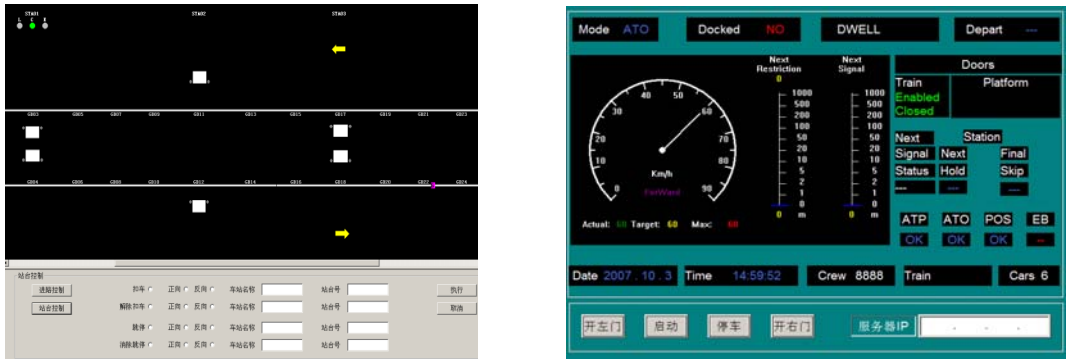
In the simulation operation, one thread simulates one train operation in one simulating clock; the train operation in the section is tagged by the time that the train runs in the section. It counts from entrance time to exit time.

In the course of designing and programming the simulation system, the ATS and the ZC are set in one module and the train simulating operation and vehicle on-board operation are set in another module. The ATS, the ZC, and the vehicle on-board ATC system use UDP to realize real-time communication by the

network.

The simulating system is created using the VC++ programming language. The simulating control interface of the ATS and the TOD is illustrated in Figure 5.



(a) ATS control interface (b) TOD interface

Figure 5. Simulating control interface.

CONCLUSION

Many lines in China have adopted the CBTC, which is an advanced railway transportation signal system. The performance parameters in this paper are provided from the corresponding company and organization. This thesis aims to establish a simulation model of a train tracing operation in the framework of the CBTC system. The model includes designing simulation arithmetic, creating a simulation system by programming, and performing simulation tests that focus on train tracing operation. In an actual railway transportation system that includes dispatching and organizing, there is more uncertainty caused by trains breaking down, and the need to manage passengers. These conditions also affect train operations. Additional effort to include these factors into a simulation system needs to be done.

Research on Rapid Curing Technology of Lime-flyash-cement Stabilized Macadam

CHEN Yuanzhao[1] LI Zhenxia[1] WANG Xuancang[1]

[1]School of Highway, Chang'an University, P.O. Box 745, Xi'an, ST Middle Segment of South 2nd Ring Road; PH (+86)029-82334836; FAX (+86) 029-82334836; email: cyz740513@163.com

Abstract : In order to solve the problem of long curing time and long construction time of projects, the early strength of lime and fly-ash stabilized macadam can be increased by applying the proper amount of cement. First, compressive strength, cleavage strength and compression rebound modulus of lime-fly ash-cement stabilized macadam are tested systematically applying standard curing (T: 20±2°C, RH: ≥95%) and high-temperature curing (T: 60±2°C , RH:≥95). Secondly, a relationship curve between strength and curing age is found by applying four different regression models. Thirdly, strength gain relationship between high temperature curing and standard curing is achieved. So, the 180-day strength by standard curing can be determined from the strength cured by high temperature curing. Fourthly, the microstructure of samples is observed and analyzed systematically by applying electron microscope scanning. By the way of high temperature curing, not only can the microstructure of it be improved, but also the curing time can be shortened. Therefore, design parameters and major control index of ratio design for the lime-fly ash-cement stabilized macadam base course construction can be confirmed rapidly.

Key words: road engineering , lime-fly ash-cement stabilized macadam, rapid curing , standard curing , electron microscope scanning , design parameters .

1 Introduction

Lime-fly ash stabilized macadam is the inorganic binder stable material used for highway base and subbase layers. However, there are so much gravel and little bonding in the lime-fly ash stabilized macadam mixture that the bond force is not enough. In lime-fly ash-cement binder using the appropriate content cement, not only the will bond force be enhanced, but also the early strength of the binder will be improved, which indicates the superiority of the mixture. Furthermore, higher gravel content is beneficial to improving early strength of the mixture and anti-cracking properties, which can solve many problems, such as construction rolling, maintenance of the base, early opening to traffic and so on (SHA Aimin, 2003). And last, using fly-ash in road construction can realize waste utilization, which is beneficial for environmental protection.

At present, a rapid curing method has to be found to shorten the curing time of the semi-rigid base for the short project construction period. So the design parameters and major control index of construction mixture ratio design for the

lime-fly ash-cement stabilized macadam base course construction can be conformed rapidly. The paper adopts high-temperature curing as rapid curing method. The strength increasing rule relationship for the lime-fly ash-cement stabilized macadam, between high temperature curing and standard curing is achieved through experimental study. Then, the long term strength, cured by standard curing methods, can be determined from the strength which is gained by high temperature curing.

2 High-temperature curing study scheme for Lime -fly ash-cement stabilized macadam

(1) The 180-day compression rebound modulus and cleavage strength are chosen to be the design parameters and the main control index of construction mixture ratio design for lime-fly ash-cement stabilized macadam, cured by standard curing (T 20±2°C, RH≥95%).

(2) According to the compressive strength of lime-fly ash-cement stabilized macadam, cured by high-temperature curing(T 60±2°C, RH≥95%), the strength increasing rule for it is analyzed. Then, the strength-age regression equation and the value of design parameters can be confirmed.

(3) The comparative analysis of microstructure observation for lime-fly ash-cement stabilized macadam is carried out, whose compressive strength, cured by high-temperature curing, is equal to the 180-day compressive strength, cured by standard curing. The strength increasing rule of lime-fly ash-cement stabilized macadam, cured by two curing condition, is studied in nature. Then, the feasibility that high-temperature curing can shorten the curing age of lime-fly ash-cement stabilized macadam is validated (HE Siguo, CHU Hong&LUO Xiaogang, 2002).

3 Physical and mechanical properties tests for the mixture

3.1 basic properties test for the mixture

(1) Cement adopts “Qinling” composite Portland cement produced by Qinling Cement Company, Yaoxian, shaanxi. Indices are shown in Table 1.

3.2 Compressive strength , compression rebound modulus and cleavage strength test s

Compressive strength, cleavage strength and compression rebound modulus test results, cured by standard curing, are shown in Table 7.

Table 7. Compressive strength , cleavage strength and compression rebound modulus test results under standard curing .

age /d	compressive strength/MPa	cleavage strength /MPa	compression rebound modulus/MPa
7	2.21	0.32	-
28	3.37	0.40	852
90	6.24	0.86	1268
150	7.56	1.11	1605
180	8.22	1.24	1771

3.3 Strength increasing rule relationship analysis for samples cured by standard curing and high-temperature curing .

Refer to Figure 1 for the trendline line for unconfined compressive strength increasing with age, cured by high-temperature curing.

It can be seen from Figure 1, rate of compressive strength gained before 14d is large, and then it gains more slowly after 14d. It also can be seen from Table 7 and Figure 1, that the 28d compressive strength value under high-temperature curing, 8.25MPa exceeds 8.22MPa, 180d compressive strength value under standard curing.

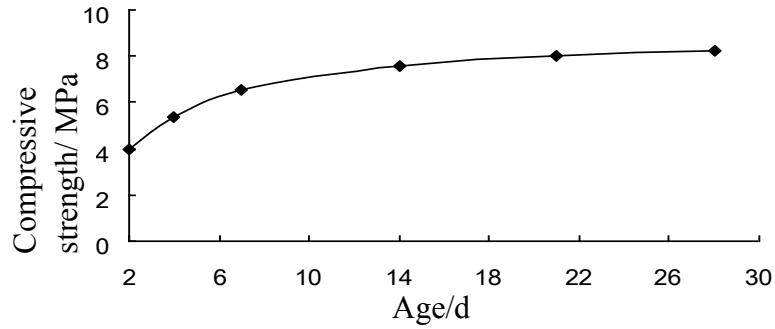

Figure 1. Tendency line for unconfined compressive strength increasing with age under high-temperature curing .

Curve fitting for logarithmic curves, power function curves, hyperbola and S curves is carried out by applying SPSS software. Large-variability test data is eliminated in order to ensure the consistency of the growth tendency line with the actual situation. Refer to Table 8 for the concrete fitting data.

Based on the curing test results of lime-fly ash-cement stabilized macadam, regression calculation applying the logarithmic method, power function method, hyperbola method, S curve method and strength growth tendency line under high-temperature curing, the 150d and 180d strength values under standard curing can be calculated applying the regression formula. The relationship curve equation

(refer to Table 9) between age and strength under high-temperature curing, corresponding time for the strength value, cured by high-temperature curing, is equal to stipulate age strength value under standard curing.

Table 8. Compressive strength and fitting data with different models by high-temperature curing .

age /d		2	4	7	14	21	28	correlation
test values /(MPa)		3.95	5.4	6.58	7.54	8.01	8.25	-
regressio –n value	logarithmic method	4.21	5.34	6.25	7.38	8.04	8.51	0.981
	power function method	3.83	5.70	6.75	7.56	7.85	8.00	0.946
	hyperbola method	4.29	5.18	6.03	7.28	8.13	8.79	0.953
	S curve method	3.63	5.92	6.91	7.57	7.79	7.90	0.986

According to the compressive strength growth tendency of lime-fly ash-cement stabilized macadam, cured by high-temperature curing, and corresponding relation with the age for standard curing, the conclusions are as follows:

(1) Under the high-temperature curing condition, the compressive strength of lime-fly ash-cement stabilized macadam increases with the increase of curing age. Compressive strength increases rapidly along a straight line before a certain curing age, and after that age, compressive strength increases slowly, even stops, and fluctuation phenomena for the strength takes place, too. During the hardening period, the internal pressure stresses of stabilized materials cause it. During the hydration process, the compressive strength increases with the development of hydrate. But the hydrate goes on hydrate, and its volume increases, which causes internal pressure, even break the covering film. Under certain conditions, tiny split defects may take place in the stabilized material, or a bladder is formed caused by an external hard shell strength formed rapidly. Strength is damaged by them. Strength goes on increasing with the development of hydrate. However, tiny split defects and bladders increase with the development of hydrate, too. Tiny split defects and bladders will do harm to the internal structure on a certain level, which arouse fluctuation phenomenon of the test value at the critical time (WANG Long, MENG Shutao&XU Quanliang, 2006).

Table 9. Relationship between unconfined compressive strength (abbre viation Rc) and age (abbreviation t) under high -temperature curing .

regression method	curve equation between R_c and t under high- temper -ature curing	corre la-tio n coeff ic-ien t	150d		180d	
			R_c under standa d curing /MPa	age for high temper at-ure curing /d	R_c under standar- d curing /MPa	age for high-tem -perature curing /d
Logarithmic method	$R_c = 1.631 \ln t + 3.077$	0.981	7.85	19	8.22	24
power function method	$R_c = 3.556t^{0.272}$	0.946	7.85	18	8.22	22
hyperbola method	$R_c = 8.226 - 9.187/t$	0.953	7.85	24	8.22	-
S curve method	$R_c = e^{(2.136-1.585/t)}$	0.986	7.85	21	8.22	-

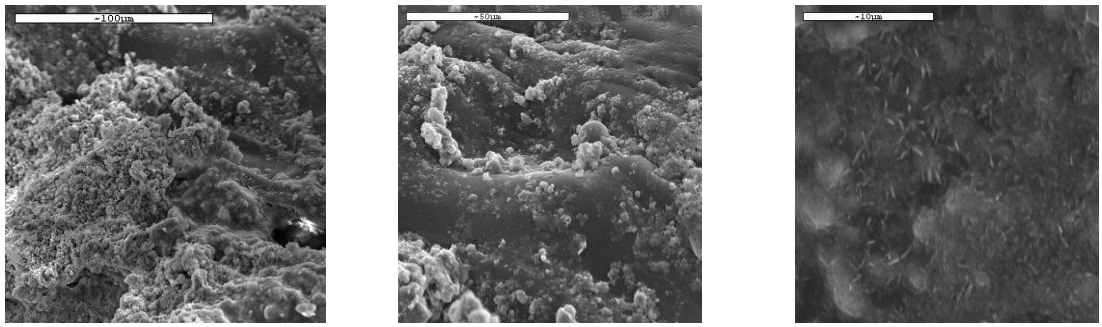
(2) The test regression results show that regression coefficients of cleavage strength and compression rebound modulus are larger applying the logarithmic method, power function method and S curve method and strength growth tendency line under high-temperature curing. Regression variability is less, and regression effect is more noticeable. Compared with the power function method and S curve method, the regression effect applying the logarithmic method is better, and is more suitable to the growth law of cleavage strength and compression rebound modulus increasing with the curing age. Therefore, logarithmic method is put forward to use.

4 Microstructure observation comparative analysis of lime-fly ash-cement stabiliz ed macadam cu red by high -temperature curing and standard curing

Samples of the maximum curing age under high-temperature curing are chosen to carry out microstructure analysis. Samples under standard curing for 180d are chosen, too. See to Figure 2 and Figure 3 for images of the microstructure of lime-fly ash-cement stabilized macadam (2:6:14:80) under different curing condition and curing age.

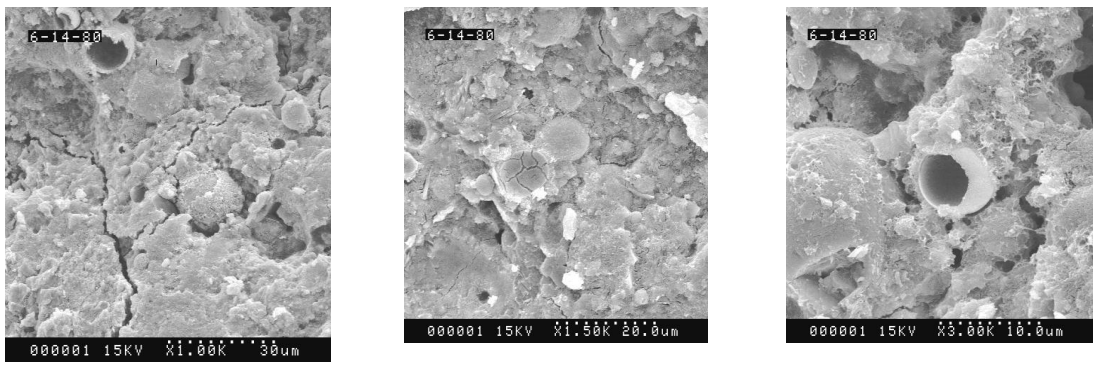
It can be seen from Figure 2 and Figure 3 that the microstructure under high-temperature curing for 21d is denser. Defects, such as holes, tiny cracks and bubbles almost do not exist. Hydration gels, produced by hydration reaction and pozzolanic reaction of lime and fly ash, almost cover up the whole sample, and the surface of the sample seems more smooth. Plenty of holes, cracks and bubbles take place in the sample cured by standard curing for 180d. These defects spread widely, and the crack is wide and runs through the whole sample. Crystals and aggregate have not been

cemented completely by hydration gel material, and lots of gaps exist between them.



(a) amplification1000 times (b)amplification1500 times (c)amplification3000 times

Figure 2. Microstructure cured by high -temperature curing for 21d.



(a) amplification1000 times (b) amplification1500 times (c)amplification3000 times

Figure 3. Microstructure cured by standard curing for 180d.

From the above observation analysis, it is clear to see that the sample microstructure, cured by high-temperature curing for 21d, is denser than that of cured by standard curing for 180d. And the structure is better. Conclusively, the sample microstructure cured by high-temperature curing grows more rapidly and better. And there are no visible defects in lime-flash-cement stabilized macadam, such as holes, microcracks and bubbles. The holes become smaller, and the structure becomes more symmetrical, compact and complete when applying high-temperature curing. Connection performance and the early strength of stabilized material are improved. The conclusion can be drawn from microstructure observation contrast cured by two curing method and macroscopic strength value analysis. The microstructure of lime-flash-cement stabilized macadam can be improved by applying high-temperature curing. The early strength can be increased, and the curing age can be shortened. The engineering design needs can be met. It is feasible to shorten the curing age of lime-flash-cement stabilized macadam through high-temperature curing (JIANG Zengguo& ZHAO Yuan, 2005).

5 Conclusions

(1) By adopting high-temperature curing as a rapid curing method for lime-fly ash-cement stabilized macadam, strength increasing rule relationship of it between high-temperature curing and standard curing is found out through test. According to the relation, strength for the long age cured by standard curing can be determined by that of short age cured by high-temperature curing.

(2) Strength increasing rule analysis for lime-fly ash-cement stabilized macadam, cured by high-temperature curing, is carried out applying regression analysis methods for mathematical statistics. The compressive strength-age regression equation and the value of design parameters for lime-fly ash-cement stabilized macadam are confirmed. The corresponding curing age for high-temperature curing is determined by the strength through standard curing.

(3) Change in the microstructure with curing age of lime-fly ash-cement stabilized macadam, cured by high-temperature curing, is observed and analyzed applying electron microscope scanning. The strength increasing rule for rapid curing is studied and explained. The comparative analysis of microstructure observation for lime-fly ash-cement stabilized macadam is carried out, whose compressive strength, cured by high-temperature curing, is equal to the 180-day compressive strength, cured by standard curing. The strength increasing rule of lime-fly ash-cement stabilized macadam, cured by two curing condition, is studied. The results indicate that microstructure of lime-flash-cement stabilized macadam can be improved applying high-temperature curing. The early strength can be increased, and the curing age can be shortened. The engineering design need can be meet. It is really feasible to shorten curing age of lime-flash-cement stabilized macadam by high-temperature curing.

ABSTRACT

In order to study the mechanical properties of shear connectors for a composite beam under complex stress conditions, two 1:2 reduced-scale model tests with different types of shear connectors are conducted. These models are designed base on a real composite beam bridge in Guangzhou. Comparative analysis about the relative slipping on the steel-concrete interface of the rigid shear connector model and flexible shear connector model under the same boundary conditions is studied in detail. Responses of two types of shear connectors under three different load cases are also compared. The model test results show that the ultimate bearing capacity of concrete is the key factor of relative slipping on the steel–concrete interface and differences between rigid and flexible shear connectors are large. It is useful as references for future research and designs of shear connectors in composite beams.

1 INTRODUCTION

The steel-concrete composite beam bridge is an advantageous bridge style because it takes full advantage of both steel's tensile properties and concrete's compression properties. These two materials are connected by shear connectors in order to transfer shear force on the interface between the steel beam and concrete slab. Good performance of the shear connectors can allow the steel beam and concrete slab bear the load together. Different shear connector types and arrangements afford different shear resistance, which dominates the relative slipping between the steel beam and concrete slab and affects the bearing capacity of the composite beams (Zhan YL, 2006).

The shear bearing capacity of shear connector is easy to calculate (Nie JG, 1999), but the withdrawal capacity of the shear connectors often requires experimental research to be done because it is difficult to be solved with the general mechanical method (Fang ZZ, 2002). Studies on various issues concerning

experimental research on shear connectors have been reported. Dennis Lam et.al (D.Lam, 2005) proposed an effective numerical model using the finite element method to simulate the push-off test and performed parametric studies to investigate variations in concrete strength and shear stud diameter. Cem Topkaya et.al (Cem Topkaya, 2002) proposed a new push-out test to study the composite shear stud strength at early concrete ages. Test results revealed that shear transfer is achieved at very early concrete ages. Ellobody E and Young B (E. Ellobody, 2006) studied the structural performance of shear connection in composite beams with profiled steel sheeting; an accurate and efficient nonlinear finite element model was developed to study the behavior of headed stud shear connectors welded through-deck. Kim YH et.al (Kim YH, 2006) performed a series of push-out tests to evaluate the performance of several existing shear connectors. Results show that the perforated shear connector with flange head is superior to existing shear connectors such as a general headed stud, perfobond, etc. It is efficient as a rigid shear connector. Kim HY (Kim HY, 2006) investigated the behavior of steel-concrete composite bridge decks with perfobond ribs through push-out, full-scale flexural, and deck-to-girder connection tests. Test results confirmed the effect of perfobond ribs.

Mechanical properties of shear connectors for the composite beam under complex stress condition are studied in detail through two model tests. The models are designed based on a prototype of the three spans of the pre-stressed steel-concrete composite beams bridge in Guangzhou with the main span length of 50+70+60m. Load–Relative slipping behavior and the shear capacity of the shear connector in composite beam are obtained from the experimental model test including three different load cases: horizontal loading, vertical loading, and a combination of horizontal loading and vertical loading. The results presented in this paper are useful as references for future research and designs of shear connectors in composite beams.

2 MODEL DESIGN

Two model tests are conducted. One uses shear studs as the shear connector, which is labeled Model 1, the other uses profiled sheeting as the shear connector, which is labeled Model 2. Design parameters of the two models are the same except the structural type and arrangement of the shear connector. In these two models, the section of steel box girder is 1000 mm high, 2000 mm long, and 850 mm wide. The section of the concrete slab is 2000 mm long and 4250 mm wide. The base of the steel box girder and the top of the concrete slab were connected by an embed bolt. Materials of the model adopt 16Mnq steel, C60 concrete, and HRB335 reinforced bar (JTG D62, 2004). Vertical plans of the model and loading device are shown in Figure 1. The geometric and physical similarity relation between the model and prototype is listed in Table 1.

Table 1 Geometry and physical similarity ratio (model/ prototype)

item	size	material parameter	load	stress	strain

similarity ratio	1/2	1/1	1/4	1/1	1/1

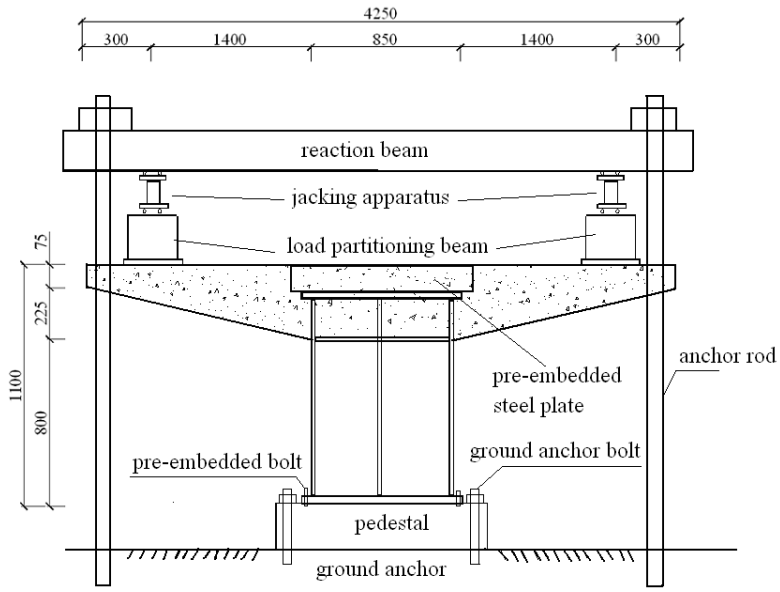

Figure.1. Vertical plan of model and loading device

2.1 Shear connector arrangement

In Model 1, the arrangement of shear studs, which are 11mm diameter×60 mm long, is 5 rows and 10 lines with the grid of 200×200mm. In Model 2, the arrangement of profiled sheeting, which is 50mm long×4.5 mm thickness, is 3 rows and 7 lines with the grid of 300×300mm. Both of the two models have the same steel ratio of the shear connector. The areas of the two kinds of shear connector are: $A_n = 4751.7mm^2$ and $A_c = 4725.0mm^2$, respectively, so it can be considered equal.

2.2 Loading procedure

There are three kinds of load cases in the model test: horizontal loading, vertical loading, and a combination of horizontal and vertical loading. For horizontal loading, the load applied to the studs model has no specific direction, but the load applied to the profiled sheeting model is specified from the direction of the mouth of the channel beam. The horizontal load of the two models is loaded from 0kN to 100kN gradually. For vertical loading, there are five loading steps from 0kN to 50kN at every 10kN and the loading is repeated three times. For the combination of horizontal and vertical loading, the horizontal load of the two models is stabilized at 100kN and the vertical load of the two models is loaded from 0kN at a separation of 10kN until the models fail.

2.3 Measuring-point arrangement

Six strain gages are affixed on the surface of the concrete slab, six high performance reinforcement meters are affixed on the surface of the reinforced bars, and eight strain gages are affixed on the surface of horizontal baffle of steel box

girder in each model. Moreover, fifty BTM strain meters are affixed on the shear studs in Model 1 and forty-two 120-3AA strain gages are affixed on the profiled sheeting in Model 2.

3 SUMMARY AND DISCUSSION OF THE RESULTS

3.1 The strain of shear connector

Shear connectors are divided into 5 rows (labeled 1# and 2#... 5# from left to right) and 10 lines (labeled 1L and 2L... 10L from front to back) in Model 1 and are divided into 3 rows (labeled 1#, 2#, 3# from left to right) in Model 2. The test results and discussions are as follows:

(1) Under horizontal loading, the regularity of the axial strain of shear studs can be found (see Figure.2) in Model 1. The axial strain of shear studs of the first line (nearly the loading point) is bigger than that of the rest, it decreases from the first line to the fifth line. The rest (far) can be neglected. The regularity of the axial strain of profiled sheeting cannot be found in Model 2 because the value of the strain is very small.

(2) Under vertical loading (no larger than 50kN), shear studs of the #1 and #5 rows are in tension while that of rows #2～#4 are in compression in Model 1. The profiled sheeting of the #1 and #3 rows are in tension while that of the #2 row is in compression in Model 2. The axial strains of two kinds of shear connectors has linear relationship with the load, but the value of that is very small (see Figure.3).

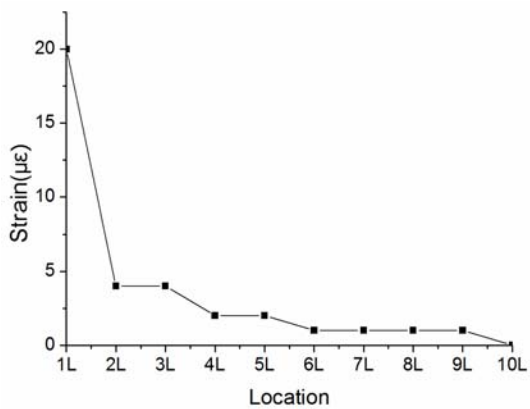

Figure.2. The average axial strain of shear studs under horizontal loading in each row

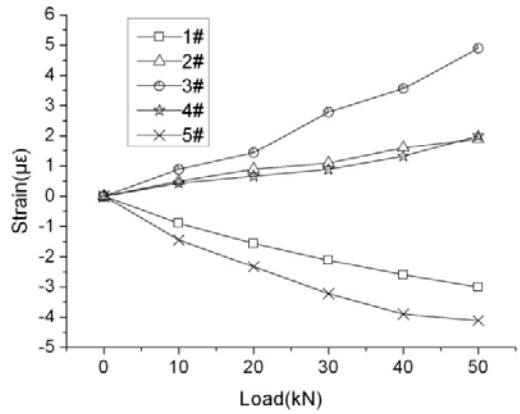

Figure.3. The average axial strain of shear studs under vertical loading in each row

(3) Under the combination of horizontal and vertical loading, when the horizontal load is stabilized at 100kN and about 80kN of the vertical load is applied to shear studs in Model 1 while about 110kN vertical load is applied to the profiled sheeting in Model 2, tiny cracks appear on the concrete.Then the stress of the shear connector increases rapidly. Finally, all shear connectors are in tension.

(4) Under the combination of horizontal and vertical loading, when the horizontal load is stabilized at 100kN and before the vertical load reach 100kN, the

strain of the two kinds of shear connectors increase slowly at the beginning of destruction. The axial stress of profiled sheeting does not exceed 18.0 MPa and the axial stress of shear studs is between 5.0 MPa and 34.0 MPa when the model has destructed (see Figure.4 and Figure.5).

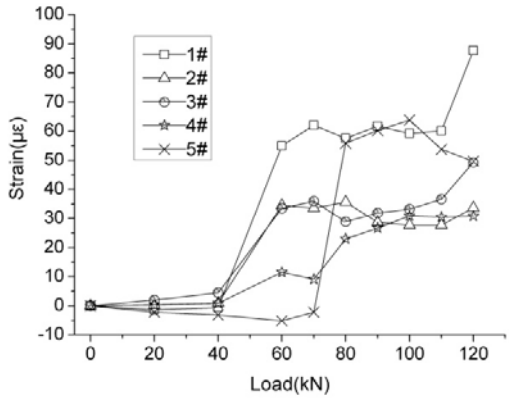

Figure.4. The average axial strain of shear studs under horizontal and vertical loading in each row

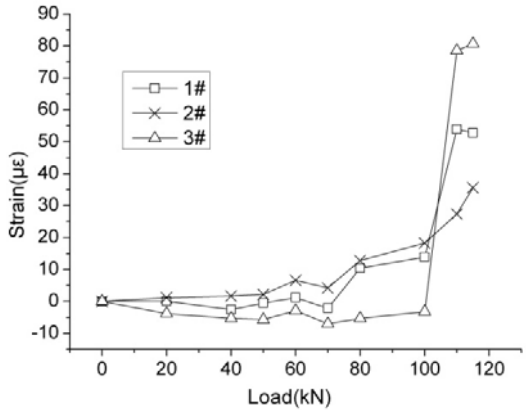

Figure.5. The average axial strain of profiled sheeting under horizontal and vertical loading in each row

3.2 Test results of relative slipping on the steel-concrete interface

Under horizontal loading, the relative slipping between the concrete slab and box girder is very small. When horizontal loading is up to 100kN, the relative slipping on the steel-concrete interface is 0.18 mm in Model 1 and 0.15 mm in Model 2. A linear relationship between the relative slipping and the load is shown on the Load-relative curve in two test models. Moreover, there are no obvious cracks and the slipping can recover when the load is removed. Figure.6 presents the relationship curve between the load and the relative slipping in Model 2.

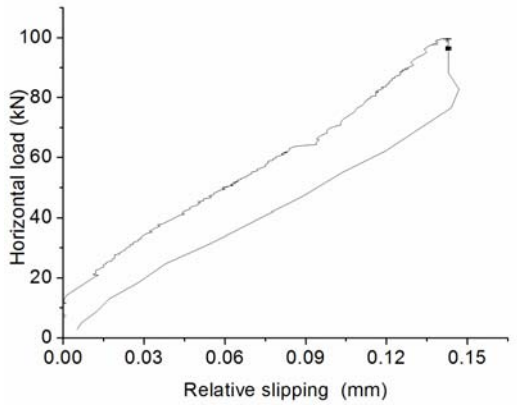

Figure.6. Load-relative slipping curve (model 2)

4 CONCLUSIONS

This paper takes the three spans of the continuous composite beams bridge in Guangzhou as a background and conducts experimental research on two 1:2 reduced-scale test models with different shear connectors. The main conclusions are as follows:

(1) The ultimate bearing capacity of reinforced concrete is the key factor to the relative slipping on the steel-concrete interface under complex stress conditions, and the relative slipping increases rapidly after concrete cracks.

(2) Both rigid and flexible shear connectors can effectively resist load, but the model of profiled sheeting has better slip resistant performance and recovery performance compared to the model of shear studs. The main reason is that profiled sheeting has a stronger restriction to concrete for its big stiffness when the strength of concrete is close to the ultimate strength.

(3) Under 100kN horizontal loading, the relative slipping is 0.18 mm on the steel-concrete interface in Model 1 while the relative slipping is 0.15 mm in Model 2. It indicates that the rigid shear connector can reduce the relative slipping on the steel-concrete interface under the same load.

(4) In the same steel ratio of the shear connector, the withdrawal resistance of profiled sheeting is greater than that of shear studs while the axial stress of profiled sheeting is smaller than that of shear studs.

Abstract : Vehicles generally run at high speeds on the highway, so the presence of retrograde vehicles on the road greatly increases the probability of traffic accidents. In view of this situation, we introduce a new macro-method to detect retrograde vehicles based on optical flow. Our approach mainly uses pyramids with the Lucas-Kanade motion estimation method, which greatly reduces computational complexity. Since the flow of traffic is regular and physically measurable, its optical flow field is also orderly and regular, allowing the optical flow vector to accurately reflect the velocity of traffic flow. Experiments show that retrograde vehicles on the highway can be well detected by finding abnormal changes in the optical flow field.

Key words : retrograde vehicle, optical flow field, image pyramids

1. Introduction

In recent years, rapid economic development and swift growth in the number of vehicles has contributed to an exponential increase in traffic density and congestion. Subsequently, the rate of traffic incidents rises year after year. Retrograde vehicles on the highway are particularly vulnerable to dangerous traffic situations like congestion, accidents, and so on. There is an urgent need to detect retrograde vehicles automatically, quickly, and accurately.

There are two ways to detect retrograde vehicles: one is based on indirect data (non-video) and the other uses video. Video-based methods have been widely used in recent years, typically as difference algorithms between consecutive frames (Lipton et al., 1998; Wang Ning, 2005). This method uses the time difference between pixels of two or three successive frames in an image sequence. It extracts the range of motion and the direction of the moving objects by selecting a threshold to then identify the retrograde vehicle. Non-video based methods are also used widely, such as the algorithm of retrograde vehicles based on wireless sensor networks (Akyildiz et al., 2002; Zhao Dian-kui, 2007). Wireless networks detect the deformation of a magnetic field that follows the movement of vehicles, thereby sensing their direction.

Optical flow method belongs to the field of moving-object detection based on

video images. Its advantages are obvious - the background of the video is not required in advance; the calculation results depend only on the relative motion of the consecutive frames; and it avoids interference from complex environments, thereby enhancing the reliability and accuracy of detection. At present, this method is widely used by researchers to detect and track moving objects (Li Xi-ying, Ni Guo-qiang, 2002), however it is rarely used to detect traffic incidents. Aiming at the identification of retrograde vehicles on the highway, this paper presents a new detection method based on the optical flow field. Experiments show that this method can directly obtain the figure of the retrograde vehicles, and the retrograde vehicles can be well detected by finding abnormal changes in the optical flow field.

2. Lucas -Kanade Motion Estimation using Pyramids

2.1 Introduction of the Optical Flow Method

The concept of optical flow was first proposed by Gibson in 1950. Optical flow is the distribution of apparent velocities of movement of brightness patterns in sequential images. The optical flow field is the surface motion of image patterns. Research of the optical flow method seeks to determine the movement of each pixel according to its time-domain variation and the relativity of the pixel intensity in sequential images. Currently, there are many methods which have been proposed for computing optical flow. By examining basic theory and mathematical methods, Barron (Barron et al., 1994) and others divided optical flow technology into four types: gradient-based methods, region-based matching methods, energy-based and phase-based techniques. Compared to the other four techniques, the original gradient-based constraint is superior because it has simple principles and low computational complexity. Accordingly, this paper chooses the Lucas-Kanade method, which is based on gradient (Lucas BD, Kanade T, 1981), to calculate the optical flow field of images in a traffic scene.

The Lucas-Kanade method uses partial information from the image to calculate optical flow. Assume that the optical flow remains unchanged within a small neighborhood Ω of the image, the optical flow-v in each small spatial neighborhood Ω can be obtained by minimizing:

$$\sum_{m\in\Omega} W^2(m)(\nabla I * v + \frac{\partial I}{\partial t})^2 \tag{1}$$

where

$$\nabla I(m) = (I_x, I_y)^T \tag{2}$$

W(m) denotes a window function that gives more influence to constraints at the center of the neighborhood than those at the periphery. $V=(u,v)^T$ is the optical flow vector within a small spatial neighborhood Ω, its dimension is the pixel/frame. I is

the gray of the point (x,y) in the image. The abbreviations Ix、Iy and It are the partial derivatives of image gray with respect to x, y and time, respectively.

For n-points m_i at a single time t, the solution to (1) through weighted least-squares is given by:

$$A^T W^2 Av = A^T W^2 b \tag{3}$$

where:

$$A = (\nabla I(m_1),..., \nabla I(m_n))^T \tag{4}$$

$$W = diag(W(m_1),..., W(m_n)) \tag{5}$$

$$b = -(\frac{\partial I(m_1)}{\partial t},..., \frac{\partial I(m_n)}{t})^T \tag{6}$$

The solution to (3) is $v=(A^TW^2A)^{-1}A^TW^2b$, which is solved in closed form when A^TW^2A is nonsingular, since it is a 2*2 matrix:

$$A^T W^2 A = \begin{bmatrix} \sum W^2(m) I_x^2(m) & \sum W^2(m) I_x(m) I_y(m) \\ \sum W^2(m) I_x(m) I_y(m) & \sum W^2(m) I_y^2(m) \end{bmatrix} \tag{7}$$

where all sums are taken over points in the neighborhood Ω.

2.2 Representation of the Image Pyramid

The Lucas-Kanade algorithm has simple principles, low computational complexity, and it can attain exact optical flow field. But it also has limitations in its application. For example, it only applies to small image motion, requiring that moving objects offset in less than one pixel between consecutive frames. To address this situation, we use the layered structure and multi-resolution characteristics of an image pyramid to set the moving object's dynamic extension at different image resolution levels.

Image pyramids, which can be built by several methods, are often used for multi-resolution display. This paper uses the most simple sub-sampling method, namely, for a N * N image (N is the integer power of 2, N = 2n, n is an integer). The pyramids at each level are created by applying a filter to the images and selecting alternative rows and columns, where the pixels of such selections can constitute a N/2*N/2 image. In other words, it can acquire a miniature of the original image via two-dimensional sub-sampling. If continued, the original image can be reduced to a 1*1 image. Each image with a greater subscript is smaller than its predecessor in size therefore creating a pyramid data structure. In light of our actual needs for this paper, we have selected a 4-level pyramid structure. Seen in Figure 1, the highest resolution level of the pyramid is the original image, which is also the first level of the image.

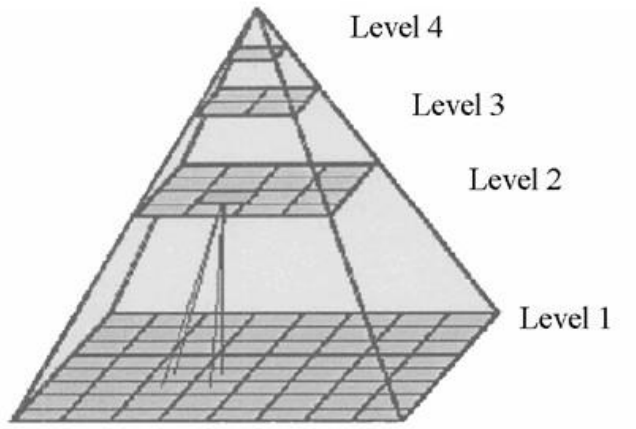

Figure 1. Image pyramid st ructure

While using pyramids, the lower high-resolution level can be used to analyze details, and the higher low-resolution level can be used to analyze larger objects. Consequently, the motion can initially be estimated at lower resolution, and then further estimates can be made more accurately from top to bottom. In the experiments, a four-level image pyramid is used. First, calculate the fourth level's optical flow field. Second, estimate the optical flow field of the third level by amending that of the fourth level. Step by step, the first level's optical flow field can be obtained. As there is an abundance of motion information in the first level, this level's optical flow field is selected for analysis.

2.3 The algorithm Based on Hierarchical Optical Flow Field

After attaining the 4-level image pyramid, it can calculate the optical flow field through multi-resolution pyramid data structure, use the following algorithm:

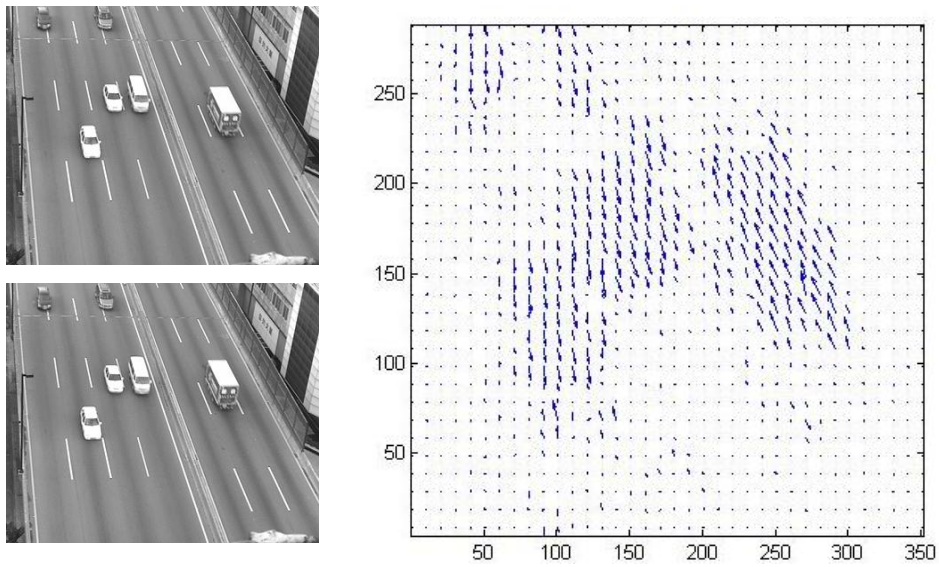
(1) Compute simple LK at highest level;

(2) At level i:

- Take flow u_{i-1}, v_{i-1} from level i-1
- Bilinear interpolate it to get u_i^*, v_i^* matrices of twice resolution for level i
- Multiply u_i^*, v_i^* by 2
- Compute f_t from a block displaced by $u_i^*(x,y)$, $v_i^*(x,y)$
- Apply LK to get $u_i'(x,y)$, $v_i'(x,y)$ (the correction in flow)
- Add corrections: $u_i = u_i' + u_i^*$, $v_i = v_i' + v_i^*$

(3) Repeat Step 2, until able to calculate the first level's optical flow field.

Figure 2 (a) is the two successive frame images; the above figure is the first frame, and the following figure is the second frame, after 1/25 second. In the figure, the left side of the vehicles is normal, and the right side is considered retrograde; Figure 2 (b) is the final optical flow field calculated by the 4-level pyramid.



(a) two successive frame images (b) Optical Flow field of Image Pyramid

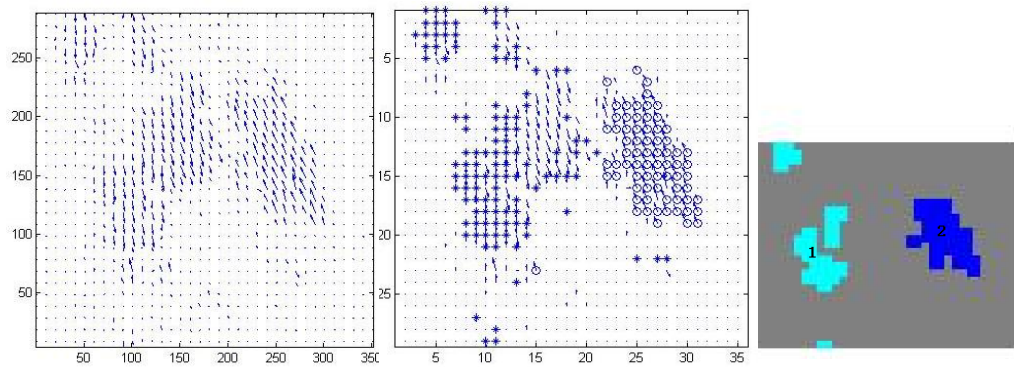
Figure 2. Lucas-Kanade Motion Estimation using Pyramids

3. Retrograde Vehicle Detection

A typical character of the retrograde vehicle is that it travels in the opposite direction of the normal one. Therefore, in the case of the retrograde vehicle, the common process is to detect the vector direction of the optical flow field to find anomalies. Comparing Figures 2(a) and Figure 2(b), one sees that the vector direction of optical flow for normal vehicles and retrograde vehicles coincide with the actual direction. In order to distinguish vehicle direction accurately and automatically, the whole optical flow angle is divided into 15 regions, so that every 24° becomes one region. The steps taken to make out the direction are as follows: First, compartmentalize all optical flow vectors into the above 15 regions. Second, locate the region within the range of 0° to 180° that has the maximum optical flow vector number, and designate this as the normal vehicle region. Third, locate the region within the range of 180° to 359° that has the maximum optical flow vector number, and designate it as the retrograde vehicle region. Finally, use a certain threshold to limit the reverse region. If the reverse region area is too small, it is considered to be non-existant and vice versa.

Figure 3 shows the results of the retrograde vehicle detection. Figure 3 (a) is the original optical flow field calculated above. Figure 3 (b) is the further processed optical flow field based on a 15-region division. In the figure, the region marked with "*" is the optical flow vector of the normal vehicles, and the region marked with "o" is the optical flow vector of the retrograde vehicles. Figure 3 (c) is the final image of moving object detection based on clustering algorithms. In the figure, the blue region

2 is the retrograde vehicle region. That is, when the blue region 2 is obtainable, there are retrograde vehicles in the traffic scene.



(a) (b) (c)

Figure 3. Retrograde vehicles detection results based on the optical flow field

4. Conclusion and Prospect

Experimental results show that when the retrograde vehicle region is large enough, the method mentioned in this article does well in detecting retrograde vehicles. Therefore, this method illustrates a good prospect of application and extension in the field of automatic detection technology. But this technology still has limitations, such as the large amount of time required for calculation. Further research will investigate how to improve the operational efficiency of the existing method, and how to enhance the method's capabilities in order to deal with more types of road conditions. In addition, video-based data is a precondition for vehicle detection based on the optical flow field. Though video equipment is not yet prevalent on all highways, its installation is an inevitable trend of the future, providing a good application foundation for the optical flow method.

Research on A Risk Analysis System of Vessel-Bridge Collision

FU Tao[1], WANG Junjie[1], ZHANG Junjian[1]

[1]Department of Bridge Engineering, Tongji University, Shanghai, 200092, China; PH (086) 021- 65983116-2708; email: greenvillage_17@163.com

Abstract: Due to the construction of bridges crossing inland waterways, straits and gulfs, as well as the rapid development of vessel transportation, collisions between vessels and bridges occur frequently which leads to great concern about the safety of bridges crossing navigation channels. Thus, it becomes vital to analyze the risk of vessel-bridge collisions. In the paper, a risk analysis system of vessel-bridge collision is proposed which mainly includes an assessment database system, a probability of vessel-bridge collision assessment, a module for anti-collision resistance calculation of the pier, a probability of collapse assessment, a consequence assessment system, an auxiliary decision-making system as well as a risk disposition system. The key contents of every subsystem are represented. This system can provide a guide for vessel-bridge collision design and assessment.

Key words: vessel-bridge collision; risk analysis; reliability theory;

1. Introduction

With the development of economy in the world, a large number of bridges crossing inland waterways, straits and gulfs are constructed or in the planning phase. The numerous bridges bring generous economic profit while influencing vessel transportation significantly. According to statistical data, vessel-bridge collision accidents occurred more than 100 times in the past several decades, which caused enormous casualties, property loss, and environmental destruction (Geng, B, 2007). Vessel collisions with bridges occurred frequently in the past and will likely continue to occur in the future. The catastrophic events force researchers and officials to take a closer look at the frequency of vessel collisions and methods to prevent further accidents from occurring. It has become a more and more of a concern to carry on vessel-bridge collision risk analysis rationally in practice.

2. Risk analysis system of vessel-bridge collision

In view of the severity of vessel-bridge collisions, some research work has been developed by a number of researchers all over the world in the recent years. The research is either specific projects (e.g. Great Belt Bridge Project in Denmark and New Sunshine Skyway Bridge in America) or general design guidelines of bridges (e.g. AASHTO 1991, AASHTO LRFD 1994 and Eurocode 1.2.7). In AASHTO LRFD, a vessel-bridge collision is considered as a risk event which provides three vessel collision design methods, namely, Methods I, II, and III, including determination of the vessel design, a collision probability analysis, a calculation of collision force, and a bridge protection design, etc. Only the collision force has been taken into account in the highway or railway design code of China with no mention

of collision risk which needs to be farther developed.

The vessel-bridge collision risk R which mainly includes the probability P of bridge against vessel impact and possible consequences C can be written as follows:

$$R = P \times C \tag{1}$$

In the paper, a complete vessel-bridge collision risk analysis system is proposed with inclusion of the following parts: assessment database system, module for probability of collision assessment, module for anti-collision resistance calculation of pier, module for probability of collapse assessment, consequence assessment system, auxiliary decision-making system, and risk disposition system. Figure1 illustrates the composition of a risk analysis system of vessel-bridge collision.

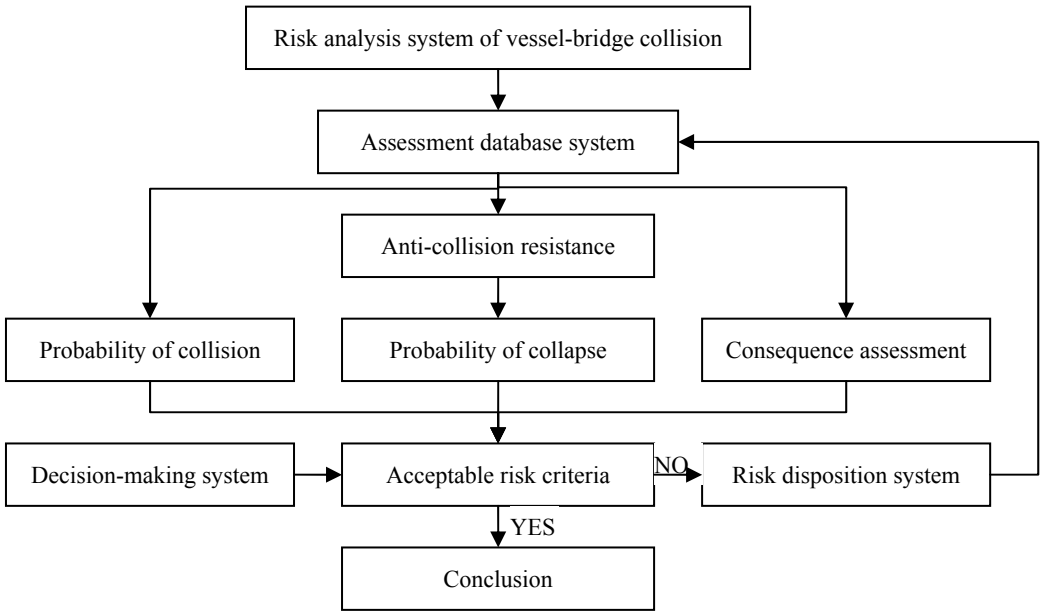

Figure1. Risk analysis system of vessel-bridge collision

2.1 Assessment database system

The probability calculation of vessel-bridge collision involves a great deal of information including: bridge navigable clearance, waterway condition and natural environment in bridge area, information about vessels transiting the waterway, etc. A database should be set up for risk analysis according to classification. The other modules of the system transfer the data from the database and then write the result into the database after calculation. The database also has the function of data management and query. Assessment of the database system includes the following several sub-databases:

(1) Basic information in the database includes the name of the bridge, bridge type, span arrangement, etc. (2) Navigation information in the database includes the span clearance, navigation density, geometry of the waterway, water depth at location of bridge piers, sailing path of vessel, etc. (3) In the vessel information database, the vessels are divided into ship, barge, and fleet with the parameters of deadweight tonnage, draft, and displacement of no-load and full-load, width, length, and height of

the vessel, etc. (4) The natural environment information in the database includes the angle of current, and the annual average velocity of current, water level, wind direction, etc. (5) The accident information in the database of vessel-bridge collision. (6) Active and passive protection measures information database.

2.2 Probability of vessel-bridge collision assessment

The statistical analysis method and mathematical model method are applied in calculating the probability of a vessel-bridge collision. The statistical analysis method may encounter difficulties because of the discontinuity and incompleteness of data. Regarding the mathematical model method, some typical models have been put forward, mainly including the IABSE Model (O.D.Larsen, 1993), the AASHTO Model, the Eurocode Model, the Kunz Model (C.U.Kunz, 1998) etc.

The vessel track, vessel location and accident rate per voyage unit are taken into account by the Kunz Model and Eurocode Model. Both of them are appropriate for research in progress and mechanism of accident while inconvenience in application.

The probability of aberrancy and geometric probability are considered in the AASHTO Model and the IABSE Model. The probability of aberrancy in the IABSE Model is mainly based on observation data while a formula is proposed to calculate the probability of aberrancy in the AASHTO Model with consideration of correction factors with bridge location, vessel traffic density, and current velocity. With respect to geometric probability, the AASHTO Model uses a normal distribution to account for it which is applied extensively at present compared with the IABSE Model.

The correction factors used in the AASHTO LRFD code are just a few of the many different variables that determine whether a bridge will suffer a collision. Other variables such as wind, visibility conditions, navigation aids and human error have a strong influence on the probability of a collision but they are not directly included in the AASHTO LRFD code as they are considered to be difficult to be quantified. However, if any one of these is particularly significant at a given channel and bridge location its influence on the results would not be ignored.

In the paper, a new concept about the probability of a vessel-bridge collision assessment is proposed. The district of upstream and downstream can be divided into small areas. The probability of a collision of each area can be calculated according to the method used in seismic risk analysis, and then the key problems are to determine the principles of area division. The total probability of collision is the superposition of each area.

2.3 Calculation module for anti-collision resistance of pier

The nonlinear characteristics of concrete and reinforcement should be considered in the calculation of anti-collision resistance. P-Y curve is used to describe the pile-soil interaction. The structural internal force can be obtained by finite element method. The pile is considered to be destructed while the section under horizontal force exceeds the limit bending ability. According to the failure mode, resistance is the horizontal force while the main compressive stress of the section exceeds the

allowable value while increasing the horizontal force progressively.

2.4 Probability of collapse assessment

With respect to the probability of collapse analysis, only the AASHTO LRFD code and the Eurocode propose the methods to calculate it by now. The AASHTO LRFD code which addresses the probability of collapse is developed by Cowiconsult based on studies performed by Fujii and Shiobara using Japanese historical damage data on vessels colliding at sea (Fujii, Y. and Shiobara, R, 1978). The damaged data of the bridge is based on the observations of damages between vessel-vessel collisions, while there is little accurate damage data of bridges during vessel-bridge collisions. It proposes a method to calculate the probability of collapse based on the relationship of the anti-collision resistance of a pier and the vessel impact force, if the anti-collision resistance, H, is greater than the vessel impact force, P, the probability of collapse will be zero. As the H/P ratio decreases, the probability of collapse remains low until the ultimate lateral pier strength becomes less than one-tenth of the vessel impact force. From then on, small reductions in the H/P ratio cause the probability of collapse to increase quite sharply.

While the approach recommended by the AASHTO code for the calculation of probability of collapse can often provide reasonable answers, some of its shortcomings can be addressed: (1) It comes from empirical data of vessel-vessel collisions rather than vessel-bridge collisions; (2) It is not derivate based on a strict theory of probability; (3) It can not cover various components of the bridge. In fact, once a bridge suffers a ship collision, the calculation of the probability of collapse is a complicated problem, which is a function of many variables. It depends on the randomness of the vessel impact force as well as the characteristic of the structure. Recognizing the shortcomings of the AASHTO code, a new concept of probability of collapse assessment is proposed based on reliability theory. The bridge safety condition can be expressed by a reliability index through the relationship between impact force probability distribution and anti-collision resistance probability distribution, and the limit state equation of a bridge can be set up. Then the failure probability is calculated based on reliability theory. Obviously the anti-collision resistance varies with material properties of the concrete, steel reinforcement and soil, water level, and impact angle. The anti-collision resistance of a pier can be written as $R(\eta,\Delta,\theta)$, where η, Δ, θ denote material properties, water level and impact angel respectively. The vessel impact force can be expressed as $P(v, DWT)$, where v and DWT denote impact velocity, and deadweight tonnage of vessel respectively. Then the limiting condition equation can be formulated as:

$$G(X) = R(\eta,\Delta,\theta) - P(v, DWT) \tag{2}$$

As $R(\eta,\Delta,\theta)$ is implicit functions, it should be calculated by FEM to obtain the

function value. Three methods are applied to calculate the failure probability, as seen in Figure 2. After determining the probability distributions of parameters, the failure probability can be obtained based on reliability theory which can reflect the risk level of vessel-bridge collision more accurately.

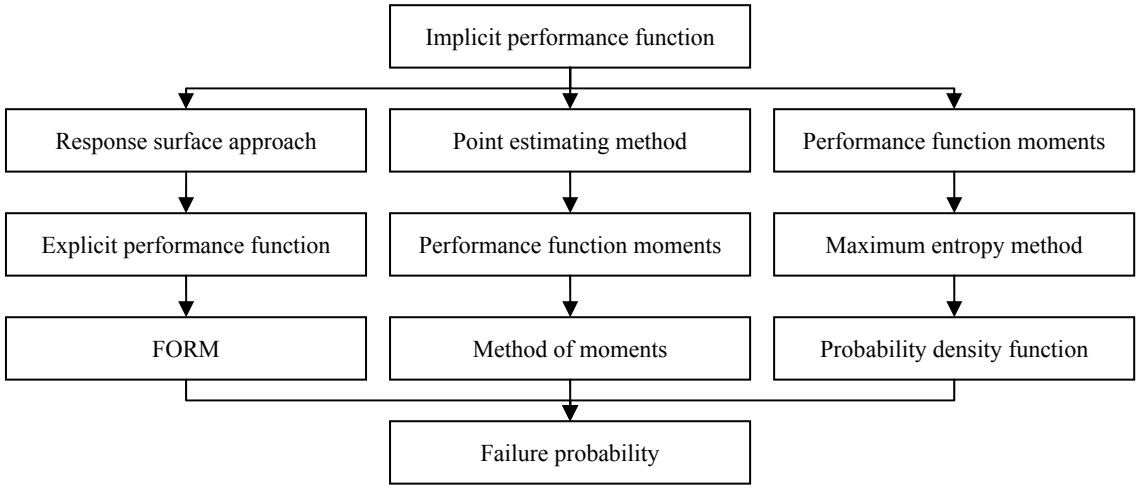

Figure 2. Flow chart of probability of collapse analysis.

2.5 Consequence assessment system

Regarding to consequences assessment about vessel-bridge collision, it can be divided into direct consequences and indirect consequences. The direct consequences mainly include bridge loss (e.g. reconstruction cost, bridge benefit loss etc), user's loss (e.g. casualty cost, vehicle and goods cost etc) as well as vessel loss (e.g. salvage and repair cost etc). The direct consequences mainly include traffic delay loss, environmental loss and society loss.

Some of the consequences are difficult to measure financially. How to quantize the consequences is still a subject to be researched further.

2.6 Auxiliary decision-making system

The key problem of an auxiliary decision-making system is to determine the acceptable risk criteria. The determination of acceptable risk criteria is a complicated problem involving technology, economy, politics, and culture. At present, the methods to determine acceptable risk criteria mainly include: the ALARP principle, the F-N Diagram, Risk matrix, PLL value, etc.

Eurocode recommends minimum values for the reliability index according to different classes of structure. In the AASHTO LRFD code, bridges are categorized as either "critical" or "regular". For a bridge classified as "critical", the annual frequency of collapse must not be greater than 0.0001 while the required annual frequency of collapse for a bridge designated as "regular" must be no larger than 0.001. Acceptable risk criteria of the AASHTO LRFD code is used world-wide in vessel-bridge collision risk assessment.

The vessel-bridge collision accident may cause loss. High acceptable risk criteria imply high initial cost. The owners should balance the cost and benefit to determine

the acceptable risk criteria. How to determine suitable acceptable risk criteria according to an actual situation is still a subject to be studied.

2.7 Risk disposition system

As for the bridge discontent with the acceptable risk criteria, measures must be taken to reduce a vessel-bridge collision risk. Three kinds of measures can be applied to decrease the risk of a vessel-bridge collision: (1) Limitation of vessel velocity; (2) Modification of bridge design; it mainly includes change of span arrangement, foundation type and channel width, increasing of the reinforcement ratio, etc. (3) Anti-collision device design; it contains active protection design and passive protection design. Active protection design refers to reasonable measures to avoid a collision between a vessel and a bridge which mainly includes set navigational remarks, perform sailing route regulations, assign sailing warning regions, pilotage for special vessels, AIS for vessels and VTS in the bridge area. Regarding the bridges with a high risk level, the protection structure that should be adopted mainly include: artificial island fenders, steel boxed cofferdam fenders, group-pile fenders, attachment structures, sand-filled and capsule structures, gravity pendulum structures ,etc.

3. Conclusions

(1) The risk assessment of vessel-bridge collision is a complicated subject which refers to many influence factors. In the present paper, a risk analysis system of vessel-bridge collision is developed with seven subsystems with a definition of the relationship among them.

(2) A new concept with consideration of more influence factors for calculating the probability of a vessel-bridge collision is put forward based on seismic risk analysis. Because of the shortcomings in the calculation of the probability of collapse, a reliability-based method is proposed which can reflect the risk level of a vessel-bridge collision accurately.

(3) Some problems which need to be further researched are represented, including: how to quantize consequences of a vessel-bridge collision, how to make reasonable risk criteria, and the effects of measures for reducing a vessel-bridge collision risk.

Methods of Setting Maximum Speed Limits on Freeways

Guozhu Cheng and Yulong Pei

School of Transportation Science and Engineering, Harbin Institute of Technology, P.O.Box 202, Harbin, 150090; PH(86)451-86282832; FAX(86)451-86282832; email:guozhucheng@126.com, yulongp@263.net

ABSTRACT

Using the ideas of multi-objective optimization, the paper brought forward the maximum speed limit methods based on efficiency, safety, economic and comfortable quality of freeways. The maximum speed limit value under the conditions of at-grade straight lines section, free traffic flow, good pavement and weather was taken as a basic value. Minimizing the sum of time cost and fuel consumption cost were taken as the objective function. The death rate of accidents and passenger's comfortable quality that met corresponding allowed range was taken as constraint conditions. The basic value of the maximum speed limit calculation model was established based on minimum generalized operating costs of vehicles. A mathematical method of extremism solution was adopted to obtain the basic values. At last, it was given that basic values according to different design speeds and different vehicle types.

INTRODUCTION

Freeways are the most important component of highway networks, and how to realize its function of efficiency, safety, economics and comfortable quality is always one of the key subjects for all segments of the society. In order to guarantee realizing the above functions of freeway, the method of setting maximum speed limit has been usually adopted to manage freeway. Practice has proved that reasonable speed limits can promote increased efficiency, safety, economic and comfortable level of freeways, however, inappropriate speed limits will result in the opposite results. Now, being restricted to finance, technology and conception, the management level of freeways have been generally low speed limits, but standards of setting still lack theoretical results as technical support in China. This paper studied the method of setting maximum speed limits that embodies the system's dynamic characteristic of freeways to provide gist for speed management of freeway.

METHOD

Basic method. Freeway's operation should realize four objects. They are efficiency, safety, economic and comfortable ride quality. However, there is mutual conditionality between them. Under the condition of free flow, operation speed is higher, efficiency is higher but safety and comfortable quality will decrease. Therefore it is the basic thought to determine reasonable maximum speed limit values that multi-objective optimization method is adopted to look for the best relationship among efficiency, safety, economic and comfortable quality.

Method of setting maximum speed limit. Multi-objection optimization method was adopted to study and give objective functions and constraint conditions.
The key meeting objective functions and constraint conditions were defined as the

fiducial value of the maximum speed limit. It means the maximum speed limit value under ideal conditions. Ideal conditions include design speed of 120km/h, at-grade straight lines sections with free flow, good pavement and weather.

The fiducial value of the maximum speed limit should be given according to vehicle type. The fiducial value determined by the method of this paper is for cars. The trucks' fiducial value, it can be obtained by contrasting their observed operation speed data. Furthermore, it can be calculated through the ratio of design speed for freeways with other design speeds. For curved sections, sloped sections, constrained flow, damaged pavement and bad weather conditions, the fiducial value should be corrected.

OBJECTIVE FUNCTIONS AND CONSTRAINT CONDITION

Objective functions Drivers can be divided into three types, they are adaptive, conservative and hazardous (Zhou Wei, 2001). Adaptive type drivers should be the research focus when determining the fiducial value of the maximum speed limit. Time cost was caused by operation speed being less than speed under ideal conditions. Time cost function was defined as equation (1).

$$C_{\mathrm{t}} = \frac{G}{365 \times 8} \times E \times Q \times (\frac{L}{v} - \frac{L}{v_i}) \tag{1}$$

Where, C_{t} is time cost of passengers on freeway. G is GDP per person. E is mean carry coefficient (persons/veh); Q is traffic volume(veh/d) ; L is the length of freeway(km). v is operation speed(km/h). v_i is speed under ideal condition(km/h).

2.1.2 Fuel Consuming Cost Function

Fuel consuming data had been surveyed on the Cheng-yu Freeway, Kun-yu Freeway, Kun-qu Freeway, Jing-shi Freeway and Tai-jiu Freeway. The model relationship between speed and fuel consuming volume of at-grade straight line section was established by regression.

$$F = 0.0013 v_{\mathrm{t}}^2 - 0.2518 v_{\mathrm{t}} + 22.497 \tag{2}$$

Where, F is fuel consuming volume per 100km(liter/100km)。

According to equation (2), economic speed of at-grade straight line section v_{e} can be calculated to be 97km/h, and corresponding minimal fuel consuming volume $F_{\min}$ equal to 10.3liter/100km. The fuel consuming cost function was defined in equation 3.

$$C_{\mathrm{g}} = (0.0013 v^2 - 0.2518 v + 22.497) \cdot \frac{L}{100} P_{\mathrm{g}} \cdot Q_{\mathrm{d}} \qquad v > v_{\mathrm{e}} \tag{3}$$

Where, C_{g} is fuel consuming cost(yuan) ; P_{g} is gas price(yuan/liter) ; Q_{d} is traffic volume per day (veh/d) ; v_{e} is economic speed(km/h).

Supposing the power of time cost and fuel consuming cost is same, generalized running costs of vehicles was defined as the sum of them. Objective function was defined in equation 4.

$$\min(C) = \min(C_{\mathrm{t}} + C_{\mathrm{g}}) \tag{4}$$

Constraint conditions of safety. According to the data of NCSS，the death rate of traffic accidents is proportional to four power of speed grads (Du 2002). The

relationship between them can be seen in equation 5. When speed exceeds 114.24km/h, the probability of death caused by accident is 100%.

$$I_{\text{Death}} = (\frac{\Delta v}{114.24})^4 \tag{5}$$

Where, I_{Death} is death rate of traffic accident (%). Δv is speed grads, i.e. the difference of vehicle's speed and mean speed (km/h).

The maximum speed limit should assure that the death rate of traffic accidents is less than the accepted value. Based on this principle, the constraint condition of safety was defined as equation 6.

$$\begin{aligned} I_{\text{Death}} &= 6E-07(v_{\text{h}}-\bar{v})^4 + 6E-17(v_{\text{h}}-\bar{v})^3 - 1E-14(v_{\text{h}}-\bar{v})^2 \\ &+ 3E-13(v_{\text{h}}-\bar{v}) < [I_{\text{Death}}] \end{aligned} \tag{6}$$

Where, v_{h} is the maximum speed limit value (km/h). $\bar{v}$ is the mean speed(km/h). $[I_{\text{Death}}]$ is the accepted value of the death rate of traffic accidents (%).

Constraint conditions of comfortable quality. It is important that how to increase comfortable quality of road traffic (Lu Nan, 2005). Interrelated study has given the relationship between R.M.S. of acceleration (a_{w}) and person's sense through test of taxi with 1.3L exhaust volume (seen table 1). Data of speed and a_{w} are be listed in table 2 (Huang Yi, 2005).

The relationship model between them can be obtained by regression as shown in equation 7.

$$v = 0.048 a_{\text{w}}^{0.5425} \tag{7}$$

Table 1.The Relationship between the R.M.S. of acceleration and Person's sense

a_{w}(m/s^2)	People's Sense
<0.32	comfortable
0.32~0.68	comfortable relatively
0.68~0.80	uncomfortable relatively
0.80~1.60	uncomfortable

Table 2. Survey Data of Speed and a_{w}

speed(km/h)	a_{w} (m/s^2)	speed(km/h)	a_{w} (m/s^2)
30	0.287	80	0.490
40	0.345	90	0.551
50	0.475	100	0.584
60	0.442	110	0.614
70	0.467	120	0.644

The relationship between speed and comfortable quality can be obtained according to table 1 and equation 7. It can be seen from table 3 that passengers will be uncomfortable when speed exceeds 132km/h and the uncomfortable quality will increase sharply when speed exceeds 179km/h. The maximal threshold value of comfortable relatively was regarded as the constraint condition of comfortable quality. It was described in equation 8.

$$v_{\text{h}} \leq 132\text{km/h} \tag{8}$$

PARAMETERS CALIBRATION

Parameter of time cost functions. According to economic statistic data

promulgated by National Bureau of Statistics of China, GDP per person was determined as 23220 yuan per person per year.

Table 3 The Relationship between speed and passengers' comfortable quality

speed(km/h)	Passengers' Comfortable Quality
$v \leq 32$	comfortable
$32 < v \leq 132$	comfortable relatively
$132 < v \leq 179$	uncomfortable relatively
$v > 179$	uncomfortable

According to interrelated study (Feng 1993), the proportion of cars will be greater and will reach 90% in 2020. It has been predicted that the average seats in cars will reach 8.77 in 2020 and the carry ratio will be 80%. Therefore, the mean carry coefficient E can be calculated to be 7.016 person per car.

According to the current status of automobiles in China, the design value of the maximal speed is 160~200 km/h (Shen 2006). A medium sized car with good capability was selected as a representative vehicle type in this paper. Its ideal speed was determined by mean value of design speed given in literature (Shen 2006), i.e. v_i equal to 180km/h.

Average operation speed. According to surveyed operation speed data on Freeway of Harbin city, average operation speed of cars is 109.1km/h and that of trucks is 81.1 km/h at at-grade straight line section.

Accepted death rate of accident. According to the number of traffic accidents, the death toll and mortality rate of partially developed countries and China (Pei 2004), it can be found that the U.K. is the developed country with the lowest accident death rate, which is 1.5%. France is the developed country with the highest accident, which is 6.4%. In China, the accident death rate reaches 23.6% and is higher than that of developed countries. The maximum value of developed countries' death rate of accident was regarded as accepted death rate of accident in this paper, i.e. $[I_{\text{Death}}]$=6.4%. The maximum speed corresponding accepted death rate of accident can be obtained (seen table 4). Constraint condition of safety is give according to data of table 4.

$$\begin{cases} \text{car}: \quad v_{\text{hb}} \leq 127.3\text{km/h} \\ \text{truck}: \quad v_{\text{hb}} \leq 99.3\text{km/h} \end{cases} \tag{9}$$

Table 4.The Maximum speed corresponding to accepted accident death rate

vehicle type	car	truck
accepted accident death rate (%)	6.4	6.4
corresponding speed grads(km/h)	18.17	18.17
average operation speed(km/h)	109.1	81.1
corresponding maximum speed (km/h)	127.3	99.3

Gas price. According to data promulgated on Chemical Net of China, gas price i.e. Pg equal 4.88 yuan per liter.

KEY OF MODEL

Solution method. According to time costs and fuel consumption cost

functions, the key of fiducial value can be described as the minimum key in equation 10.

$$f(v) = \mathrm{a}v^2 - \mathrm{b}v + \frac{\mathrm{c}}{v} + \mathrm{k} \qquad (\mathrm{a},\mathrm{b},\mathrm{c} > 0) \tag{10}$$

Looking for differential coefficient of equation 10, equation 11 can be obtained.

$$f'(v) = 2\mathrm{a}v - \mathrm{b} - \frac{\mathrm{c}}{v^2} \tag{11}$$

When differential coefficient of $f(v)$ equals zero, the minimum key of equation 10 can be obtained.

$$2\mathrm{d}v^3 - \mathrm{e}v^2 - \mathrm{f} = 0 \tag{12}$$

Equation 13 is the exclusive real key of equation 12. Speed calculated by equation 13 is the key of the car's fiducial value of maximum speed on the freeway.

$$\begin{aligned} v = {} & \frac{1}{6\mathrm{d}}[54\mathrm{d}^2\mathrm{f} + \mathrm{e}^3 + 6\mathrm{d}\sqrt{3\mathrm{f}(27\mathrm{d}^2\mathrm{f} + \mathrm{e}^3)}]^{\frac{1}{3}} + \\ & \frac{\mathrm{e}^2}{6\mathrm{d}}[54\mathrm{d}^2\mathrm{f} + \mathrm{e}^3 + 6\mathrm{d}\sqrt{3\mathrm{f}(27\mathrm{d}^2\mathrm{f} + \mathrm{e}^3)}]^{-\frac{1}{3}} + \frac{\mathrm{e}}{6\mathrm{d}} \end{aligned} \tag{13}$$

Optimal key of model. The sum of the car's time cost and fuel consuming cost is defined as $f(v)$.

Making $f'(v) = 0$, then

$$2.6\mathrm{E}\text{-}05P_g v^3 - 2.518\mathrm{E}\text{-}03P_g v^2 - \frac{G \cdot E}{2920} = 0 \tag{14}$$

According to equation 14 and above calibrated model parameters, equation 15 can be obtained.

$$\begin{aligned} \mathrm{d} &= 2.6\mathrm{E}\text{-}05 \times P_{\mathrm{g}} / 2 = 6.344\mathrm{E}\text{-}05 \\ \mathrm{e} &= 2.518\mathrm{E}\text{-}03 \times P_{\mathrm{g}} = 1.229\mathrm{E}\text{-}02 \\ \mathrm{f} &= G \times E \ / 2920 = 55.792 \end{aligned} \tag{15}$$

According to equation 15 and equation 13, the model key can be obtained, *v is* equal to 124.99km/h. This key is bigger than economic speeds and smaller than ideal speeds but meets the constraint conditions. Thus, it can be regarded as the optimal model key.

Determination of fiducial value. Fiducial value of the car's maximum speed limit on the freeway, with a design speed of 120km/h, can be determined that v_{hbc} equals to 125km/h according to the above optimal model key.

The fiducial value of a truck's maximum speed limit can be calculated according to equation 16.

$$v_{\mathrm{hbt}} = \frac{\overline{v}_{\mathrm{t}}}{\overline{v}_{\mathrm{c}}} \times v_{\mathrm{hbc}} \tag{16}$$

Where, v_{hbt} is the fiducial value of a truck's maximum speed limit, $\overline{v}_{\mathrm{c}}$ is the average operation speed of cars and $\overline{v}_{\mathrm{t}}$ is the average operation speed of trucks.

Then fiducial value of a truck's maximum speed limit can be obtained that v_{hbt} equal to 95km/h. The fuducial value for freeways with other design speeds can be calculated by equation 17.

$$v_{\text{hb-}d} = \frac{v_d}{120} \times v_{\text{hb}} \tag{17}$$

Where, $v_{\text{hb-}d}$ is fiducial value of maximum speed limit corresponding freeway with different design speed (v_d equal to 120km/h, 100 km/h, 80 km/h and 60km/h). They are listed in table 5.

Table 5. The maximum speed limit fiducial value of freeway

design speed(km/h)	calculated value(km/h)		suggested value(km/h)	
	car	truck	car	truck
120	124.99	92.92	125	95
100	104.17	82.47	105	85
80	83.33	65.97	85	65
60	62.50	49.48	65	50

CONCLUSION

The multi-object optimization method of setting maximum speed limits was put forward based on efficiency, safety, economic and comfortable quality. The definition and suggested value of the fuducial value of maximum speed limits were given. It can provide reference gist for setting reasonable speed limit value in China.

ABSTRACT

All over the world, earthquakes have been broken up more frequently than ever before. The huge disaster of an earthquake challenged the capability of government to handle an emergency. The emergency evacuation corridor planning will be more significant for restoration of a disaster area. This paper proposes a methodology for the research on carrying capability of a regional earthquake evacuation corridor based on macro-simulation to prove the availability and rationality of a predetermined regional earthquake evacuation plan. The proposed approach includes three processes: 1) Estimate the evacuation demand of the earthquake affected area and estimate traffic volume of each link and node of roadway network; 2) Confirm the OD-pairs based on the location of shelters and the preplanned direction of evacuation; 3) build up the earthquake evacuation network through the macro-simulation software, OREMS, as well as input the outcome of procedure 1) and 2). Evaluate the carrying capability of the preplanned regional earthquake evacuation corridor through evacuation clearance time and average evacuation speed which are the output of OREMS. In the end, the proposed approach was employed in the Beijing case and proved the availability and rationality of the Beijing earthquake evacuation corridor planning.

1 INTRODUCTION

The earthquake in Wenchuan, in the Sichuan province, has challenged the capability of Chinese government to handle an emergency. The emergency evacuation corridor planning will be more significant for rescue and restoration of

the disaster area. The data collected from the earthquake in Tangshan has show that the survival rate has a significant relationship with evacuation time (see Table 1).

Table 1. Relationship Between Evacuation Time And Survival Rate

Evacuation Time	Survival Rate
Half an hour	95%
One day	81%
Two days	53%
Three days	36.7%
Four days	19%

The earthquake evacuation corridor was different from traditional transportation systems that serve the normal traffic demand for are two reasons. First, subway and railroad may be damaged during an earthquake. Even though the facilities are still there, they cannot be used for evacuation for safety considerations. Second, due to limited capacity and the constraints of geographic conditions, ferries or helicopters are seldom considered in the process of an evacuation plan. Therefore, surface transportation systems look much more flexible and sustainable. It is evident that surface transportation systems are very important for earthquake evacuation. It is necessary for all levels of government to preplan an earthquake evacuation corridor and evaluate the availability and rationality of a regional earthquake evacuation corridor planning.

At present, there are two main aspects about emergency evacuation technology: 1) research on methodology of emergency evacuation planning, 2) research on management strategies of emergency evacuation traffic. Evacuation planning includes three aspects such as: evacuation demand estimate, evacuation distribution estimate, and evacuation-related traffic assignment. Current practice in hurricane evacuation demand estimation involves the estimation of the total evacuation demand in the first step, followed by the estimation of its temporal distribution in the second. A study (Haoqiang Fu, 2007) proposed two ways of estimation of hurricane evacuation demand. Participation rate models are the primary method to estimate evacuation demand and response curves are used for the temporal distribution. The sequential Logit model is the other way to provide estimates of dynamic disaggregate travel demand for hurricane evacuation. The study demonstrated the superiority of the sequential Logit model over the traditional two-step method in modeling hurricane evacuation travel demand. Evacuation distribution estimation also involves aggregative model and disaggregative model (Guangxiang Cheng, 2008). However, there still was no case study to prove the accuracy of these two models.

In general, evacuation efficiency can be improved by setting up the programming model to optimize the destination and route assignments in the network. An evacuation assignment model could be classified into two categories: static and

dynamic, according to the evacuation demand and impedance function that can be either time-dependent or not (Elise Miller-Hooks, 2008). The dynamic assignment model can not only be used in evacuation planning but also used in improving the management strategy of evacuation traffic (Heng Wei, 2008)(Yue Liu, 2008). Due to the fact that the dynamic evacuation traffic assignment model needs a more high-powered computer, it is hard to apply this model in the actual urban road network.

Although there has been some research on management strategy of emergency evacuation traffic, this research is focused on the effectiveness of a single strategy in the situation of hurricane evacuation (Virginia P. Sisiopiku, 2007)(Brian Wolshon, 2007). There is still lack of case studies on the carrying capability of an earthquake evacuation corridor. This paper proposes criterion for selecting the earthquake evacuation road, the methodology for searching availability and the rationality of earthquake evacuation corridor planning.

2 PRINCIPLES AND METHODOLOGY

2.1 Principle in the Selection Of Earthquake Evacuation Corridor

According to the relative rule of law, an earthquake evacuation corridor must be provided with high-capacity and high anti-seismic ability. The selection principle of an earthquake evacuation corridor involves five aspects: 1) safety and flexibility; 2) high capacity; 3) integrate with urban network planning; 4) convenient for surveillance; 5) adaptable either during normal conditions or emergencies.

2.2 Methodology Of Assess The Carrying Capability Of Earthquake Evacuation Corridor

Macro-simulation Model (OREMS)

After an earthquake, the most important mission is to transfer people to the shelter as soon as possible through the preplanned earthquake evacuation corridor. This paper used the macro-simulation model (OREMS) that is based on the UE (User Equilibrium) principle to optimize the earthquake evacuation procedure. This objective model could be mathematically described as follows.

$$\text{Objective:} \quad \min Z(x) = \sum_a \int_0^{x_a} t_a(\omega) d\omega$$

$$\text{S.T.} \quad \sum_k f_k^{rs} = q_{rs} \quad \forall r,s$$

$$f_k^{rs} \geq 0 \quad \forall k,r,s$$

$$x_a = \sum_r \sum_s \sum_k f_k^{rs} \delta_{a,k}^{rs} \quad \forall a$$

$$t_a(x_a) = t_a^0 \left[1 + \alpha \left(\frac{x_a}{C_a} \right)^{\beta} \right]$$

Where, $Z(x)$:the objective function, is the sum of the integrals of the link performance functions;

x_a :flow on link a, vehicle;

$t_a(x_a)$:impedance function, minute;

t_a^0 :travel time on link a in free speed, minute;

f_k^{rs} :flow on path k connecting O-D pair r-s, vehicle;

q_{rs} :flow rate between origin r and destination s, veh/hr;

$\delta_{a,k}^{rs}$:indicator variable; $\delta_{a,k}^{rs} = \begin{cases} 1 & \text{if link } a \text{ is on path } k \text{ between O-D pair } r\text{-}s \\ 0 & \text{otherwise} \end{cases}$;

C_a :capacity of link a, veh/hr;

α, β :pending coefficient;

Algorithm of Optimization Model

The macro-simulation model of an earthquake evacuation traffic assignment is a nonlinear programming model with linear constraints. The convex combination algorithm is especially useful for determining the equilibrium flows for transportation networks. The algorithm itself, when applied to the solution of the UE problem, can be summarized as follows:

Step0: Initialization. Perform all-or-nothing assignment based on $t_a = t_a(0), \forall a$. This yields $\{x_a^1\}$. Set counter $n = 1$.

Step 1: Update. Set $t_a^n = t_a(x_a^n), \forall a$.

Step 2: Direction finding. Perform all-or-nothing assignment based on $\{t_a^n\}$. This yields a set of flows $\{y_a^n\}$.

Step 3: Line search. Find α_n that solves $\min_{0 \le \alpha \le 1} \sum_a \int_0^{x_a^n + \alpha(y_a^n - x_a^n)} t_a(\omega) d\omega$

Step 4: Move. Set $x_a^{n+1} = x_a^n + \alpha_n (y_a^n - x_a^n), \forall a$.

Step 5: Convergence test. If convergence criterion are met, stop (the current solution, $\{x_a^{n+1}\}$, is the set of equilibrium link flows); otherwise, set $n = n + 1$ and go to step 1.

Through the convex combination algorithm, we can find the best solution of the evacuation traffic assignment model. The outputs of the macro-simulation model (OREMS) include evacuation time and speed. The availability and rationality of a preplanned earthquake evacuation corridor could be assessed by these simulation results.

3 CASE STUDY

3.1 Objective Evacuation Network

"Statistics Yearbook Of Beijing 2004" shows that the population density in the central district of Beijing was 42 times more than the average population density in the entire city of Beijing. This data implied that the central district of Beijing a

higher threat of earthquakes. In this paper, the central urban area is identified as the study area, such as Dongcheng, Xicheng, Chongwen, Xuanwu district. According to the aforementioned selection principal of an earthquake evacuation corridor, identified 13 east-west, 12 north-south main street and 3 expressway in the 3rd ring to make up an earthquake evacuation corridor.

3.2 Earthquake Evacuation OD

Beijing statistics shows that cars per capita is 0.2. Automobile occupancy should be 4 persons/vehicle during an earthquake evacuation. The capacity of buses used in earthquake evacuation is 180 persons/bus. The bus should be converted to the car equivalent. The conversion coefficient is 2.5. Based on the above rules, the earthquake evacuation demand expressed as the number of the car equivalent (see Table 2).

Table2. Earthquake Evacuation Demand In Central District Of Beijing

District	Population (million)	Evacuation Demand (vehicle)
Dongcheng	0.69	139917
Xicheng	0.83	168306
Xuanwu	0.61	123694
Chongwen	0.41	83139
Total	2.54	515056

In accordance with the relative rules about the emergency shelter planning, recommended area per capita of earthquake emergency shelters was 2.0m^2. The planning earthquake shelters include all parks and stadium in the central district of Beijing. The capacity constrain of shelter also expressed as the number of equivalent car. (see Table 3)

Table 3. The Capacity Constrain Of Earthquake Shelter

District	Park	Green Area (m^2)	60% Green Area (m^2)	Capacity (person)	Capacity (pcu)
Dongcheng	7	1318798	791278.8	395638	80224
Xicheng	7	1400906	840543.9	420270	85220

3.3 Validation Analysis of Carrying Capability

After setting up the evacuation network and inputting the evacuation demand OD by the OREMS, the objective area was divided into four quadrants by the Chang

Avenue and the middle Axial Road (Figure1 and Figure2). This paper adopts two evacuation strategies, one-way and contra-flow, to evacuate people to the shelter (Figure 3).

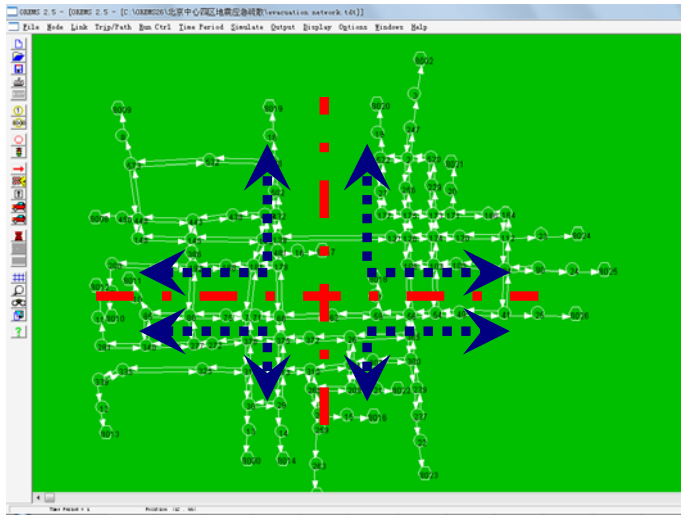

Figure 1. Earthquake Evacuation Direction.

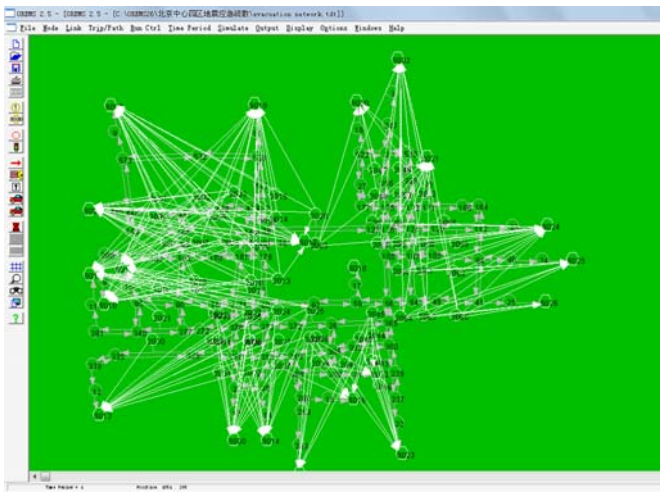

Figure 2. Evacuation Demand Distribution.

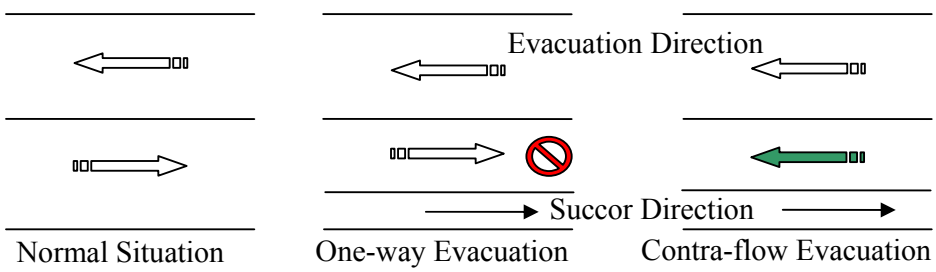

Figure 3. One-way Evacuation and Contra-flow Evacuation.

After applying the macro-simulation model, the result of the analysis of the carrying capability of an earthquake evacuation corridor is show in Table 4.

Table 4. Analysis Result of Carrying Capability of Evacuation Corridor

Evacuation Strategy	Evacuation Time	Average Evacuation Speed
One-way Evacuation	4:02 hours	24.6 mile/hour
Contra-flow Evacuation	2:33 hours	32.7 mile/hour

The output of OREMS shows that the carrying capability of an earthquake evacuation corridor, based on the selection principle, fulfills the earthquake evacuation demand. For the same network, a contra-flow evacuation strategy would significantly improve the evacuation efficiency. The time spent on evacuating 95% of the population was shortened from 2 hours and 45 minutes to 1 hour and 35 minutes. According to the data shown in Table 1, the preplanned earthquake evacuation corridor based on the selection principle could reduce the loss of life caused by an earthquake.

Although a contra-flow evacuation strategy could achieve a positive evacuation result, three important things should be accomplished before an actual evacuation is executed: 1) venue for community to get on evacuation vehicles must be preplanned; 2) the traffic management person has to assign the key intersection to regulate the evacuation traffic. 3) the traffic in the reverse lanes need to be cleared up before a contra-flow evacuation begins. The evacuation time obtained from the proposed methodology does not include mobilization time. Forecasting the length of the mobilization time needs further research. The publicity about evacuation is also important for the success of an earthquake evacuation.

4 CONCLUSION AND FUTURE STUDY

This paper puts forward a set of principles to select a suitable earthquake evacuation corridor and proposes a methodology for the research on the carrying capability of a regional earthquake evacuation corridor, based on macro-simulation to prove the availability and rationality of a preplanned regional earthquake evacuation corridor. In the end, the proposed approach was employed in the Beijing case study and proved the availability and rationality of the Beijing earthquake evacuation corridor planning. There are still some inadequacies in this paper. Such as, this paper does not consider the effect by the time-dependent variation of evacuation demand, and, does not take into account access capacity constraints in the earthquake shelter . Therefore, there leaves much to be improved in future studies.

Abstract : Traffic flow state is a vague concept. It can not be measured off in different traffic flow states by using a specific index, which is in line with the fuzzy clustering characteristics. The Fuzzy C-Means (FCM) algorithm is used to analyze the traffic flow state in fog and non-fog periods in terms of a large amount of data of speed, density, and volume. The traffic flow state is classified into three, four, and six categories, respectively. By comparing and analyzing the traffic flow state in the two periods, results show that the regularity in fog is more obvious than that in non-fog. The traffic flow state in the fog period can be well described by four categories.

1. Introduction

In an intelligent traffic guidance system, the real-time traffic data and the historical traffic data are usually merged together in order to make the best estimate of road traffic flow at the moment. The identification of a traffic flow state should be based on the category of an existing state. While in different weather and road conditions, the traffic flow state may change dramatically even if the volume has not changed (Daniel and Matthew, 1983). It is necessary to study the flow states separately under different weather conditions, especially in rain, snow, and fog. The classification of a traffic flow state on a general road has been studied (CHEN, 2005; JING and MENG, 2007). The author studies the traffic flow state in fog to provide a basic theory for an intelligent traffic guidance system of the expressway.

2. The definition and classification of fog

Fog is the hydrometeor near ground, which is an aerosol system composed of the tiny water droplets or ice crystals suspended in the air. The existence of fog reduces visibility. If the visibility of target is down to less than 1000 meters, there is hydrometeor in the air near the ground that is called fog (PAN and JIANG, 2006).

3. Data Acquisition and Processing

3.1 data selection

The influence of volume on traffic flow classification is minimal. At the same volume, the state may be diametrically opposed (CHEN, 2005). For example, when the volume is zero, it may be a free or a congested flow. In addition to volume, speed and density is a linear relationship, each of them can be able to reflect the variation of a traffic flow state intuitively (Daniel and Matthew, 1983). As the speed increases, the

traffic flow state becomes better. Speed is one of the most important parameters of the drivers. The state continues to deteriorate with density increasing, so density is more concerned by administrators (JING and MENG, 2007). For reasons given above, the speed and density are selected as a basic parameter to judge the flow state.

3.2 data investigation location and time

In this paper, the data was collected from January 2002 to September 2008 on Zhanglong (Zhangzhou-Longyan) and Longchang (Longyan-Changting) expressway. The data includes visibility that is lower than 300m in fog and higher than 1000m in non-fog.

3.3 data preprocessing

Because the units of the speed and density are inconsistent, the collected data of speed and density should be standardized on the premise that their influence on a traffic flow state is equal, as shown in formula (1).

$$x'_{ik} = \frac{x_{ik} - \bar{x}_k}{s_k} \qquad (1)$$

When k = 1, k is for density; when k = 2, k is for speed; x_{ik} is the raw data of speed or density; $\bar{x}_k$ is the mean; s_k is the variance; x'_{ik} is the standardization. In order to compress standardized data between 0 and 1, we use the method based on the standardization of range as shown in formula (2). $x'_{k\max}$ is the maximum; $x'_{k\min}$ is the minimum.

$$x''_{ik} = \frac{x'_{ik} - x'_{k\min}}{x'_{k\max} - x'_{k\min}} \qquad (2)$$

4. Fuzzy clustering algorithm

Clustering is a process that distinguishes and classifies things according to certain requirements and rules. Traditional clustering analysis is a hard classification with the quality of either this or that. It has an uncertainty description of sample to clusters on fuzzy clustering (GAO, 2004). Traffic flow state is a very vague concept. There are no specific indicators to separate two different states, which is in accordance with the characteristics of fuzzy clustering. Thus, this paper analyzes the traffic flow state by using fuzzy clustering.

More attention is focused on the research to clustering analysis method based on the objective function. The Fuzzy C-Means (FCM) clustering algorithm is one of the most perfect. The objective function of the FCM algorithm is described as follows:

$$J_m(U, P) = \sum_{k=1}^{n} \sum_{i=1}^{c} (u_{ik})^m (d_{ik})^2$$

Where U is the dividing matrix; P is the clustering center vector; u_{ik} is membership that the data of No. k belongs to the clustering center of No.i, $u_{ik} \in [0,1]$;

$(d_{ik})^2$ is Euclidean distance between sample x_k and the clustering center of No. i; m is a weighted index (JING and MENG, 2007).

The steps are as follows:

Initialization: give a cluster c and set stop threshold ε of iteration; initialize clustering center $P^{(0)}$; set iteration counter b=0.

Step1. Calculate or renew dividing matrix $U^{(b)}$ by using the following formula:

$$u_{ik}^{(b)} = \left\{ \sum_{j=1}^{c} \left[\left(\frac{d_{ik}^{(b)}}{d_{jk}^{(b)}} \right)^{\frac{2}{m-1}} \right] \right\}^{-1}$$

Step2. Renew the clustering center $P^{(b+1)}$ by using the following formula:

$$p_i^{(b+1)} = \frac{\sum_{k=1}^{n} (u_{ik}^{(b+1)})^m . x_k}{\sum_{k=1}^{n} (u_{ik}^{(b+1)})^m} \quad , i=1 , 2 , \dots , c;$$

Step3. If $\| P^{(b)} - P^{(b+1)} \| < \varepsilon$, output U and P; otherwise set b = b + 1 , turn to the first step.

5. The classification of traffic flow state

There are different classifications of a traffic flow state because of the road conditions and traffic guidance systems. Free flow, transition flow, and congested flow is usually described as the traffic state (JIANG, 2004). In China, the service level that describes the road traffic flow operating conditions is classified into four categories on each class of highway. The density and speed is the standard of classification (CHEN and YAN, 2003). The United States Highway Capacity Manual (HCM) classifies the service level of the urban main road into six categories from A to F by using average overall speed as a grading index (Javy and Norman, 2000). In this paper, the traffic state in fog and non-fog is classified into three, four, or six categories in accordance with the usual classification, the highway service level in China, and the United States HCM service level. There is a comparative analysis to the traffic flow state of different categories and periods.

The data of speed and density between 0 and 1 in fog and non-fog is obtained by using the method based on the standardization of range on formula (1) and (2). Then, the data is classified and processed by using FCM algorithm in MATLAB.

5.1 The traffic flow state is classified into three categories

After 21 iterated operations, the objective function value of a traffic flow state in fog reached 4.5677; after 33 iterated operations, the objective function value of a traffic flow state in non-fog reached 8.536214. Their accuracy were 10^{-5} as the condition of control. The Clustering results are shown in Table 1.

Table 1. The Clustering Results of Three Traffic Flow States.

Categories	Clustering center of fog		Clustering center of non-fog	
	Density (cars. $km^{-1}.lane^{-1}$)	Speed($km.h^{-1}$)	Density (cars. $km^{-1}.lane^{-1}$)	Speed($km.h^{-1}$)
State I	6.5605	70.0381	3.4166	82.7641
State II	9.2635	61.0643	10.6355	68.2015
State III	16.2558	50.5954	5.6575	55.0227

The three categories of clustering density and speed data in fog and non-fog were measured by plotting the density on the abscissa and speed on the ordinate on Figure 1 and Figure 2. The conclusions are shown as follows:

(1) Traffic flow state is gradually transit from free to congestion as the density increases and speed decreases. The clustering center of three traffic flow states is nearly in a straight line. The approximate boundary of speed between free flow (state I) and transition flow (state II) is 64 km/h, but between transition flow and congested flow (state III) is not clear because of wide fluctuations of speed. The boundary of density among the three traffic flow states is not clear.

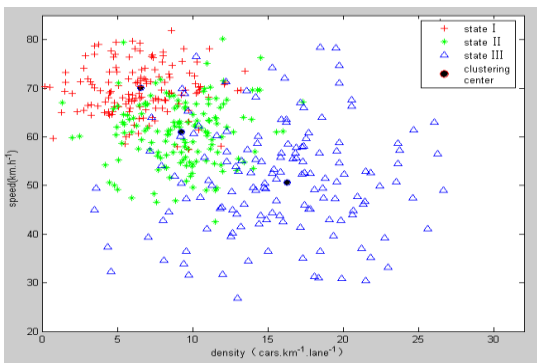

Figure 1. Three traffic flow states in fog.

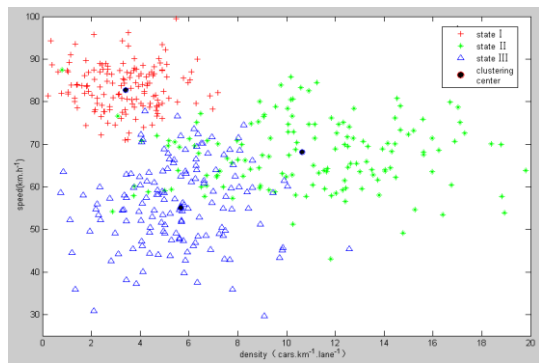

Figure 2. Three traffic flow states in non-fog.

(2) In a non-fog period, the traffic density does not increase as the speed decreases. The density of the transition flow is higher than the congested flow. The clustering center of three traffic flow states shows as a triangle on Figure 2. The clustering center of transition flow is the farthest from the origin, that is to say the volume of the transition flow is much larger than that of the congested flow and slightly larger than that of free flow.

(3) The speed of the clustering center in non-fog is higher because the speed has a wider distribution. In a non-fog period, the free and congested flow density of the clustering center is higher. The speed data is dispersed, which made the result different from in fog by using FCM algorithm.

(4) The three traffic flow states show strong significant correlation, so the density and speed data of fog period as classified into three categories is reasonable.

Because the range of speed variation in non-fog is much wider than that in fog, three categories do not comparatively show the characteristics of traffic flow state.

5.2 The traffic flow state is classified into four categories

After 25 iterated operations, the objective function value of a traffic flow state in fog reached 4.1352; after 64 iterated operations, the objective function value of a traffic flow state in non-fog reached 5.876359, their accuracy was 10^{-5} as the condition of control. The Clustering results are shown in Table 2.

Table2 . The Clustering Results of Four Traffic Flow States .

categories	Clustering center of fog		Clustering center of non-fog	
	Density (cars. $km^{-1}.lane^{-1}$)	Speed($km.h^{-1}$)	Density (cars. $km^{-1}.lane^{-1}$)	Speed($km.h^{-1}$)
Ⅰ	6.4240	72.6385	3.2194	83.8083
Ⅱ	8.8615	64.4835	14.7145	70.5079
Ⅲ	12.5367	55.177	8.9775	58.5605
Ⅳ	15.7721	47.4290	10.8866	52.0220

The four categories of clustering density and speed data in a fog and non-fog period were measured by plotting the density on the abscissa and speed on the ordinate on Figure 3 and Figure 4. The conclusions are shown as follows:

(1) The traffic flow state shows strong significant correlation when classified into four categories in fog. The lower the speed is the higher the density is. The clustering center of the four traffic flow states is nearly in a straight line.

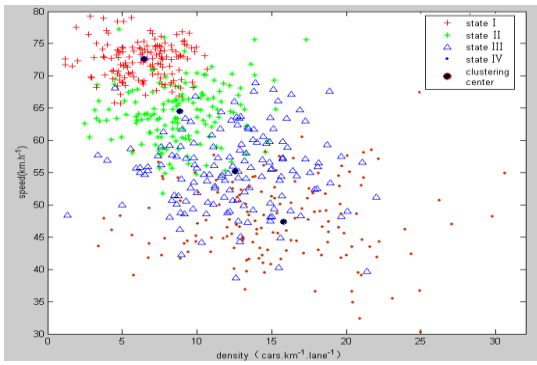

Figure 3. Four traffic flow state s in fog.

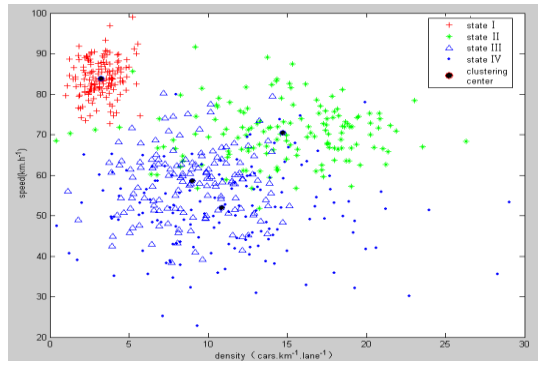

Figure 4. Four traffic flow states in non-fog.

(2) The mingled data of the three categories is classified into the extra traffic flow state by the comparison of Figure 2 and Figure 4. In this way, the state Ⅰ, Ⅲ and Ⅳ have more obvious regularity . The volume of state Ⅱ is the largest and the highway capacity gets the maximum use out of it.

(3) The speed of clustering a center in non-fog is higher than that in fog, which is harmonious with our perceptual intuition. The density of a clustering center in non-fog is almost smaller than that in fog.

(4) The four traffic flow states in fog show strong significant correlation. Making detailed analysis on the traffic flow state by classifying them into four

categories is favorable to understand.

5.3 The traffic flow state is classified into six categories

After 53 iterated operations, the objective function value of a traffic flow state in a fog period reached 3.4536; after 57 iterated operations, the objective function value of a traffic flow state in a non-fog period reached 3.011431, their accuracy was 10^{-5} as the condition of control. The Clustering results are shown in Table 3.

Table3 . The Clustering Results of Six Traffic Flow States .

categories	Clustering center of fog		Clustering center of non-fog	
	Density (cars. $km^{-1}.lane^{-1}$)	Speed($km.h^{-1}$)	Density (cars. $km^{-1}.lane^{-1}$)	Speed($km.h^{-1}$)
Ⅰ	5.8432	74.3105	3.06145	85.5535
Ⅱ	7.1675	68.1437	7.0753	77.0277
Ⅲ	13.6269	60.1605	5.0805	70.8625
Ⅳ	10.8374	55.9393	10.4561	66.0724
Ⅴ	18.6135	50.2905	9.2151	59.7655
Ⅵ	15.6269	47.3190	12.7775	52.5495

The six categories of clustering density and speed data in a fog and non-fog period were measured by plotting the density on the abscissa and speed on the ordinate on Figure 5 and Figure 6. The conclusions are shown as the follows:

(1) As shown in the Table 3, the speed of a clustering center in non-fog is higher than that in fog. The density of a clustering center in fog and non-fog mingled with each other, but the maximum density in fog is much higher than that in non-fog.

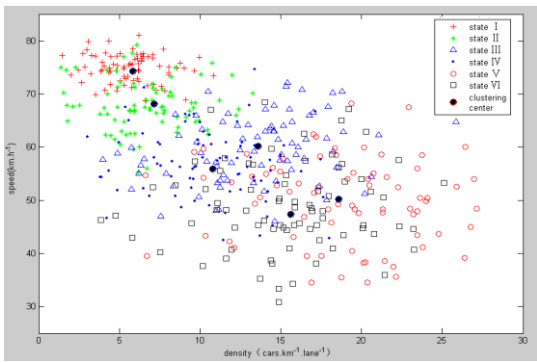

Figure 5. Six t raffic flow states in fog.

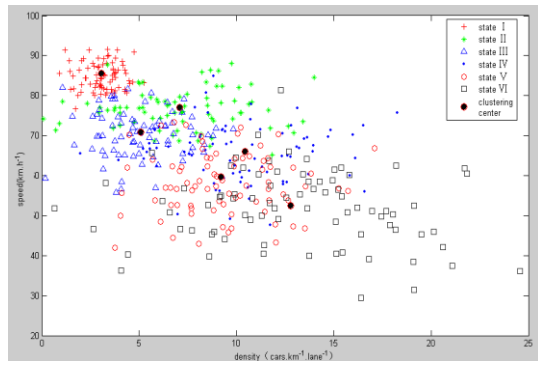

Figure 6. Six traffic flow states in non-fog.

(2) The density of state Ⅰ, Ⅱ, Ⅲ, Ⅴ and Ⅰ, Ⅱ, Ⅳ, Ⅵ in fog is smaller with the increasing of the speed. But the volume of state Ⅲ and Ⅴ are obviously larger than state Ⅳ and Ⅵ That is equal to classify the traffic flow state into six from density, speed and volume.

(3) The traffic flow state Ⅰ, Ⅲ and Ⅴ in non-fog have linear relationships, the same to the state Ⅰ, Ⅱand Ⅳ. The state Ⅵis the transition flow to the state Ⅳand Ⅴ.

(4) The consistent traffic of all states is carefully described by classifying the traffic flow state of fog and non-fog into six categories.

6. Conclusion s

Traffic flow state in fog has its particularity that reflects at the classification of the traffic flow data on the same road by using FCM algorithm. The traffic states in fog are much different from that in a non-fog mostly because of the different speed in the two periods. In a fog period, drivers are more cautious and the speed variation of the vehicle is smaller, which makes traffic flow states more regular than in non-fog. By increasing the classification, the description of traffic flow states in fog and non-fog are more detailed. The traffic flow state should be classified according to the requirements, especially in fog. The traffic flow state as classified into four categories is appropriate, not only to put emphasis the regularity of traffic flow, but also overcome the disadvantage of too much classification.

It should be noted that this study only evaluated a traffic flow state by using the speed and density and suppose the two indicators have the same influence on a traffic flow state. Deciding whether the two indicators influence on a traffic flow state is different and how to determine the weights would be required for an intensive study.

Research on the Impact of Divers' heart rate on Longitudinal Slope of Freeway Tunnel

Zhao Jianyou[1]， He Cao[1] and Shi Yanni[1]

[1]Automobile Institute of Chang'an University, P.O. Box: 567 City: Xi'an, Shanxi, 710064, PH：（029）82334069; FAX (029)82334069 Email: jyzhao@chd.edu.cn

ABSTRACT

This paper researched the longitudinal slope of a tunnel from the driver's psychological view, and analyzed the heart rate changes in different drivers. According to the measured data, we established the quantitative model between the driver's physiological and psychological response by an increased heart rate, and the longitudinal slope of the tunnel and running speed with a regression analysis. This model proved capable of describing the response of drivers driving through the contrast between field data and model calculated data. Finally, we calculated a safe slope of the tunnel and security pace value according to the model.

INTRODUCTION

With high-grade freeways extended to the western region, there have been an increasing number of tunnels, and some of these formed tunnel groups. The so-called tunnel groups are a number of tunnels which the distance of two tunnels is less than 2km under normal circumstances (design speed is 80 km/h)) (ZHOU Zhong-ye et al. 2008).Tunnel groups change the driving environment frequently in a short period, it brings great impact on drivers either psychologically or physiologically and it can become a security risk; at the same time, the tunnel alignment will also have a certain impact on the drivers. The restriction on the slope by traditional theory is mainly based on the power of the vehicles. Uphill, the traditional theory is only concerned about how much the car can climb up the slope, and does not take the subjective factors of people described and the state when the drivers are climbing the slope into consideration sufficiently(ZHANG Sheng-rui et al 2007). The tunnel belongs to the bottleneck section of the road net of the highway, so light traffic accidents may also affect the operational efficiency of the entire road network. Therefore, it is necessary to carry out studies about the impact physiologically and psychologically on the drivers according to the tunnel longitudinal slope in order to improve the safety of the operation of the tunnels.

EXPERIMENTAL DESIGN

Experimental object. Choose 5 male and 3 female drivers with different ages and different driving experiences as the Experimental object. Considering the high rate of accidents on the road, do not choose the new drivers with less than 3 years experience, and input the drivers' information in Table 1. Before the test we must make sure the

drivers should have enough sleep, avoid food and drugs which can influence the heart rate such as smoking, drinking tea, wine, and coffee, and avoid strenuous exercises.

Experimental Equipments. (1)Experimental car, FORD TRANSIT. (2)KF-2 Physiological Detector, Record the driver's ECG Database (Display sensitivity:10mm/mv, Error≤±5%, Scanning velocity :25mm/s, Error≤±10%), Breathing wave（Precision≤±5%），Body temperature（Error±5%），Galvanic Skin Reflex(GSR)(Error≤10%),and the Physiological parameter about the body moves the change intensity.

Table 1. The information of drivers.

Experimental Routes. Choose the section from the Bridge of ZhiFang (K42+800) to the export of Qinling tunnel NO.1 (K64+827) as the uplink and downlink experimental route, the speed limit of all the uplink route is 80km/h, and the speed limit of all the downlink route is 60km/h. There are 22 tunnels in this section (Shaanxi Provincial Highway Survey and Design Institute. 2007); the longitudinal slope of the tunnel is in Table 2 and Table 3.

Table 2. The distribution of down-steam's longitudinal slope for grade line.

Downlink tunnel NO.	01	02	03	04	05	06	07	08	09	10	11

Longitudinal slope of tunnel（‰）	26.5	27.22	20.2	40	40	21.35	16.5	29	38.13	38.13	23

Table 3. The distribution of up-steam's longitudinal slope for grade line.

Uplink tunnel NO.	Zhifang	21	20	19	18	17	16	15	14	13	12
Longitudinal slope of Tunnel（‰）	22.13	28	28	37	37	16.5	25	25	42	20	20

Uplink tunnel NO.	11	10	09	08	07	06	05	04	03	02	01
Longitudinal slope of Tunnel （‰）	32.91	25.82	35.41	35.5	26	30	30	45	43	38	46

Experimental Procedures. Test for 10 minutes' the static heart rate as a normal heart rate before driving and compare with the dynamic heart rate in the following test of driving. When arriving at the experimental route, make sure the driver wears the physiological detector and record the time of entering the car as the start of the test. When collecting the electrocardiosignal read the instant velocity and record the time manually under special circumstances (e.g. the time of entering the tunnel hole and the time of exiting, or overtaking another vehicle, etc.).When the test is finished, get out of the car and record the time. The test requests that the recording time of the manual and physiological detector are the same, so as to make sure all the data is synchronous.

EXPERIMENTAL DATA ANALYSIS

We can get the sample data of all variables through Statistics Theories and general knowledge excludes some abnormal data, then build a regression model about the heart rate, velocity, Longitudinal slope of the Tunnel by the theory of regression analysis.

It could not fully reflect the influence of the longitudinal slope of the tunnel to drivers by comparing the increase of the drivers' heart rates because of the differences of each driver. So we used the increased rate of heart rate. A drivers' heart rate in calm is shown in Table 4. The increased rate of heart rate = (the heart rate in driving-the heart rate in calm)/ the heart rate in calm. Research shows that the drivers will be nervous when the heart rate increases more than 20% and the drivers will be frightened when it increases more than 40% (Huang Xi-ting .1988; ZHAO Jian-you. 2003).

Table 4. Drivers' average heart rate in calm.

Drivers NO.	1(M)	2(M)	3(M)	4(M)	5(M)	6(F)	7(F)	8(F)
Average heart rate in calm （Times/min）	61	67	70	72	62	65	52	79

The comparison of different drive speed and increased heart rate in different drivers. The different mental status, driving experiences and driving technologies, performance in different driving behaviors, and mental experiences will certainly be different. In order to facilitate the problem, compare the 5 male drivers' average with the 3 female drivers' average.

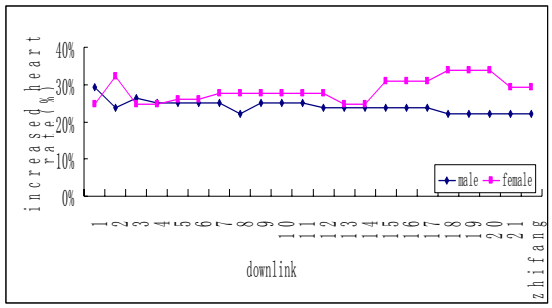

Figure 1. Male and female drives' speed distribution in downlink.

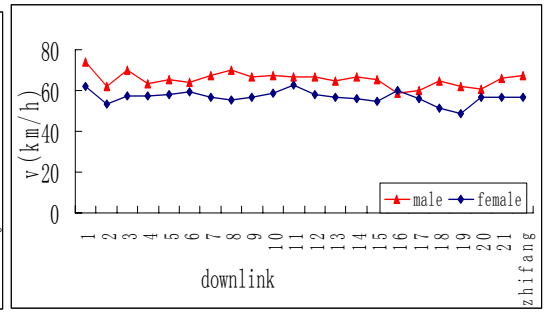

Figure 2. Male and female drives' increased heart rate in uplink.

Figure 1 and Figure 2 show male and female drivers' speed and increased heart rate in down-steam, so we can get the conclusion that male drivers have a higher speed and a lower heart rate than a female, while female drivers' have a lower degree of psychological stress than males in downlink.

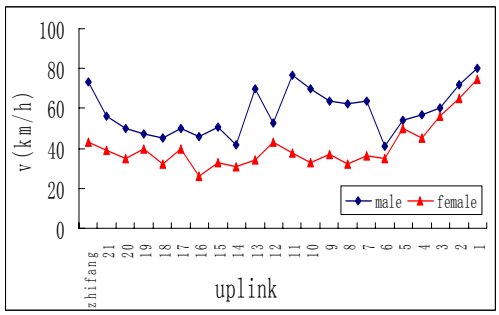

Figure 3. Male and female drive' speed distribution in downlink.

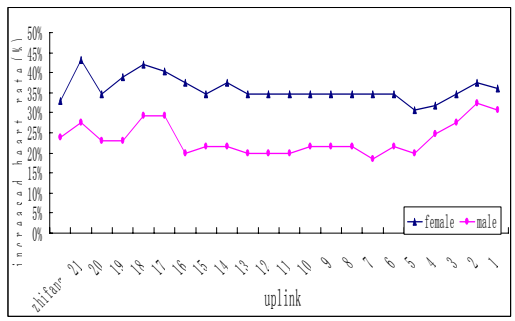

Figure 4. Male and female drives' increased heart rate in uplink.

Figure 3 and Figure 4 show male and female drivers' speed and increased heart rate in uplink, so we can conclude that male drivers have a higher speed and lower increased heart rate than females, while female drivers have a lower degree of psychological stress than males in uplink too.

Contrasting the information of drivers, we can get the reasons that lead to it: the average driving age of male drivers is more than females so they have much more driving experience; in addition, the extent of familiarity is deeper than females, and it indicates that male drivers' psychological qualities are better than females' in the tunnel groups of the freeway section, they can tackle the changing road conditions easily, and the drastic changes of heart rate can not happen. On the other hand, it also shows that the expectation of velocity of male drivers is much higher and they can not feel too much tension with high speed and complex road sections.

Built a Relation Mode between Longitudinal slope for Grade Line, Drive Speed and Increased Rate of Heart rate. According to the measured data, established the quantitative model between driver's physiological and psychological response by an increased heart rate, and Longitudinal slope of tunnel and running speed with regression analysis. The measured data of the uplink and downlink are shown at the

Table 5 and Table 6 respectively.

Table 5. The corresponding date of longitudinal slope of tunnel, running speed and the increased heart rate when downlink.

Longitudinal slope of tunnel i（‰）	23	38.13	38.13	29	16.5	21.35	40	40	20.2	27.22	26.5
Running speed v（km/h）	55	57	58.2	56.8	57	57.4	59.8	60.8	61.6	60.4	60

Model applicable scope: 0<i<5%
The correlation coefficients of mode: R=0.67

The regression mode of figure 8: $n=-0.0006i^2+0.0321i-0.0579$

Model applicable scope: 0<i<5%
The correlation coefficients of mode: R=0.72

Figure 5 and 7 shows that the whole distance of downlink section is more than 20km at the test section with the slope between 0 and 5%,the drivers usually brake to slow down the speed because of 60km/h's limiting at downlink, and in the uplink the speed limit is 80km/h the driver usually accelerate, so the speed of upraise is much higher than that of down, Figure 6 and 8 shows that when the longitudinal slope of tunnel' s range is 0~5%, with increasing angle of the longitudinal slope of the tunnel the increased heart rate first increases, then decreases, the angle of the longitudinal slope of the tunnel is about 3% when the increased heart rate is max.

Contrast the data of measured increased heart rate with the data of calculated value (the average of downlink and uplink), and get 22 groups data, as Figure 9 showed, the maximum error of model calculations is 15.32%, the least error is 0.05%, the average error is 6.34%, Through the comparison, we can regard as the precision of model calculations is much better and it can reflect the changes of increased heart rate in driving.

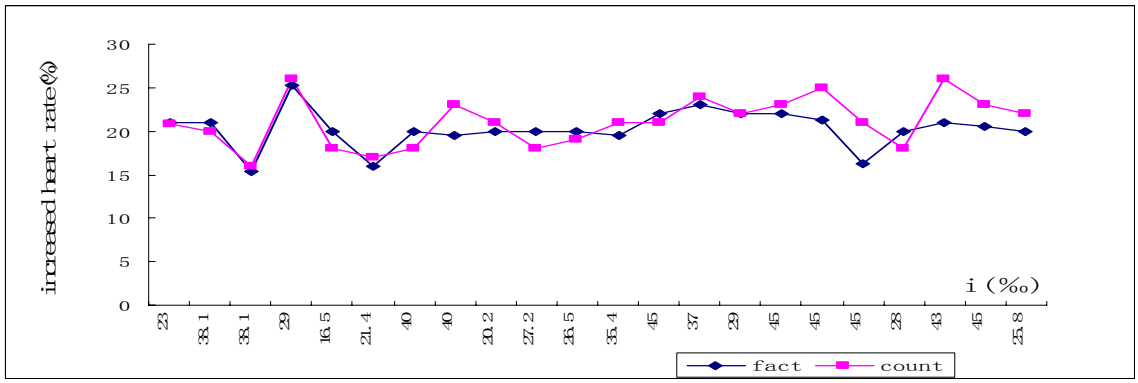

Figure 9. The comparison of the tested and model calculations of the increased heart rate.

THE SAFE SLOPE OF THE TUNNEL AND SECURITY PACE VALUE

The Safe Slope. According to the highway tunnel design codes, the longitudinal slope of the tunnel should be no less than 3‰ and no more than 30‰, to be limited by the topographical condition it can be appropriately increased, but no more than 40‰ (WANG Shu-ling et al 2007).

The related research indicated that the increased heart rate is not surpasses 40%, otherwise the driver's psychological overload is vulnerable to accidents, when the increased heart rate is 40% of the marginal value, take it into regression equation we can know that the max of the longitudinal slope of the tunnel at uplink is 30‰, it indicates that the longitudinal slope of the tunnel at downlink is corresponding to the design standard. Similarly we can known the max of the longitudinal slope of tunnel at uplink is 27‰, so the safe slope of the tunnel value at uplink is 27‰.

The Security Pace. Take the marginal value of slope into the regression mode of the longitudinal slope and velocity, we can see that the security pace value at downlink is 60.2 km/hand the security pace value at uplink is 73.7km/h.

CONCLUSION

Though the test of practical driving, the paper makes a study about the effects of the longitudinal slope of the tunnel on the heart drivers and velocity, the conclusions are as follows:

(1) Male drivers have higher speed and lower increased heart rate than female but increased heart rate is lower than female.

(2) The expectation to velocity of male drivers is much higher than female, and in the high velocity and complex road section they can maintain a stable heart rate.

(3) According to the measured data, the quantitative model that established between driver's physiologically and psychologically response by increased heart rate and the longitudinal slope of the tunnel and running speed have high precision and

can reflect the changes of increased heart rate in driving.

(4) The max of the longitudinal slope of the tunnel at uplink is 27‰, at downlink is 30‰; Security pace value at downlink is 60.2 km/h and the security pace value at uplink is 73.7km/h.

ABSTRACT

The Zhijing River Bridge is a CFST arch bridge in Hubei province. The limitations are more cables, as the angles of some cables are very small and made cable adjusting difficult in construction. The Iterative optimization method with once-tension principle and alignment controlled by pre-cambers is introduced into the alignment control and cable-force calculation of the erection stage. All cables should have been removed after the arch rib closure in the original design, but in the latter hoisting construction, the early cable force and elevation were influenced seriously and the inner force of main arch rib became uneven. The influence by the time, order and method of cable-removing are calculated in the optimization process and the new cable-removing schemes are brought forward. In that, part of the cables removed before closure, and they are analyzed and compared to each other, and then a best scheme with easier control is determined.

INTRODUCTION

The cableway erection without supporting frame is always used in the construction of arch bridge, and later the method is developed with jack inclined drawn and steel wires buckled-hanged, and applied widely in the erection of long span concrete-filled steel tubular arch bridge. Because the prestress wire is used as buckle cable in the cable-stay erection of steel arch ribs, the line of arch rib become relatively easy to control.

In the erection of long-span arch bridge, the coordinate and cable force of each segment is continuously changing. For every segment fixed with bolts, the line of arch rib and cable force unfit for usually adjust. The line of arch rib direct affects the accuracy of rib closure. Hence, the time sequence and method of remove cable make impact on the line and internal force of arch ribs. Therefore, it is necessary to analyze the remove cable scheme and carry on optimization, compare and choose.

PROBLEM BACKGROUND

Zhijing River Bridge is a concrete filled steel tube arch bridge in the Hu-Rong West Expressway in Hubei province. The span of main arch crosses the degree as 430 meters. Fig.1 shows a photograph of the bridge. Each arch rib of the bridge is divided into 30 segments for the limits of construction space and transport conditional. Double-rib assembled in the deck of the bridge span and hoistinged together. The oblique-draw-buckle-hanged system consists of 10 major segments and each segment divide into 3 parts that slinged with 4 cables which anchored to juncture pier at one end and through steel beam to the arch rib at the other.The concrete block is poured on the cap of juncture pier as anchor beam to Subject to all of the construction load by cable. As a matter of convenience for construction and allay expenses,the double juncture piers as buckle pier for its body is high and the double abutment as anchor beam.Because single longitudinal slope and the inconsistent elevation of juncture piers on both sides, the height of buckle point and cable angle are unconformability.The quantity of calculation analysis is enlarged and the line control become inconvenient.The layout of cable-stay system is showed on Fig.2.

Figure 1. Photograph of the Zhijing river bridge, Hubei, China.

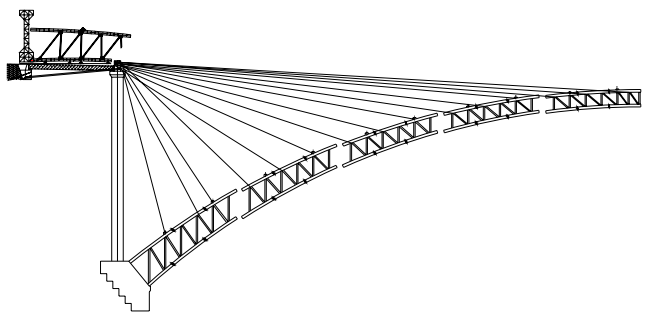

Figure 2. Layout of cable-stay system.

In the actual construction, the line of arch ribs consistent with the design by adjusting the cable. The cable-stay system of this bridge has more cables with small angle, which add more difficulty on cable adjusting. Further more, adjust arch rib

line with these cables must be difficult and dangerous. It needs to look for a optimization method for line adjustment.

MATHEMATICAL OPTIMIZATION METHOD

To find out the best path to erect the arch rib, optimization calculation theory is loaded into the forward iteration analysis calculation. Base on the space finite element analysis of the arch bridge, the cable force is deduced reversely via optimization theory. Buckling cable force taken as design variable, the displacement and stress of the arch rib taken as state variable. Through setting appropriate objective function, the optimal cable force of each segment in the erection is obtained. The line of arch bridge after construction matches the design expectation, and the inner force of the structure in the optimal state after construction. Function approximation optimization method is called zero-order method for the dependent variable is used instead of partially derivative in the principle. The relationship between objective function and variables method is set up via least square and curve fitting. The principle is achieved through a few design variable sequences to calculate the objective function and then obtained the least-squares between all data points.

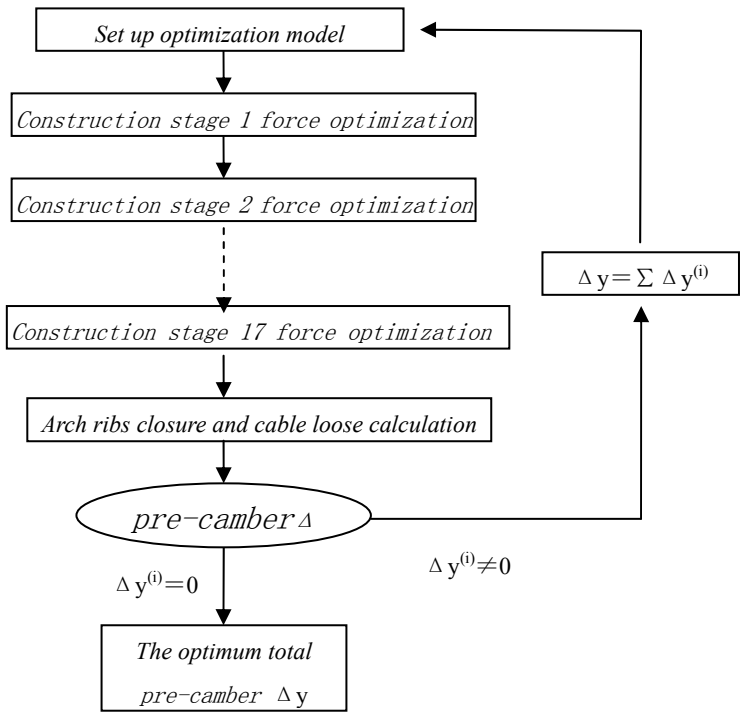

Fig 3.Optimization process of cable force.

Base on the principle of pulling rib to place with cable once tension, the calculation ruler be order as follows: the cable force adjusting is carried out once in the arch rib fixing with buckle cable and not to be adjusted until the closure of ribs and unlock cables, but the cable of Z1、Z2 have another construction stage for cable

force adjusting respectively. Each construction stage has an independent optimization circle. After optimization cycles same times as construction stages, all cable forces in every stage can be obtained. Because there is one group cable forces to be optimized in both sides respectively, two variables for optimization are set in each calculation phase. The stress of steel arch rib and the displacement of cable point in the lifting are set as state variables. The objective function is the absolute displacement summation of new additive cable points in both sides and other cable points displacement needn't to be controlled.

The line control target of steel ribs can be described as: the control line=manufacture line(arch line + pre-cambers)-deflection curve of hingeless arch bridge with dead load. The optimization process of cable force is shown in Fig 3.

CABLE REMOVE SYSTEM ANALYSIS AND SELECTION

The problem of original proposal

All buckle cables will be removed after rib closure in the original program. In the cable-stayed system, the fastening-tower is replaced by juncture pier. The cable in the vicinity of midspan approach horizon and the horizontal angle of Z5 on both sides only are 3.095 ° and 0.795 °.More temporary cable not be remove before closure make the more trouble for cable adjusting in the follow construction stage. With the cantilever length increase, the cable force gradually digressed and the elevation deflection of control point enhanced in the early stages.

Determination of the new program

The time sequence and method of remove cable after ribs closure will affect the line and inner force of arch ribs. It is necessary to adjust the original remove cable program and develop a new convenience construction control program. The calculation results of original program show that the cable force, deviation of control points and stress of control section are the largest in the large cantilever. The cable force of Z1, Z2, L5, L6 in early stages are only 79%, 69%, 72%, 76% of its early rally and L5, L6 hold a very small force. In the erection program, the deviation in the L / 4 of arch rib is larger than others.

Based on the above analysis, the cable adjusting scheme should focus on the four group cables. There is five schemes for selection.

Scheme 1: Z1 cable removal;

Scheme 2: Z2 cable removal;

Scheme 3: L5, L6 cables removal;

Scheme 4: Z1, Z2 cables removal; and

Scheme 5: Z1, L5 and L6 cables removal.

Above five schemes were calculated of the arch ribs in the biggest bracket state via above optimization method. The optimization cable force, the vertical deviation of arch rib node and steel rib stress of control section are obtained and

showed in the table 1 and table 2.

Table 2.Control Section Stress of Arch Rib Before Closure (MPa).

	scheme	arch spring	L/8	L/4	3L/8
top boom	origial scheme	-86.821	-42.153	-4.573	-12.730
	scheme 1	-74.750	-45.841	-5.222	-12.623
	scheme 2	-69.129	-39.987	-13.071	-15.973
	scheme 3	-73.626	-37.988	-19.796	-18.762
	scheme 4	-54.413	-43.935	-14.133	-16.026
	scheme 5	-59.827	-41.797	-20.760	-18.773
lower boom	origial scheme	-11.733	-33.250	-73.161	-44.864
	scheme 1	-18.273	-30.429	-72.521	-44.970
	scheme 2	-22.961	-33.570	-64.808	-42.865
	scheme 3	-20.398	-35.628	-60.392	-40.982
	scheme 4	-30.599	-30.530	-63.711	-42.874
	scheme 5	-27.649	-32.747	-59.391	-41.020

Program selection

Compare the results we can see that the deviation and stress in the scheme 1 to 5 have great improvement to original program. In the scheme 4 and 5, the deflection of arch rib nodes is only about half of the original and the peak stress has been largely reduced. Therefore, scheme 4 and 5 will be the more satisfactory adjustment programs in the deflection and stress of arch ribs.

The cable force is vital control factor in the erection construction. If some cable force bigger than others, the variance of inner force of cable-stay system will be enhanced and the construction risk enlarges. Compare the cable force of every scheme before ribs closure we can see that all cable force did not exceed their early rally, but the cable force of Z5 to increase above 10% in the scheme 3 and 5.

Because the force of Z5 cable is the largest and dangerous, and not be allowed to increase too much, the scheme should be excluded. Scheme 1 should be excluded for the unobvious adjust effect. Therefore, scheme 4 is the ideal cable remove program.

CONCLUSION

It is effectively on adjusting the line and the adverse stress of arch ribs that removes some cables that exert negative impact on line and inner force of arch ribs before closure. The defect of line control via adjusting pre-camber that cable tensioned once in place can be overcome to some extent. The method has much better operability and safety. In the concrete implementation, the cables are completely loosed instead of demolition for lowering risk and improving safety reserves. Only some aspects of remove cable scheme are analyzed. It is a complex problem that remove cables affect the arch ribs line and inner force of steel tube in different construction stages and the problem need to be further thorough research.

Abstract

Edge rate is the important source for a driver's speed perception. This paper briefly introduces the concept of edge rate, the theory for a driver's speed perception and control which are based on the edge rate, and an application effect of edge rate in foreign and domestic autos. According to the concept of edge rate and Newton's equation of motion, the speed control design model, which is based on the assumption that the driver maintains the constant edge rate with the comfortable deceleration rate, is deduced. By using the 3DMAX, the edge rate experiment videos that car moving on the highway are made, 260 stimulation of Subjectively Equal Speed experiments are designed by using the Forced-Choice Method, through 6 males and 2 females' experiment results, the experiments results show that driver's speed perception value is the largest when the edge rate is 8HZ, but the difference between 8HZ and 16HZ is litter, considering driver's speed perception value is the largest when the edge rate is 12HZ under the fog environment, then 12HZ is selected as the reasonable value. According to experiment result, the edge rate spacing for controlling the speed from 120km/h to 90km/h is calculated.

Key words: Driver; Speed Perception; Speed Control; Edge Rate; Design Theory

1. Introduction

About 1/3 of road traffic accidents for fatal collisions were related to speeding in the United States. The study of traffic experts in Australia showed that the accident rate increased 2 times as speed increased 5km/h when speed exceeds 60 km/h, and the severity of the accident increases exponentially. So how to effectively control the speed and its difference is a key to reducing the total number and the severity of accidents. The process for a drivers control speed is divided into four stages as the speed information perception, judging it, making a decision, and acting. During the speed information perception stage, more than 90 percent of the information comes from the visual system, of which edge rate is an important source for a driver's speed perception. This paper focuses on the theory and method about a driver's speed perception and control from the perspective of edge rate.

2. Speed control measure by using constant edge rate

2.1 The definitions of edge rate

Edge rate is the number of the optical elements passing across an observer's

visual field in unit time (Christopher, 2003). If an observer knows the ground-texture spacing, speed can be estimated from the edge rate. When the edge rate increases (ground-texture spacing decreases), the observer's perception speed increases.

When driving through constant spacing texture, with speed v, which length is S, T_X is the spacing between texture elements，the number of elements in length S is $n = S/T_x$， transverse time $t = S/V$， according to the concept of edge rate we can get ER=V / T_X, where，ER is the edge rate.

2.2 Application of edge rate in deceleration

ATSSA (2006) have paved horizontal lines with diminishing spacing on an export ramp. Two months later, the 85 percent speed reduced by 24 percent, the total collision number reduced by 43 percent, MassSAFE (2004) found that the speed can be significantly reduced by paving the cross-sectional lines on the entire lane in the mode of gradually reducing the spacing between the two adjacent cross-sectional lines. The cross-sectional lines or the edge line paved on the lane is a form of expression of the edge rate. From the above we can see that the edge rate can be used for reducing speed. For the "unconscious" application of edge rate, three design concepts were adopted, which are the constant spacing, diminishing spacing by stage, diminishing spacing by every marking, and both tridimensional edge rate and planar edge rate were used. Yet, so far there is no relevant theory and method for practice guidance. In theory, an edge line with diminishing spacing is ideal, which can guarantee that the edge rate passing through the driver's visual field keeps increasing or is constant and tempts the driver to decelerate continuously and achieve a more effective slowdown. For the edge line with constant spacing, the edge rate passing through the driver's visual field will decrease as the speed reduces, producing a false impression that speed is decreasing, which may lead the driver to accelerate. Therefore, the slowdown effect of an edge line with constant spacing is restricted, which has been confirmed in a touch test (Whltney, 2003). In this paper, research was made on the theory and design method about edge line for speed control, with the edge rate keeping constant during the uniformly retarded motion course.

3. Design theory of edge rate density

3.1 Constant edge rate design model with comfortable deceleration rate

Design principle：The driver maintains the constant edge rate with the comfortable deceleration rate. Then if the driver does not reduce speed，the decreased spacing will result in increasing edge rate which will compel the driver to reduce speed. According to the concept of edge rate，when a vehicle arrives at the nth edge line, the time is t，then $ER = n/t$， $t = n/ER$；according to Newton's equation of motion，the following equation are deduced, which are shown as following：

$$x_n = \frac{1}{2} a t^2 + v_0 t = \frac{1}{2} a (\frac{n}{ER})^2 + v_0 \frac{n}{ER} \quad (1)$$

$$v_n = v_0 + a \frac{n}{ER} \quad (2)$$

Where, x_n is the position of the nth edge line, v_0 is the initial speed, a is a comfortable deceleration rate, v_n is the instant speed when a vehicle arrives at the n_{th} edge line.

3.2 Reasonable edge rate

Theoretically speaking, the larger the edge rate is, the larger the driver's perception speed will be. However, the human vision has the character of Critical Flicker Frequency. When the marking spacing reduces to a certain value, people will tend to regard the discontinuous line as a continuous straight line, which will lead to the underestimation of speed. So it is necessary to carry on research to the reasonable edge rate density. Using the 3DMAX, videos of a simulated car moving on the highway are made with different edge rates, then psychophysical experiments are conducted to measure the influence that edge rate has on speed perception.

(1) Index of the driver's perceived speed

The experiment takes the SSES (Shen, 2005) (Stimulation of Subjectively Equal Speed) as an index to measure the driver's perceived speed. The meaning of SSES is that the subject feels the speed of SSES with comparison stimuli is the same as the speed of standard stimuli. So if the SSES is lower than the speed of standard stimuli, the driver underestimates speed with the scenery condition of standard stimuli, and vice versa.

(2) Experiment procedure

Forced-Choice Method (Frank, 2006) is selected to measure SSES.

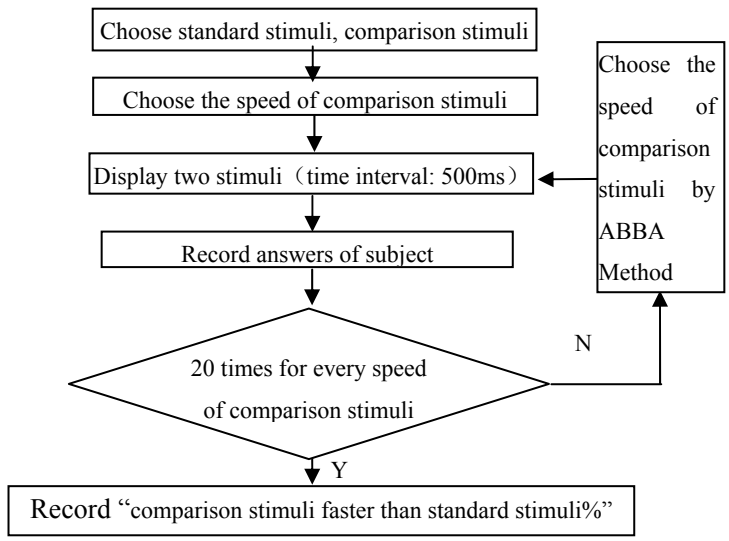

Figure 1.Process of the speed-comparison experiment

The standard stimuli are the videos with different speed (100km/h，120km/h，140 km/h，160km/h is chosen in the experiment) and different edge rates (2、4、8、16HZ is chosen in the experiment); the comparison stimuli are the videos of a standard freeway in China, with the speed range of 90km/h~220km/h; the speed step-rate is 10km/h. So the total comparison scenarios are 260 groups of Subjectively Equal Speed experiments (4×5×13). Every comparison scenario is carried out twenty times by every participant. The experiment adopts multi-level ABBA method to control deviation (Ruud, 2005). The form is shown in Table 1.

Table 1. The form of multi-level ABBA.

The display order of comparison stimuli	Front	behind	behind	Front
Speed of comparison stimuli	Increase	decrease	decrease	Increase

According to the experimental result, "faster%" was taken as a horizontal axis,

physical speed of comparison stimuli was taken was vertical axis, then speed $v50\%$ was obtained by a method of linear interpolation –then it is SSES.

(3)Experiment scenarios

The scene of the road is made according to the relevant norm of highway design in China: Two-way, four lanes of roads, the width of each lane is 3.75m, the width of the hard shoulder is 3.5m, the width of the line of demarcation of each lane is 15cm, the length of each marking is 6m, the distance during two markings is 9m, such as figure 2a. The standard scene has altered spacing λ of the line of demarcation of a lane (such as figure 2b), edge rate $ER = v / \lambda$.

Figure 2. Experiment scenario (a is standard stimuli, b is comparison stimuli).

(4) Participants

There were 8 participants (6 men and 2 women, 4 men and 1 woman among them hold the driving license.) took part in the experiments. They were naïve as to the purposes of the experiment; the eyesight or corrected eyesight of them is no less than 1.0.

(5) Results

Participants' average value of SSES is summarized as shown in Fig. 3 X-Y1（real line）. Through the single-factor analysis of variance we get $F = 6.22 > F_{0.01}(10,54)$, which indicates that edge rate has significant effect on the driver's speed perception. Considering the difference of physical speeds, we select the ratio between perceived speed and physical speed to reflect the physical speed's influence on perceived speed, as Fig. 3 X-Y2 shown (dashed line). The ratio>1 indicates the scenery condition of standard stimuli results in underestimation of speed, and vice versa.

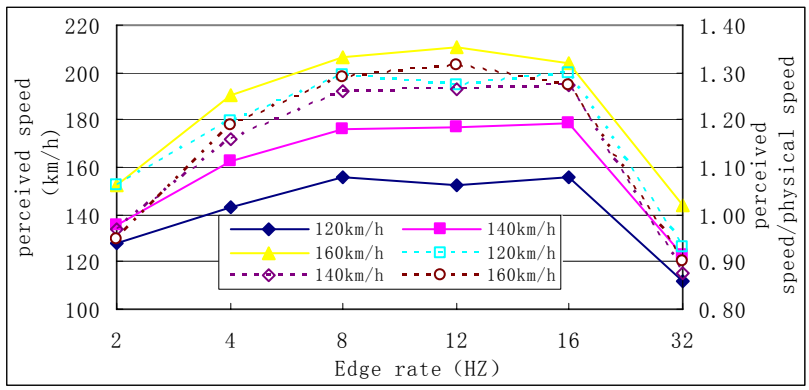

Figure 3. The relationship of SSES/physical speed, edge rate and physical speed.

(6)Discussion

Looking at Figure 3, we find that drivers exhibit 3 overall characters under 3 different speeds:

A. When the edge rate is 2HZ drivers not manifest overestimation effect, they even

underestimated speed when speeds are 140km/h and 160km/h, this phenomenon is associated with the frequency of a conventional lane demarcation line passing across an observer's visual field. The real line of conventional lane demarcation line is 6m，the spacing between adjacency lines is 9m, so the frequency that a lane demarcation line passes across an observer's visual field is $ER = v_0/(3.6\times 15) = v_0/54$，when speeds are 120km/h, 140km/h and 160km/h respectively, the edge rate of lane demarcation lines are 2.22, 2.59 and 2.96HZ respectively. In the above situation, if the edge rate is smaller than 2 then the driver will underestimate speed. As a result, when we utilize the edge rate to reduce speed, the edge rate value should be larger than the frequency of a conventional lane demarcation line passing across an observer's visual field.

B. When the edge rate is in the range of 4~16HZ, the subjects overestimate the speed and the overestimation becomes larger as the edge rate increases, however, the difference in perception speed between different drivers is subtle when the edge rate is in the range of 8~16HZ. With the ANOVA, we find: when the edge rate is 12HZ, the Standard Deviation is the smallest; the subjects are most sensitive to the perception of speed when the edge rate adopts the value 12HZ.

C. When the edge rate increases to 23HZ, drivers underestimate speed. This phenomenon is associated with the eye's Critical Flicker Frequency, when the flicker frequency increases to some degree, people will perceive flicker as an absolutely steady or successive light, but not as flicker, which is the flicker fuse phenomenon. Critical Flicker Frequency (CFF） indicates the stimuli flicker frequency when flicker fuse phenomenon appears. Different people have different CFF, but people's CFF is about 20～55HZ usually (David, 2007). When the edge rate is 32HZ, the influence of CFF will result in the driver's underestimation of speed.

According to the above analysis, 8~16HZ is the reasonable interval of the edge rate, and when we carry out the same experiments in a fog environment, the results indicate the driver's perceived speed is largest when the edge rate is 12HZ. Aiming at making the design of the edge rate can be applied into wider road environments, we select 12HZ as the reasonable value of the edge rate.

4. Case Study

4.1 Design of edge rate spacing

According to the judgment of comfortable deceleration rate by AASHTO (2001) (American Association of State Highway and Transportation Officials), we choose -3.0m/s^2 as a comfortable deceleration rate, when the initial speed is 120km/h and the governor's expectation speed is 90km/h we choose $ER = 12HZ$, the ratio between a real line and a blank of edge of the line is 9:6. According to equation(1) and (2) we can calculate the position of the edge line and the speed when the driver arrives at nth the edge line, the spacing is the different value between positions of the adjacenct edge line, as shown in Table 2.

Table 2. Spacing value.

No	Position （m）	Speed （km/h）	Spacing （m）	No	Position （m）	Speed （km/h）	Spacing （m）	No	Position （m）	Speed （km/h）	Spacing （m）
0	0.00	120.00	2.77	14	37.19	109.50	2.53	28	70.97	99.00	2.28

12	32.08	111.00	2.56	26	66.35	100.50	2.32	40	97.22	90.00	2.07
13	34.64	110.25	2.54	27	68.67	99.75	2.30				

4.2 Verification of rationality

We made an experimental video with the spacing as shown in Table 2, and then let 8 participants judge the moving mode of the vehicle. Every judgment has 3 options: uniform motion, acceleration motion, deceleration motion, and each participant carries out 10 judgments. From the experiment we find： under the design mode of keeping the edge rate constant the number of times for uniform motion, acceleration motion, and deceleration motion is 50, 17, 13, while the uniform motion and acceleration motion accounts for 83.6 percent. The result indicates the design of the edge rate gets a favorable effect.

ABSTRACT

For the dispatching decision of wagon-flows in railway terminals, the transferring wagon-flows should be primary, and the local should support the transferring. The allocation of local wagon-flows into outbound trains is drawn from the dispatching decision results of transferring wagon-flows in the terminal. A mixed-integer programming model with the minimization of stopping time for the local wagons in the terminal is built for determining dispatching decision of the local wagon-flows. Because of the timing requirements for dynamic dispatching and the characteristics of the model, an improved genetic algorithm is presented. Finally, one example is presented to validate the ideas, model and algorithm.

INTRODUCTION

The wagon-flows in a railway terminal come from the arterial railroads, and return to them. The organization of wagon-flows on the arterial railroads is global and primary. The organization of wagon-flows in the railway terminal is local and subordinate. The latter should be subject to the needs of the former, and both should cooperate with each other. During the process of the wagon-flows dispatching decision in the railway terminal, various wagon-flows are layered, which means that the transferring should be managed. The local should support the transferring.

On the basis of the above fundamental analysis and the complexity and uncertainty of wagon-flows organization, the dispatching decision of various wagon-flows in a railway terminal should be solved step by step (Yan, 2001). Three problems should be sequentially solved. The first is the dispatching decision of the transferring, and at its core is to decide assembling content and wagon-flows source of the outbound trains. On the basis of the above, the second is making further dispatching decisions on the local wagon-flows with a focus on their allocation. The third is to decide the organization plan of transship trains.

At present, the combination of the transferring and local wagon-flows is seldom considered. Furthermore, the majority is static, and dynamic dispatching decision is seldom studied (Niu, 2001; Wang, 2002). So, the dynamic dispatching

decision of the local wagon-flows in a railway terminal with IRTS is studied on the basis of the optimization result of the transferring wagon-flows dispatching decision.

The group number and quantity of the wagon-flows that are allocated into the outbound trains are drawn from the dispatching decision results of transferring wagon-flows, which are supplied by the local wagon-flows. The research is conducted for the dispatching decision of the local wagon-flows based on the condition that the loading quantity is bigger than the unloading.

MODELS

The start time for dispatch is T_s, and the end time is T_e.

In the periods of dispatching, the number of inbound trains is n, and their arriving time is T_i^{dd}. These trains are made up of the following three parts: wagon-flows that are waiting for marshalling in the switchyard at the beginning of dispatching, which can be regard as an inbound train; trains that are waiting for technical operation or being operated at the beginning; and trains that will reach the terminal in succession during the periods of dispatching.

In the periods of dispatching, the number of outbound trains is m, and their departing time is T_j^{cf}.

k ($k = 1,2,\cdots K$) is the group number of the departing wagon-flows, which is distinguished by the destination for heavy wagons and by the sorts for empty wagons.

Through the optimization of the transferring wagon-flows dispatching decision, FBM_j is drawn and denotes the quantity of the local wagons allocated into the outbound trains j.

Among the inbound train i in the period of dispatching, the quantity of the end heavy wagons is DZM_i. After unloading, these heavy wagons are loaded again and formed the number k group of wagons whose quantity is DZM_{ik}. Their operating time is t^z. The quantity of these heavy wagons allocated into the outbound train j is q_{ijk}.

Among the inbound train i in the period of dispatching, the quantity of the end empty wagons is DKM_i. After loading, the quantity of the No. k group of wagons is DKM_{ik}. Their operating time is t^k. The quantity of these heavy wagons allocated into the outbound train j is p_{ijk}.

At the beginning of dispatching, the end wagon-flows can depart after being operated for some time. According to the operating time, these end wagon-flows can be divided into L sorts (The wagon-flows which will be operated for the same time are the same sort), the quantity of every sort of the wagons is YZM_l, and the No. k group of wagons is YZM_{lk}. Their operating time is t_l^{yz}. The quantity of these wagons allocated into the outbound train j is s_{ljk}.

β_{ijk}, β'_{ijk} and β_{ljk} are Boolean variables. β_{ijk} is 1 if the local wagons from the end heavy wagons among the inbound train i that are allocated into the outbound train j accord with the assembling groups number 0 otherwise. β'_{ijk} is 1 if the wagons from the end empty wagons among the inbound train i that are allocated into the outbound train j accord with the assembling groups No, 0 otherwise. β_{ljk} is 1 if the wagons from the No. l sort that are allocated into the outbound train j accord with the assembling groups number0 otherwise.

α_{ij}, α'_{ij} and α_{lj} are Boolean variables. α_{ij} is 1 if the local wagons from the end heavy wagons among the inbound train i that are allocated into the outbound train j accord with meeting time, 0 otherwise. α'_{ij} is 1 if the wagons from the end empty wagons among the inbound train i that are allocated into the outbound train j accord with the meeting time, 0 otherwise. α_{lj} is 1 if the wagons from the l sort that are allocated into the outbound train j accord with the meeting time, 0 otherwise.

The optimization model of dynamic dispatching decision of local wagon-flows in terminal with IRTS is the following:

$$\min f = \sum_{i=1}^{n}\sum_{j=1}^{m}\sum_{k=1}^{K}\left(q_{ijk}+p_{ijk}\right)\left(T_j^{cf}-T_i^{dd}\right)+\sum_{l=1}^{L}\sum_{j=1}^{m}\sum_{k=1}^{K}s_{ljk}\left(T_j^{cf}-T_s\right)$$
$$+\sum_{i=1}^{n}\left(DZM_i+DKM_i-\sum_{j=1}^{m}\sum_{k=1}^{K}\left(q_{ijk}+p_{ijk}\right)\right)\left(T_g-T_i^{dd}\right)$$
$$+\sum_{l=1}^{L}\left[YZM_l-\sum_{j=1}^{m}\sum_{k=1}^{K}s_{ljk}\right]\left(T_g-T_s\right) \quad (1)$$

s.t.

$$q_{ijk}\le M\beta_{ijk}\ ,\ p_{ijk}\le M\beta'_{ijk}\ ,\ s_{ljk}\le M\beta_{ljk} \quad (2)$$

$$\sum_{j=1}^{m}q_{ijk}\le DZM_{ik}\ ,\ \sum_{j=1}^{m}p_{ijk}\le DKM_{ik}\ ,\ \sum_{j=1}^{m}s_{ljk}\le YZM_{lk} \quad (3)$$

$$q_{ijk}\le M\alpha_{ij} \qquad T_i^{dd}+t^z\le T_j^{cf},\ \alpha_{ij}=1,\ \text{otherwise}\ \alpha_{ij}=0$$
$$p_{ijk}\le M\alpha'_{ij} \qquad T_i^{dd}+t^k\le T_j^{cf},\ \alpha'_{ij}=1,\ \text{otherwise}\ \alpha'_{ij}=0$$
$$s_{ijk}\le M\alpha_{lj} \qquad T_s+t_l^{yz}\le T_j^{cf},\ \alpha_{lj}=1,\ \text{otherwise}\ \alpha_{lj}=0 \quad (4)$$

$$\sum_{k=1}^{K}\left(\sum_{i=1}^{n}\left(q_{ijk}+p_{ijk}\right)+\sum_{l=1}^{L}s_{ljk}\right)\le FBM_j \quad (5)$$

q_{ijk}、p_{ijk}、$s_{ljk}\ge 0$ and integer (6)

Above, $i=1,2,\cdots n$, $l=1,2,\cdots L$, $j=1,2,\cdots m$, $k=1,2,\cdots K$

of the quantity of the wagons. Expression (4) denotes the constraints of the meeting time. Expression (5) denotes the constraints of the number of every outbound train.

IMPROVED GENETIC ALGORITHMS

The dynamic dispatching decision model of local wagon-flows in railway terminals is a nonlinear large-scale combinatorial optimization one. The complexity of the problem is NP-Hard. Because of the validity of genetic algorithm in solving these problems, it is used to solve the model.

According to the characteristics of the model, the integer code is used. The variable q_{ijk} , p_{ijk} and s_{ljk} are regarded as genes that directly make up a chromosome, so the length of the chromosome is entirely decided by a combination of the number of variables q_{ijk} , p_{ijk} and s_{ljk} .

The method of penalty function is used to deal with the constraints, so that the problem is transformed into an unconstrained optimization problem. The fitness ratio of every individual is:

$$\varepsilon_l = \frac{F_{\max} - F_l}{F_{\max} - F_{\min}} \tag{7}$$

To prevent the best individual from being eliminated, a strategy is used that combines the methods of fitness ratio and the best individual preserved.

The self-adaptive genetic operators P_c and P_m are calculated by the following formulations:

$$P_c = \begin{cases} P_{c1} - \dfrac{(P_{c1} - P_{c2})(\varepsilon' - \varepsilon_{avg})}{\varepsilon_{\max} - \varepsilon_{avg}}, & \varepsilon' \geq \varepsilon_{avg} \\ P_{c1}, & \varepsilon' < \varepsilon_{avg} \end{cases}$$

$$P_m = \begin{cases} P_{m1} - \dfrac{(P_{m1} - P_{m2})(\varepsilon_{\max} - \varepsilon)}{\varepsilon_{\max} - \varepsilon_{avg}}, & \varepsilon \geq \varepsilon_{avg} \\ P_{m1}, & \varepsilon < \varepsilon_{avg} \end{cases} \tag{8}$$

In the above formulations, $\varepsilon_{\max}$ is the maximum fitness ratio, ε_{avg} is the average of every generation, ε' is much more maximum between two individuals that will be crossed. ε is the fitness ratio of mutated individuals. P_{c1} and P_{m1} are bigger crossover and mutation ratios. P_{c2} and P_{m2} are smaller.

AN ILLUSTRATIVE EXAMPLE

Various data for some terminals are shown as the following tables. For the parameters of genetic algorithm, population_size N is 80, P_{c1} is 0.8, P_{c2} is 0.3, P_{m1} is 0.08, P_{m2} is 0.01, and the maximum number of generation T is 300. The

algorithm is programmed with c++, and runs on a portable computer with T2050. Until generation 287, the best result is drawn.

CONCLUSIONS

In this paper, the dispatching decision of the local wagon-flows in the railway terminal is studied. An optimization model is constructed and a rapid algorithm is designed. An idea for innovation of our railway operation organization based on informed decision making is introduced. But the idea is validated simply in the thesis, which is far removed from the practical application. Further research should release the constraints step by step in order to fully reflect the actual conditions.

ABSTRACT

In this study, temperature of mixing under the condition of construction decreased by more than 20℃ through adding the Sasobit modifier into mixes. Rutting test, bending test at low temperature, fatigue test and dynamic modulus test were conducted to evaluate the performance and mechanical characteristics of the asphalt mixes adopting LH90# base asphalt, LH90#+3%Sasobit modified asphalt, LH90#+3%SBS+3%Sasobit modified asphalt and LH90# + 4%SBS modified asphalt respectively. It was induced that the dynamic stability and dynamic modulus increased notably and the anti-deformation ability at high temperature enhanced for the mixtures with 3%Sasobit, the crack resistance at low temperature and fatigue resistance ability decreased for the mixtures with LH90#+3%Sasobit and increased for the mixtures with SBS modified asphalt +3%Sasobit.

Key words: road engineering, warm mix asphalt, Sasobit, fatigue, dynamic modulus

1. Introduction

Hot mixed asphalt has been widely utilized in pavement construction and at the mixing and paving procedures, binders and aggregates will be heated up to 145°C-170°C and 150°C-220°C respectively, and then mixed at greater than 160°C. The mixes will maintain the temperature of 135°C-185°C, afterward be paved at over 125°C and grinded at over 120°C. Such high temperature not only speeds up asphalt aging and reduces the service life of mixes but also leads to consume a large amount of energy and increase the emissions of CO, CO2, SO2 and NOx (Pinchin Environmental Limited Air & Noise Group, 2005). This is also not in harmony with the strategy of sustainable development of China.

To solve these problems the WMA (warm mix asphalt) technology is employed that the temperature of mixing and paving are between HMA and cold mixed asphalt and performances of mixture attain the requirements of HMA. Furthermore, the decrease in emissions represents a significant cost savings (Hampton,

T., 2005). In this study for the WMA used in Liaoning, performances at high and low temperature, the anti-water ability and anti-fatigue ability were investigated.

2. Original Materials

In this study, mineral materials were produced in Xiaotun, a town of Liaoyang City in Liaoning province, and original binders were Liaohe 90# base asphalt and the modified asphalt with SBS.

The process of warm mixing was attained by an additive, in particularly, branded Sasobit®. It is a kind of hard wax, which has a molecule chain comprising 40~115 of carbon atoms. The density is 0.94 g/cm^3 at 25°C, the viscosity is 0.012Pa·s at 135℃ and the melting point is 115℃. As temperature is less than the melting point, Sasobit forms the net crystalloid structure and this may add the stability of asphalt and enhance the anti-rutting ability of mixes. It has been testified that Sasobit will distribute uniformly in asphalt by simply mixing at high temperature compared with some other modifiers, such as PP, SBS. In this study, the optimum Sasobit content in asphalt was 3 %(Zhang Y. et al., 2006).

3. Mix Design

Marshall Method was used and grade size AC-13 was adopted because WMA is mainly used in surface layer .Sieve results for mineral materials were shown in Table 1 and the grade curve was shown in Figure 1.

Table 1. Sieve results of mineral materials

Aggregate	Passing for below sieve sizes(mm)/%									
	16.0	13.2	9.5	4.75	2.36	1.18	0.6	0.3	0.15	0.075
13.2～16	100.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0
9.5～13.2	100.0	96.3	4.3	0.0	0.0	0.0	0.0	0.0	0.0	0.0

Filler	100.0	100.0	100.0	100.0	100.0	100.0	100.0	98.8	94.9	82.9
Synthetic grade	100.0	97.0	82.5	50.2	30.4	24.2	16.9	10.6	8.1	6.6
Up limit	100	100	85	68	50	38	28	20	15	8
Down limit	100	90	68	38	24	15	10	7	5	4

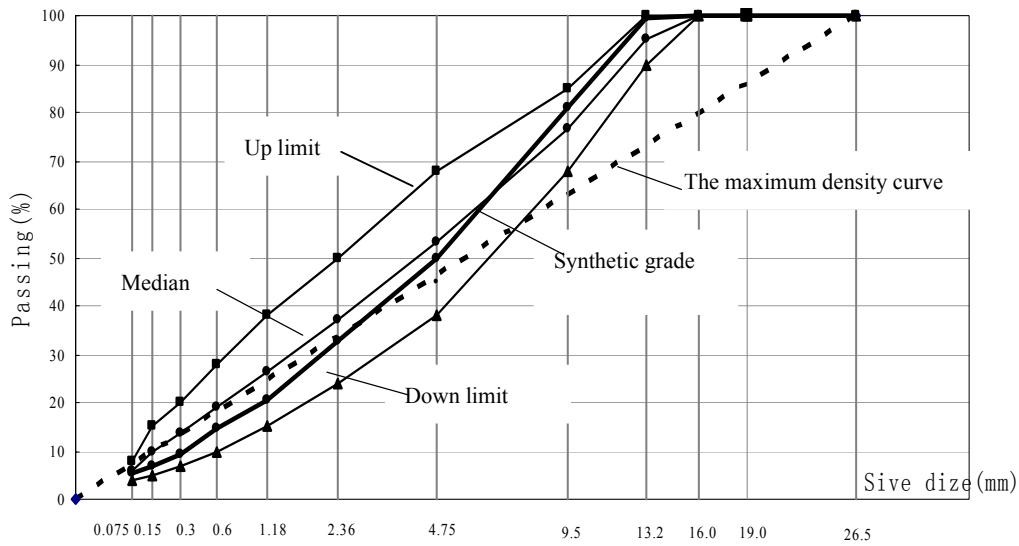

Figure 1. Grade curve for AC-13

Density results of aggregates were shown in Table 2 and the ratios of aggregates was show in Table 3.

Table 2. Density results of aggregates

size	water absorptive rate /%	Apparent specific density /γ_a	Bulk specific density /γ_b
16～19mm	0.22	2.740	2.723
13.2～16mm	0.19	2.738	2.724
9.5～13.2mm	0.31	2.737	2.714
4.75～9.5mm	0.39	2.746	2.717
2.36～4.75mm	0.55	2.750	2.709
1.18～2.36mm	0.91	2.741	2.675
0～1.18mm	0.63	2.741	2.694
Filler	—	2.826	2.826

Table 3. Aggregate ratios

Mineral materials	9.5～13.2	4.75～9.5	2.36～4.75	1.18～2.36	0～1.18	Filler
Ratio /%	20	31	18	8	17	6

Marshall Test was conducted to decide the optimum asphalt content after the optimum grade had been determined. Specimens were prepared by standard method and the density, VV, VMA, VA, VFA and flow value and Marshall Stability were measured. Finally, the optimum asphalt aggregate ratio was determined as 4.5%.

4. Performance tests of WMA

Four types of binder, i.e., LH90# base asphalt, LH90#+3%SBS, LH90#+3%SBS +3%Sasobit and LH90#+4%SBS, were used and the performance tests of mixes at high and low temperature, water stability test, anti-fatigue test and dynamic test for mixes with the four types of binder were carried out. It was shown that the mixing temperature for mixes added Sasobit in decreased by 20℃ (Yang

Yanhai et al, 2008).

4.1 Rutting test

The dynamic stability DS (time/mm) at 60℃ was used to express the performance of mixes at high temperature and the test results were shown in Table 4.

Table 4. Compare of rutting test results

Binder size		Deformation at 45min/mm	Deformation at 60min/mm	DS /(number/mm)	Average DS /(number/mm)
LH90#	1	9.764	10.010	550	440
	2	7.864	9.781	329	
LH90#+3%Sasobit	1	3.001	3.476	1326	1234
	2	3.394	3.946	1141	
LH90#+3%SBS +3%Sasobit	1	2.219	2.402	3438	3700
	2	1.696	1.855	3962	
LH90#+4%SBS	1	2.067	2.233	3795	3424
	2	2.647	2.853	3052	

It was indicated that the asphalt LH 90#+3%Sasobit contributed largely to the stability of mixes at high temperature in contrast to LH90#, in particular, the DS increased by 180% but was still very small in contrast to the SBS modified asphalt; for LH90#+3%SBS+3%Sasobit and LH90#+4%SBS, the former added 8% more than the latter to the high temperature stability. Consequently, it was concluded that Sasobit effectively increased the stability of mixes at high temperature and this influence was more remarkable for base asphalt.

4.2 Bending tests at low temperature

The bending tests at low temperature were conducted to evaluate the anti-cracking performance of WMA. The failure strain at -10℃ was used as the analytical index and the results were sketched in Figure 2 .

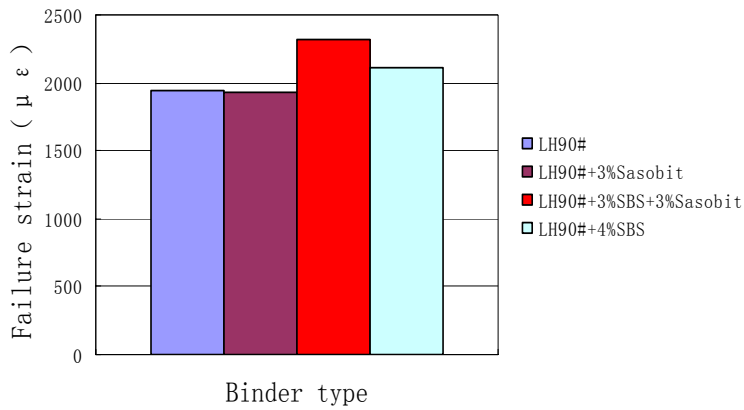

Figure 2. Failure strains for different types of binder

Observations from Figure 2 indicated that the failure strains maintained the same level for LH90#+3%SBS and LH90#; the failure strain for LH90#+3%SBS+3%Sasobit increased by 9.8% in contrast to LH90#+4%SBS. Therefore, it was concluded that Sasobit applied a positive effect on the modified asphalt but influenced little on the base asphalt on the performance of mixes at low temperature.

4.3 Water stability tests

Two indexes, strength and residual stability, were used to evaluate the water stability of WMA . The relevant test results were listed in Table 5 and Table 6.

Table 5. Indirect tensile test results

Binder type	Tension strength /MPa		TSR /%
	-	After frozen and threw	
LH90#	0.6812	0.5933	87.09
LH90#+3%Sasobit	0.7168	0.6004	83.76
LH90#+3%SBS+3%Sasobit	0.6178	0.5602	90.67
LH90#+4%SBS	0.6416	0.5879	91.63

Table 6. Marshall Test results

Binder type	Marshall stability /kN		Residual stability /%
	In water for 30min	In water for 48h	
LH90#	9.48	8.20	86.5
LH90#+3%Sasobit	11.27	9.51	84.35
LH90#+3%SBS+3%Sasobit	14.36	12.77	88.9
LH90#+4%SBS	13.8	12.64	91.6

From table 5 and table 6, it was indicated that Sasobit decreased the water stability but still met the requirements of relevant standards no matter for the base asphalt or for the modified asphalt.

4.4 Fatigue Tests

Fourth points bending beam fatigue test was used to analyze the fatigue performance of mixes under the condition of controlled strain (Graham C. et al, 2005). The test results were drawn in Figure 3.

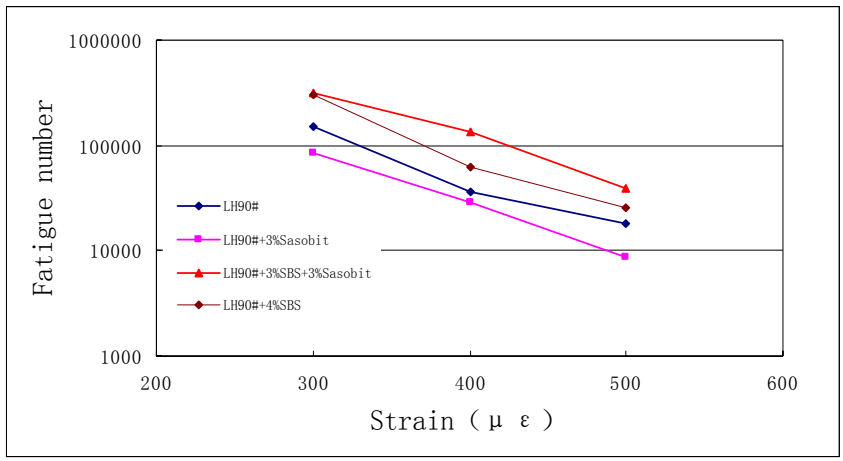

Figure 3. Relationship between strain and fatigue number for different types of binder

From figure 3, Sasobit had a positive action to the SBS modified asphalt but had a negative action to the base asphalt (LH90#) on the fatigue performance.

4.5 Dynamic modulus tests

Mixes are subjected to dynamic load in reality and the dynamic modulus of mixes has a close relationship with service performance of mixes. In the study, the size of specimens was 150mm×100mm(height×diameter), produced by coring from coarse specimens with the size of 150mm×170mm.the continuous half-sinusoidal load and no confining press was subjected, test temperature was 15℃ and 45℃, test frequencies were 0.01Hz, 0.1Hz, 0.2Hz, 0.5Hz, 1Hz, 2Hz, 5Hz, 10Hz, 20Hz, and 25Hz. The test results were shown in Figure 4 and Figure 5.

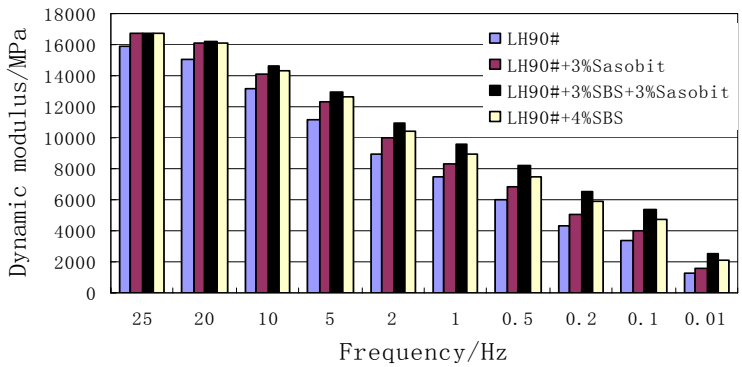

Figure 4. Dynamic modulus with frequency at 15℃

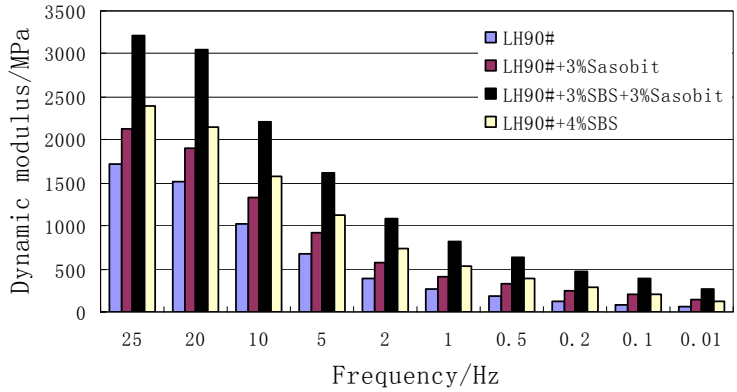

Figure 5. Dynamic modulus with frequency at 45℃

Observations from Figure 5 and Figure 6 indicated that Sasobit contributed much more to dynamic modulus of mixes at 45℃ than at 15℃. This also verified the good performance of anti-rutting of Sasobit.

5. Conclusion

As the binder was added into 3% Sasobit,

(1) the temperature of mixing decreased by 20℃,

(2) and the dynamic stability increased significantly.

(3) Sasobit had a positive effect on the SBS modified asphalt but had a negative effect on the base asphalt on the anti-cracking ability and fatigue performance of Mixes.

(4) The dynamic modulus of WMA with Sasobit advanced remarkably and this enhanced the stability of mixes at high temperature.

ABSTRACT

Periodic non-roundness of railway wheels causes various vehicle-track coupling system dynamic responses, which has a detrimental influence on both the track and vehicle components. In order to guarantee safety and stability, and to minimize costs for repair and maintenance, it is desirable to determine a range for acceptable roundness values and to detect, remove, and repair out-of-roundness wheels in time. This paper analyzes the problem of out-of-round railway wheels that are in service and creates categories for non-roundness of railway wheels. A calculation method using long wavelength to determine periodic non-roundness is proposed. In addition, a new mathematical model is put forth to numerically simulate wheel ovalization, which is called the second order periodic non-roundness of the wheel. Wheel ovalization is converted to track geometric irregularity as system excitation in the traditional way. In the numerical simulation, the dynamic model of a half railway vehicle coupled with a tangent track is employed, in which elliptical railway wheels are considered in the calculation of the wheels and the rails in rolling contact. Using this new numerical method investigates vehicle-track coupling system dynamic responses including lateral and vertical displacement of wheelsets and the vehicle, and lateral and vertical vibration acceleration of the track at different phase angles of the two side wheels of the same wheelset. These responses are compared with those of the traditional model. The numerical results show that the discipline and frequency of dynamic responses are accordant; however, the amplitude and the phase of lateral dynamic responses are different. It is concluded that the traditional track geometric irregularity excitation model does not truly simulate the effect of periodic wheel ovalization on vehicle-track coupling system dynamic behavior. The new model is more accurate and reasonable.

0 INTRODUCTION

Wheel out-of-round (OOR) phenomena have been widely found in railway traffic [1]. The non-roundness of railway wheels causes various on vehicle-track coupling system dynamic responses, which has a detrimental influence on both the track and vehicle components. Now that the range of modern high speed trains has become higher and newer building substructures have become “stiffer,” measurements show that small radius deviations have enlarged rapidly of some

typical OOR shapes.

Therefore, in order to minimize costs for repair and maintenance and to meet noise legislation, there is a large economic incentive for detecting and replacing non-round wheels promptly. Also, it is desirable to investigate the cause of OOR wheels in order to identify suitable countermeasures.

Regarding these problems, many published papers have reported relevant results including the dynamic influence and development mechanism of OOR (Ahlbeck, D. R., 1987; Barke, D. W., 2005; Jenkins, H. H., 1974; Johansson, A., 2003; Meinke, P., 1999; Meywerk, M.. 1999; Morys, B., 1997; Morys, B., 1999; Nielsen, J. C. O., 2000; and Newton, S. G., 1974). The studies by Jenkins, et al., and Newton and Clark are contributions in experimental detection and numerical simulation of OOR that have played a significant role in the early understanding of OOR wheels. A literature survey written by Nielsen, J. C., O. and Johansson, A., (2000) discussed 1) impact loads present on the Northeast Corridor high-speed track in North America (Ahlbeck and Hadden), 2) research on periodic OOR on ICE trains in Germany (Zacher and Pallgen), 3) experiments on the Gotthard line (UNRA, an international workgroup), and 4) another experimental and theoretical investigation of periodic OOR (Werner). A series of numerical methods for predicting OOR are put forward by foreign scholars. Meinke, P., and Meinke, S., adopted rigid body dynamics in combination with a wear model in predicting longer-wavelength non-roundness considering the rotor dynamics of high-speed wheelsets. Morys, et al., have investigated a rigid body model of an ICE carriage on an elastic track model. Johansson, A., and Nielsen, J.C.O., et al., have carried out full-scale experiments, analyzed causes of different types of OOR wheels, simulated the influence of OOR on wheel/rail vertical contact force and track dynamics responses, put forward wavelength-fixing mechanisms of periodic OOR, and proposed the development of periodic OOR wheel profiles.

However, mathematical models simulating periodic OOR wheels have not been generally known thus far. In this paper, a new mathematical model is put forward to numerically simulate wheel ovalization. It provides the theoretical foundation to conduct further research on the mechanisms that cause the development of periodic OOR. It also provides the foundation for determining the range of out-of-roundness which is beneficial to detect, repair, and remove non-round wheels promptly.

1 PROBLEM OF OUT-OF-ROUND RAILWAY WHEELS

Imperfections on wheel tread are basically divided into two types: defects along part of the wheel circumference, and defects around the complete wheel circumference. These are both regarded as types of wheel OOR. The former includes imperfections such as wheelflat, spalling, etc. Figure 1 shows these two common types of local OOR wheels which mainly result from braking thermal damage and rolling contact fatigue.

The latter includes wheel corrugation and wheel polygonalization. This type of OOR has a periodic radical irregularity around the wheel circumference.

The first four orders of periodic polygonalization of railway wheels are depicted in Figure 2.

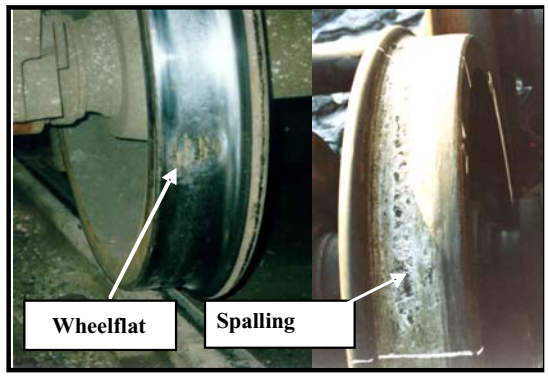

Figure 1. Non-roundness of wheelflat of railway wheels.

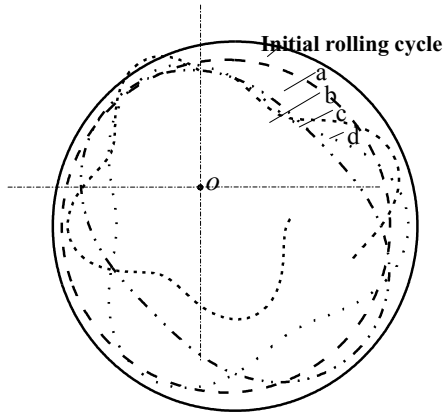

Figure 2. Periodic polygonalization and spalling.

The deformed circular **a**, **b**, **c**, and **d** are defined as firs, second. third, and fourth order polygonalization, respectively. The latter three polygonalizations are probably caused by initial small irregularity development over long-time wear, but the exact causes are not entirely understood. Periodic non-roundness includes irregularities for which it can be clearly seen that one OOR order dominates, as sketched in Figure 2, whereas it is difficult or impossible to determine a dominating OOR order when the wheel OOR falls into non-periodic non-roundness. Wheel OOR generation and development mechanisms are considerable complicated.

Periodic railway wheel OOR presents serious problems for rail transportation, of which the most severe is wheelsets hunting along the rail. It not only affects vehicle running stability and safety, but it may also result in long-wavelength rail corrugation, as depicted in Figure 3.

When wheelsets hunting run at high speed, high-frequency lateral wheel/rail contact vibrations will occur at wheelsets hunting peaks, which leads to short-wavelength rail corrugation (Jin X.S.,2006). If wheelsets hunting go on for a long time, wheel flange root and wheel tread trail will wear relatively severely, resulting in the origin of dents wear or wave wear along the wheel tread, as shown

in Figure 4. Region A and region B correspond to the contact plane of the wheel flange root and the wheel tread trail, respectively, where dents are generated. It should be emphasized that there are other reasons that dents are generated.

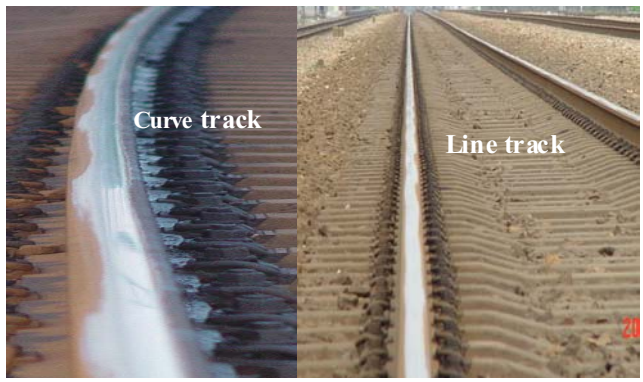

Figure 3. Rail corrugation resulting from wheelset.

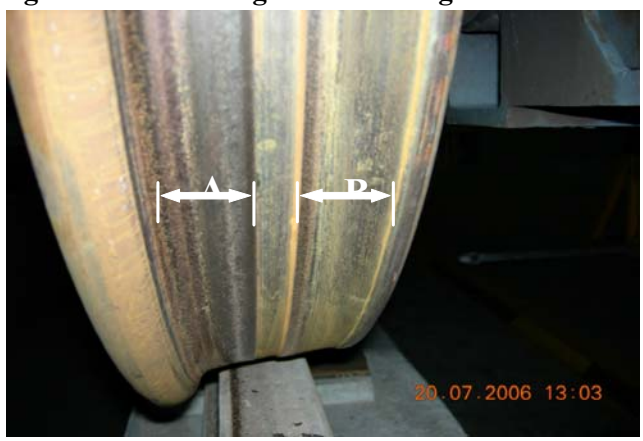

Figure 4. Dents wear of railway hunting.

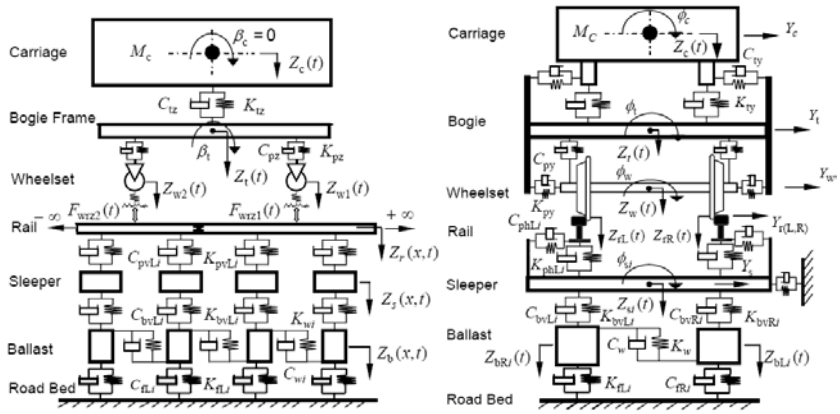
2 DYNAMIC MODEL OF VEHICLE-TRACK

In order to investigate the influence of ovalization on vehicle-track coupling system dynamic responses, a vehicle-track spatial coupling dynamics model is applied, based on the theory of Zhai. The half-passenger car considered is equipped with a bogie with two wheelsets and double suspension systems. The calculation model of the half-passenger car and the track is shown in Figure 5.

The key part of modeling vehicle-track coupling dynamics is the wheel/rail contact calculation model which has a direct influence on the precision and the speed of the computing analysis. In this paper, the normal forces of wheel-rail are calculated by a Hertzian nonlinear contact spring with a unilateral restraint; the creep forces of wheel-rail are decided by the nonlinear creep theory of Shen. The creepages and creep forces are concerned with the parameters of contact geometry of the wheel/rail. It is emphasized that the rolling circle is elliptical, and not ideal circle. Vehicle-track coupling system dynamic responses are solved with new explicit integration methods, and initial conditions and boundary conditions are referred to in the literature (Jin, X.S., 2006).



(a) Elevation (b) Side elevation

Figure 5. Coupled vehicle-track model.

3 MODEL OF WHEEL OVALIZATION

Considering the irregularity of the wheel circumference, the traditional method naturally converted it to track geometric irregularity as system excitation, where if the two side wheels of the same wheelset are in the same phase, high/low irregularity of the track is adopted to simulate the case. If the two side wheels are in different phases, tortuous irregularity of track is applied to simulate the case. In this paper, a new mathematical model is put forth to numerically simulate wheel ovalization, in which instant rolling radii of wheels are considered as a function of time. According to this method, the parameters of contact geometry of the wheel/rail are calculated. The instant rolling radii can be expressed as

$$r(t)=\frac{ab}{\sqrt{a^2\sin^2\theta(t)+b^2\cos^2\theta(t)}} \qquad (1)$$

where, a, b is the length of the semi-major, semi-minor axis of ovality, respectively, $\theta(t)$ is the angle between the initial contact radius of the elliptical railway wheel and the horizontal axis at t time, as depicted in Figure 6, and calculated from Equation (2)

$$\theta(t)=\theta(t-1)+\omega\Delta t \qquad (2)$$

where, ω is the rotational velocity of the wheel, and Δt is the time step length of integration. The corresponding program has been compiled, which modifies the elliptical wheel initial nominal contact radius at each time step, and the parameters of the contact geometry of the wheel/rail are obtained.

The model of the second order periodic OOR wheel is described in Equations (1) and (2) and illustrated in Figure 6. The two side wheels of the same wheelset are frequently asymmetrical. In this paper, we consider the general condition, and assume that the two side wheels of the same wheelset are asymmetrical, that is, there is phase angle difference Φ, as shown in Figure 7. The difference between the length of the semi-major axis and the semi-minor axis is defined as the ovalization extent.

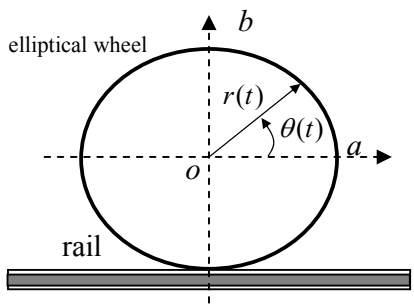


Figure 6. Model of railway wheel.

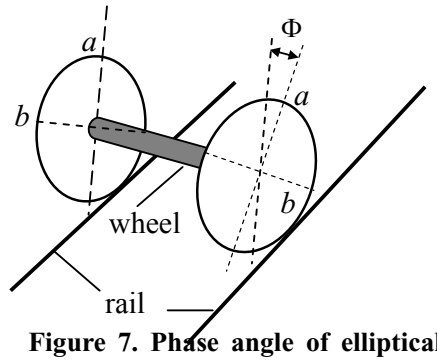

Figure 7. Phase angle of elliptical railway wheels.

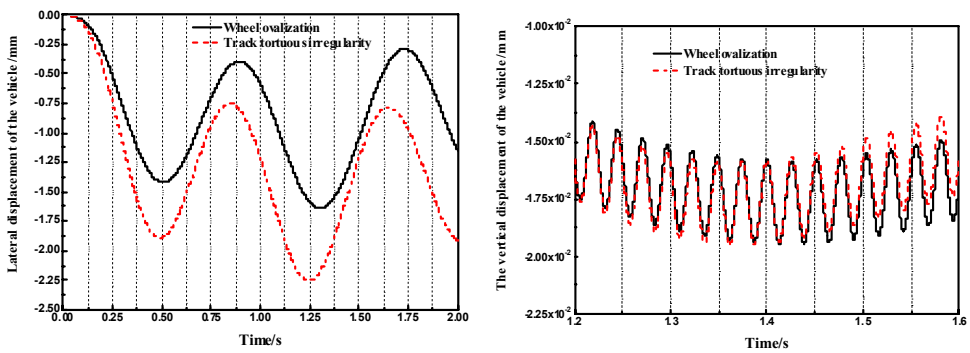
4 NUMERICAL RESULTS AND DISCUSSION

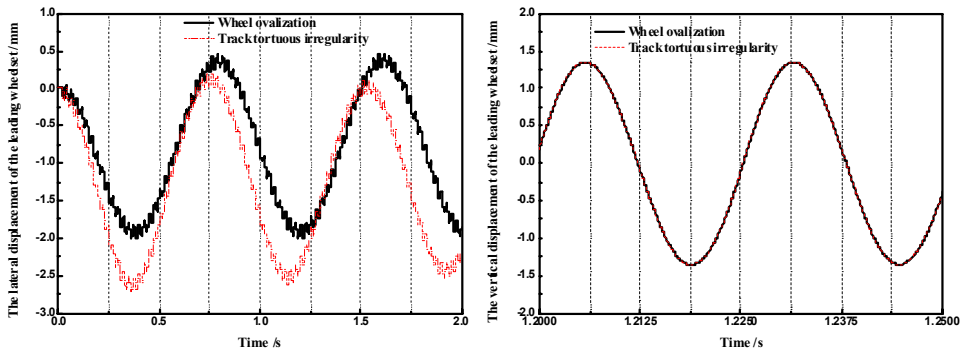
A certain China high speed railway vehicle is used and the main parameters are as follows: LMa wheel tread, wheel radius 457.5mm, 60kg/m rail. Values of other parameters of the vehicle and the track are listed in Appendix E and attached list 7 of literature (Zhai, W.M., 2002). The vehicle runs on a tangent track without any excitement. The following two cases are calculated: Case 1 corresponds to the condition that only the two side wheels of the leading wheelset are in different phases, and Case 2 corresponds to the condition that the two side wheels of the trailing wheelset are also in different phases. The phase angle difference Φ of the same wheelset changes from $\pi/12$ to π.

For brevity, only parts of the results of the two cases are plotted. When the vehicle speed is 200km/h, the phase angle difference of the two side wheels of the same wheelset is $\pi/12$ and the ovalization extent is 1mm. The numerical results of the new and traditional models are produced. Figures 8(a) and 8(b) show the vehicle lateral and vertical displacement, respectively. Figures 9(a) and 9(b) show the leading wheelset lateral and vertical displacement, respectively. Figures 10(a) and 10(b) show the left track lateral and vertical vibration acceleration of the leading wheelset, respectively.



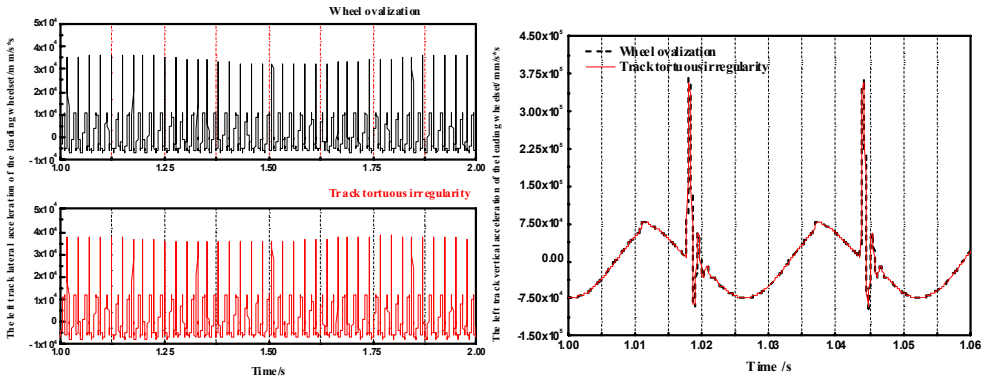
(a) Vehicle lateral displacement (b) Vehicle vertical displacement

Figure 8. Vehicle lateral and vertical displacement.



(a) Wheelset lateral displacement (b) Wheelset vertical displacement

Figure 9. Leading wheelset lateral and vertical displacement.



(a) Track lateral vibration acceleration (b) Track vertical vibration acceleration

Figure 10. Track lateral and vertical vibration acceleration.

Observing Figure 9(a), we easily find an interesting phenomenon in that the current case wheel ovalization induces in larger wavelength equal amplitude lateral hunting movement of wheelsets, whose oscillation frequency is 1.2Hz; and wavelength is about 46m. The high-frequency equal amplitude periodic vibration shown in the figure is relevant to the second order periodic non-roundness of wheels directly, its oscillation cycle depends on ovalization wavelength and high-frequency vibration frequency is about 38.7Hz. Results of other phase differences considered also indicate that different degree hunting movements of wheels which deviate from the track center appear. Therefore, at some special conditions, wheel ovalization will cause long-wavelength lateral hunting of wheelsets. Further research on the situation of wheelset hunting is required.

5 CONCLUSIONS AND PROSPECT

The calculation method of long wavelength periodic non-roundness is proposed, and a new mathematical model is put forth to numerically simulate

wheel ovalization. Vehicle-track coupling system dynamic responses are investigated, including lateral and vertical displacement of the vehicle and wheelsets, lateral and vertical vibration acceleration of the track at different phase angles of the two side wheels of the same wheelset. These are compared with that of the traditional track geometric irregularity model. The numerical results show that the discipline and frequency of dynamic responses are accordant; however, amplitude and phase of the lateral dynamic responses are different. It is concluded that the traditional track geometric irregularity excitation model does not truly simulate the effect of periodic wheel ovalization on vehicle-track coupling system dynamic behavior. The new model is more accurate and reasonable.

High speed railway wheel ovalization causes various vehicle-track coupling system dynamic responses including lateral hunting, which aggravates the running character, and even decreases the service time of both the track and vehicle components. Therefore, further investigation need to be done to explore the formation and development mechanisms of OOR in order to instruct railway traffic on-site detecting and repairing.

From Time Based Speed Series to Behavior Sequence: The Transformations and Applications of VTDR Data

Zhenfeng He and Zhenzhi Huang

School of Mathematics & Computer Science, Fuzhou University, Fuzhou, Fujian, China, 350108, email: hezhenfeng@yahoo.com.cn, zhenzhi.huang@gmail.com

ABSTRACT

Vehicle Traveling Data Recorders (VTDRs) have been universally installed on fixed-route intercity buses, and the data collected is growing rapidly. It becomes urgent to utilize VTDR data to give drivers and managers some helpful feedbacks. Two novel representations of VTDR data: Location Based Speed Series (LBSS) and Behavior Sequence (BS) are presented for the analysis of these data. The data gathered directly from VTDR is Time Based Speed Series (TBSS), which defines the speeds at different time points. The fixed intercity route makes it feasible to covert a TBSS to an LBSS, which defines the speeds at different locations. BS is then proposed to extract the dynamic information, such as the speed change pattern at a segment of an LBSS. For converting an LBSS to a BS, a Background Based Symbolization (BBS) approach is presented. Based on the background of an average speed curve, five typical behavior patterns are defined. During the BBS process, each length-fixed segment of an LBSS is labeled as one of the five patterns, and the consequent pattern sequence is a BS. A simple example is presented to illustrate the transformations. The applications of LBSS and BS are illustrated with the analysis of FuQuan Highway data. The LBSS is effective in the evaluation of the driving behavior at Xiangsiling Tunnel. And BS is more suitable in mining sequential patterns than those symbolized by Symbolic Aggregate Approximation (SAX).

INTRODUCTION

Vehicle Traveling Data Recorders (VTDRs), also known as In Vehicle Data Recorders (IVDRs), are onboard devices to record many valuable states of vehicles, such as speed, brake, lights etc. (As speed is the most important state parameter, we will only discuss the transformation of speed series.) There have been some approaches to track the use of VTDR, its positive effects are proved (Toledo 2008), and various types of feedbacks are even expected by the drivers (Roetting 2003).

For the past years, China has been promoting the installment of VTDR on passenger vehicles. Now most intercity passenger vehicles have been equipped with VTDR, and the data collected are growing rapidly. It becomes urgent to analyze the data to give helpful feedbacks. Yet, we haven't seen any report focused on the analysis of VTDR data gathered from passenger vehicles. Here we'll explore the nature of passenger vehicles' running records, and transform them into two new representations: the Location Based Speed Series (LBSS) and Behavior Sequence

(BS). The transformation process will be further illustrated with a simple example. And the usage of these representations will be also provided.

THE VTDR DATA FROM PASSENGER VEHICLE

Scheduled passenger service is important for China's intercity bus transportation system, many scheduled buses run between each pair of neighboring cities each day. For example, there are about 70 passenger vehicles run from Fuzhou to Quanzhou over regular routes every day (most of them go through the 161 kilometers long FuQuan Highway). The data used here are all on FuQuan Highway (from Fuzhou to Quanzhou), collected by Fujian Minyun Transportation Company.

VTDR are not required to fit GPS (Global Position System) by China's National Standard GB/T19056-2003, and most of the VTDR equipped by Minyun are not with GPS. So there's no location info in the data gathered. Yet, the extraction of location information is feasible. As the route of a passenger vehicle is usually predefined, the location of a vehicle can be inferred based upon the distance it has run: if a vehicle has run about 26.5km from Fuzhou Highway Entrance, it would be at Xiangsiling Tunnel (a 400m long tunnel in the highway); if it has run 161km, it should be near the Quanzhou Highway Exit.

The intrinsic location information in fixed-route vehicle data, such as passenger vehicles, enables the comparison between different driving processes without the interference of changeable road condition. We can make a road as "background", and the comparison is only between the driving behaviors under the same "background". That is, compare driving sequences based upon the location. For example, we will compare the behavior of different driving processes at a specified high crash risk location, such as the Xiangsiling Tunnel. And we will not try to directly compare the driving behavior at a specified time point, such as 20 minutes after driving on Fuquan Highway. Since the vehicle would be at different locations after 20 minutes of driving, where the road conditions could be quite different, which would complicate the comparison of driving behaviors.

THE REPRESENTATIONS OF THE DATA

Time Based Speed Series (TBSS). The data gathered by VTDR is a TBSS, $V_T=(v_1, v_2, \ldots v_n)$ where v_i is the speed at time point t_i, and $t_1<t_2<\ldots<t_n$. Many VTDR record speed at a fixed interval, so we can suppose $c=t_{i+1}-t_i$, where c is a constant.

Location Based Speed Series. An LBSS $V_L=(v_1, v_2, \ldots v_n)$, Where v_i is the speed at location l_i. The location can be defined as the distance from the entrance of the Highway, so they are comparable; suppose $l_1<l_2<\ldots<l_n$. To simplify the data analysis task, the interval between consecutive locations is set to a constant $l=l_{i+1}-l_i$.

For a TBSS, it is easy to compute the location L_k at time point t_k:

$$L_k = \int_0^{t_k} v dt \approx \sum_{i=1}^{k} v_i * c \qquad (1)$$

In Equation 1, the interval between neighboring time points is c.

So we get Crude LBSS (CLBSS) $V_{CL}=(v_1, v_2, \ldots v_n)$, where v_i is the speed at location L_i. For a CLBSS, the distance between neighboring locations L_{i-1} and L_i is $\Delta_i = v_i * c$. When v_i changes, Δ_i will change accordingly. To convert a CLBSS to an LBSS, an interpolation process is necessary.

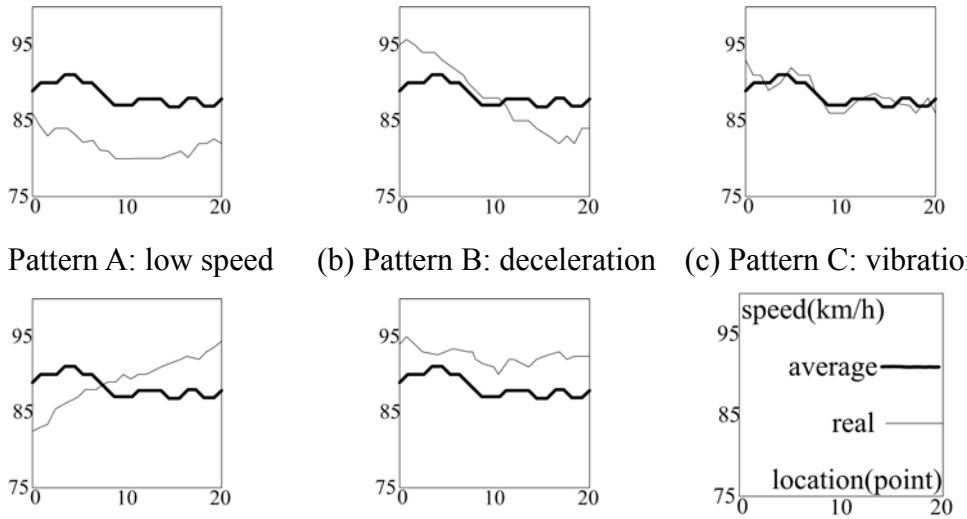
Behavior Sequence. LBSS defines the speeds at different locations, but it does not consider the relations between neighboring locations. So LBSS only provides a static view of a driving process.

From a dynamic point of view, a driving process is actually a sequence of speed-changes. Different driving behaviors may result in the same speed-change, and we cannot decide driving behaviors only based upon the speed-change. But there are close relationships between driving behavior and speed-change. Therefore we can suppose a speed-change signifies a driving behavior, and a speed-change sequence becomes a behavior sequence.

There are unlimited forms of the speed-change. Yet, to enable the driving behavior analysis, the number of behavior forms should be limited. Only five typical speed change patterns are considered. They are presented in Figure 1: the bold line is the average speed at each location, and the thin line is the real speed for the driving process in analysis. Compared with the average speed curve, a vehicle can be:

(1) Low Speed (Run at a speed that is less than the average) (Pattern A, Figure 1a);
(2) Deceleration (Pattern B, Figure 1b: the speed curve crosses the average speed curve, and the speed is bigger than the average speed at the left of the cross-point, lower than the average speed at the right of the cross-point);
(3) Vibrate around the average speed (Pattern C, Figure 1c);
(4) Acceleration (Pattern D, Figure 1d: contrary to pattern B),
(5) High speed (Patter E: which is contrary to pattern a, Figure 1e).

A small sliding window is usually employed to segment a time series; we can divide an LBSS into a set of subsequences by this approach. Based upon the five patterns presented, we can decide the behavior pattern of each subsequence one by one. So the Behavior Sequence could be extracted. As the average speed curve plays a background role in the symbolization process, the process is named as a Background Based Symbolization (BBS) process.



(a) Pattern A: low speed (b) Pattern B: deceleration (c) Pattern C: vibration

(d) Pattern D: acceleration (e) Pattern E: high speed (f) Notation

Figure 1. Five patterns of speed change comparing to the average speed curve

THE TRANSFORMATION OF SPEED SERIES

We will illustrate the transformation process with a short time series V_T=(0,3,5,7,10,11,13,15,16,18,19,20,19,17,15,12,9,5,3,2,0) as shown in Figure 2. The length of V_T is 21. It is recorded every one second, and the unit of speed is m/s (meter per second). During the short period, the vehicle has run 219 meters.

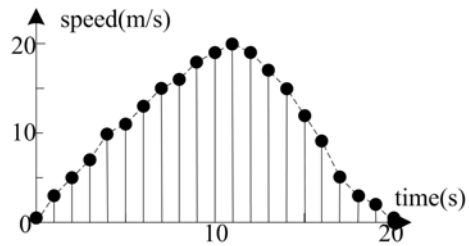


Figure 2. The original TBSS

If the location at the beginning is 0, the location at other time points can be computed by formula (1). So V_T is converted to a CLBSS (Figure 3).

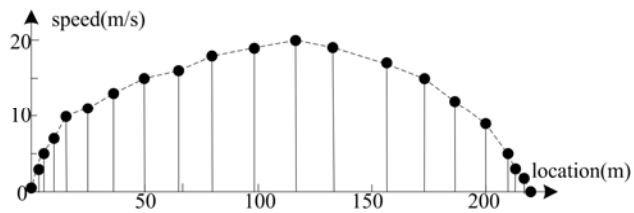

Figure 3. CLBSS (an LBSS directly converted from TBSS)

The next step is the interpolation process. Suppose the target LBSS defines speed for every 10 meters, then we should compute the speeds at location 0, 10, 20, 30, …, 200, 210, 220. And the CLBSS in figure 3 becomes an LBSS (Figure 4).

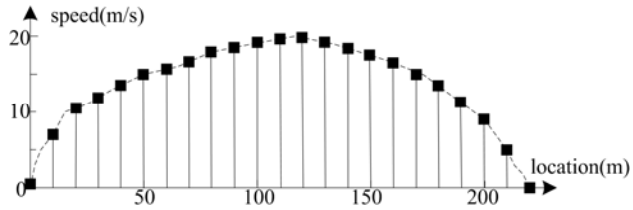

Figure 4. LBSS after interpolation

Now, considering the background information (Figure 5), the background is the average speed for each location, which is represented by a solid line.

The behavior pattern is the speed change pattern in a small location window. Suppose the length of the window is 40 meters, using the patterns defined in Figure 1, we can get the corresponding BS as: EBADBA.

It should be stressed that the pattern is a "relative pattern". The speed change should be studied with the background information (the average speed curve). For example, in the second window (location 40-79m), the speed is actually increasing. But compared with the average speed curve, the speed has changed from "above average" to "below average". So this is a "relative deceleration" process, and the speed-change pattern should be Pattern B. As the road condition can influence a driver's behavior significantly, absolute speed is relatively meaningless. On the other hand, average speed summarizes the general behavior of many driving processes; the comparison with average speed curve would be more meaningful.

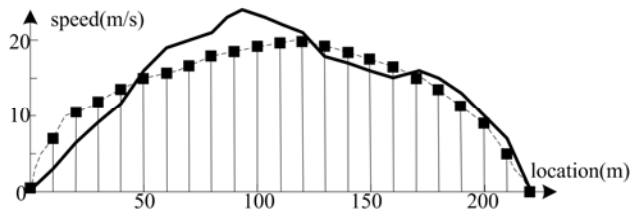

Figure 5. LBSS with the background info

APPLICATIONS OF THE TWO REPRESENTATIONS

Location based behavior analysis. As an LBSS specifies the speed based on location, it enables us to focus our attention on some sensitive locations. Based upon a Box-and Whisker Diagram (Huang 2008) that displays the speed at different locations near the Xiangsiling Tunnel (from Fuzhou to Quanzhou), it is obvious that the speed is more dispersive just before entering the tunnel, where outliers are crowded. This suggests that this area is a relatively high-risk area. The conclusion conforms to actual observation: two accidents involve five vehicles just happened on this range on August 8th, 2008, among which two of the vehicles are passenger vehicles. Clearly, the location based behavior analysis could provide the needed feedbacks for road designers and transportation risk analyzers. There are other interesting usages for LBSS, such as the extraction of general patterns (Huang 2008).

Behavior pattern analysis. Base upon the BS, it is easy to mine sequential patterns. As sequential patterns may present the connections between consequent behaviors (Hand 2001), it can help us to understand a driver's behavior at higher level, and to do some sort of short-term predications.

To evaluate the BS, we shall compare it with the sequence symbolized by SAX(Symbolic Aggregate Approximation) (Lin 2003) The symbolization process of SAX does not consider the background information. Table 1 lists the top 8 sequential patterns mined from two types of sequences (ordered by support rate).

Table 1. The top 8 sequential patterns mined based on BS or SAX

Order	Based on BBS	Based on SAX
1	<3,5,5>	<3,3>
2	<5,5,5,5>	<3,4>
3	<3,3,3>	<5,5>
4	<5,3,1>	<4,3>
5	<1,1,1,3>	<1,1>
6	<3,1,1,1>	<3,2>
7	<5,5,3>	<4,4,4>
8	<1,1,1,1,1,1,1>	<2,3>

For SAX approach, the symbols 1-5 are the levels of speed, with 1 the lowest and 5 the highest speed (breakpoints are based on Gauss distribution) (Lin 2003). For BBS approach, the symbols 1-5 are patterns presented in Figure 1. Clearly, the patterns mined from the sequence by SAX symbolization approach are very short (mostly comprise of 2 items only) and not interesting (usually represent a simple speed change). While the patterns mined from the BS are relatively longer and interesting: <5,3,1> is a deceleration process, a very long sequence <1,1,1,1,1,1,1> suggests that a driver is more likely to keep at a relatively lower speed for a comparatively longer distance.

CONCLUSION

We have presented the different representations for fixed-route vehicle data collected from VTDRs. We can extract the speed curve based upon the location-change pattern to get an LBSS; and a BS can be got by a background based symbolization approach. Both the LBSS and the BS are proved to be effective. A different representation may provide us with a more informative view on a given dataset. In the future, we would try other representations of VTDR for mining the passenger vehicle data efficiently and precisely. Upon the representations presented, we would further explore other usages.

ABSTRACT

Mixed traffic is a significant feature of Chinese traffic flow on urban street network, which is also a major cause of traffic congestion and frequent traffic accidents. In sections where motor vehicles and non-motor vehicles moving in same direction without separation, they would interfere with each other. This interference has serious impact on the capacity of sections, and simultaneously increases the accident risk. This paper analyzed the data through the method of probability theory and statistics, and got the result that "the number of non-motor vehicles and the lateral distant between motor vehicles and non-motor vehicles are both interference factors aroused by non-motor vehicles". Finally, non-motor vehicles' disturbance model to the motor vehicles were set up based on data analysis and proved to be correctly. The research provided a theoretical and basis to the traffic safety management under the mixed traffic environment.

KEYWORDS: Mixed traffic flow; Traffic safety; Road condition; Urban transport

INTRODUCTION

As a big country with large number of non-motor vehicles, the mixed traffic is the most important reason of the traffic congestion in the major cities of our country, and the accidents caused by mixed traffic showed year-on-year growth trend (Study on Road Traffic Delay Caused by Non-Motorized Vehicle, 2004).. Urban transport in China has a significant more number of bicycles than other developed countries, and there is no isolation or discrete barrier between motor vehicle and non-motor vehicle lanes in sections. Due to the different characteristics in their respective share of road space and operating speed between motor vehicle and non-motor vehicle, non-motor vehicles affect the speed of motor vehicles a lot, which caused serious traffic congestion even blockage and led to China's general low urban road vehicle operating speed and relatively high traffic accident rate. Therefore, the operation and safety research under the conditions of mixed traffic sections has a practical significance.

NON-MOTOR VEHICLE'S INFLUENCE OF MOTOR VEHICLE ANALYSIS IN SECTIONS

In roadway sections, the interference from non-motor vehicle to motor vehicle is mainly the lateral interference. The degree of interference depends on two factors: the number of non-motor vehicles in the lateral, and the lateral distance between them (IMPBMVT, 2006). Based on the video capturing of the traffic flow data collection methods, these two factors were utilized to carry out quantitative analysis of the impact.

In support of this thesis research, Jiaodadonglu Road in Haidian District was selected for data collection. To obtain representative data, data were collected during the afternoon peak hours (17:30-18:30) of the two business days (April 7, 2008 and April 21, 2008, which is both Monday). The chosen section is on a two-way road, which has mixed traffic. There are two motor vehicles lanes with the width of 3.5m and one non-motor vehicles lane with the width of 3m. Observation points are located at both ends of the bridge across the street, as shown in Figure 1. The labeled size in Figure 1 is the distance got in data acquisition.

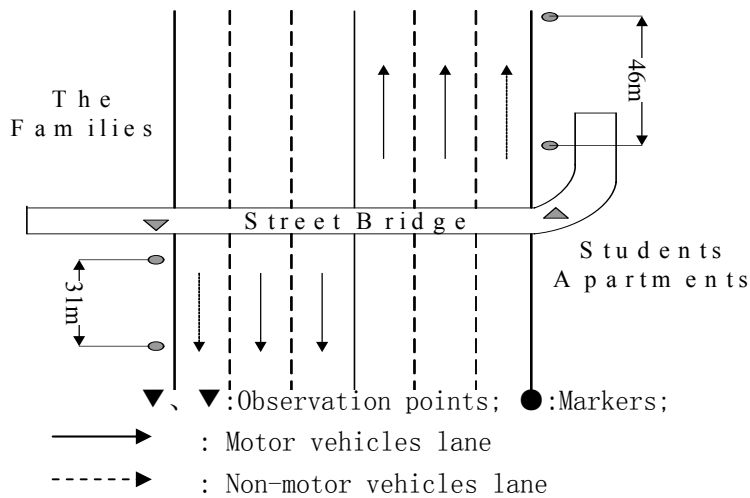

Figure 1. Section schematic of Jiaodadonglu Road

Upon completion of filming, the video was firstly transferred into computer, and then the samples were processed. 368 groups of samples were collected; the data items include motor vehicle speed, the number of non-motor vehicles in lateral side of motor vehicles and the distance between them. Through the data collected the following two relationships were obtained:

(1) Relationship between the speed of motor vehicles and the number of non-motor vehicles in lateral side

The distribution of the speed of motor vehicle and the number of non-motor vehicles in lateral side is as shown in Figure 2. From the figure, one can generally see that with the number of non-motor vehicles increasing, the motor vehicle speed has a

downward trend. These two can consider having a linear relationship, that is, with the increase in the number of non-motor vehicles, motor vehicle speeds linearly decline.

(2) Relationship between the speed of motor vehicles and the lateral distance with the non-motor vehicles

The relationship between the speed of motor vehicles and the lateral distance with the non-motor vehicles is shown in Figure 3. This relationship can also be regarded as a similar linear relationship, that is, the speed of motor vehicles increase as the lateral distance between them raised.

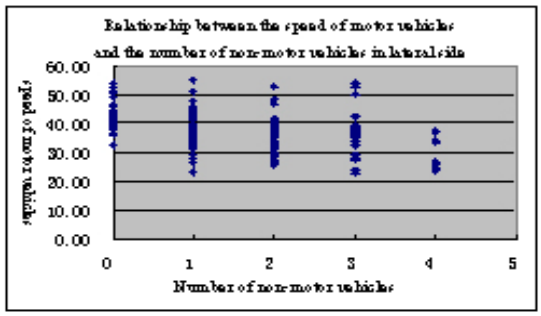

Figure 2. Relationship between the speed of motor vehicles and the number of non-motor vehicles in lateral side

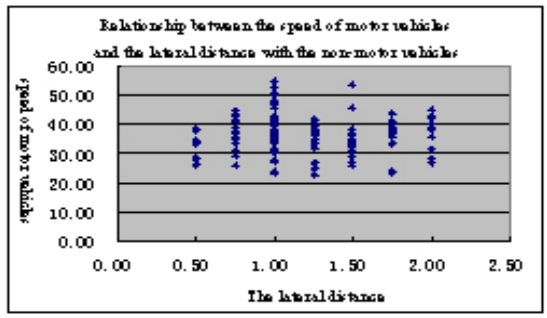

Figure 3. Relationship between the speed of motor vehicles and the lateral distance with the non-motor vehicle

NON-MOTOR VEHICLE INTERFERENCE MODELS

From the above Scatter, the speed of motor vehicles, y, the number of non-machine, x1, and the vehicle lateral distance, x2, are similar to a linear relationship. First, we assume that y and the two independent variables x1, x2 has a linear correlation, establish a dual linear regression equation, and then return to test whether the effect of the equation was significant (Probability statistics and random process,2000)According to data collected, then:

$$y = b_0 + b_1 x_{i1} + b_2 x_{i2} + \zeta_i$$

From a representative data including 25 groups, the least squares estimation of

$$28.96b_1 + 0.39b_2 = -104.3$$
$$0.39b_1 + 4.44b_2 = 5.13$$

b0, b1, b2 can be obtained. The following are the two equations derived:

$$b_1 = -3.62, \qquad b_2 = 1.47 \qquad b_0 = \bar{y} - b_1\bar{x}_1 - b_2\bar{x}_2 = 45.48$$

Solution of this equation is:

Therefore, the obtained regression equation was

$$\hat{y} = 45.48 - 3.62x_1 + 1.47x_2$$

The b1， b2 in equation both has a clear meaning. For b1, the speed of motor vehicles will reduce 3.62 km / h for each non-motor vehicle.; For b2 = 1.47, it can be expressed as that the lateral distance between non-motor vehicles and motor vehicles for each additional 1m, motor vehicles will increase the speed of 1.47 km / h.

The equation previous described is under the assumption that there is a linear relationship among them, it is necessary to carry out the linear regression significant testing. The linear regression test of significance tests whether regression coefficients b1， b2 are all zero. If they are all zero, there is no significant linear relationship. If not all zero values, there is a significant linear relationship. To this end, the proposed null hypothesis is:

H_0： $b_1=b_2=0$

Here use the F statistic to test the hypothesis H0, the expression for

$$F=\frac{S_R/m}{S_S/(n-m-1)}, where \mathrm{S_R},\ \ S_S$$

$$S_T=\sum y_i^2-25\bar{y}^2=875.29, S_R=b_1l_{1y}+b_2l_{2y}=385.11$$

$$S_\tau=S_T-S_R=875.29-385.11=490.10$$

Thus, the observed value of the test F statistic is

$$F=\frac{S_R/2}{S_\varepsilon/(25-2-1)}=8.64$$

Given significant level α = 0.01, from the F distribution table has,

$$F_{1-\alpha}(m,n-m-1)=F_{1-0.01}(2,22)=5.72$$

Because of F = 8.64> 5.72 = F1-0.01 (2, 22), we should reject H0. Therefore, the number of non-motorized vehicles and the lateral distance has significant linear affect at the speed of the vehicle at the level of α = 0.01. Thus, these two factors have significant effect on the speed of motor vehicles.

IMPROVEMENTS

In light of the fact that the situation of mixed traffic will exist in our country for a long time, the paper integrates the safety research and analysis above under the conditions of mixed sections of road, and presents the following countermeasures:

(1) Separate the motor vehicles from non-motor vehicles (Urban Transport of China, 2007). On urban roads of China, the mixed traffic of motor vehicles and non-motor vehicles occurred in the absence of physical isolation on the road. Motor vehicles and non-motor vehicles travel in the same lane when they travel in the same direction. The speed difference between them and the unstable of non-motor vehicles are the two major reasons of the interference to motor vehicles. Setting up physical isolation between motor vehicles and non-motor vehicles, that is, to separate non-motor vehicles from the space, can fundamentally solve the problem of the mixed

traffic conflict on road that has no physical isolation. It will fundamentally solve the security issues that brought by mixed traffic.

(2) Plan a reasonable road network for non-motor vehicles. According to the existing road conditions and traffic policy, build non-motor vehicles path at different levels with different functions in the city, and form a non-motor vehicles path system. This can not only achieve motor vehicle and non-motor vehicle traffic diversion, provide safe, comfortable and efficient environment for non-motor vehicles, but also reduce interference to motor vehicles in section and improve the operating efficiency of motor vehicles at the same time.

(3) Set up crosswalks pavement marking and traffic islands. If pedestrians and non-motor vehicles randomly cross the street, there must have conflict with motor vehicles on the road, which endanger the safety of non-motor vehicles at the same time will also affect the normal traffic. Cross the street at a location where has prevailing crosswalk line or traffic island is much safer than there is none. The better the traffic management facilities across the street, the less the danger is. Crosswalks line and traffic islands installed to protect the safety and control traffic order can have a significant impact.

(4) Improve the roadway lighting (Road Safety, 2004). When vehicles traveling on the road, in the context of the background surface brightness, the first thing that a driver sees is the outline of the object, and then they decide whether it is necessary to take appropriate measures. Therefore, it is necessary to make the road and obstructions on road have sufficient brightness to ensure traffic safety. Rational arrangement of lighting can not only make vehicle drivers see the front of the road and the obstacles, but also be beneficial to the removal of the side to see whether there is any non-motorized traffic. Therefore, it could prevent collisions caused by drivers who failed to see the non-motor vehicle.

(5) Limit the speed of motor vehicles. When the volumes of non-motor vehicles lanes are high, they often overflow into adjacent motor vehicles lane. as the non-motor vehicles form of arbitrariness, as well as the different speed between motor vehicles and the non-motor vehicles, rear-end conflict can easily occur between them. For slowdown conditions, the greater the initial velocity, the longer brake stopping distance, the greater the possibility of rear-end collision. Non-motor vehicles always inserted into the motor vehicles when there is a gap. The size of the gap depends on the rider. If he chooses a smaller gap insertion, then the brake stopping distance of the motor vehicle behind will not be enough, causing an accident. Non-motor vehicles traffic during peak hours is high, which makes management difficult. Therefore, limiting motor vehicle speed is an effective means of reducing the rate of conflict between them.

(6) Enhance the traffic laws and safety education (Urban Roads Bridges & Flood Control, 2004). An important element of accident prevention is comprehensively improving the quality of the traffic safety of participants. Accident prevention should

start with the nursery for the safety of the system on education. During the different levels of education before high school, students should mandatorily receive traffic safety education, which can help them establish the concept of traffic law, road safety, traffic safety, good ethnics, and the ability to obey traffic law from the beginning. Traffic safety education targeting different groups from all levels of society should adopt different approaches and methods.

CONCLUSIONS

For the serious situation of mixed traffic in China, the paper investigated a sample roadway segment and built a regression model of non-motor vehicle interfering with motor vehicles with regression analysis parameters. The paper obtained the following conclusions: In a section of mixed traffic between non-motor vehicle and motor vehicle, the number of the non-vehicles and the spacing between them not only have a significant influence on speed, but also lead to the road traffic safety factors which should not be ignored. For these two factors, paper proposed a series of traffic management countermeasures to improve traffic operation and safety, which have certain theoretical significance and practical application value.

ABSTRACT

Road frictional coefficient is a key factor to calculate the vehicle pre-impact speed in traffic accident analysis. Statistical data show that no-sideslip single side skid cases often occur in traffic accident. The traditional method adopts simple vehicle two-dimensional dynamic model to compute the equivalent frictional coefficient. This model can not accurately reflect vehicle dynamic state. This paper established a three-dimensional dynamic model of the vehicle driving, derived the no-sideslip single side skid equivalent frictional coefficient formula according to vehicle real conditions, and presented the ultimate expression of no-sideslip single side skid equivalent frictional coefficient. Experiment results show that the above analysis is rational and accurate.

INTRODUCTION

Road frictional coefficient is a key factor to calculate the vehicle driving speed. It relates to some factors such as tire pressure, ground state, and vehicle driving speed and so on (Bradley, et.al. 2004). In some traffic accidents, when a vehicle brakes non-synchronically at its four wheels, its equivalent frictional coefficient is different from that of the synchronal braking case. So it is unsuitable to compute the pre-impact speed using the parameters in synchronal braking frictional coefficient. This paper established three-dimensional dynamic model of the vehicle driving, derived a no-sideslip single side skid equivalent frictional coefficient formula according to vehicle real conditions, and presented a final expression of no-sideslip single side skid equivalent frictional coefficient.

ESTABLISHMENT OF DYNAMICAL MODEL

Introduction of classical vehicle single axis skid dynamical model

. Considering a vehicle's four tires with the same braking, the frictional force formula is as follow: $F = mg\varphi$, Where φ is road frictional coefficient and m is the vehicle mass, and g is gravity acceleration.

As to the vehicle single axis braking, there are forces working on vehicle as Figure. 1.

Li has fully analyzed the process of calculating equivalent frictional

coefficient of the vehicle single axis skid and presented the equivalent frictional coefficient formula as follow (Li).

$$\varphi_e = \frac{\varphi_1 - \lambda_x(\varphi_1 - \varphi_2)}{1 - \lambda_z(\varphi_1 - \varphi_2)} \quad (1)$$

Where φ_1 is fore axis frictional coefficient. φ_2 is back axis frictional coefficient. λ_x is the ratio of between mass center and fore axis distance to two axis distance, $\lambda_x = l_1/L$. λ_z is the ratio mass center height to two axis distance, $\lambda_z = z_c/L$.

According to the above formula, when a Jetta^{TM} car brakes, fore axis brakes

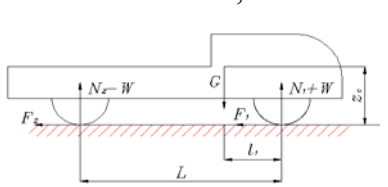

Figure 1. Single axis skid tow-dimensional force

and back axis keeps free, its which equivalent frictional coefficient is 0.495; Contrarily back axis brakes and fore axis keep free, its which equivalent frictional coefficient is 0.36. The value of equivalent frictional force will be affected by different skid state, and then the calculating result of equivalent frictional force will affect on vehicle driving speed, which further affects traffic accident survey results.

Analysis of equivalent frictional coefficient of no-sideslip single side skid.

No-sideslip single side skid vehicle often occur in traffic accidents. When vehicle single side brakes, but the other side is free. Traditional calculation method of equivalent frictional coefficient of no sideslip single side skid is $\varphi_e = \varphi/2$, but it exits a large error between analyzed pre-impact speed and real pre-impact speed.

Force model of no-sideslip single side brake vehicle.

First we research on left side skid vehicle force model. It is shown as following Figure 2, which is three dimensional force model, because traditional two dimensional force model can not reflect on real state.

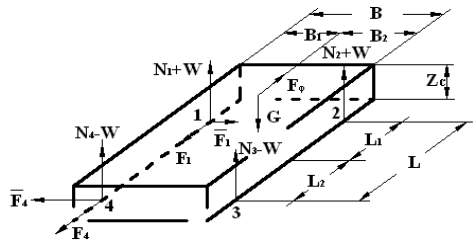

Figure 2. No-sideslip left skid dynamic

For the above model, when vehicle driving, the upright force of ground working on four tires should be first solved, but this force model is statically indeterminate. To approximate the model, we assumeed that vehicle driving four tires force model is simple as shown in Figure 3 and Figure 4.

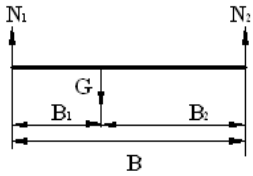

Figure 3.vehicle fore projective force

Based on Figures 3 and 4 the force equations can be given as : $N_1 + N_2 = x$; $N_3 + N_4 = y$.

Setting model force equation as: $y \cdot L_2 = x \cdot L_1$, $x + y = G$.

We have

$$N_1 + N_2 = G(1-\lambda_x) \quad (2)$$

$$N_3 + N_4 = G\lambda_x \quad (3)$$

Vehicle fore projective force model is defined as follow Figure 4.

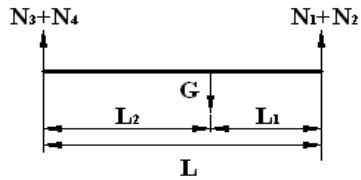

Figure 4. vehicle side projective force

Setting model force equation as: $N_1 \cdot B_1 = N_2 \cdot B_2$; $N_1 + N_2 = G(1-\lambda_x)$.

We have

$$N_1 = G(1-\lambda_x)(1-\lambda_B)\ ; \quad N_2 = G\lambda_B(1-\lambda_x) \quad (4)$$

Same as analysis method, we have

$$N_3 = G\lambda_x\lambda_B\ ; \quad N_4 = G\lambda_x(1-\lambda_B) \quad (5)$$

where N_4 is defined coordinates center, setting dynamic balance equation and moment balance equation:

$$\overline{F}_4 = \overline{F}_1 \quad (6)$$

$$F_1 + F_4 = F_\varphi \quad (7)$$

$$N_1 + N_2 + N_3 + N_4 = G \quad (8)$$

$$GL_2 + F_\varphi z_c = (N_1 + w)L + (N_2 + w)L \quad (9)$$

$$G \cdot B_1 = (N_2 + w)B + (N_3 - w)B \quad (10)$$

$$\overline{F}_1 \cdot L = B_1 \cdot F_\varphi \quad (11)$$

Setting frictional force equation of N_4 point and N_1 point as:

$$\overline{F}_1^{\,2} + F_1^2 = \varphi^2 (N_1 + w)^2 \quad (12)$$

$$\overline{F}_4^{\,2} + F_4^2 = \varphi^2 (N_4 - w)^2 \quad (13)$$

According to the above equation, we can deduce as:

$$a_1\varphi_e^4 + a_2\varphi_e^3 + a_3\varphi_e^2 + a_4\varphi_e + a_5 = 0 \quad (14)$$

where $a_1 = \frac{1}{4} + \frac{B_1^2}{L^2} - \frac{z_c^2\varphi^2}{2L^2}$; $a_2 = \frac{\varphi^2 z_c(1-\lambda_B)}{2L} - \frac{\varphi^2 z_c(1-\lambda_x)(1-\lambda_B)}{L}$;

$$a_3=\frac{\varphi^2(1-\lambda_B)^2(1-2\lambda_x)}{2}+\frac{\varphi^4(1-\lambda_B)^2 z_c^2}{4L^2}-\varphi^2(1-\lambda_x)^2(1-\lambda_B)^2;$$

$$a_4=\frac{\varphi^4 z_c(1-\lambda_B)^3(1-2\lambda_x)}{2L};\quad a_5=\frac{\varphi^4(1-\lambda_x)^4(1-2\lambda_x)^2}{4}。$$

Formula (14) is used to calculate equivalent frictional coefficient of vehicle in no sideslip left side skid. If we have car structure parameter, we can solve the equivalent frictional coefficient of vehicle in no sideslip left side skid by Matlab software.

Modification of theoretical frictional coefficient

Braking time of liquid skid vehicle is 0.2s from zero to vehicle max skid force(Xu). When vehicle skid force arrives at max value, v_1, skid force changing is shown as Figure 5. In the traffic accidence, theoretical frictional coefficient is used to calculate and analyze vehicle driving speed of before traffic accidence, but the calculated vehicle driving speed does not agree with real vehicle driving speed. This error comes into being for omitting 0.2s effect from v_0 to v_1 of skid force.

Analyzing and amending relation between computed fricational coefficient in the traffic accident and theory frictional coefficient

The skid force model is described as follow:

$$F=kt\ ,\ t\in(0,0.2] \tag{15}$$

where φ is theoretical frictional coefficient, m is vehicle mass, g is gravitational accelerate.

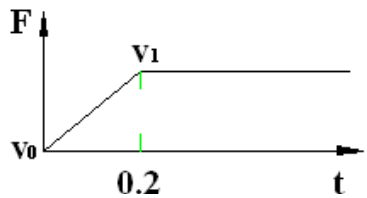

Figure 5. Skid force curve when braking

We can also deduce $k=\frac{\varphi mg}{0.2}$ and $0.1\varphi g=v_0-v_1$.

In general, based on tire marks at the scene, we are to investigate the pre-impact vehicle velocity in traffic accident. This formula is defined as follow: $v=(2g\varphi S)^{0.5}$,where g is gravitational accelerate, φ is frictional coefficient, S is tire marks of traffic accident vehicle.

Hence,

$$v_1=(2g\varphi S)^{0.5} \tag{16}$$

$$v_0=\left[2g(\varphi S+\varphi_1\Delta S)\right]^{0.5} \tag{17}$$

where ΔS is vehicle driving distance at 0.2s, φ_1 is equivalent frictional coefficient within the ΔS range.

From Equations 16 and 17, we can obtain

$$\sqrt{\varphi_e} = \sqrt{\varphi} + \frac{0.1\varphi g}{\sqrt{2gS}} \tag{18}$$

According to the above formula, we can determine the relation between computed frictional coefficient and theoretical frictional coefficient, and we apply computed frictional coefficient to calculate accident vehicle driving speed which is accordant with practical vehicle driving speed.

EXPERIMENT

We completed an experiment test on Aug. 8, 2008, and obtained some real testing data of no-sideslip left side skid. The experiment equipments include: CTM-2002 (non contact laser velometer), tapeline, and a Jetta™ car.

CTM-2002 is shown in Figure 6. It can record the vehicle skid speed and distance. But we want to analyze and calculate the vehicle pre-brake speed to use visible tire marks in traffic accident, so we must use amended theoretical frictional coefficient. Figures 7, 8 and 9 presented the installing and debugging process. The testing data are as shown Table 1.

Figure 6. CTM-2002c non-contact velometer

Figure 7. Installing of CTM-2002c on Jetta™ car

Figure 8. Debugging of CTM-2002c on Jetta car

Figure 9. In-car debugging of CTM-2002c

Table 1. No-sideslip Left Skid Testing Data

Num	Skid speed	Skid distance	Equivalent frictional coefficient
1	5.56m/s	3.5m	0.45
2	5.2m/s	3.2m	0.43
3	5.8m/s	4.3m	0.4
4	6.6m/s	5.2m	0.43
5	7.2m/s	5.3m	0.5

According to the above five group of testing data, we can obtain that the average value of single side skid equivalent frictional coefficient is 0.442, and average skid distance is 4.3m. By the no-sideslip single side skid equivalent friction coefficient Equation 14 and Jetta car parameters in Table 2, we can derive theoretical equivalent frictional coefficient, which is 0.3905.

Table 2. Jetta^{TM} car construction parameters

Jetta^{TM} car construction parameters	index
Axis distance	2.48m
Tire distance	1.46m
Mass center to fore axis distance	1.04m
Mass center to left side distance	0.6m
Mass center high	0.5m
Frictional coefficient	0.75

By amending Equation 18, we derived amended theoretical equivalent friction coefficient; the amended value is as follow:

$$\varphi_e = \left(\sqrt{\varphi} + \frac{0.1\varphi g}{\sqrt{2gS}} \right)^2 = \left(\sqrt{0.3905} + \frac{0.1 \times 0.3905 \times 9.8}{\sqrt{2 \times 9.8 \times 5.3}} \right)^2 = 0.4388$$

Tabel 3 shows the errors of single side skid equivalent frictional coefficient theoretical value and testing equivalent frictional coefficient value by experiment, the equivalent frictional coefficient by tradition method.

Table 3. Error Analysis

Absolute error	Testing data: 0.442(left) 0.2374(right)	tradition value: 0.375
Amended theoretical value of left side skid: 0.4388	0.72%	14.5%
Amended theoretical value of right side skid: 0.2372	0.84%	58%

From error analyzing table one can see that the amended theoretical value of vehicle no sideslip left side skid almost equals with testing data by experiment. But the absolute error between equivalent frictional coefficient by tradition method and testing data by experiment is much bigger, as is 14.5%. However, the right side

tradition friction coefficient error are surprisingly as high as 58% and this error could not be tolerance.

CONCLUSION

We put forward the new model of No-sideslip single side skid equivalent frictional coefficient formula, and then, amend this model. This new model is right by experiment data analyzing. By different conditions road friction coefficient, we can also calculate No-sideslip single side skid equivalent frictional coefficient applying to the model in this paper, so this model can justly and objectively calculate No-sideslip single side skid vehicle pre-impact driving speed in the accident.

Research result of this paper can support traffic police officers justly and objectively deal with traffic accident, thus it has significance meaning.

ABSTRACT

Traffic route's alignment survey is among the important works required in location survey stage. This paper concisely introduces both conventional and contemporary techniques of traffic route's alignment survey. It also analyzes and discusses the question that while traffic route's alignment survey is being conducted by conventional diagrammatic method (or called offset method), how to improve the accuracy of diagrammatized centerline stations' coordinate parameters for staking-out by the principle of least squares to reduce the workload of repeatedly threading, checking on and adjusting the laid-out centerline stations. Finally, the authors draw the conclusion that the laid-out traffic route's center line stations based on staking-out coordinate parameters obtained by the principle of least squares are able to satisfy the required tolerance of location survey of traffic route's centerline stakes.

Key Words: traffic route, alignment, surveying method, least squares

1. INTRODUCTION

Alignment survey, one of the important works required in traffic route's location survey stage, is a process of staking out preliminarily-designed centerline in field. Its fundamental task is to stake out intersections, a series of straight lines separated by certain distances and directions of the centerline proposed by a plan.

In alignment survey, method used to acquire staking-out coordinates of centerline stations includes analytical method and diagrammatic method. With analytical method, coordinates of centerline stations (including starting point, ending point and intersections etc.) are provided by designing calculations, and these stations are staked out later in field by polar coordinate method and included-angle method. On the other hand, diagrammatic method means to take measurements of coordinates of centerline stations for staking-out directly from strip map or aerial map and lay out these stations by diagrammatic method. Analytical method always provides higher level of accuracy compared with diagrammatic method.

The reason for analytical method's higher level of accuracy is that the available staking-out data are provided by the designing plan and thus no contradiction exists

between them. On the other hand, the reason for diagrammatic method's lower level of accuracy is that the deviation of diagrammatized coordinate parameters of centerline stations for staking-out is too large to ensure the laid-out stations are precisely in one straight line and therefore it is necessary for surveyors to repeatedly thread, check and adjust the laid-out center line stations (Zhang Kunyi 1999).

2. BRIEF INTRODUCTION ON METHODS OF TRAFFIC ROUTE'S ALIGNMENT SURVEY

Along with the rapid development of surveying techniques, especially the widely application of EDM instruments and total stations, the methods for alignment survey of traffic route have been improved greatly. The GPS RTK technique will be applied more extensively in alignment survey of traffic route and its construction.

2.1 Methods of Alignment Survey with Conventional Techniques and Instruments

Methods of alignment survey with conventional techniques and equipments include analytical method and diagrammatic method. Here the conventional instruments and equipments refer to theodolites, steel type and range finders.

In analytical method, the centerline of traffic route and coordinates of intersections of centerline straight segments (or any point) are both determined by designing plan. Therefore the lengths and directions of lines from traverse stations to centerline straight segments' intersections (or any point) can be inversely calculated from coordinates of laid-out traverse stations so that intersections of centerline straight segments can be laid out with polar coordinate method.

Diagrammatic method enables (Gong 1992) coordinates of intersections of centerline straight segments (or any point) to be taken directly from strip map or aerial map, and then laid out in field by polar coordinate method with inversely calculated lengths and directions of lines from traverse stations to centerline straight segments' intersections (or any point) and (2)centerline stations to be laid out in field by diagrammatic method (or called offset method) with staking-out offset parameters which have been diagrammatized directly from strip map or aerial map, such as d_4, d_5 (see Fig.1).

2.2 Methods of Alignment Survey with Modern Techniques and Instruments

(1) Application of Total Station in Alignment Survey of Route

Total station consists of electronic theodolite, electro-magnetic range finder, and micro-processor and is able to perform functions of measuring angles, distances, and elevations. Besides its function of measuring angle or distance as an electronic theodolite or electro-magnetic range finder respectively, total station supported by its program modules is able to accomplish the procedure of three-dimensional coordinate surveying, laying-out surveying, RDM and REM etc.

Based on designed coordinates of intersections of centerline straight segments (or any point), the location survey of traffic route can be carried out by applying total station's function of laying out coordinates. On the other hand, the distance between two adjacent intersections of centerline straight segments and included angle between two intersected centerline straight segments can be inversely calculated from formerly designed coordinates of intersections of centerline straight segments so that the location survey of traffic route is able to be accomplished by applying included-angle method and total station's function of laying out angles and distances.

Directly diagrammatized coordinates of centerline straight segments' intersections from strip map or aerial map can also be laid out by applying total station's function of laying out coordinates. Because of the lower accuracy of diagrammatized coordinates, it is necessary to thread, check and adjust the laid-out stations and then locate them by intersecting straight segments of centerline.

(2) Application of GPS RTK in Alignment Survey of Route

GPS RTK is developed from real-time dynamic differential techniques in phase measurement of carrier wave. It is able to provide three-dimensional coordinate in designated coordinate system of stations with centimeters accuracy. In RTK surveying, reference station conveys both their measurements and coordinates of themselves via data link to mobile station besides receiving data from reference station via data link. Mobile station collects GPS observational data and processes differential measurements real-timely to gain location measurements of centimeters accuracy.

The flow of work of alignment survey by GPS RTK is approximately as the following: firstly, make preparations of laid-out data; secondly, set up RTK reference station at known points and start GPS receiver to ensure differential signals are sending off from reference station; then start GPS receiver at mobile station, and with RTK setting to alignment surveying mode conduct alignment survey by selecting proper method.

Before, during and after staking-out traffic route, it is advisable for surveyors to perform necessary checks at known points.

Alignment survey by GPS RTK is composed of office work and field work. The former mainly includes designing centerline straight segments for later staking-out in GPS electronic field book with formerly designed coordinate data of intersections of centerline straight segments, starting and ending points of curves, centers and radii of circles. The latter includes locating the designed route in field with GPS RTK set to alignment surveying mode.

When applied in route's alignment surveys, especially for long traffic routes, RTK technique has unique advantages compared with conventional surveying techniques, which include (a) being handled expediently and operated flexibly. With

RTK technique, alignment survey can be conducted either consecutively or to start from any position of a route at any moment. This is convenient for several instruments to be operated jointly; (b) being direct-viewing, clear-displaying and convenient. The designed route can be displayed directly on RTK operating screen and the operator can lay out the points accordingly; (c) demanding less workers and thus resulting in higher efficiency; (d) measurements can be checked on in real time so the reliability of measurements is enhanced. Beware to check on positions of known points at any moment during alignment survey; (e) the errors of measurements are not cumulative and disseminative thus results in a higher standard of accuracy (Zhang Xiao et al. 2007).

3. APPLICATION OF LEAST SQUARES IN ALIGNMENT SURVEY OF ROUTE BY DIAGRAMMATIC METHOD

3.1 Procedure of Laying-out Centerline Stations Diagrammatically

Procedures or steps to be followed in laying-out centerline stations by diagrammatic method include

(1) diagrammatizing staking-out parameters, such as coordinates and offsets from designing plan;

(2) laying-out centerline stations in field by polar coordinate method or offset method;

(3) threading, which is equivalent to adjusting staked-out stations which have been displaced by errors stemming from diagrammatizing and laying-out back into the designed straight line;

(4) locating the intersections. The straight segments of centerline determined by preceding methods are checked to assure their validity. If they are extended, adjacent straight segments will intersect and an intersection is acquired. Therefore intersections of route's centerline straight segments are located. See Fig.1.

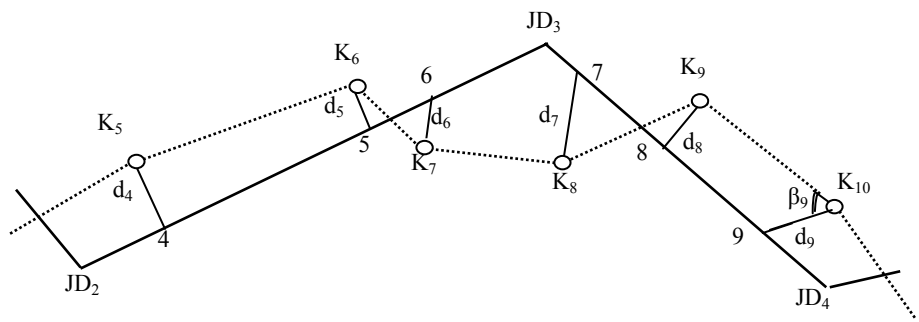

Figure 1.Sketch of alignment survey by diagrammatic method (or called offset method).

Note: In the above figure, JD_2, JD_3 and JD_4 are intersections of centerline straight

segments of route and K_5、K_6 are traverse controls . d_4、d_5、β_9 are parameters for diagrammatizing.

While centerline stations are laid out either by polar coordinate method (see point 9 in Fig.1) or by offset method (see point 4, 5 and 6 in Fig.1), the diagrammatized pairs of coordinates X and Y of centerline stations, such as point 4, 5, 6, 7, 8, and 9, can be determined by applying formerly solved parameters. Because of the effects of errors stemming from diagrammatizing and laying-out, the obtained centerline stations are not in line and the displacements are large enough to guarantee repeatedly threading, checking on and adjusting the laid-out centerline stations. By extending the adjusted centerline straight segments, the intersections such as JD_2, JD_3 and JD_4 are established. This procedure is discussed in most of the present surveying textbooks (Ji Binde et al. 2002).

3.2 Procedure and Thread in Applying Principle of Least Squares

(1)Being centerline straight segments designed from strip map, JD_2 JD_3, JD_3 JD_4 are diagrammatized as coordinates of point 4, 5, 6 and point 7, 8, 9 respectively. See Fig.1. Take these diagrammatized coordinates for observational values, because point 4, 5, 6 and point 7, 8, 9 are in line respectively.

(2)List condition equations respectively for these two centerline segments in accordance with geometry features of three points in every centerline segment

$$\hat{\alpha}_{56} - \hat{\alpha}_{54} = 180^0 ; \ \hat{\alpha}_{89} - \hat{\alpha}_{87} = 180^0 .$$

(3)Solve the above condition equations with principle of least squares so that obtain the optimum estimations of centerline stations. Lay out these centerlines stations by polar coordinate method.

(4) Accuracy verification.

3.3 Steps in Applying Principle of Least Squares

3.3.1 Set up Condition Equation Model

Based on diagrammatized coordinate observational values, list condition equations about adjustments

$$\hat{\alpha}_{56} - \hat{\alpha}_{54} = 180^0 \tag{1}$$

$$\hat{\alpha}_{89} - \hat{\alpha}_{87} = 180^0 \tag{2}$$

Suppose adjustments of coordinate $\hat{\mathrm{X}} = \mathrm{X} + V_X$, $\hat{\mathrm{Y}} = \mathrm{Y} + V_Y$. So that

$$\arctan\frac{(y_6+v_6)-(y_5+v_5)}{(x_6+v_6)-(x_5+v_5)} - \arctan\frac{(y_5+v_5)-(y_4+v_4)}{(x_5+v_5)-(x_4+v_4)} - 180^0 = 0 \tag{3}$$

$$\arctan\frac{(y_9+v_9)-(y_8+v_8)}{(x_9+v_9)-(x_8+v_8)}-\arctan\frac{(y_8+v_8)-(y_7+v_7)}{(x_8+v_8)-(x_7+v_7)}-180^0=0 \quad (4)$$

Where $\hat{\alpha}$ stands for azimuth of straight line; $\hat{X}$, $\hat{Y}$, X, Y stand for adjustments and measurements of diagrammatized coordinates; and V_X, V_Y stand for corrections of diagrammatized coordinates coordinates (Wuhan University Geodesy Adjustment Group 2005).

3.3.2 Solution of Condition Equations to Obtain Corrections

(1) Linearization of Condition Equations

From equations 3 and 4, we know that condition equations are nonlinear. Expand them by method of Taylor series, omitting quadratic term and terms after it. The following equations are obtained by rearrangement

$$\rho''(\frac{\Delta Y_{56}^0}{(S_{56}^0)^2}-\frac{\Delta Y_{54}^0}{(S_{54}^0)^2})V_{X_5}-\rho''(\frac{\Delta X_{56}^0}{(S_{56}^0)^2}-\frac{\Delta X_{54}^0}{(S_{54}^0)^2})V_{Y_5}- \quad \rho''\frac{\Delta Y_{56}^0}{(S_{56}^0)^2}V_{X_6}+\rho''\frac{\Delta X_{56}^0}{(S_{56}^0)^2}V_{Y_6}+\rho''\frac{\Delta Y_{54}^0}{(S_{54}^0)^2}V_{X_4}-$$

$$\rho''\frac{\Delta X_{54}^0}{(S_{54}^0)^2})V_{Y_4}+W_1=0 \quad (5)$$

$$\rho''(\frac{\Delta Y_{89}^0}{(S_{89}^0)^2}-\frac{\Delta Y_{87}^0}{(S_{87}^0)^2})V_{X_8}-\rho''(\frac{\Delta X_{89}^0}{(S_{89}^0)^2}-\frac{\Delta X_{87}^0}{(S_{87}^0)^2})V_{Y_8}-\rho''\frac{\Delta Y_{89}^0}{(S_{89}^0)^2}V_{X_9}+\rho''\frac{\Delta X_{89}^0}{(S_{89}^0)^2}V_{Y_9}+\rho''\frac{\Delta Y_{87}^0}{(S_{87}^0)^2}V_{X_7}-$$

$$\rho''\frac{\Delta X_{87}^0}{(S_{87}^0)^2})V_{Y_7}+W_2=0 \quad (6)$$

They are linear condition equations where ρ'' --206265"; ΔX^0, ΔY^0 stand for computed increments of X coordinate and Y coordinate from diagrammatized coordinates; S^0 stands for approximate corresponding side length computed from diagrammatized coordinates; and misclosure

$$W_1=\alpha_{56}^0-\alpha_{54}^0-180^0;\ \ W_2=\alpha_{89}^0-\alpha_{87}^0-180^0$$

Where α^0 stands for approximate value of straight line's azimuth reversely calculated from diagrammatized coordinates.

(2)Solution of Linear Condition Equations by Method of Least Squares

From linear condition equations 5 and 6, we know that the two equations contain twelve unknown variables and have indefinite solutions. It is a mathematical

problem of solving function's extremum with conditions for surveyors to solve V from function $V^T PV = \min$. Basic equations are established and solved with the following result

$$\mathrm{V} = -QA^T (AQA^T)^{-1} W \tag{7}$$

where Q stands for covariance factor of measurements and adopts the value of I (suppose diagrammatized coordinates are independent); A stands for Coefficient matrix of condition equations; and W stands for misclosure of condition equations.

After corrections being solved, the most probable value (or adjusted value) of observed coordinates can be obtained as the following

$$\hat{\mathrm{X}} = X + V_X \; ; \quad \hat{\mathrm{Y}} = Y + V_Y \; .$$

(3)Accuracy Estimation

Root mean square error of unit weight (RMSE)

$$\hat{\sigma}_0 = \sqrt{\frac{V^T PV}{r}} \tag{8}$$

Accuracy of adjusted value of diagrammatized coordinates

$$\hat{D}_{\hat{L}} = \sigma_0^2 (Q - QA^T (AQA^T)^{-1} AQ), \tag{9}$$

where P stands for weight of measurements , and adopts the value of I ; r stands for the number of condition equations; $\hat{D}_{\hat{L}}$ stands for variance-covariance matrix for adjusted value of diagrammatized coordinates.

3.4 Example for Demonstration

Diagrammatized coordinates of the three points on each straight segment of traffic route's centerline are shown in Table1. Adjusted coordinates based on least squares methods are listed in Table 1 (Liang Yubao et al. 2008).

Table 1. Data sheet of diagrammatized coordinates of traffic route stations.

Station number	Diagrammatized coordinates (m)		Station number	Diagrammatized coordinates (m)	
	X	Y		X	Y
4	3740500.0	38434719.3	7	3740000.0	38436364.0
5	3740413.5	38435000.0	8	3739500.0	38436986.5
6	3740259.5	38435500.0	9	3739312.5	38437220.0

Related data are calculated and then substituted into linear condition Equations 5 and 6. After rearranging, we get

$$-1.835V_{X_4} - 0.566V_{Y_4} + 1.932V_{X_5} + 1.726V_{Y_5} - 3.768V_{X_6} - 1.160V_{Y_6} - 29.8'' = 0$$

$$-2.014V_{X_7} - 1.618V_{Y_7} + 7.385V_{X_8} + 5.930V_{Y_8} - 5.371V_{X_9} - 4.312V_{Y_9} - 27'' = 0$$

Solve the above condition equations, then we get

$$\underset{6\ 1}{V_x} = \left[V_{x_4}, V_{x_5}, V_{x_6}, V_{x_7}, V_{x_8}, V_{x_9} \right]^T = \begin{bmatrix} -2.10 \\ 2.22 \\ -4.33 \\ -0.38 \\ 1.39 \\ 1.01 \end{bmatrix} cm \qquad \underset{6\ 1}{V_y} = \left[V_{y_4}, V_{y_5}, V_{y_6}, V_{y_7}, V_{y_8}, V_{y_9} \right]^T = \begin{bmatrix} -0.65 \\ 1.98 \\ -1.33 \\ -0.30 \\ 1.11 \\ -0.81 \end{bmatrix} cm$$

Accuracy estimation can be performed by the following steps.

From Equation 8, root mean square error of unit weight

$$\hat{\sigma}_0 = \sqrt{\frac{V^T PV}{r}} = \sqrt{\frac{39.3}{2}} = \pm 4.43 cm.$$

From Equation 9, accuracy of adjusted value and location error of diagrammatized coordinates are computed and shown in Table 3.

Table 2. Data sheet of diagrammatized coordinates of traffic route stations by least squares.

Station number	Diagrammatized coordinates (m)		Station number	Diagrammatized coordinates (m)	
	X	Y		X	Y
4	3740499.979	38434719.293	7	3739999.996	38436363.997
5	3740413.522	38435000.019	8	3739500.014	38436986.511
6	3740259.457	38435499.987	9	3739312.510	38437219.992

Table 3. Data sheet of accuracy of adjusted value of diagrammatized coordinates of traffic route stations by least squares

Station number	accuracy of adjusted value of diagrammatized coordinates (cm)		Error in station location (cm)	Station number	accuracy of adjusted value of diagrammatized coordinates (cm)		Error in station location (cm)
	σ_X	σ_Y	σ		σ_X	σ_Y	σ
4	±4.13	±4.40	±6.03	7	±4.36	±4.38	±6.82
5	±4.09	±4.16	±5.83	8	±3.49	±3.84	±5.19
6	±2.97	±4.31	±5.23	9	±3.96	±4.13	±5.72

Regulations for highway surveying specified tolerance of deviation of stake locations for high order highway's centerline stakes as followings: in longitudinal direction, S/200 +0.1m (S stands for location measurements of centerline stakes, in meters); in transverse direction, 10cm (China Ministry of Communications 1992).

Take half the tolerance of deviation of centerline stake locations for tolerance of RMSE in lengthwise and transverse directions of centerline stake locations, i.e.

$$\sigma_{\mathrm{L}} = \frac{1}{2} \times 10 = \pm 5\mathrm{cm}; \qquad \sigma_{\mathrm{T}} = \frac{1}{2} \times 10 = \pm 5\mathrm{cm}$$

So that tolerance of RMSE of centerline stake locations

$$\sigma_{\mathrm{C}} = \sqrt{\sigma_{\mathrm{L}}^2 + \sigma_{\mathrm{T}}^2} = \sqrt{5^2 + 5^2} = \pm 7.07\mathrm{cm}$$

4. CONCLUSION

The following conclusion can be drawn from the above discussions:

If the designed coordinates of intersections of route's centerline straight segments are known, surveyors can conduct alignment survey for traffic route by either conventional surveying techniques or contemporary surveying techniques. The choice depends on actual situation. If the coordinates of intersections of route's centerline segments have not been designed, surveyors may directly diagrammatize coordinates from strip map or aerial map, and conduct alignment survey for traffic route by diagrammatic method (or offset method). When using diagrammatizing method, beware to diagrammatize coordinates of at least three evenly distributed centerline stations for each centerline segment. Then eliminate contradictions within diagrammatized coordinates and work out the optimum estimation by applying method of least squares.

From estimated accuracy of adjusted value of diagrammatized coordinates, we can see that location accuracy of diagrammatized coordinates which have been handled by method of least squares is within the range of tolerance of RMSE of centerline stake locations specified by regulations($\sigma_{\mathrm{C}} = \pm 7.07\mathrm{cm}$). Therefore surveyors can directly apply this method in laying out centerline stakes, such as starting point, ending point and intersections of centerline's straight segments without any troubles of repeatedly threading, checking on and adjusting the laid-out centerline stations. The related complicated computational process conforms to strong regularity and can be handled by computer programs that can be operated conveniently and practically.

In brief, this paper concisely introduces both conventional and contemporary techniques of traffic route's alignment survey. It also analyzes and discusses the question that while traffic route's alignment survey is being conducted by conventional diagrammatic method (or called offset method), how to improve the accuracy of diagrammatized centerline stations' coordinate parameters for staking-out by principle of least squares in order to reduce the workload of repeatedly threading, checking on and adjusting the laid-out centerline stations. Finally, the authors draw the conclusion that the laid-out traffic route's centerline stations based on staking-out coordinate

parameters obtained by principle of least squares are able to satisfy the required tolerance of location survey of traffic route's centerline stakes.

ABSTRACT:

In the recent years, in china, speeding is one of the most serious road traffic violations and is one of the main reasons that cause road traffic accidents. In 2007, the road traffic accident fatalities caused by speeding account for 14.06% of the total, ahead of the main reasons for the accident, so the treatment of speeding is the main task of the traffic control department. This article, from the point of view of expected speed of driver, studies the mechanism of its formation, and establishes the relationship model between speeding rate and traffic volume through the measured data in the field. The model can help traffic control department to identify road sections and time sections in which speeding happens very often. That will allow police to focus on control and improve law enforcement efficiency and reduce the cost of law enforcement.

Key words: *expected speed, speeding rate, traffic volume, enforcement efficiency*

1.The harm of speeding driving

The speeding driving is described that the speed of the automobile driving on the road exceeds the specified speed. The implementation of the road traffic safety regulation arcticle 45 provides (Huang Changjie, 2004): the speed of motor vehicle driving on the road shall not exceed the speed limit marked on the traffic signs and lines. Without any speed limit mark on the road, motor vehicle's maximum speed shall not exceed the following speed limit: if without road central line, 30km/h on the urban road and 40km/h on the highway; if there is only 1 driveway in each direction, 50km/h on the urban road and 70km/h on the highway. Arcticle 78 prescribes: the driving speed on each driveway on the expressway should be marked, what's more, the maximum speed shall not exceed 120km/h.

The ultimate purpose of speed limit is to guarantee the safety of driving, but according to the PRC's road traffic accident statistics annals (Traffic Management Bureau in Ministry of Public and Security, 2008)[1] reported that there are 327209 traffic accidents ranking above common accident in the whole country in 2007, resulting in 81649 deaths, 380442 injured, and direct property loss 1.199 billion yuan.

And the accidents, deaths, injured population and direct property loss resulting from speeding driving separately account for the total 10.23%,14.06%,9.63% and 11.22%, further more, speeding driving is located in the forefront of all kinds of causes. The following figure 1 illustrates the distribution of the traffic fatality accident reasons. From the figure, we can directly see that the deaths caused by speeding driving arranges in second, only inferior to the reason of other influencing factor, above all, far more than other illegal behavior causing death. The road traffic accident statistics annals also reports that the speed driving, converse driving and illegal meeting are the main accident reason, and there are 244 fatality accidents with 3 deaths each time and 33 with more than 5 deaths resulting from speeding driving, respectively accounting for the total 16.7%, 12.6%; that resulting from converse driving respectively accounting for the total 9.7%, 13.8%; that resulting from illegal meeting respectively accounting for the total 7.1%, 10.5%. Obviosly, speeding driving is one of the most serious road traffic illegal activities, also one of the primary causes of road traffic accidents. Therefor it is the main contents of law enforcement for traffic management department in the past, present and future to tackle speeding driving.

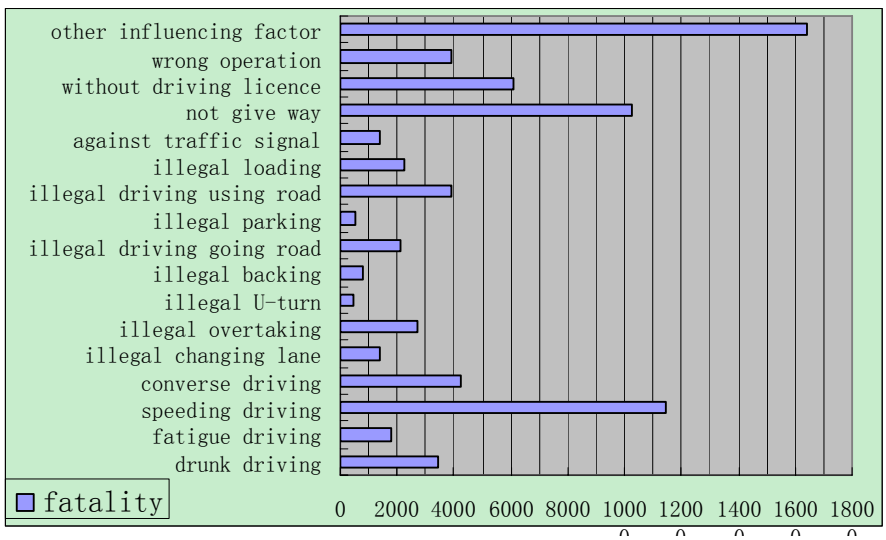

Figure 1 distribution of the traffic fatality accident reasons with driver in 2007.

2 The analysis of the formation process of speeding

2.1 The definition of expected speed

Expected speed refers to the driver hopes to achieve a highest “safe” speed without or generally without the influence of other motor vehicle (Ou Jushang, 2006). Here the meaning of “safe” speed is just the specific driver consider a kind of safe driving speed from individual mentally, but not the real meaning of road traffic safety speed. From the formation process of expected speed, it is a target speed which drivers get after considering all kinds of factors such as road condition, traffic condition, vehicle performance, climate condition and so on. It is going to have an effect on vehicle actual operation speed. Obviously the different individual driver has

different standard to the formation of "safe" speed, and so the expected speed is also different. From the aspect of psychology (Jin Zhifu, 2004), the process of formation can be divided into 4 stages: initially identification, adjustment, confirmation, and maintenance. It is a continuous cycle process, as shown in figure 2.

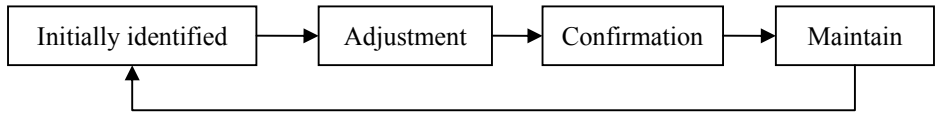

Figure 2 The formation process of expected speed.

2.2 Mechanism of speeding driving formation

According to the above driving behavioral analysis, in the driving process, the vehicle drivers continuously collect the information of road alignment, pavement condition, traffic flow, natural climate and so on, and analyse the information in order to identify the expected speed. At last, the analysis result is distributed to hands or feet to control the speed of vehicle, then the driver continuously adjust the vehicle speed in a safe range in the light of information obtained. On the contrary, if driver has carried on the wrong analysis in various stages, and the correction ability don't prompt play a role, speeding will happen. Therefore, speeding driving may exist in following svevral stages owing to wrong judgment or incorrect operation.

1) Not get comprehensive information in the stage of obtaining traffic information. The drivers don't obtain comprehensive traffic information in time, so they make incomplete analysis and judgment only on the basis of partial information, thus resulting in wrong analysis result and speeding driving. For example, the driver did not see speed limit sign and line because of the lack of concentration, thus the actual speed of vehicle exceeds the speed limit.

Make wrong analysis and judgment in the stage of analysis and judgment of traffic information.

2) The drivers make wrong analysis and judgment. This is due to the decline of driver's ability to analyze and judge temporarily. Fatigue driving, drunk driving, sudden illness or lack of driving experience and other factors may cause the driver's ability to reduce, and can't do correct analysis and judgment base on the obtained traffic information, which lead to the expected speed higher than safet driving speed, thus result in speeding.

3) Do wrong operation in implementation stage. The drivers obtain comprehensive and true traffic information in the stage of obtaining traffic information, and do correct analysis and judgment about this traffic information, and also output correct instruction to executive organ, but executive organ make an error in the implementation of instruction because it did not follow the enter instruction. That results in the actual speed of vehicle exceeding the safe driving speed. This is

mainly due to the driver's lack of experience and good psychological quality.

4) Drviers' correction ability does not play a role in time. At the aforementioned every stage, if drivers' correction ability can play a role in time, the speeding driving can be prevented. On the contrary, after the drivers making wrong analysis and judgment, driver's correction ability doesn't play a role in time, so the vehicle's driving speed exceeds the safe speed. The primary reason is that drivers are absent minded, fatigue driving, driving under the influence of alcohol, inexperience, paroxysmal sickness and so on.

3. The relationship between speeding rate and traffic volume in expressway

Expressway's speeding rate and traffic volume have the direct relation (Pei Yulong et al, 2004). Thinking from the direct-viewing angle, we usually believe that along with the increase of traffic volume, the freedom of vehicle driving falls, so the possibility of speeding reduces. But in actual data analysis process, author discovered that when traffic volume was small, the speeding rate increased along with traffic volume increase; when traffic volume was more than a critical value, the speeding rate reduced along with traffic volume increase. Next this problem will further explain through a concrete measured road section.

Yuyi expressway in Chongqing

Yuyi expressway is a expressway from Chongqing to Yi'chang in Hubei province. The entire line is 266 kilometers. Yuyi expressway has three sections, which respectively are Chongqing to Chang'shou, chang'shou to liang'ping, liang'ping to wan'zhou. One half is old (section of Chongqing to Chang'shou, open in 2000), the other half is newly built (sections of chang'shou to liang'ping and liang'ping to wan'zhou, open in 2003). There are two lanes in each direction in old section and three lanes in each direction in new sections. The new sections is obviously better than the old in road alignment and pavement condition, therefore speeding driving is very serious in new sections. The design speed of Yuyi expressway is 80 km/h and there is only one speed limit value 80 km/h on the entire line. The examination spot we choosed was a straight line segment, in the direction of leaving Chongqing. The grade is 0.5% and the examination period is 24 hours. The data collected is grouped for every hour. Table 1 lists the statistic analysis.

Carrying on the regression analysis with the data in above table, we obtained the quadratic curve relation between speeding rate and traffic volume per lane. The relation model as follows:

$$SR = 14.409 + 0.667Q - 0.002Q^2 \qquad (1)$$

Where SR——speeding rate（%）;

Q——traffic volume（pcu/h/lane）

The model is showing that with the increase of traffic volume, the speeding rate doesn't always reduce, but the speeding rate is increasing first and then reducing. So traffic management department could focus on control when speeding rate is very

high, and thus improve law enforcement efficiency. Figure 3 is the relation curve figure between speeding rate and traffic volume.

Table 1 statistic analysis between speeding rate and traffic volume in Yuyi expressway

Time	Traffic volume /pcu	Speeding vehicle /pcu	Traffic volume per lane/(pcu/h/lane)	Speeding rate /%
0	128	53	42.67	41.41
1	113	39	37.67	34.51
2	76	19	25.33	25.00
3	80	28	26.67	35.00
4	94	23	31.33	24.47
5	99	34	33.00	34.34
6	185	114	61.67	61.62
7	528	434	176.00	82.20
8	650	548	216.67	84.31

10	747	607	249.00	81.26
11	598	459	199.33	76.76
12	426	316	142.00	74.18
13	568	433	189.33	76.23
14	582	474	194.00	81.44
15	571	445	190.33	77.93
16	553	431	184.33	77.94
17	470	387	156.67	82.34
18	357	258	119.00	72.27
19	377	284	125.67	75.33
20	340	232	113.33	68.24
21	281	170	93.67	60.50
22	195	107	65.00	54.87
23	195	101	65.00	51.79

4 conclusion

This article explains the formation process of speeding driving from the aspect of expected speed, and further carry on regression analysis with actually measured data. At last, the relation model is obtained, which provides a theoretical basis for controlling speeding driving behavior. But also there are some problems. Because of the sample size, whether the model is universal or not is still needs further study; for different expressways, the influencing factor of inflexion point on the model curve needs to be further discussed.

ABSTRACT

Vehicle tracking is one of the essential tasks in a video-based Intelligent Transportation System. A novel method for vehicle tracking is proposed in this paper. First, we analyze the disadvantages of the traditional parameterized model and compare them to the merits of the nonparametric model. Then the mean shift algorithm is deduced by using kernel density estimation in multi-dimensional space. Its convergence is proven using a simple method. In order to overcome the disadvantages of the original mean shift algorithm, this paper proposes an adaptive template and a kernel weights selecting method. The new method accelerates the convergence speed of the algorithm. When we apply this adaptive method, the experimental results show that the proposed method performs well with video-based vehicle tracing.

INTRODUCTION

The mean shift algorithm (Cheng, 1995) is derived from the density gradient of probability distribution which was first proposed by Fukunaga (1975). Due to the complexity of the feature space, it is hard to use a common parameter model to estimate the distribution of the feature space in a computer image (Duda, 2001). But this approach is promising when used in nonparametric estimation. While inadequate in the sample distribution, the density distribution can be directly described by samples in nonparametric estimation. Meanwhile it can be used to analyze any feature space. The kernel estimator mentioned in the paper (Cacoullos, 1966) is a frequently used nonparametric estimation function. Though conditions for traditional parameter estimation are very strict, the distribution model of the feature space can be known in advance. However, the distribution should be estimated approximately, according to the samples, and a traditional parameter estimation method may lead to a large error in the data. Our approach, using nonparametric estimation can overcome these shortcomings. Thus this paper proposes a novel vehicle tracking method based on a nonparametric estimation.

Nonparametric density estimate functions (Parzen,1962, Rosenblatt,1956) have been used widely in object tracking, image segmentation, information fusion and so on (Fashing and Tomasi, 2005; Li and Tang, 2008; Minwoo Park, 2008; Tao, 2008; Li, 2008). Usually, a histogram is considered to be the simplest nonparametric estimate in many cases. In addition, the kernel density estimation and the neighborhood estimation are also regarded as being types of nonparametric estimation. The kernel density estimate is the most common nonparametric density estimation. The most commonly used kernel functions include the Gaussian kernel function, the Polynomial kernel

function, the Sigmoidal kernel function, and so on. The advantage of using nonparametric technology is that it does not require a priori knowledge, but only requires the taking of samples. Thus it is has been widely used in object tracking (Z. Li and Tang, 2008; Park, 2008; P. Li, 2008).

MEAN SHIFT ALGORITHM

Definition 1:Let $k(x)$, $x \in [0,+\infty)$ be a positive function and monotone decreasing, if it satisfies

$$\int_0^{\infty} k(x)dx < +\infty \quad , 0 < k(0) < +\infty \tag{1}$$

Then $k(x)$ is a kernel function (e.g. $k(x) = e^{-x}$). The Gaussian kernel is the most commonly used kernel function. It is here defined as $k(\| x - x_c \|) = \exp(-\| x - x_c \|^2 / (2\delta^2))$, where x_c is the kernel center, and δ is a parameter used to modulate the radial range of the kernel.

Definition 2: Let $k(u)$ $u \in (-\infty,+\infty)$ be a measurable Borel function (X. Liu, 2001), for a given constant h_n ($h_n > 0$) and a data set $s = \{x_i, i = 1...n\}$ (where n-dimensional space), if the corresponding kernel function is $k_h(x)$, then the density function $f(x)$ at the point of x can be estimated as

$$f_n(x) = \frac{1}{n}\sum_{i=1}^{n} k(x - x_i) = \frac{1}{nh_n}\sum_{i=1}^{n} k(\frac{x - x_i}{h_n}) \tag{2}$$

Here $k(\cdot)$ is the kernel function and x is the center of the kernel. If the samples are adequate, the estimated density function can infinitely approximate the real density function. However, in multi-dimensional space, the point x can be represented by a vector and it has $\| x \|^2 = x^T x$. Correspondingly, the kernel function $K(x)$ mentioned in (1) became a multi-variable kernel function (also named under Radial symmetry kernel function), where $K(x) = ck(\| x \|^2)$ and $k(x)$ is the profile function of $K(x)$, $x \geq 0$ and c is a normalized constant. In d -dimensional Euclidean space R^d , if $k_\Sigma(x)$ is the kernel function, then the probability density can be defined as

$$\hat{f}(x) = \frac{1}{n}\sum_{i=1}^{n} k_{\Sigma_i}(x - x_i) \tag{3}$$

Here

$$k_{\Sigma_i}(x - x_i) = c_{k,d,i}\left|\Sigma_i\right|^{-1/2} K(\Sigma_i^{-1/2}(x - x_i)) = c_{k,d,i}\left|\Sigma_i\right|^{-1/2} k(\| x - x_i \|^2_{\Sigma_i}) \tag{4}$$

And here, $\| x - x_i \|^2_{\Sigma i} = (x - x_i)^T \Sigma_i^{-1}(x - x_i)$ is Manhatton distance, and Σ is the bandwidth of the matrix. A different sample point has a different effect on the kernel function, thus (2) can be refined as

$$\hat{f}(x) = \sum_{i=1}^{n} w_i k_{\Sigma_i}(x - x_i) \tag{5}$$

Where w_i is the weight at the sample point x_i, and it has $\sum w_i = 1$, $w_i \geq 0$. Thus the density function of $f(x)$ is obtained:

$$\hat{f}(x) = \sum_{i=1}^{n} w_i c_{k,d,i} |\sum_i|^{-1/2} k(\|x - x_i\|^2_{\Sigma_i}) \tag{6}$$

Here $\sum_i$ ($d \times d$ dimension) is the sample covariance. In order to reduce the calculation, it uses $\sum_i = diag(h_1^2 .....h_d^2)$ or $\sum_i = h^2 I_d$. Substitute $\sum_i = h^2 I_d$ to (6), the kernel density estimation of the function becomes

$$\hat{f}(x) = \frac{c_{k,d,i}}{n^d} \sum_{i=1}^{n} w_i k(\left\| \frac{x - x_i}{h_n} \right\|^2) \tag{7}$$

In order to obtain the largest data density distribution zone, the density gradient estimation can be used. The kernel density gradient is equivalent to the partial differential with the variable x in (6). Then we have

$$\nabla \hat{f}(x) = 2c_{k,d} \sum_{i=1}^{n} w_i \sum_i^{-1} \sum_i^{-\frac{1}{2}} k'(\|x - x_i\|^2_{\Sigma_i})(x - x_i) \tag{8}$$

Let $g(x) = -k'(x)$, then

$$\nabla \hat{f}(x) = 2c_{k,d} \sum_{i=1}^{n} w_i \sum_i^{-1} \sum_i^{-\frac{1}{2}} k'(\|x - x_i\|^2_{\Sigma_i})(x - x_i) = 2\sum_{i=1}^{n} w_i \sum_i^{-1} \sum_i^{-\frac{1}{2}} g(\|x - x_i\|^2_{\Sigma_i}).m_{\Sigma_{i,g}}(x) \tag{9}$$

Equation (9) contains two parts. The second part is defined as the mean shift vector: $m_{\Sigma_{i,g}}(x) = \sum_{i=1}^{n} w_i x_i \sum_i^{-1} |\sum_i|^{-\frac{1}{2}} g(\|x - x_i\|^2_{\Sigma_i}) / \sum_{i=1}^{n} w_i \sum_i^{-1} |\sum_i|^{-\frac{1}{2}} g(\|x - x_i\|^2_{\Sigma_i}) - x$ (10)

From definition 2, we know that $g(x)$ is the profile function of the $G(x)$, and it has $G(x) = g(\| x \|^2)$. Let

$$\hat{f}_{\Sigma i,g}(x) = 2\sum_{i=1}^{n} \hat{w}_i |\sum_i|^{-1/2} g(\|x - x_i\|^2_{\Sigma_i}) \tag{11}$$

Where $\hat{w}_i = w_i \sum_i^{-1}$, then we have

$$m_{\Sigma i,g}(x) = \nabla \hat{f}(x) / 2\hat{f}_{\Sigma i,g}(x) \tag{12}$$

Obviously, $m_{\Sigma i,g}(x)$ is direct proportion to $\nabla \hat{f}(x)$. This indicates that the kernel center always shifts to the largest spatial density of the samples. Now suppose that the target center x is initialized as x_0. It iterates j times, the centre point shifts to x_j. Then the iterative formula at the time $j+1$ is

$$x_{j+1} = x_j + m_{\Sigma_{i,g}}(x) = \sum_{i=1}^{n} w_i x_i \sum_i^{-1} |\sum_i|^{-1/2} g(\|x - x_i\|^2_{\Sigma_i}) / \sum_{i=1}^{n} w_i \sum_i^{-1} |\sum_i|^{-\frac{1}{2}} g(\|x - x_i\|^2_{\Sigma_i}) \tag{13}$$

$w_i = 1/n$ is used in many papers (Parzen, 1962; Rosenblatt,.1956; Xue,1993; Fashing and Tomasi, 2005), but this is not reasonable. This is because different distances between the sample points would produce different effects on the object. Thus this paper proposes a novel method, using an adaptive weight algorithm. The weight is

$$w_i = \exp(\lambda[1 - (x_i - y_j)^2 / \sigma_j^2])/n, \text{ and } \sum_{i=1}^{n} w_i = 1 \tag{14}$$

Where λ is a normalized coefficient and it has

$$\sigma_j^2 = \frac{1}{n}\sum_{i=1}^{n}(x_i - y_j)^2 \tag{15}$$

For $\forall \varepsilon > 0$, if $\| m_{\sum i,g}(x) \| < \varepsilon$, the mean shift vector is obtained. Thus the program ends the iteration. As is well known, the convergence is very important to an algorithm. In this part, the convergence of the mean shift algorithm is proven. From the theorem 5.59 in the paper (Liu-gen, 2001), the kernel function is derivative at almost every point. That is to say, the Lebesgue measure is zero at the un-derivative points. If the definition of the un-derivative points is added, then $k'(x)$ exists in the whole definition domain of the kernel function $k(x)$. From the definition 2 of $k(x)$, $k(x)$ the monotone decreases and where larger than zero, at almost every point it is $k'(x) \le 0$. According to (6), the following result is obtained

$$\nabla \hat{f}(x) = 2c_{k,d} w_i \left|\sum_i\right|^{-\frac{1}{2}} k'(\left\|x - x_i\right\|^2_{\Sigma_i}) \sum_i^{-1}(x - x_i) \tag{16}$$

$$\text{Let} \quad Z_i(x) = -2c_{k,d} w_i \left|\sum_i\right|^{-\frac{1}{2}} \sum_i^{-1} k'(\left\|x - x_i\right\|^2_{\Sigma_i}) = 2c_{k,d} w_i \left|\sum_i\right|^{-\frac{1}{2}} \sum_i^{-1} g(\left\|x - x_i\right\|^2_{\Sigma_i}) \tag{17}$$

This shows that where $Z_i(x)$ is a positive definite matrix, then the density gradient becomes

$$\nabla \hat{f}(x) = \sum_{i=1}^{n} Z_i(x) x_i - \sum_{i=1}^{n} Z_i(x) x \tag{18}$$

Thus the mean shift vector is

$$m_{\sum i,g}(x) = [\sum_{i=1}^{n} Z_i(x)]^{-1} \sum_{i=1}^{n} Z_i(x) x_i - x \tag{19}$$

And the iterative algorithm is obtained

$$y_{j+1} = [\sum_{i=1}^{n} Z_i(y_j)]^{-1} \sum_{i=1}^{n} Z_i(y_j) x_i \tag{20}$$

If $\sum Z_i(y_j)$ is irreversible, then it has $y_{j+1} = y_j$. Thus it has $y_{j+1} = y_j$ only if $\nabla \hat{f}(x) = 0$. If it has $y_{j+1} \neq y_j$, then the direction of the vector moving is also the gradient direction according to (17)-(20). Thus the shift series moves towards to the increasing direction of the function value. We will prove that the shift series is rigidly increasing in the following part.

According to the definition of the kernel function, $k(x)$ is a bounded function. And $\hat{f}$ is also a bounded function according to (4-6). Thus $\hat{f}(y_j)$ is also a bounded function. In order to prove the convergence of $\hat{f}(y_j)$, we only need to prove $\hat{f}(y_j)$ monotonically increases when $j = 1,2,3\cdots$. The following results can be easily obtained (and the detailed derivation is omitted)

$$\hat{f}(y_{j+1}) - \hat{f}(y_j) \ge \sum_{i=1}^{n} c_{k,d} w_i \left|\sum_i\right|^{-1/2} g(\| x - x_i \|^2_{\Sigma_i}) \| y_{j+1} - y_j \|^2_{\sum_i} \tag{21}$$

When $y_{j+1} \neq y_j$, it has $\hat{f}(y_{j+1}) - \hat{f}(y_j) > 0$ from $g(x) \ge 0$. Thus for any given j, it satisfies $\hat{f}(y_{j+1}) - \hat{f}(y_j) \ge 0$. That is to say $\hat{f}(y_j)$ is strictly increasing. The monotonous series is a definitely bounded convergence, thus $\hat{f}(y_j)$ is convergent and $\hat{f}(y_{j+1}) - \hat{f}(y_j)$ converges to zero. $\| y_{j+1} - y_j \|$ is convergent from (20). Thus $\{y_j \mid j = 1,2,3....\}$ is a Cauchy series and convergent.

OBJECT TRACKING BASED ON MEAN SHIFT ALGORITHM

The basic tracking method is to find the best match between the objects from a video sequence. Suppose that the center of the candidate region of one object is y and the histogram in that candidate region can be expressed as

$$p(y,\sum_q)=\{\ \hat{p}_u(y,\sum q)_{u=1.....m}\ \} \tag{22}$$

where u is the eigenvalue which expresses a feature of the histogram that has $\sum \hat{p}_u(y,\sum q)=1$. The probability density function that belongs to u is

$$\hat{p}_u(y,\sum_q)=c\sum_{i=1}^{N_{\sum q}} K_{\sum q}(y-x_i)\delta[b(x_i)-u] \tag{23}$$

Where c is a normalization factor. If the distribution feature of the target model can be expressed as

$$\hat{q}_u=C\sum_{i=1}^{N_{\sum q}} k(\|\mathbf{x}_i^*\|^2)\delta[b(\mathbf{x}_i^*)-u] \tag{24}$$

The similarity between $\hat{q}_u$ and $p(y,\sum_q)$ can be measured by Bhattacharyya distance J_B, where $J_B=-\ln[\int \hat{q}_u p(y,\sum)]^{1/2}du$ (Maggio, 2005). To make J_B get the minimum value is equivalent to making $\int[\hat{q}_u p(y,\sum)]^{1/2}du$ get the maximum value. According to the discrete character of pixels, it has

$$\rho(\hat{q}_u,\hat{p}(y))=\sum_{u=1}^{m}\sqrt{\hat{q}_u p(y,\sum_q)} \tag{25}$$

If the image is in RGB color space, the degree of similarity in each subspace is described as

$$\hat{p}_t(y,\sum_q)=c\sum_{i=1}^{N_{\sum t}} K_{\sum q}(y-x_i)\delta[b(x_i-u_t)]\ t\in\{R,G,B\} \tag{26}$$

Then it has $\hat{p}(y)=\hat{p}_R(y,\sum_q)\times\hat{p}_G(y,\sum_q)\times\hat{p}_B(y,\sum_q)$. Thus the original template information can be described as $\hat{q}_u=\hat{q}_{u_R}\times\hat{q}_{u_G}\times\hat{q}_{u_B}$, where $\hat{q}_{u_t}$ is the color component information calculated by (24). In (25), the series can be expressed as using Taylor series expansion at $(y,\sum q)$

$$\rho(\hat{q}_u,\hat{p}(y))\approx\sum_{u=1}^{m}\sqrt{\hat{q}_u p(y_0,\sum_q)}+c\sum_{i=1}^{N_{\sum q}} w_i K_{\sum q}(y-x_i) \tag{27}$$

Here
$$w_i=\sum_{u=1}^{m}\sqrt{\hat{q}_u/p(y_0,\sum_q)}\delta[b(x_i)-u] \tag{28}$$

To maximize $\rho(\hat{q}_u,\hat{p}(y))$ is to obtain the second type maximum. It is surprising that to obtain the second type maximum we can deduce the Mean Shift vector, thus the mean shift algorithm can ensure the best match between templates of the objects.

According to Lindeberg theory (Bretzner and Lindeberg, 1998), the normalized density function of $\hat{f}(x)$ can be defined with the parameter r as $\hat{f}_r(x)$, and it satisfies

$$\hat{f}_\gamma(x)=|\sum_i|^{\frac{\gamma}{2}}\hat{f}(x)=\frac{1}{n}|\sum_i|^{\frac{\gamma}{2}}\sum_{i=1}^{n}k_{\Sigma_i}(x-x_i)=\sum_{i=1}^{n}w_i c_{k,d,i}|\sum_i|^{\frac{\gamma-1}{2}}k(\|x-x_i\|^2_{\Sigma_i}) \tag{29}$$

Computing the partial derivative of $\hat{f}_r(x)$ with Σ_i, then it obtains

$$\partial\hat{f}_\gamma(x)/\partial\sum_i=\frac{\gamma\text{-}1}{2}\hat{f}_\gamma(x)\sum_i{}^{-1}-\sum_{i=1}^{n}w_i c_{k,d,i}|\sum_i|^{\frac{\gamma-1}{2}}\varphi \tag{30}$$

$$\partial \hat{f}_\gamma(x)/\partial \Sigma_i = -\frac{\gamma-1}{2}\hat{f}_\gamma(x)\Sigma_i^{-1}[\frac{2}{\gamma-1}\psi - \Sigma_i]\Sigma_i^{-1} \quad (31)$$

Where $\varphi = k'(\|x-x_i\|^2_{\Sigma_i})(x-x_i)^T\Sigma_i^{-2}(x-x_i)$

$$\psi = (\sum_{i=1}^{n} w_i c_{k,d,i}|\Sigma_i|^{\frac{\gamma-1}{2}} k'(\|x-x_i\|^2_{\Sigma_i})(x-x_i)^T(x-x_i))/\hat{f}_\gamma(x) \quad (32)$$

And γ is a constant between zero and one. In (31), the changed value $\Delta\Sigma_i$ can be obtained by $2\psi/(r-1)-\Sigma_i$. $\Delta\Sigma_i$ and $\partial\hat{f}_\gamma(x)/\partial\Sigma_i$ are directly proportional according to (26). This ensures that the mean shift algorithm can find the best match between templates. Thus the adaptive iterative algorithm that uses the bandwidth Σ_i is $\Sigma_{i+1}=2\psi/(\gamma-1)$ .Thus the tracking algorithm can be implemented as follows: first, calculate $m_{\Sigma i,g}(x)$ and w_i , then assign $m_{\Sigma i,g}(x)$ to x , return to the first step until $\|m_{\Sigma i,g}(x)-x\|<\varepsilon$. Here, ε is a given error.

EXPERIMENTAL RESULTS

In order to verify the efficiency of the proposed method, many real-time traffic surveillance videos were tested on the VC++6.0 platform. Figure 1, Figure 2 and Figure 3 display tracking a white car, a red car, and a black car respectively. In these experiments, the algorithm adopted the adaptive kernel histogram. For the statistical characteristic of the adaptive kernel histogram, the mean shift algorithm achieved both faster convergence speed and higher sensitivity. Thus it fulfilled the needs of a real-time tracking environment. However, the histogram may vary even while tracking the same car at different times. This is because tracking a moving car in different scenes may capture different initial information at each different initial time. But our adaptive mean shift algorithm can effectively track the same car in different scenes. In the experiment, the algorithm can track the moving vehicle traveling between 10 and 130 km per hour. In Figure 1, the white car has a speed of 20 km per hour. In Figure 2, the red car is traveling at 100 km per hour. Figure 4 shows the results of multiple vehicles being tracked at the same time, where the moving speed ranges from 90 to 120 km per hour.

Figure 1. One white car tracking result.

Figure 2. One red car tracking result.

Figure 3. One black car tracking result.

Figure 4. Multi vehicles tracking results.

CONCLUSION

A mean shift algorithm is a non-parameter estimation method based on a density gradient. It can converge to a stable point of a recent probability density function. So a mean shift algorithm can be used in video tracking. In video tracking based on mean shift algorithm, the bandwidth of the kernel has a significant impact on the estimated results. This is because the mean shift kernel bandwidth not only determines the quantity of the samples which involve in the iterative algorithm, but also reflects the size of the tracking window. However, in many papers, the kernel bandwidth is determined by the initial tracking window, and does not change during the whole tracking procedure. This can result in a great location error. Thus this paper proposes the changed-scale adaptive tracking algorithm, where the kernel bandwidth is adaptively adjusted. So the change of the kernel bandwidth is directly proportional to the gradient of the kernel density function.

Thus this new method overcomes the disadvantage of the original mean shift algorithm by using the adaptive bandwidth and weights. This proposed method accelerates the convergence speed of the algorithm. The adaptive method is effectively applied to video-based vehicle tracking. And the vehicles tracked in our experimental results have shown that the new algorithm performs well in video-based tracking.

ABSTRACT

Based on the principles of investment management, this paper analyzes the content of statistical indicators of investment benefit in highway construction, and establishes a relevant index system. Finally, it employs fuzzy comprehensive evaluation methods to evaluate the micro-benefit of a highway construction project in Shaanxi Province tests the feasibility of evaluation index systems. The results indicate that this method could have strong maneuverability and practicability.

INTRODUCTION

While the global financial crisis has impacted the Chinese economy, it has providing an economic "lubricant" for its transportation infrastructure. In order to boost domestic demand and promote sustained growth, the Chinese Government has proposed a business encouragement policy with the investment of 4000 billion yuan by the end of 2008. At the same time, the Ministry of Transport is also planning a investment plan of 5 trillion yuan in 3-5 years, in which the vast majority of funds are used for highway construction. These measures are intended to achieve maximum investment returns with minimal input, which is the common goal of any investment activity (Yuan et al. 2001). Setting up a complete system of statistical indicators with investment benefits is necessary in order to adapt to the increasing investment in highway construction and the rapid development of highway transportation. Thus, in order to attain the goal of investment in highway construction, in this article the system of statistical indicators on investment benefits is established to study the evaluation of investment micro-benefit in highway constructions.

THE MICRO-BENEFIT EVALUATION INDEX SYSTEM

The Connotation of Statistical Indicators of Investment Efficiency. Investment benefit is an aspect of the relationship between the effective results of an investment and labor, namely the relationship between highway construction input

and output (Zhou et al. 1998). From the input perspective, investment activities have three main details: funds, materials and manpower. The output of highway construction investment activities is mainly displayed by new fixed assets and new engineering benefits.

The calculation of various indexes through comparing investment input and output and construction represents concrete forms of investment efficiency. Investment efficiency is a broad category, but can be divided into investment economic efficiency, investment social efficiency and investment environment efficiency. This paper primarily studies investment economic efficiency. The investment efficiency index must reflect economic efficiency and the contrast relationship between the output and input of the highway construction process. Namely, the investment efficiency index must be the opposite index rather than the gross index.

There are various indexes reflecting the economic benefit of investment. When considering the characteristics of the highway construction process and, in order to adapt to the needs of investment classification management according to the economic benefit of investment, it is important to divide investment benefit indexes into micro and macro categories. This paper mainly studies micro investment benefit evaluation.

The Determination of Micro-benefit Evaluation Indexes. Considering comprehensive, comparability, and operability principles, the following premise is investigative, universal, and covers all aspects of investment efficiency. It also reflects different information in that it determines microscopic evaluation index systems according to the different stages of highway project construction, as follows:

Construct prior microscopic evaluation efficiency index. The evaluation of prior construction in investment benefits primarily reflects controls over the investment decision-making as a feasibility study, (exploration design as well as the design progress). This paper chooses a project decision-making periodic rate and the design cycle rate. When applying the project decision-making periodic rate, the computed value should be 0 if the benefit is good. If not, explain prophase work plan is not accurate enough. When applying the project design cycle rate, the actual design cycle in the actual work should be stipulated in the contract design cycle. The value of the project design cycle rate should be near 0. If not, the contract is not practical enough or there are some problems with design work. The preparatory work and the quality of design are hard to guarantee.

Microscopic investment efficiency indicators in complete period. For the benefit of the project construction period, it reflects on the achievements of investment namely new project efficiency, quality, etc, Selected index is as follows:

The investment accomplishment ratio should have an optimal value of 100%.The project benefit accomplishment ratio value is between 0~1. From this numerical size we can see the construction section of project. The value is close to 1, the project close to completion. ③The accumulated fully funded ratio should reflect the progress of the project. With the capital progressively in place, the value should increase gradually from 0 to 1. If unplanned factors such as a rise in materials' price occurs and the extended construction period results in accumulated funds that are more than the total amount of the plan, the value is more than 1. For the project plan accomplishment ratio, check the implementation of the project with the index. The optimal value should be at 100%. An excellent project ratio reflects the quality of project construction. Only good quality can ensure good benefits. The optimal value is 100%.

Microscopic investment benefit indexes for completed period. Completed period means the project is completely consigned for use. Define unit mileage construction cost ratio and construction period ratio to reflect the benefit variation of this stage. Unit mileage construction cost rate should reflect the bias between actual cost and investment plan in unit mileage of a single project. It is convenient for project managers to analyze investment cost saving or waste. The optimal value is near zero. The construction period variation refers to the deviation degree between the actual construction period and the national project unified quota period, or designed and planned schedule. The actual construction period is more or less than the planned construction period .The optimal value should be nearby 0. However, this does not mean that a shorter time is better. A too-short time period will not guarantee quality. Too long will affect the investment benefit.

A structure drawing of the above-mentioned indexes and investment benefit in each construction process is shown in Figure 1.

THE EVALUATION METHOD OF INVESTMENT MICRO-BENEFIT

In order to enable management and decision-making that will precisely assess and analyze the investment effectiveness based on the above established index system of the investment micro-benefit in highway construction projects, a comprehensive evaluation of investment effectiveness must be carried out by synthesizing all of the gained statistical information of the investment. In this paper we apply the Fuzzy Comprehensive Evaluation method to comprehensively evaluate the investment micro-benefit in a highway construction project by making a comparison with the same period (Ma et al. 2005). The concrete steps of evaluation are as follows:

Ascertain the set of comment grade $V=(v_1,v_2,v_3,v_4,v_5)$.The set of comment grade is expressed as five grades: bad, below average, average, above average and

good with v_1、v_2、v_3、v_4 and v_5.

Construct the evaluation index system (general goal criterion index).

Corresponding to the established evaluation index system above, the hierarchical structure of evaluation is made up as follows.

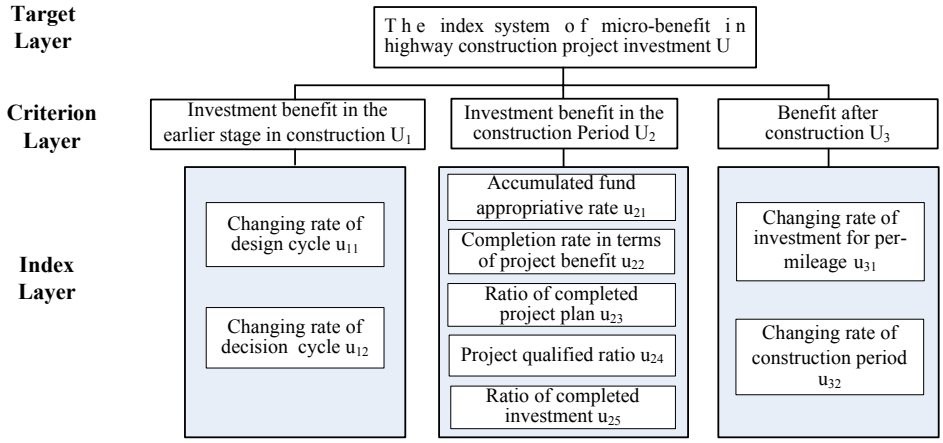

Figure 1.The Hierarchical Structure of Evaluation Indexes of Micro-Benefit.

Ascertain weighing. Ascertain the weighing vector A_t(t=1、2、3) about the bottom layer of index relative to criterion layer, and the weighing vector A about criterion layer relative to the overall goal. Each weighing vector is shown as A_1(a_{11}, a_{12}), A_2(a_{21}, a_{22}, a_{23}, a_{24}, a_{25})，A_3(a_{31}, a_{32})，A(a_1,a_2,a_3). This article determines weights using AHP and constructs the judgment matrix subjectively by multiple comparisons among indexes, then deals with figure and consistency tests according to judging matrix. From there, the relative importance weights of each indicator can be concluded.

Ascertain the grade of membership function of each level according to the content and its number range of each index.

For each index value under each criterion layer, ascertain its vector of membership degree R_{tj} (t=1,2,3;j=1,2,3,4,5);

For each criterion, construct the matrixes of membership degree R_t=(R_{t1}，R_{t2},….) by its membership vector, and solve the vector of membership degree B_t= A_t • R_t of each index;

Construct the matrixes of membership degree R=[B_1, B_2, B_3]of each criterion about overall goal by B_t, and solve the vector of membership degree B=A • R；

Solve the fuzzy evaluation value W=B·V^T of project investment effectiveness, in which V^T=(20，40，60，80，100) is the set of comment grade and W is single value. We can evaluate the quality by comparing W value of evaluation objects to comment grade.

Table 1. The Criterion of Grade and Comment.

Criterion	0～20	20～40	40～60	60～80	80～100
Comment Grade	bad	below average	average	above average	good

Use the above method for highway construction projects to evaluate the micro-benefit of investment for highway construction projects. Make certain the level and position of effectiveness is according to the evaluation scores of investment performance for construction projects.

EXAMPLE ANALYSIS

By using 2002 for the evaluation base year, this article takes Yulin-Jingbian expressway in Shaanxi province as an evaluation project to count and evaluate its investment performance. YuJing expressway is the first desert highway (134.174km) with 1.817 billion yuan in its project budgetary estimate. The project started in December 15, 1999 and ran until late September 2003. The practical project ran ahead 40 days of its planned duration of 39 months.

Determine the index weight. At the start of the evaluation, five experts were asked to determine the evaluation matrix according to the relative importance between the various indicators. The evaluation matrix included too many indicators to list.. For more details see references (Chang'an University, 2006).The forms judged by each experts were collated, and each expert's individual weight vectors of sub-indicators and indicators were calculated using AHP. Then the average weight vectors were worked out to educe the weight matrix A_1,A_2,A_3 of indicators strata and the weight matrix A of criterion strata.

A_1 = (0.29, 0.71) A_2 = (0.09, 0.17, 0.17, 0.50, 0.07)

A_3= (0.333, 0.667) A = (0.137, 0.625, 0.238)

In order to ensure the horizontal comparability of investment returns between different construction projects, each evaluation index weight adopts a unified standard.

Evaluation result. After working out the relative weight of each index, the evaluations of estimate, which reflect the different construction phases of the project investment efficiency were calculated. The final evaluation result W is shown in Table 2.

Table 2. The Evaluation Result of investment efficiency of Yujing Expressway.

Project Name	**Composite Scores**	**Total Comment**
Yulin-Jingbian Expressway	88	good
Each Index Name	**Actual Value of Index**	**Comment**
Changing rate of decision cycle	0.3333	below average

Changing rate of design cycle	-0.25	good
Accumulated fund appropriative rate	0.7401	above average
Completion rate in terms of project benefit	1	good
Ratio of completed project plan	——	——
Project qualified ratio	0.8065	good
Ratio of completed investment	1.0004	good
Changing rate of investment for per-mileage	-0.2685	good
Changing rate of construction period	-0.037	good

From the project evaluation results we can see that the overall investment performance of Yujing expressway is excellent, and the evaluation of sub-indicators in each phase of pre-construction, construction and construction completed are good or above average**.** The results indicate that the project not only shows good benefit in the pre-decision making and design aspects, but also in the organization and management of the construction process.

CONCLUSIONS

(1) Based on the analysis of the effective statistical indicators in highway construction investment, and according to the different construction phases of highway projects, this article sets up an evaluating index system of the investment micro-benefit in highway construction projects.

(2) Using the theory of fuzzy comprehensive evaluation combined with qualitative and quantitative analysis, the investment micro-benefit evaluation model in terms of a highway construction project is established. Finally, examples demonstrate the interoperability and practicability of the method to enhance the scientific and objective features of decision-making.

(3) To improve the evaluation system, the concrete usage should also be included. Some issues such as membership grade should be resolved gradually in follow-up studies in order to improve the reliability of the method.

ABSTRACT

A double crank four ring-plate-type cycloid reducer is a new drive that has high load capacity and high transmission efficiency. The vibration and noise tests of the reducer prototype are completed using the HEAD acoustics multi-channel noise test and analysis system. The noise distributing laws of the reducer surface at different rotational speeds and different loads are obtained. The main noise sources of the reducer are identified as the noise: 1) generated by involute spur gears when they mesh; 2) generated by the four ring-plates and cycloidal gear; and 3) radiated by the cylinder block vibration because of internal excitements. The relevant noise reduction measures are proposed for each of these noise sources. The experiment results show that noise reduction is achieved.

INTRODUCTION

A cycloidal pinwheel drive provides many advantages, including low volume, light weight, a high reduction ratio and high efficiency. The double crank four ring-plate-type cycloid reducer driven by three gears requires no output unit and the stiffness of the output shaft is high. The tumbler bearings are placed outside the gear, instead of inside the gear as in the traditional cycloid planetary drive. Hence, the size of the bearings is no longer restricted. The double crank four ring-plate-type cycloid reducer is able to transfer larger torques than a typical planetary cycloid drive. So, it is a new drive with large value of research and development (He W.D., 2000; Li L.X., 2005; Li X., 2004). However, it generates great noise, as does other machinery, that causes great harm to workers' health. So, noise reduction research is very urgent. The vibration and noise tests of the reducer prototype are completed using the HEAD acoustics multi-channel noise test and analysis system. The characteristics of the vibration and noise are obtained and the noise sources are identified. The paper also identifies appropriate noise reduction measures.

NOISE SOURCE IDENTIFICATION

Test contents.

The vibration and noise tests of the reducer prototype are completed using the

HEAD acoustics test and analysis system in an ordinary laboratory. Two noise test points and ten vibration test points were positioned in the test procedure. The location of the test points is shown in Figure 1. In order to grasp the noise distributing laws of the reducer, four different speeds and four different loads were selected. The four rotational speeds are 500 rotations per minute, 750 rotations per minute, 1000 rotations per minute and 1500 rotations per minute, respectively. The four loads are 25%, 50%, 75% and 100% of the full load, respectively.

Figure 1. Location of the test points.

Calculation of noise and vibration frequency generated by the reducer.

Noise and vibration frequency generated by involute spur gears.

The meshing frequency of gears can be expressed as

$$f_n = \frac{nz}{60} \tag{1}$$

where n is the gears speed and z is the teeth number of the gears.

The shaft frequency can be expressed as

$$f_s = \frac{n}{60} \tag{2}$$

The actual meshing frequency can be expressed as (He Yunru,1998)

$$f = lf_n \pm mf_s \tag{3}$$

where l and m are arbitrary integers. L is high harmonic frequency and m is the sideband number of modulation frequency when it is equal to shaft frequency. The teeth number of involute spur gears is 78, so the meshing frequency and the shaft frequency can be calculated by (1) and (2) shown in Table 1.

Noise and vibration frequency generated by ring-plates and cycloidal gear.

The teeth number of pin wheel in the ring-plate is 78. The noise and vibration frequency generated by ring-plates and cycloidal gear when they mesh can also be calculated using (1) and (2). The results are shown in Table 2.

Table 1. Frequency of involute spur gears.

rotational speed (r/min)	f_n(Hz)	f_s(Hz)
500	650	8.33
750	975	12.5
1000	1300	16.67
1500	1950	25

Table 2. Frequency of ring-plates and cycloidal gear.

rotational speed (r/min)	f_n(Hz)	f_s(Hz)
500	291.67	8.33
750	437.5	12.5
1000	583.3	16.67
1500	875	25

Test results and analysis.

Vibration frequency spectrum analysis.

Figure 2 shows the vibration frequency spectrum diagram of acc1 test point and Figure 3 shows the vibration frequency spectrum diagram of acc2 test point at 500 rotations per minute. The frequency spectrum diagrams of the other points are not given here due to limited space.

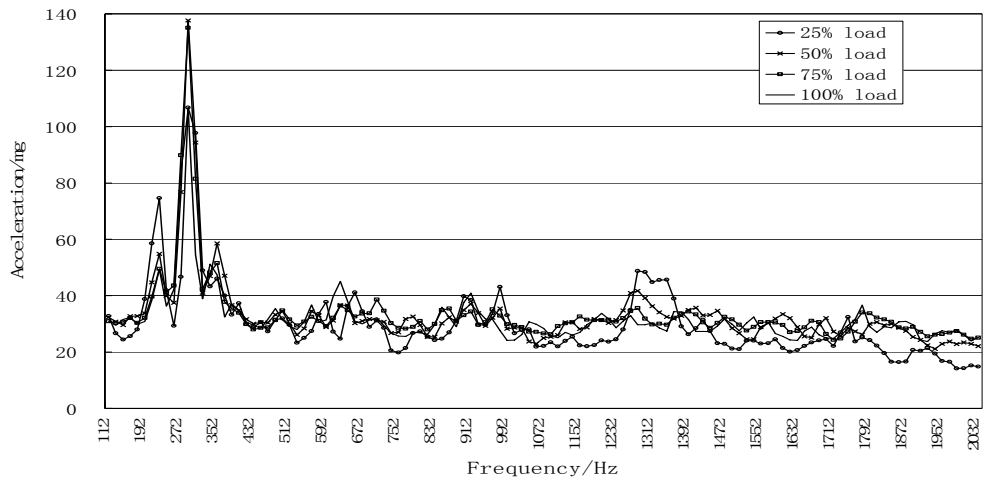

Figure 2. Acc1 spectrum diagram of different loads at the speed of 500r/min.

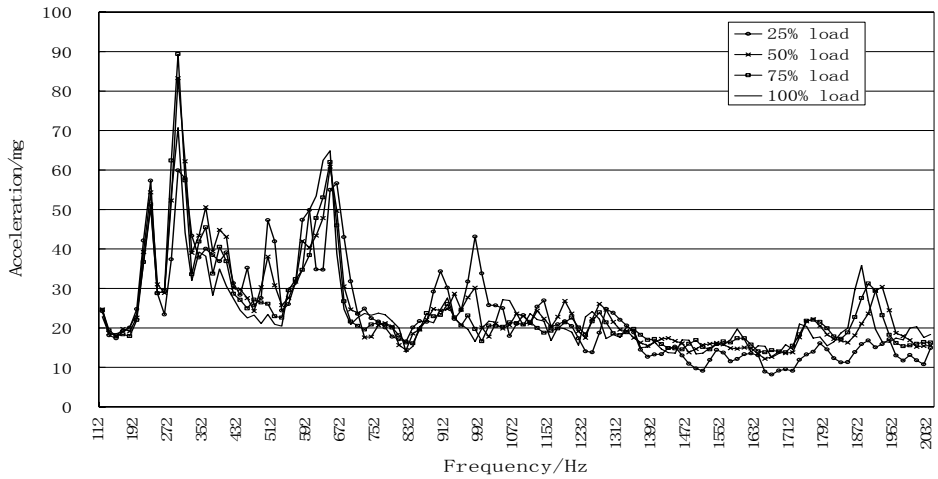

Figure 3. Acc2 spectrum diagram of different loads at the speed of 500r/min.

When the rotational speed is certain, the laws of vibration acceleration curves are roughly consistent with the changing of load. The peak frequencies are basically the same, but the peak values vary. In general, there are two frequency-bands. One is near 224Hz and the other is near 288 Hz at 500 rpm. For two frequency-bands, one is near 244Hz and the other is near 464 Hz at 750 rpm. For three frequency-bands, one is near 288Hz , one is near 608Hz ,and one is near 1296 Hz at 1000 rpm.

Noise frequency spectrum analysis.

Figure 4 shows the noise frequency spectrum diagram of mic1 test point at 500 rotations per minute. From the diagram, we can conclude that there are two frequency-bands. One is near 288Hz and the other is near 624 Hz at 500 rpm. And 288 Hz is the meshing frequency of ring-plates and cycloidal gear. From (3), we can determine that the third-order band below of the involute spur gears is 624Hz. The noise generated by involute spur gears when they mesh is larger than that of ring-plates and cycloidal gear at the speed of 500 rpm. And,the noise generated by ring-plates and cycloidal gear is larger than that of involute spur gears at the speed of 750 rpm and at the speed of 1000 rpm.

Main noise sources.

There are mainly two noise sources inside the reducer. One is the noise generated by ring-plates and cycloidal gear when they mesh and the other is the noise generated by involute spur gears when they mesh. The noise generated by involute spur gears is the main source at lower speed, while the noise generated by ring-plates and cycloidal gear is the main source at higher speed.

Acc1 and acc2 is symmetrical layout, so the frequency their spectrum diagram should be basically consistent in theory. However, their frequency spectrum diagrams

are very different actually, because the four ring-plates are not balanced. The four ring-plates do high-speed eccentric movement when they work. It is not possible to make the four ring-plates identical so the four ring-plates are not balanced.

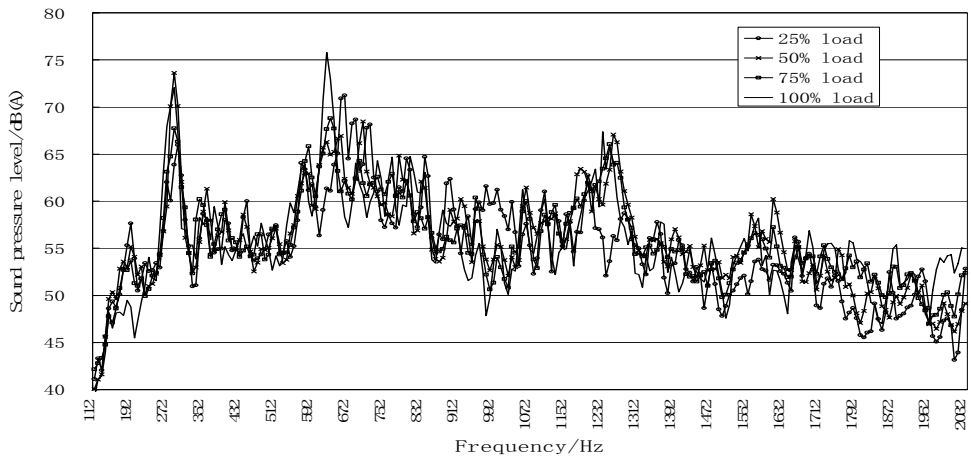

Figure 4. Mic1 spectrum diagram of different loads at the speed of 500r/min.

The resonance happens when the natural frequency of a component part is close to the exciting frequency. The exciting frequencies of the reducer mainly contain vibration frequencies generated by involute spur gears and vibration frequencies generated by ring-plates and cycloidal gear and their side-band frequencies. Test results show that the natural frequency of cylinder block is close to the exciting frequency so the resonance occurred. So the noise radiated by the cylinder block vibration is very large (Bao, J.H., 2005; Guo, W.Q., 2008; Qi J. Z., 2007).

NOISE REDUCTION MEASURES

In order to reduce the noise, the following measures can be adopted:

Damping ring.

Damping rings should be installed in the internal groove of the gear flanges. Damping rings decrease the gear damping from three aspects: systematic damping, structural damping and material damping. The vibration and noise would decrease after the use of damping rings.

Ring-plate reconstruction.

The inertia moment is smaller with the decrease of the ring-plate quality. So the ring-plate quality should be reduced as much as possible.The four ring-plates should be made identical as far as possible. Improving the accuracy of manufacturing and installation of ring-plates could also reduce the vibration and noise.

Cylinder block reconstruction.

The original cylinder block thickness is 12mm. The cylinder block thickness

should be 16mm after calculating in order to prevent resonance,. Test results show that the noise peak value of mic1 is reduced by 4.1 dB(A).

CONCLUSIONS

Double crank four ring-plate-type cycloid reducer is a new drive that has high load capacity and high transmission efficiency. The characteristics of the vibration and noise are obtained after the vibration and noise tests. The noise sources are identified. The experiment results show that the better effect of vibration and noise reduction is achieved.

ABSTRACT

In order to improve traffic safety and reduce the rate of traffic accidents on the flat curve of two-lane highway, this paper studied the operating speed of vehicle in straight line and little radius. Through the speed experiment, we collected the speed that vehicle traveled on a flat curve, and then ensured the critical radius of the two-lane highway. Finally, the paper established the modeling of the element of flat curve and speed, the element of flat curve and side friction factor coefficient. The model can be applied in safety evaluate of two-lane secondary highway in our country. The improvement is considerable.

INTRODUCTION

The geometric alignment of highway directly influences traffic safety and transportation operational efficiency. From the distribution of traffic accident on two-lane secondary highway (Du, 2002), we confirm that the horizontal curve sections especially minor radius of curve sections are concentrated with traffic accidents. Therefore, the master curve with the safety inherent in the relationship between the radius of the horizontal curve safety design and safety sections of both curves remediation is of great significance. Through many field surveys and analyses of the curve section of the vehicle at speed laws, a small radius curve segments operating speed and the radius of model was set up, and our country two-lane secondary highway curve radius of the critical value was derived. The future safety of Horizontal Curve design standards to provide basic information and research methods were also set up.

DATA ACQUISITION

The scope of this research is to study horizontal curves when we collect experimental data. Based on the research in the past, we select horizontal curve sections which have curve radius between 125m and 800m on secondary highway (Chang'an University 2005). Experimental times are from 9:00 to 11:00 in the morning and 15:00 to 17:00 in the afternoon. In order to ensure the accuracy of speed observed value, the minimum number of vehicles (sample size) using the

following formula to compute.

$$n = (\frac{\sigma K}{E})^2 \qquad (1)$$

In the equation, n- the minimum number of sample size, E- allowable error of speed observed value, K- confidence level, general selection 95% of confidence level ,that is k=1.96

Under traffic free flow condition, we set the speed measuring radar gun at straight line segment of entering the curve, mid-point of curve and line segment of leaving the curve. The data were used for measuring uninterrupted operating speed of vehicles. At the same time we recorded the situation of vehicle operation using DV cameras, recorded the travel time, and to calculate the speed of the vehicles. The layout of experimental apparatus is shown in Figure 1.

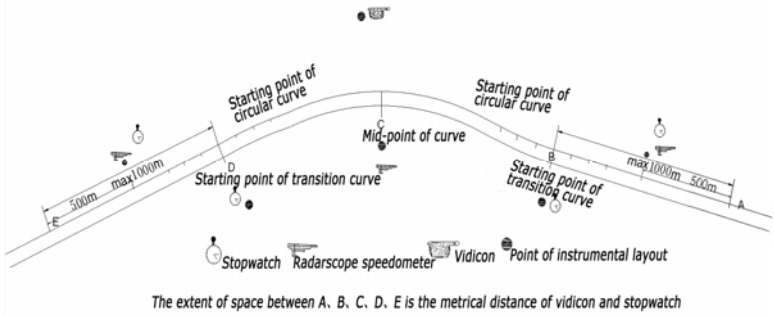

Figure 1. The Layout Schematic Diagram of Experimental Apparatus

DATA ANALYSIS

Data analysis for operating speed of line segment

In order to calibrate operating speed of motor-car and medium truck adjacent straight-line segments on two-lane secondary highways, we surveyed speeds of straight-line segments which adjacent minor radius of curve sections on Qinghai-Tibet Highway, Yanhu Highway, Meitai Highway and Fuhe Highway. The operating speeds collected were entered into SPSS. The speed histograms are shown in Figures 2 and 3, one can see the speed largely followed a normal distribution.

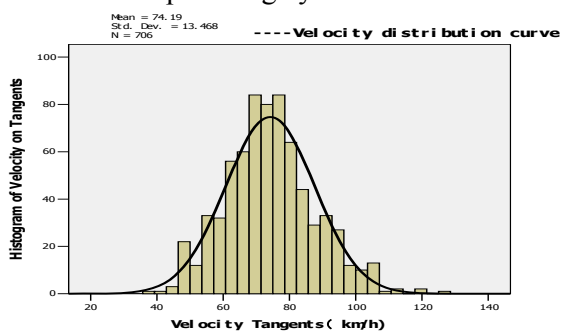

Figure 2. Speed Histogram for Straight-line Segment of Adjacent Curve (Motor car)

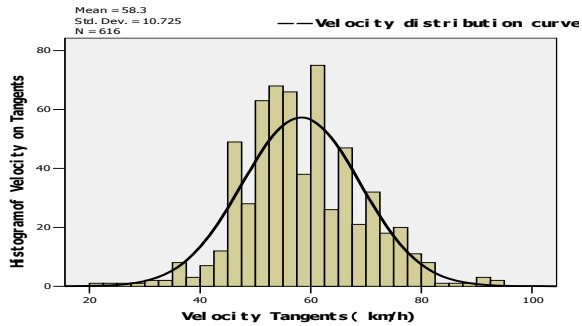

Figure 3.Speed Histogram for Straight-line Segment of Adjacent Curve (Medium truck)

Through analyzing operating speed data, we obtained the characteristic speed for motor-car and medium truck of straight-line segment on two-lane secondary highway.

Motor car: $V_{85\%}$=89km/h，$V_{50\%}$=73km/h；Medium truck: $V_{85\%}$=67km/h，$V_{50\%}$=50km/h

Data analysis for operating speed of minor radius of curve sections

Generally speaking, for the vehicles traveling on a curve, along with the transition curve - enter the curve - leaving curve, there will have a process of slowing to enter - maintaining stability – accelerating away. This article analyzed the change of vehicle speed before and after entering the curve based on the condition of different drivers at the same radius curve to driver. The author selected the minor radius of curve with radius of 200m, 300m and 500m, unfolds the effects of speed changes on traffic safety with different radius of curves.

(1) When the curve radius R = 200m, the distribution maps of operation law for motor car and medium truck as shown in Figures 4 and 5.

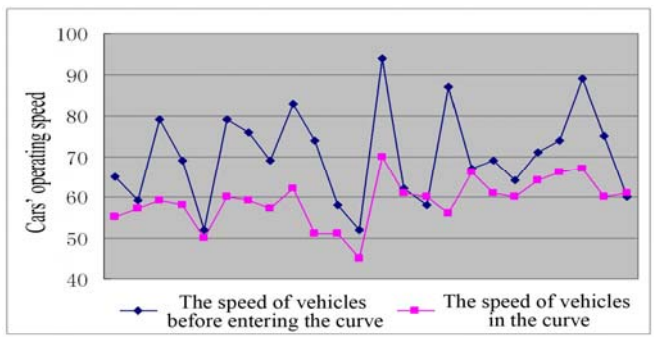

Figure 4. Speed Diagram of Motor car (R=200m)

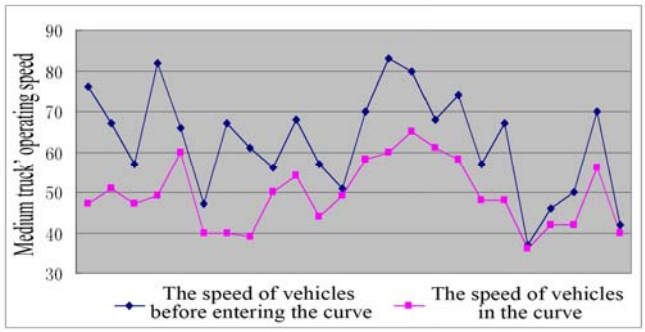

Figure 5.Speed Diagram of Medium truck (R=200m)

Figure 4 shows the situation of operating speed for motor car at a radius R=200m section of curve. The range of speed difference is -2 - 31km/h between before and after entering the curve, and the average of speed difference is 13.7 km/h. The bigger the speed is before entering the curve, the greater change of speed difference after entering the curve, only when the speed at 60km/h or so, the change of speed after entering the curve is not obvious. Figure 5 reflects the situation of operating speed for different medium trucks at a radius R=200m section of curve. The range of speed difference is 1 - 33km/h between before and after entering the curve, and the average of speed difference is 13.1 km/h. Compared with the motor car, the speed differences of medium truck are larger, and trucks have different deceleration. For medium trucks, the operating speed is about 50km/h when the curve radius is 200m.

(2) When the curve radius R =300m, the operation law of vehicles are basically the same as R = 200m.

(3) When the curve radius R = 500m, the distribution maps of operation law for motor car and medium truck as shown in Figures 6 and 7.

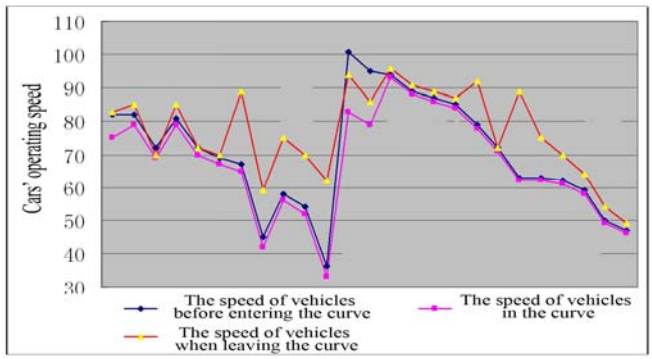

Figure 6. Speed Diagram of Motor Car (R=500m).

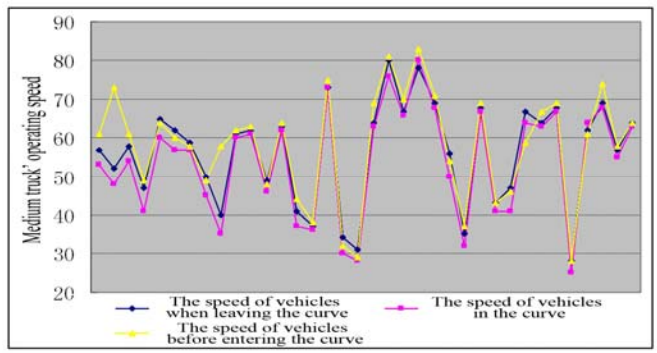

Figure 7. Speed Diagram of Medium Truck (R=500m)

Figure 6 shows the situation of operating speed for motor car at a radius R=500m section of curve. The range of speed difference is 1 - 18km/h between before and after entering the curve, and the average of speed difference is 3.08 km/h. The change range of speed difference is 1 - 29km/h between exit the curve and within the curve. It shows that the motor cars are accelerated when exiting the curve, and the exit speed is greater than the speed before entering the curve. Figure 7 shows the situation of operating speeds for medium trucks at a radius R=500m section of curve. The range of speed difference is -2 - 6km/h between before and after entering the curve, and the average of speed difference is 2.53 km/h. We can see that the changes of speed differences for medium trucks at a radius R = 500 meters have not been obvious before and after entering the curve. These results mean that the curves whose radius R = 500m are regarded as straight line when drivers of medium truck through it.

Based on the above analysis, we obtained some rules for vehicle operation of small radius of curve sections.

- There will have a process of slow to enter - maintain stability - accelerate away from when vehicles through the curves.
- The smaller the curve radius, the greater changes of speed difference between enter the curve and within the curve.
- The change process of vehicles speed before and after the centre of curve approximately showed a quadratic curve.
- The operating speed of vehicles increased with the increase of curve radius, and the range of motor cars speed increases is greater than that of medium trucks.

MODEL

According to the related research results about highway (Helmut et al.1995; Nicholas, 2001) vehicles run within the Horizontal Curve with less than the value of critical curve radius R_0 (critical radius is the radius when the curve radius is larger than this value, the running state of vehicles consistent with the straight line), and

the relationship between operating speed and curve radius can be expressed by power function. The model curve of "operating speed-radius" reflects the relationship between operational status of vehicles and the curve radius. Based on this theory, the model of vehicle operating speed which fit the actual situation in China is selected as follows:

$$V_{85\%} = aR^b \qquad (2)$$

Where: $V_{85\%}$ - 85 percentile speed, km/h; R - circular curve radius, m; a, b - model parameters.

Survey data were from some horizontal curves with radius of 200m, 250m, 300m, 400m, 500m, 600m and 650m on the two-lane secondary highway with the design speed of 80km/h, highway width of 11~15m, flat grade, and good or very good pavement condition without distresses. Based on the systemizing and analysis of the operating speed on the curve, the value of vehicles' operating speed, $V_{85\%}$, can be concluded and shown in Table 1. Its operating speed and the model of curve radius are shown as Equations 3 and 4. And the operating speed and the regression chart of curve radius are shown in Figures 8 and 9.

Table 1. The $V_{85\%}$ Value of Vehicles on the Horizontal Curve with Small Radius.

Radius of horizontal curve(m)	$V_{85\%}$ of cars(km/h)	$V_{85\%}$ of medium trucks(km/h)
200	64.0	44.5
250	67.0	46.8
300	73.0	53.0
400	79.0	57.9
500	84.0	66.4
600	88.0	68.8
650	90.0	69.0

The operating speed model for motor cars:

$V_{85\%} = 13.016R^{0.300}$, R^2=0.995 (3)

The operating speed model for medium trucks:

$V_{85\%} = 5.245R^{0.402}$, R^2=0.981 (4)

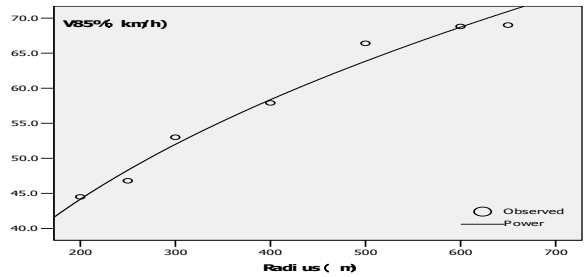

Figure 8. $V_{85\%}$ and Curve Radius Regression Chart (Motor Car)

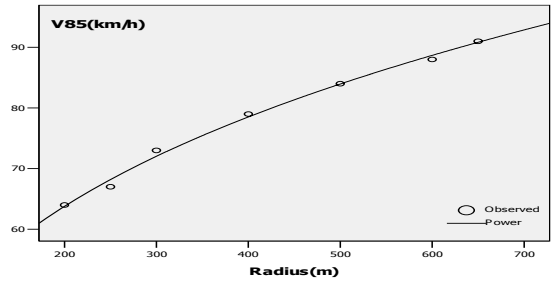

Figure 9. $V_{85\%}$ and Curve Radius Regression Chart (Medium Truck)

Because of the different performances on various vehicle types, the corresponding critical radius must be different at the same highway classification. A number of survey data have shown that, compared with the other models, critical radius of motor car is the biggest on highway at all levels. The critical radius of motor car for the secondary highways is 610m, and the critical radius of curves with small radius of medium truck is below 550m. The survey data revealed that, when vehicles entrance the horizontal curve with the radius R> 600m, the changes of vehicle speed are random and have no necessary connection to horizontal curve among these taken samples. Therefore, taking R_0=610m as the critical radius is reasonable.

CONCLUSIONS

(1) We have studied the characteristics of speeds of vehicles on straight line segment of two-lane secondary highway in China (motor car $V_{85\%}$＝89km/h, $V_{50\%}$ =73km/h; medium truck $V_{85\%}$＝67km/h，$V_{50\%}$=50km/h), and the operation law of motor car and medium truck on straight line segment and curve section with small radius.

(2)The models of operating speed and curve radius on curve section with small radius of two-lane secondary highway for motor cars and medium trucks are established. The model of operating speed for motor car is $V_{85\%} = 13.016R^{0.300}$, and the model of operating speed for medium truck is $V_{85\%} = 5.245R^{0.402}$.

(3)In this paper, the critical radius R_0=610m of curves with small radius of two-lane secondary highway in China is proposed.

ABSTRACT

Safety is essential for the great ship which are sailing in the restricted channel, by estimating the squat and the Under Keel Clearance (UKC) correctly. This paper conducted the study on the method for calculating the squat in restricted channel. While the ship is sailing in the restrictive channel, the squat is affected by ship boundary layer. In this paper, hydrodynamic theory and flat boundary layer theory were applied to put forward the approximate formula to calculate ship boundary layer. Considering the impact of ship boundary layer, the method of squat calculating was put forward. Finally, the method was verified by real ship data.

KEYWORDS: Squat, Restrictive Channel, Boundary Layer, Hydrodynamic Theory

1 BACKGROUND

When the ship is navigating in the restricted channel, the phenomenon will appear such as increasing of the draw, squat of the ship, or decreasing of Under Keel Clearance (UKC). Incorrect estimating of squat will lead to a series of maritime accidents, e.g. aground, grounding, out of control etc. It can be seen that the correct estimation on ship squat is significant to ensure the safety of the ships navigating in the restricted channel.

At first, theoretical analysis was used into the research of ship squat. Havelock (1939) used ship wave-making theory to study the squat of ship in the unrestricted water. This research did not consider the effect of the water depth on the squat. Constantine (1961) considered the water depth and put forward that hydrodynamic equation of one dimension should be applied to study the water flow around the hull in the shallow and confined channel. But he assumed that the speed of water flow was stationary. Afterward, some researches also studied the squat based on the previous results, such as Tuck (1966), Taylor (1970) etc.

The other way to research the ship squat was the experimental method. This method achieved the squat by simulating ship moving and exactly measuring, and then finding the relationship between the squat and the related factors. Theses researches included Hooft (1974), Huuska (1976), ICORELS (1980), Norrbin (1986), Millward (1990), Eryuzlu (1994), Soukhomel (2002). The research of ship squat in our county was behind other developed countries.

Although lots of results were obtained, few has mentioned the effect of fluid boundary layer on the ship squat. This paper analyzed the affect of restricted channel and fluid boundary layer on the ship squat. The hydrodynamic theory and flat boundary layer theory were applied to deduce the equation for calculating the ship boundary layer and squat.

2 SHIP SQUAT IN THE RESTRICTED CHANNEL

While the ship is navigating in the restricted channel, it displaces large amount of water and a blank field appears behind the poop of the ship. At the same time when the water surrounds the ship flows to fill the blank field, the water level at the side of the ship decreases. So the position of the ship also decreases. The decreasing distance is called "squat".

2.1 THE AFFECT OF THE RESTRICED CHANNEL ON THE SQUAT

In the open water, there was enough water to fill the blank field in the poop, so the squat was slight. But in the restricted channel, the amount of water was limited because of the restriction of the width and height of the restricted channel. So the water moving to the poop came from the bottom and the sides of the ship. The phenomenon increases the extent of the ship squat.

2.1 THE AFFECT OF THE SHIP BOUNDARY LAYER ON THE SQUAT

(1) Ship Boundary Layer

Boundary layer was provided by L.Prandtl (1904), a Germany scientist. Boundary layer is defined as a thin fluid layer at the surface of the object, in which the speed of the fluid increases from zero to the same speed around the water.

While ship is moving in the water, a boundary layer is established around ship. The width of the layer varies large by gradually changing, showed as Figure 1.

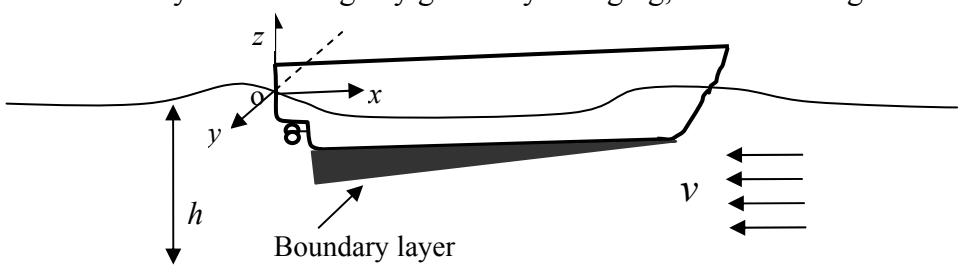

Figure 1. Draft of ship boundary layer

(2) Affect of the Ship Boundary Layer on the Squat

In the hydrodynamic theory, Bernoulli equation of constant and incompressible fluid is:

$$\frac{v^2}{2}+\frac{p}{\rho}+gz=\text{Constant} \tag{1}$$

Where, v is the speed of the fluid; $v^2/2$ is the kinetic energy of fluid per unit mass; p/ρ is the pressure of the fluid, at the surface, p/ρ=0; z is the height of the water lever; and gz is the potential energy of the fluid per unit mass.

Equation (1) describes the potential energy per unit mass of the fluid is constant at the same water level. Based on this, the Bernoulli equation of the water line *AB* in Figure 2 is

$$\frac{v_A^{\ 2}}{2} + gz_A = \frac{v_B^{\ 2}}{2} + gz_B = \text{Constant} \tag{2}$$

The points, *A* and *B,* were at the same waterline, and located at the middle and front of the ship respectively since the surface, p/ρ=0.

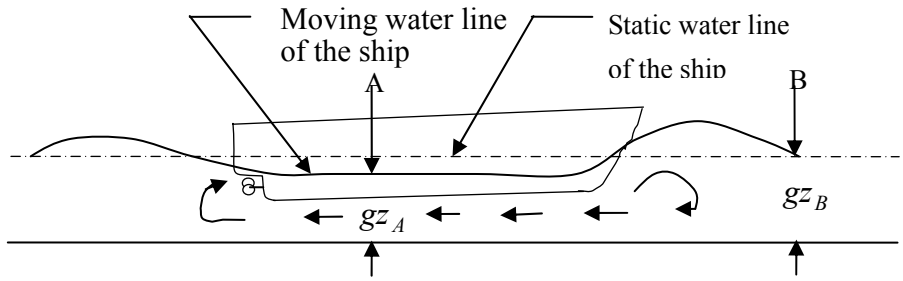

Figure 2. Energy components about the moving water line of the ship

The continuous equation of incompressible fluid is

$$Sv = \text{Constant} \tag{3}$$

Here, *S* is the cross-sectional area of the passing water. At the A and B,

$$S_A v_A = S_B v_B = \text{Constant} \tag{4}$$

Because of the existence of the ship hull, $S_A < S_B$. Regarding to the equation (2) and (3), $v_A > v_B$, $v_A^{\ 2}/2 > v_B^{\ 2}/2$, $gz_A < gz_B$. So it is known that the cross-sectional area of the passing water decreases due to the existence of the ship boundary layer and the squat increase further.

3 CALCULATING OF THE SQUAT IN THE RESTRICTED CHANNEL

3.1 CALCULATION OF THE WIDTH OF THE SHIP BOUNDARY LAYER

Based on the boundary theory, the width of the ship boundary layer is:

$$\delta(x) = 0.37x\,\mathrm{Re}_x^{-\frac{1}{5}} \tag{5}$$

Here, $\delta(x)$ is the width of the ship boundary layer and it varies with *x*. Re_x is Reynolds number which is formulated as:

$$\mathrm{Re}_x = \frac{vx}{\upsilon} \tag{6}$$

υ is the coefficient of moving sticky of fluid.

$$S_0 v = (S_0 - S(x))v', \qquad v' = \frac{S_0 v}{S_0 - S(x)} \tag{7}$$

So the width of the ship boundary layer is

$$\delta(x) = 0.37x^{\frac{4}{5}}(\upsilon)^{\frac{1}{5}}\left(\frac{S_0 v}{S_0 - S(x)}\right)^{-\frac{1}{5}} \tag{8}$$

3.2 CALCULATION OF THE SHIP SQUAT

Any point *x* at the ship, the cross-sectional area of the passing fluid $A(x)$ is

$$A(x) = S_0 - S_1 - S_2 - S_3 \tag{9}$$

S_0 is the cross-sectional area in channel, $S_0 = Bh$, B and h is the width and height of the channel; S_1 is the cross-sectional area of the ship hull under the water surface; S_2 is the variant area around ship hull, $S_2 = [B - b(x)]\zeta$, $b(x)$ is the width of ship hull under the water, ζ is the variation of water surface around the hull; S_3 is the area of the boundary layer, $S_3 = [2T + b(x)]\delta(x)$, T is the draw. After exchanging, $A(x)$ can be formulated as follows:

$$A(x) = Bh - S_1(x) - [B - b(x)]\zeta - [2T + b(x)]\delta(x) \tag{10}$$

Because of $v'(x) \cdot A(X) = v \cdot S_0$, $v'(x)$ is the function of v, if $v'(x) = \tilde{q} \cdot v$, then

$$\tilde{q}\{1 - \frac{S_1(x)}{S_0} - [1 - \frac{b(x)}{B}]\frac{\zeta}{h} - \frac{[2T + b(x)]\delta(x)}{S_0}\} = 1 \tag{11}$$

At any waterline of the surface, $g\zeta + \frac{1}{2}(\tilde{q}\, v)^2 = \frac{1}{2}v^2$, and at the waterline around hull, $\frac{P}{\rho} + gz + \frac{1}{2}(\tilde{q}U)^2 = \frac{1}{2}v^2$, it is know that the pressure of the fluid P can be described by:

$$P = \rho g(\zeta - z) \tag{12}$$

The pressure of water affecting on the ship is equal to the gravitation of the ship itself. The gravitation of the ship also is equal to its displacements:

$$\rho g\Delta = \iint -P dS' \cdot \hat{z} \tag{13}$$

Δ is the displacement of the ship, S' is the total areas of the hull under water; $\hat{z}$ is the vector on the axis z.

Divergence theorem was applied to exchange the equation (13), then

$$\rho g\Delta = \iint -\nabla P \cdot \hat{z} dv = \iiint \rho g dV \tag{14}$$

Where $dV = dxdya$ is the capacity of the ship under water. It is assumed that the squat in the middle of the ship is *s* (Figure 3). Then at any point on the ship, the squat is:

$$\sigma(x) = \frac{2 \cdot s \cdot x}{L} \tag{15}$$

Where L is the length of the ship. At any point *x*, the decrease and the increase of cross-sectional area of the hull under water is $b(x)\zeta(x)$ and $b(x)\sigma(x)$ respectively.

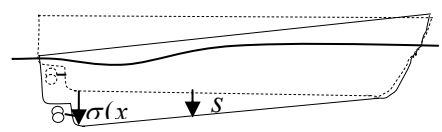

Figure 3. Draft of the Ship

The displacements of the ship is constant whether the ship is moving or not:

$$\int_0^L b(x)\sigma(x)dx - \int_0^L b(x)\zeta(x)dx = 0 \tag{16}$$

After the transformation, the ship squat is:

$$s = \frac{L\int_0^L b(x)\cdot\zeta(x)\cdot dx}{2\int_0^L x\cdot b(x)\cdot dx} \tag{17}$$

The maximum squat is:

$$S = \frac{2\cdot s\cdot L}{L} = 2\cdot s = L\frac{\int_0^L b(x)\cdot\zeta(x)\cdot dx}{\int_0^L x\cdot b(x)\cdot dx} \tag{18}$$

4 REAL DEMONSTRATIONS

The real data of the ship, Wigley, was selected to verify the proposed method. The width of hull and the cross-sectional area of hull under water are described by:

$$b(x) = b_{\max}[1-\frac{(2x-L)^2}{L^2}] \tag{19}$$

$$S(x) = \frac{2}{3}T\cdot b(x) = \frac{2}{3}T\cdot b_{\max}[1-\frac{(2x-L)^2}{L^2}] \tag{20}$$

The parameters of the restricted channel is

$L = 200m$, $b_{\max} = 40m$, $T = 9m$, $v = 5m/s$, $B = 80m$, $h = 12m$;

$S_0 = Bh = 960$; $F_h = \frac{v}{\sqrt{gh}} = \frac{5}{\sqrt{10\times 10}} = 0.46$; $b(x) = 40[1-\frac{(x-100)^2}{10000}]$,

$S(x) = 240[1-\frac{(x-100)^2}{10000}]$. If the temperature of the water is 10º, $\upsilon = 1.306\times 10^{-6}$.

The calculated results of the squat by using different methods were listed in Table 1.

Table1. Calculated results of the squat

	Considering the boundary layer	Without consideration of boundary layer	Soukhomel model
The maximum squat (m)	1.188	1.078	1.09
UKC (m)	1.812	1.922	1.91

Regarding to Table 1, it is clear that the squat is maximal and the UKC is minimal by using the method with the consideration of the ship boundary layer.

5 CONCLUSIONS

This paper studies the method for calculating the ship squat in the restricted channel. Firstly, the paper analyzed the effect of the ship boundary layer and the restricted channel on the squat. Then hydrodynamic theory and flat boundary layer theory were applied to deduce the calculating equation of the ship boundary layer and the ship squat in the restricted channel. Finally, the real ship data was used to verify the method. The compared analysis demonstrated that the result calculated by the method provided in this paper is compiled to the actual case.

ABSTRACT

The driver's visual characteristics and road safety are closely related. Previous studies show that 80% of the divers' information of the road is obtained by their eyes. Therefore, the visual characteristics are closely related to driving operations. In this paper, on the basis of the theoretical analysis at home and abroad before, dynamic visual characteristics research about two different categories of drivers (professional and non-professional drivers) in real-world road environment have been explored. In the research, eye tracking system was used to study regularity of fixation duration and the perspective distribution. Two kinds of drivers were compared and conclusion of distribution visual feature had been made. It was found from this study that the driving experience had an obvious effect on the drivers' eye movement characteristics. It was concluded from the study of perspective distribution that the drivers' concern on the vicinity was more than the objects in a distance. The findings from this study will assist the design of roadway, satisfy drivers' driving request, and make the roadways safer.

Key words: dynamic visual characteristics, visual tracking, eye tracking system

INTRODUCTION

Drivers always capture the traffic information by their eyes when they are driving on the road. Drivers' visual characteristics have a direct impact on road safety. During driving, 95% information received by drivers is dynamic visual information (Ma Y. et al. 2006). As a result, it is very necessary to study the drivers' dynamic visual characteristics and its impact on traffic safety. Drivers at home and abroad have been required to have good visual characteristics, but this inspection is carried out at the static state (Geoffrey U. et al. 2002). In this paper, the result is based on the investigation on the real road conditions. Comparison of the professional and non-professional drivers was made. Finally, the drivers' dynamic visual characteristics and its variation regularity were summarized.

DRIVERS' DYNAMIC VISUAL CHARACTERISTICS

The drives' vision when they are driving is called dynamic vision. The visual

characteristics can be affected by some influential factors (Zhao B. 1988): the driver's age and status, road environment, the relative velocity, the illumination, and color of target, etc. The information captured by drivers is very complex. And it affects drivers' decision making and other road users' safety. Thus, it's necessary for us to study the dynamic visual characteristics of drivers. In this paper, the process of drivers' visual perception was studied. Driver's dynamic visual characteristics were analyzed and described. Another focus of this paper is on some influential factors of the drivers' visual characteristics, such as the individual differences (e.g. driving experience) among drivers and road environment.

DATA COLLECTION

In this study, Smart-Eye Pro. eye tracking system was used as an observation instrument (see Figure 1) to conduct experiment. The instrument is a system which consists of four parts (Smart Eye AB. 2007): an infrared light source from the camera, a scene camera, a image and data processing host, and a software which can track and measure eye movement characteristics of the drivers. The system can make real-time status tracking of drivers' movement, such as the driver's head position, eye sight and eye closure. Its output is the corresponding original data. The eye movement experiment was conducted for both professional and non-professional drivers in different conditions, from which the data of drivers' visual behavior can be obtained.

Drivers' eye movement during driving is a complex process. Considering the characteristics of system's data collection and making reference to data of similar studies, the following data were taken as evaluation criteria (Fan H. et al. 2007): the drivers' fixation distribution, the average fixation duration, and the perspective distribution.

Data for this study were collected on the typical suburban roads and urban roads in Nanjing. The investigations were made in sunny days and non-holidays as well. The objects of investigations were professional and non-professional drivers.

Figure 1. Eye tracking system and running interface in Smart-Eye Pro

DATA PROCESSING AND ANALYSIS

Eye tracking system recorded data including the numbers of experimental data points, the coordinates of trajectory points, and so on. These data were used after reprocessing. The data of the drivers' fixation distribution and the values of horizontal or vertical perspective are obtained. The features of dynamic visualization of drivers

could be observed and analyzed by experiments.

- **Variations of drivers' fixation points**

The fixation of a driver is the instantaneous point which the driver fixes on. The process of eye movement can be directly described by fixation distribution (see Figure 2). For different drivers, the fixations are different.

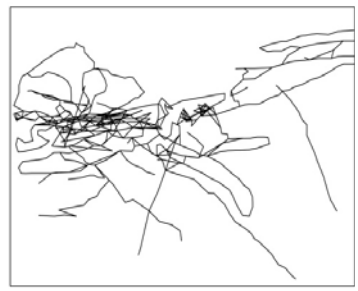

Figure 2. The driver's fixation distribution

Variation on horizontal direction

The variations on horizontal direction were analyzed based on the path types and the driving experience (see Figure 3).

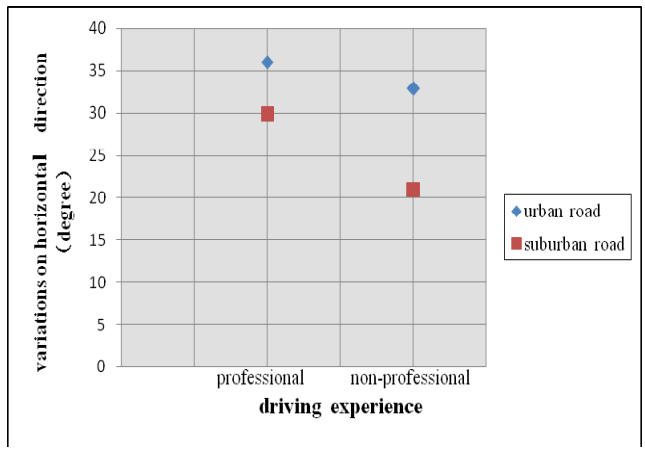

Figure 3. Chart of variations on horizontal direction

Compared with suburban roads, all drivers on urban roads have a large change in the horizontal direction of fixation points. The reason for this is the complexity of traffic information. When driving on the urban road, drivers are affected by vehicles which are in front of, in opposite direction and on the left lane. At the same time, non-motorized vehicles and pedestrians crossing the street also have some impacts on the driving behaviors. Drivers are in a condition with so much information that they need to watch wider. However, the situation is different on the suburban roadways where traffic volume is relatively low.

Due to the fact that non-professional drivers do less information search on both sides of the road, their scope of visual search is smaller than that of professional drivers. There is obvious difference between two types of drivers when they're on suburban roads. It's difficult for non-professional drivers to get the information on

roadsides when they drive on suburban roads with a high volume of heavy vehicles. As a result, the non-professional drivers' scope of visual search is smaller.

Variation on vertical direction

The variations on vertical direction were analyzed based on the path types and the driving experience (see Figure 4).

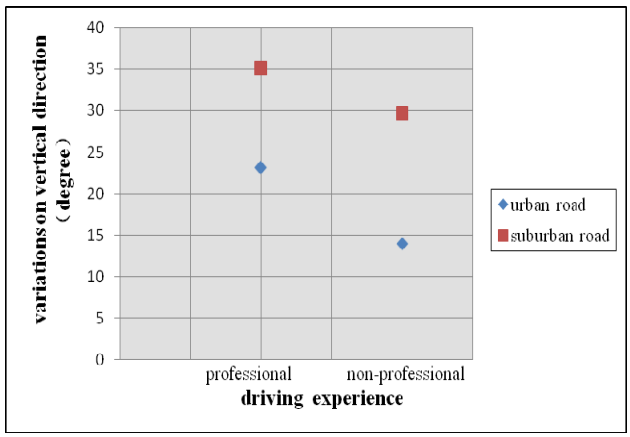

Figure 4. Chart of variations on vertical direction

According to the figure, in different types of roadways, all drivers have obvious differences on the level of vertical visual search. Compared with urban roads, drivers' fixation on suburban roads changed a lot. Due to the fact that drivers don't have enough time to look around, the situation exists when driving on urban roads. At this point, driving experience seems very important.

Although they have the same change trend, compared with professional drivers, non-professional drivers' level of vertical visual search is obviously lower. The reason for this situation is that non-professional drivers are not familiar with the road condition. They couldn't prepare for the signal indication in advance and so on.

Table 1. Variations of drivers' fixation points on different kinds of road

Road types	urban roads		suburban roads	
Driving experience	professional	non-professional	professional	non-professional
Variation on horizontal direction（degree）	36.0	33.0	29.9	20.9
Percentage(compared with professional drivers)	8.3%		30.1%	
Variation on vertical direction(degree)	23.1	14.0	35.2	29.7
Percentage(compared with professional drivers)	39.4%		15.6%	

Through the table, it can be seen that different types of drivers have different characteristics of the dynamic vision on urban roads and suburban roads. The driver on urban roads pays more attention on both sides of the road than the vehicle in front of. Through analysis, it is found that the level of non-professional drivers' visual search is significantly lower than professional drivers'. This is due to the fact that non-professional drivers are lack of driving experience. They couldn't obtain the information accurately, such as traffic signals and signs.

Nowadays, there're more and more non-professional drivers on roads, as the status of them the traffic flow will be great influenced. Road conditions and the facilities should be designed more desirable for these drivers.

- **The average fixation duration**

The average fixation duration was analyzed, which based on the path types and the driving experience (see Table 2).

Table 2. The average fixation duration of drivers on different kinds of road (seconds)

Road types	urban roads		suburban roads	
Driving experience	Professional	non-professional	professional	non-professional
The average fixation duration(seconds)	0.258	0.271	0.323	0.317
Percentage(compared with professional drivers)	5.0%		1.9%	

The experiment showed that the average fixation duration of drivers on urban roads were shorter suburban roads. The complexity information of the urban road leads the driver to spend less time to observe and judge them.

Take these two kinds of drivers for comparison, the non-professional driver's fixation duration is longer than professional driver. Then, conclusion can be made that non-professional driver needs more time to make reactions, which indicates that they will take more time to recognize and judge traffic information than the professional driver.

This message will help the traffic planners and engineers. They can design the traffic signals and signs in such a way to meet requirements of non-professional drivers.

- **Perspective distribution (horizontal direction) change**

The perspective change refers to the driver's eye rotation changes while driving. Normally, when a driver is observing an important target or dealing with some abnormal information, his/her eyes will be significantly changed in angular velocity.

Distribution of fixation regions in horizontal zone

In this study, drivers' visual field was divided into three regions with regard to different roadways (see Figure 5).

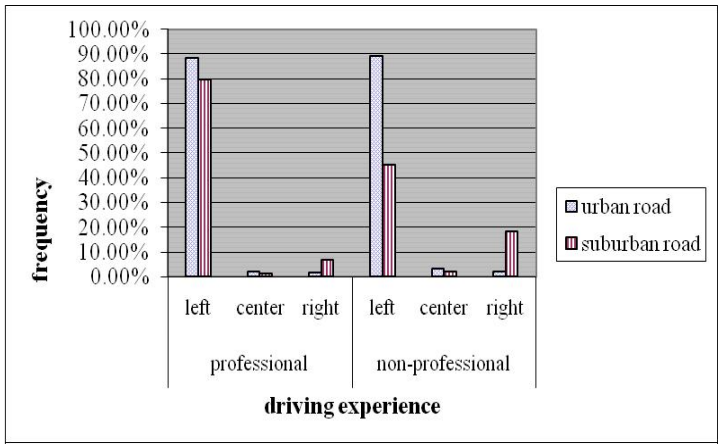

Figure 5. Chart of distribution of fixation regions in horizontal zone

Figure 5 shows that drivers gaze at the left side more frequently than central region and the right side. The frequency of professional drivers on either side doesn't change a lot. For non-professional drivers, there's a significant change. They gaze at the left side of the road more often while driving on the urban road. However, they pay more attention on the right side of the suburban road. The reason is that during investigation, the experiment vehicle run on the leftmost traffic lane, which is different from normal situation.

Some of non-professional drivers always keep slow speed even there aren't many vehicles. As the result, they always are overtaken by others. When they are overtaken, they watch the vehicles on left lanes. However, they still don't keep paying attention to the left lanes even if there aren't so many cars.

Distribution of fixation angles in horizontal direction

After analyzing the fixation angles of drivers in different types of roadways, some results were received (see Figure 6).

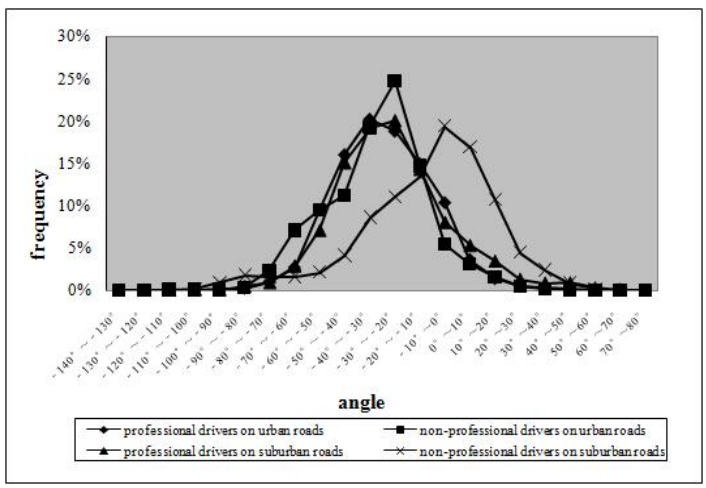

Figure 6. Chart of distribution of fixation angles in horizontal direction

The results show that drivers on the different road sections have the similar distributions. For two types of drivers, the distributions of fixation angles in horizontal direction are both the normal distributions, with all peak points being located on the left of angle 0°. As can be seen from the chart, the professional driver's search scope is larger than the non-professional driver.

Due to the differences between two kinds of drivers, the cognitive ability of non-professional drivers should be carefully considered in the design of roadways. The traffic signals and signs should be designed and installed properly for drivers, especially for non-professional drivers. The results from this study look good for improvement of the roadway safety and efficiency.

CONCLUSION

This paper investigates drivers' dynamic visual characteristics by means of eye tracking system. Corresponding experiments were conducted in the real road conditions to collect necessary data. Based on the data analysis and comparison some conclusions related to regularities of professional and non-professional drivers on fixation distribution, the average fixation duration and the perspective distribution have been reached.

From this study it is found that the road environment has great impact on the drivers' dynamic visual characteristics, especially on the non-professional drivers. During driving, the driver's eye drift to the front and left anterior. Apart from that it is observed that the non-professional driver needs more time to gain the traffic information and their ability of reacting any events is inadequate.

The other finding from this study is that driving experience has a great influence on driving behaviors, including the dynamic visual characteristics. As the number of the non-professional driver increases, it is necessary to improve the location of traffic signs and the environment, because it will enhance safety as well as improve the efficiency of roadways. This paper may have significant contribution to roadway's design and management.

ABSTRACT

In the present paper，study on the influence of hydrodynamic pressure on a 40-meter deep pile-cap pier was made on the basis of the engineering project of the Yangtze River Bridge #3 in Nanjing. Hydrodynamic pressure of the pile-cap pier was evaluated using a three-dimensional finite element model proposed for investigating the dynamical behavior of the pile-cap pier during earthquake in deep water. Two models of the pile-cap pier were proposed for the cases under the conditions with and without water, respectively. The hydrodynamic pressure along the pile caps has increased from top to bottom, and coupling effects would not be ignored in the design of deep-water piers. The numerical results were compared with those from a shaking table experiment, showing a good agreement with each other, especially in the displacement results and mode analysis of the structure.

Keywords: Numerical Analysis, Hydrodynamic Pressure, Shaking-Table Test, Dynamic Response, Earthquake

INTRODUCTION

Since the 21st century, sustained development of bridge construction in China has pulled many long-span bridges into our sights, including the design of the Sutong Bridge (with a main span of 1088m), the Stonecutters Bridge in Hong Kong (the main span is 1018m), and Zhoushan Island Bridge program in which the Xihoumen Bridge is expected to be built with a main span of 1650m.

In general, construction of bridges above deep rivers and sea are challenged by deep water. Some regions of rivers and seas are 80m deep, with the deepest up to 120 m. The effect of waves and fluid on bridge piers is obviously expected very important. Analysis of interaction between piers and water has to account for coupling effects. Solid under the action of fluid will produce deformation or movement, which in turn imposes an impact on the movement and stress of water. This process can be modeled by means of coupled equations, with unknowns to describe fluids and solids, respectively, and the solution domain covering both the fluids and solids. Morison

proposed to calculate the wave force using the Morison equations in 1950 (Morison 1950). However, since the equations include the nonlinear terms, numerical modeling and application of spectrum method for the seismic response of bridge structures becomes more difficult. Goto and Kotsubo used the Westergaard method to analyze a cylinder on the hydrodynamic pressure and found that the Westergaard solution is better for a short cylinder rather than a slender one (Goto H. et al. 1965). Yuan Yinchun discussed how the nonlinear items in the Morison formulas contribute to the seismic response of ordinary bridge pile and pier structure, and simplified the calculation of seismic response of bridges. Zhang Hailong indicated that the hydrodynamic pressure had a significant impact on the seismic response of bridge pier structures, and he suggested to incorporate the effect of hydrodynamic pressure into seismic design (Zhang et al. 2007). Zhang Guoming conducted a study on deep-water piers to compare the methods of hydrodynamic pressure computation due to earthquake between the anti-seismic bridge codes employed in Japan and in China, and analyzed the similarities and differences of the hydrodynamic pressure computations in the two codes (Zhang et al 2008)..

As opposed to the experimental study of wave forces, dynamic test of underwater structure, especially shaking table experiments in water, is rarely conducted both domestically and internationally. Lai Wei and Wang Junjie carried out a shaking table experiment on the underwater pile-group foundation, and analyzed the interaction between seismic response of that foundation subjected to hydrodynamic pressure and interaction of water and structure under different seismic wave levels (Lai et al. 2007). Zhang Guoming took the Third Nanjing Yangtze River Bridge as a benchmark project, and designed and setup a pile-cap pier model testby using the similar principles with the scale factor of 1:50. A shaking table test was completed by loading and seismic wave from Tianjin area in two cases of model: the one around water and the one without water.

SIMULATION OF DYNAMIC BEHAVIOR OF PIERS IN DEEP WATER

Nanjing Yangtze River Bridge No. 3, which is shown in Figure 1, an important part of the national highway connecting Shanghai and Chengdu, is located in the upper reaches of Nanjing Yangtze River. The total length of the traffic line is 15.6km, along which the cable-stayed bridge has a total length of 1288m with a main span of 648m. Figure 1 also shows the twin towers that are composed of steel box girders, which have double cable-plane with the south pier foundation reaching the depth of 50m below zero. This investigation mainly focuses on the hydrodynamic pressure of the south pier.

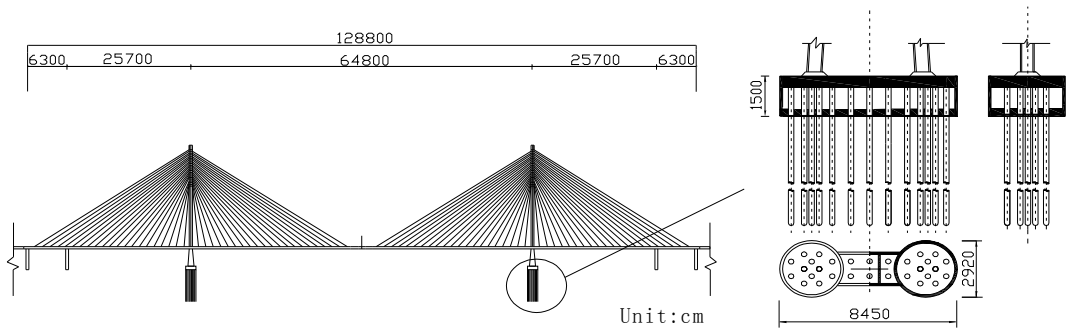

Figure 1. Nanjing Yangtze River Bridge No.3 and its south pier

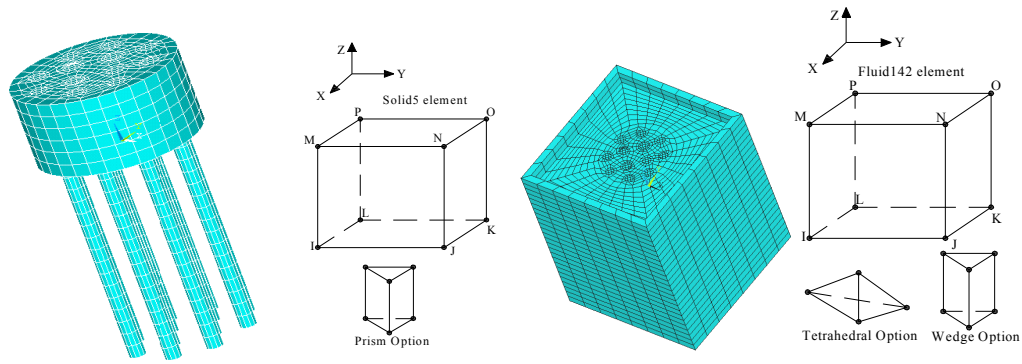
Since the fluid--structure interaction induces fluid-solid coupling effect and the Nanjing Yangtze River Bridge No.3 is supported by piles with more than 50% of their lengths in earth layers, some assumptions are introduced, including that the interface of piles and soil is rigidly jointed. Across the direction of flow, the dumbbell-shaped foundation is symmetric, so only one circle pile cap foundation is selected for research. Figure 2 shows Solid5 element and Fluid142 element, which are respectively used to simulate concrete units and water unit. In the finite element method, fluid model should be established first, and then the solid model. The fluid-solid coupling tags（also known as FSI）are imposed on the interface of fluid-solid. In this investigation, two models are established, as shown in Figure 2: one for the piles without water in the surrounding area, and the other for piles in the water, in an effort to compare mechanical properties of the piles in the water and in anhydrous state. It should be noted that the fluid elements need to be analyzed within a rigid wall, so a "sink" is built to contain the piles and water.



(a)Model of piers and Solid5 element (b)Model of water and Fluid142 element

Figure 2. Model discretization

Regarding the boundary conditions, the bottom of the piles without water is fixed while the topp part is pressed with uniformly distributed load to consider the effect of upper load; the same is true to the piles in the water, while the grid container is also fixed.

The finite element model is analyzed with the imposed boundary conditions. Analysis of the model refers to dynamic characteristics and seismic response. Results

of the first four vibration frequencies and subsequent vibration figures are listed in Table 1.

Table 1. Results of natural vibration

Order	1	2	3	4
Frequency(Hz)	0.293	0.556	4.029	4.601
Period(s)	3.413	1.798	0.248	0.217
Vibration mode				

An earthquake acceleration-time record does not accord with a defined function, but rather a series of time-varying random pulse, and vibration modes and frequencies change so much that there is without any model to discribed it. Thus, the solution to the dynamic equation is not available unless seismic waves are given versus time △T(time step) for numerical simulation. Then the basic integral equation dynamic movemet of the structure during each time step can be resolved. Finally, the structure displacement, velocity, acceleration and internal forces will be obtained.

Considering the site characteristics, seismic waves have been adjusted according to relevant principles. Tianjin seismic waves (Figure 3) were input,,with a peak acceleration of 244.62galand the main cycle of 0.55s. Frequency range of these seismic waves are wider than others, so they are more suitable for seismic design; over years they have been used as a typical example from a major earthquake.

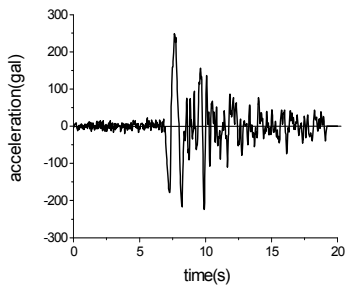


Figure 3. The acceleration-time curve of curve of seismic waves from Tianjin

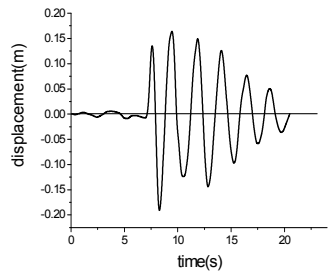

Figure 4. The Displacement-time node 4964

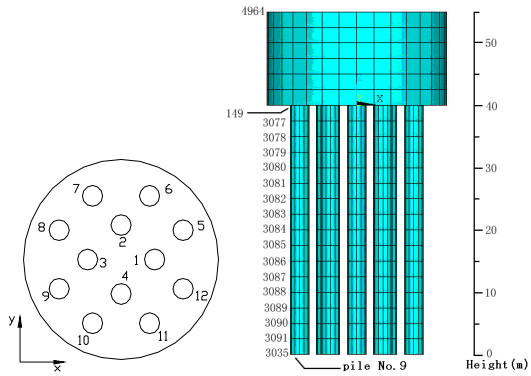

Figure 5. Location of piles and key nodes in pile cap

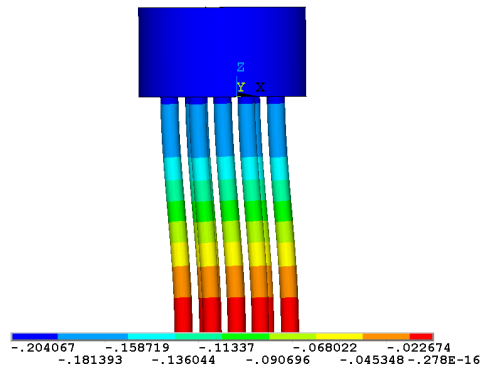

Figure 6. Nephogram of displacement in x direction

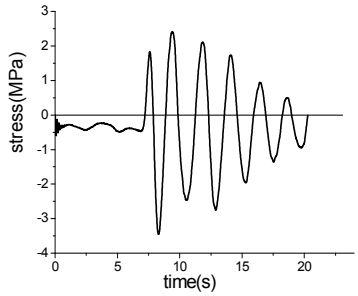

Figure 7. Stress-time curve of node 3035

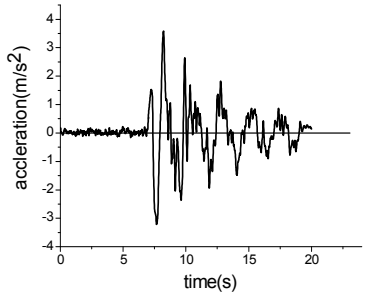

Figure 8. Acceleration-time curve of node 4964

Figure 4 is the ANSYS simulation of the displacement of node 4964 in the pile caps. This point is on the boundary of the top face of the cap as shown in Figure 5. Time-curves from the figure show the maximum displacement is 0.191m, and the cloud chart of this moment for the whole pile-cap pier is shown in Figure 6. The entire cap is basically in the translational state, while the displacement of piles increases from the bottom to the top gradually. In the whole process of the interaction, the largest compressive stress is 3.45 MPa, which appears at node 3035, as shown in Figure 5, at the bottom of the pile at the moment of 8.35s, which is not exactly consistent with the appearance of the largest displacement. And the largest tensile stress is 2.41 MPa at the moment of 9.43 s. Stress-time curve of node 3035 is shown in Figure 7.

ANSYS can not directly give the acceleration-time curve. However, after taking derivatives of the displacement twice, the acceleration-time curve of the node 4964 is shown in Figure 8, with the peak acceleration of 3.53m/s^2 at the moment of 8.20s, a little earlier then the maximum displacement and stress.

EXPERIMENTAL STUDY OF DYNAMIC BEHAVIOR OF PIERS BY SHAKING TABLE TEST

Test of interaction between water and piers mainly consists of shaking table test and vibration site test. Since shaking table test features in high repeatability and feasibility and is easy to control experimental process, it has been used by more and more researchersas a tool for analysis of solid-fluid coupling. In last several years,

with development of similarity theory and advances of anti-seismic test technology, shaking table test became the popular way to study structural dynamic problems.

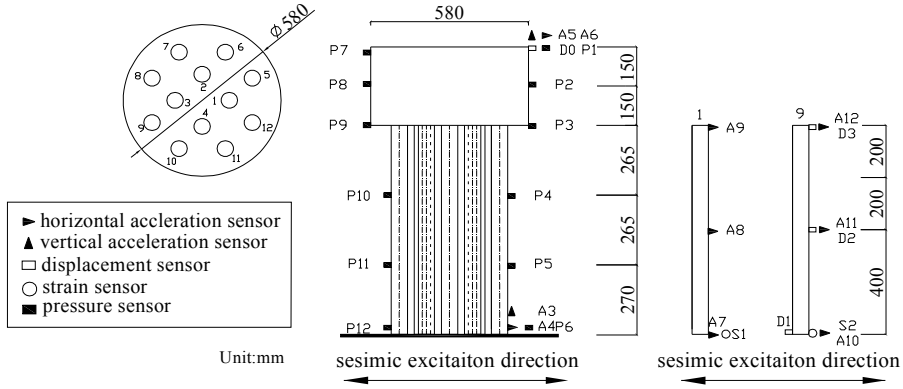

Figure 9. Layout of the testing facilities

South pier cap of Nanjing Yangtze River Bridge No. 3 is dumbbell-shaped, with a dimension of 84m (along the bridge)×29m (longitudinal to the bridge) and its thickness 7.5m. Its concrete cover is 4.6m thick. Each circle part consists of a total of 30 bored piles, and each of them is 3m in diameter and 120m in length at the deepest area. The bearing stratum is a weathering mudstone layer. South pier foundation and pile cap layout is given in Figure 9. Similarity factors are decided by the size of shaking table and the experimental model. The size of the shaking table is 1.5m × 1.5m, while the prototype diameter of the pile caps is 30m, so similarity factor is 1:50. Other similarity factors are listed in Table 2. Measuring points of the experimental model are located as shown in Figure 9. Seismic waves from Tianjin were selected for the experiment, which is the same as the waves used for numerical simulation. Thus comparisons can be made to evaluate the two methods mentioned above. A collection is made to evaluate water pressure of test piles, which is distributed at the pier elevation as shown in Figure 10, from Figure 10, hydrodynamic pressure on the pile caps has increased from top to bottom, below the height of 40cm the increase in water pressure slows down.

COMPARISONS OF RESULTS FROM NUMERICAL ANALYSIS AND SHAKING TABLE TEST

A comparison is made between the numerical and experimental results. The model similarity factor for the natural frequency is 33.5, and the expected value of natural frequency in numerical way is 6.72/33.5=0.201Hz. The test results are in good agreement with the simulation results, as shown in Table 3.

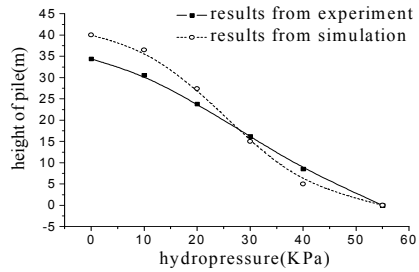

Figure 10. Comparison in hydrodynamic pressure

Table 3. A comparison of two methods

Physical Quantity	Similarity factor
Length	$S_l = 1/50$
Elastic modulus	$S_E = 6.87$
Density	$S_\rho = 6.87$
Acceleration	$S_a = 1$
Stress	$S_\sigma = S_E = 6.87$
Strain	$S_\varepsilon = S_\sigma / S_E = 1$
Inertia force	$S_F = S_E S_l^2 = 2.75\text{e}{-3}$
Water pressure	$S_P = S_l = 0.02$
Moment	$S_M = S_E S_l^3 = 5.5\text{e}{-5}$
Frequency	$S_f = S_l^{-1}\sqrt{S_\rho / S_E} = 33.5$
Time	$S_t = S_l\sqrt{S_E / S_\rho} = 0.03$
Displacement	$S_u = S_l = 0.02$

Table 2. List of similarity factors

	Numerical way	Experimental way
Vibration mode	1	1
Natural frequency(Hz)	0.210	6.72
Max-displacement(cm)	19.4	0.388

From Figure 8, the numerical simulation shows the peak displacement at the top is 19.1cm, as opposed to the experimental result of is 0.388cm. With displacement similarity factor 0.02, the expected value of peak displacement in numerical simulation is 0.388/0.02=19.4cm, which is in a good agreement with the actual result. The occurance of the largest displacement and the largest compressive stress does not coincide, just as the numerical simulation indicates. And also, the largest tensile stress comes up after the largest compressive stress, which is just like the simulation way. For the hydrodynamic pressure, which is shown in Figure 10, however, there is an obvious difference in pressure-height curve between the two methods, such as the pressure at the pile bottom by the experiment is 35kPa as compared to 40kPa in the simulation, the difference may be due to the fact that boundary conditions vary in different methods. But both curves basically follow the same trend.

CONCLUSIONS

In this investigation, with the Nanjing Yangtze River Bridge No.3 as the engineering benckmark, a finite element model of pile foundation was proposed to explore fundamental dynamical behavior of the pile-cap pier during an earthquake in

deep water. A comparison was made between the numerical and the experimental results. The numerical outcome match well with those from the experiment, especially in the displacement and mode analysis of the structure.

Actually, the water domain near the analysis boundary should have been considered infinite. In this paper, only part of the water was taken into account. Also we introduced other simplifications, such as the pile length and the structure material, which should be further investigated. On the other hand, the model test is only limite to the elastic stage of the structure, the elastic-plastic stage will be considered in the future research.

ABSTRACT

Taking the 2003-2005 highway accident data surveyed from Hada Highway and Hashuang Highway into consideration, rear-end collisions are divided into two patterns: rear-collisions and stationary object collisions. The principal analysis identified the impact level of different factors on two types of rear-end collisions. Then, significant impact factors are detected and identified by charting analysis and clustering research. The final investigation result indicates that fatigue, excessive speed, unsafe following distance, congestion et al, are main impact factors on rear collision accidents. However, excessive speed, fatigue, illegal parking, et al, have a significant effect on the occurrence of stationary object collisions, which provide a reference for highway management departments.

INTRODUCTION

Highways, as a modern transport infrastructure, play an important role in the development of society and economics, with the merits of huge traffic flow, high speed travel, well-equipped and comfortable traffic environment, et al, which leads to its high efficiency in supporting industrial development and improvement (Button et al, 2000). However, automobiles are becoming popular with urban families and becoming a need for enjoying the convenience of modern life directly brought by technological development. Severe social problems such as heavy traffic congestion, environmental pollution, and traffic accidents have become one of the central and heated issues accompanying the increase of automobiles, leading to traffic accidents that especially attract the world's attention (Hamada et al, 2006).. In China, for instance, it has been officially announced that more than one million people lost lives in traffic accidents in 2003, in which random rear-end and side-swiping collisions,

caused by an insufficient following gap and braking distance, covers about one-third of the total accidents.

To cope with this problem, a program on Intelligent Transportation Systems (ITS) has been proposed to increase road efficiency and decrease the negative effect of accident-related factors and countermeasures. Both administrative and technology measures, have also been adopted to investigate the causes and probability of traffic accidents. During the research, the rear-end collision was considered the main accident pattern on highways and its occurrence was considered to be a key idea affecting investigation results and result implications, especially rear-end and side-wiping collisions. Therefore, the research, with wide recognition, contributes to smooth traffic flow control, accident prevention and traffic safety administration.

ACCIDENT TYPE CLASSIFICATION

According to accident patterns, highway rear-end collisions are divided into two types, including rear collision, characterized by the collision between the front of the following vehicle and the rear of the leading vehicle (Davis et al, 2006). The other is the stationary object collision, which occur between the front of the following vehicle and the rear of the stationary parked vehicle. Based on this definition, accidents surveyed from Hada Highway and Hashuang Highway from 2003 to 2005 were classified into two types, as listed in Table 1 and Table 2.

Table 1. Rear-end Accident Pattern Distribution on Hada Highway

Accident Patterns	Accident Number (Times)		Death (P)		Injury (P)		Economic loss (×10^4Yuan)	
	Hd	Hs	Hd	Hs	Hd	Hs	Hd	Hs
Rear-end collisions	46	55	37	33	46	35	97.70	144.85
Stationary Object collisions	6	7	4	3	10	6	5.80	10.42

The equivalent number of accidents (Neyens et al, 2007) is introduced to analyze the seriousness of different patterns of highway accidents.

$$ER_i = K_1 F_i + K_2 J_i + R_i \quad (1)$$

where ER_i is the equivalent number of the ith rear-end accident. K_1 is the weight of dead persons in the ith rear-end accident. K_2 is the weight of injured persons in the ith rear-end accident. F_i is the statistical number of dead person in the i^{th} rear-end accident. J_i is the statistical number of the injured person in the i^{th} rear-end accident. R_i is the accident number of the i^{th} rear-end accident.

For the sake of simplicity, the weight k_1 of the dead person is considered 2.0 and the corresponding injured k_2 is 1.5 (Garcia et al, 2006). From Table 1, the equivalent numbers of each rear-end accident pattern on Hada Highway are obtained as ER_1=189, ER_2=29 and the result is the same for Hashuang Highway, ER_1=173.5 and ER_2=22. Therefore, rear-end collisions are the main cause of highway accidents.

PRINCIPAL COMPONENT ANALYSIS METHOD

To distinguish the degree of impact of the above-mentioned factors for highway rear-end collisions, the principal component analysis method which transfers a few indicators into some main indicators, is used to analyze the influence degree (Wang et al, 2008). According to its working theory, the calculation process is divided into the following six steps.

The statistical accident data is recorded as

$$X=\begin{bmatrix} X_1 \\ X_2 \\ \vdots \\ X_3 \end{bmatrix}=\begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1p} \\ x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & & \vdots \\ x_{n1} & x_{n2} & \cdots & x_{np} \end{bmatrix} \tag{2}$$

For $(i=1,2,\cdots,n;\ j=1,2,\cdots,p)$, initial accident data is standardized by Z-score as $x_{ij}^{*}=(x_{ij}-\bar{x}_j)/\sigma_j$, which means value $\bar{x}_j=\sum_{t=1}^{n}x_{tj}/n$, $\sigma_j^2=\frac{1}{n-1}\sum_{t=1}^{n}(x_{ti}-\bar{x}_j)^2$. Thus, for $(i=1,2,\cdots,n;\ j=1,2,\cdots,p)$, correlation coefficient matrix R is defined as $R=(r_{ij})_{p\times p}$, here $r_{ij}=\frac{1}{n-1}\sum_{t=1}^{n}x_{ti}^{*}\bullet x_{tj}^{*}$.

If the given values comply with $\lambda_1\ge\lambda_2\ge\cdots\ge\lambda_p\ge 0$, $a_1,a_2,\cdots,p$ is the corresponding orthogonal unit eigenvector, then the i^{th} PCA of vector X is defined as $Z_i=a_i^{t}X$, where Z_1 is named as the first principal components of investigated vector. Contribution rate of PCA is determined by $G(m)=\sum_{i=1}^{m}\lambda_i/\sum_{i=1}^{p}\lambda_i$. According to the analysis result, accident causes could be investigated.

ACCIDENT IMPACT DETERMINATION BY PCA

The purpose of analyzing the impact factors is to make the quantitative analysis of the relationship between each factor and the occurrence probability of rear-end collision and detect the main factors, which will provide a research basis[9].

Rear-end accidents. Four indictors of rear-end collisions on Hada Highway and Hashuang Highway are surveyed ranging from 2003 to 2005. The results are obtained by principal components analysis method as

Eigenvalues and eigenvectors are λ_1 =3.7192, λ_2 =0.1783, λ_3 =0.0762, λ_4 =0.0263. The eigenvector of λ_1 is Z_1 =(0.5002, 0.5164, 0.4984, 0.4845). Supposing m=1, then the contribution rate of PCA can by calculated by model (3)

$$G(1)=\sum_{i=1}^{m}\lambda_i/\sum_{i=1}^{p}\lambda_i=0.9298>80\% \tag{3}$$

The result is more than 80% and indicates the feasibility of characterizing the four indicators with a comprehensive one. The impact force of each factor can be judged by model (4), where X_i is the standardized accident data as in Table 3.

$$Z_1 = 0.5002X_1 + 0.5164X_2 + 0.4985X_3 + 0.4845X_4 \quad (4)$$

For the analysis of impact factors of stationary vehicle collisions, the result is obtained by PCA as shown in Table 4.

Table 3. Evaluation of Impact Factors for Rear-end Collision

Impact factor	Number (X_1)	Dead toll (X_2)	Injuries (X_3)	Economic losses (X_4)	(Z_1)
Over-speeding	2.046	1.638	2.157	0.866	3.36
Drunk driving	-0.535	-0.648	-0.728	-0.609	-1.26

IMPACT FACTOR DETERMINATION

The purpose of analyzing the impact factors is to make the quantitative analysis of impact factors on rear-end collisions with the calculation result of evaluation indicators, which will provide the basis to determine the relationship

between each factor and the occurrence probability of rear-end collisions (Dzianis et al, 2008).

Using charts and cluster analysis methods to choose the impact factors behind the accident, then the main impact factors can be identified. The chart method is more commonly used with the simple, direct, easy to understand features. Impact factors acquired by principal component analysis are sorted according to size, then drawn from the evaluation index chart, as shown in Figure 1, and Figure 2. Design elements are divided into three types according to curve trend, then 0 and 2 are chosen as thresholds.

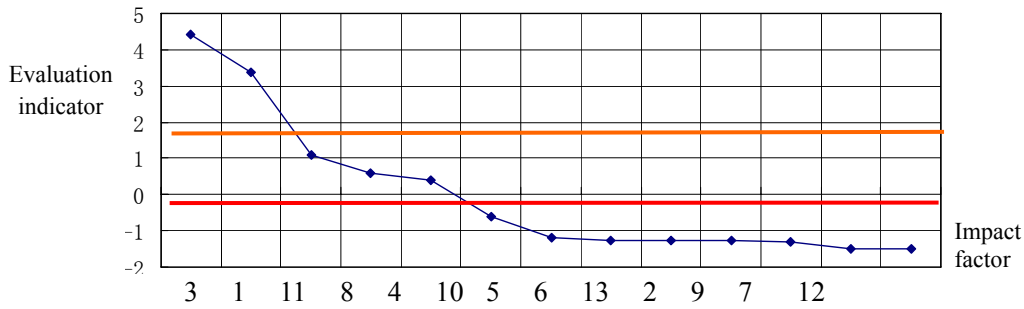

Figure 1. Index of impact factor on rear-end collision

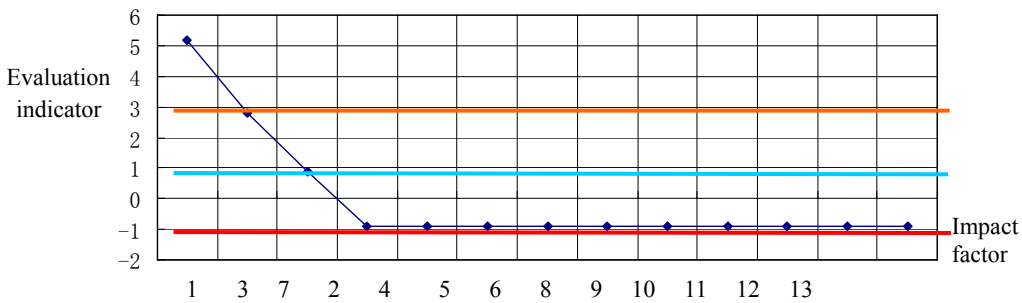

Figure 2. Index of impact factor on stationary vehicle collision

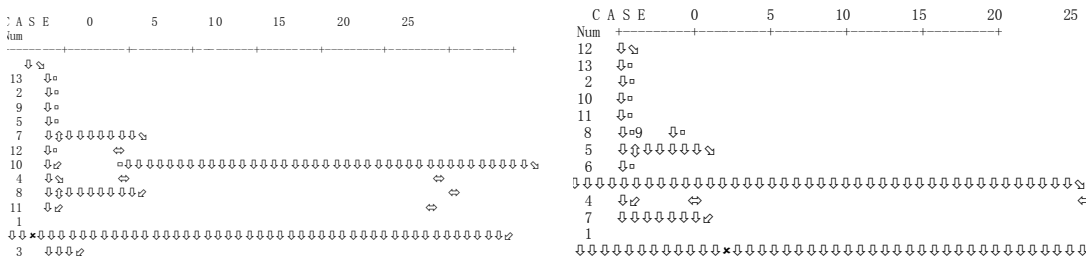
The basic idea of clustering analysis is to classify each research object in a category and combine the two that are more similar with each other, then calculate the distance and similarity between the new category and other categories. This process continues until all objects classified in a category. With SPSS, Figure 3 shows the result of the clustering analysis.



a) Rear-end collision b) stationary vehicle collision

Figure 3. Hierarchical clustering results by PCA

DISCUSSION AND CONCLUSION

The indicators are investigated to analyze the impact factors on rear-end accidents and stationary vehicle collisions by PCA. By chart analysis, three types are acquired. The first is fatigue driving and over-speeding, and the second includes vehicle factors, unsafe following distance, overloading of trucks, improper braking, passenger overloading, illegal overtaking, environmental factors, drunk driving, illegal lane-changing and road conditions.

With clustering analysis, three types are also acquired. The first is fatigue driving and over-speeding and the second is vehicle factors, unsafe following distance, and overloading of trucks. Then the third includes improper braking, passenger overloading, illegal overtaking, environmental factors, drunk driving, illegal lane-changing and road conditions. The analysis result indicates they are consistent. According to the comprehensive analysis, the outstanding five impact factors are chosen as fatigue driving, over-speeding, vehicle factors, unsafe following distance and vehicle overloading.

ABSTRACT

The index of generalized traffic demand is proposed from the property of trip time and space. Considering the factors of trip mode, trip distance, trip velocity, and a generalized traffic demand, a model is developed which can weigh the size of traffic demand per hour. The corresponding general traffic demand model of transportation model is developed according to the characteristics of motor vehicles and pedestrians. The paper uses a given city as an example and the generalized traffic demand model correlative to the impact factor is developed and the relation between traffic demand and factors is analyzed. The paper presents the countermeasures decreasing the urban transportation problem using an average case analysis. From the conclusion, the two most obvious factors which affect the majority of general traffic demand are the structure of activity patterns and the average trip velocity. An increased proportion of bus transit and commuter transportation are the most obvious factors to decrease total car trip. Increased speed of private car use is the most obvious factor to decrease the total car trip.

INTRODUCTION

Running mode of transport accounts for a total area of the road and the actual existence of the road space within a certain time and space are in general used as the indicators to measure city passenger transport demand and supply (Yao et al, 2005). Previous research on the traffic demand was discussed as to the number of standard cars in peak hours at the actual road network in a certain period of time. Scale indicators are: peak-hour traffic, mixed traffic generation, and non-motorized traffic generation, such as production. Traffic demand studies have not fully considered travel distance and travel speed (Karst et al, 2004; Ryan et al, 2003),, a single volume of traffic generation can not measure the characteristics of traffic demand, such as travel speed, trip distance etc. (Wang et al, 2008).

Louis presented the concept of consumption of time and space in his research on capacity of road network(Boamet et al, 2001).. Based on capacity of road network, road length and effective travel time which compose road resources have attributes of time and space consumption. In this paper, the study is also based on the consideration of the traditional static traffic demand to promote completion of a

resident's trip. Generalized traffic demand will describe it as the traffic generation with a certain number of travel speed travel distance per unit of time. This paper provides a good combination point for analysis on traffic demand and traffic supply, not only can the efficiency of city transport systems be analyzed to provide a basis to urban transport policy making, but it also can be used as an important part of transportation demand management.

GENERALIZED TRAFFIC DEMAND MODEL

Research Method. Traffic production includes traffic generation and traffic attraction. Traffic process can be described as generation unit and attraction unit accomplish the given traffic distance through stated traffic methods and definite speed. Previous research focused on each part step-by-step, no research took traffic process as traffic demand production. Researching and optimizing the characteristics of urban traffic demand generation can adapt limited roadway system resources (Giulio et al, 2005).

In general, pedestrian flow and vehicle flow are quite heavy. For the given city, the gross of traffic generation is fixed in a period of time, but the distribution effect is decided by different kinds of speed, distance and varying traffic modes. From the space-time demand property of traffic generation, generalized passenger transport traffic demand is raised; it is considered as the amount that is produced by diversified traffic mode and converted to equivalent car. This amount has definite traffic speed and traffic time properties. When urban roadway space-time resources are limited, the effect is different. Research on traffic demand optimization not only optimizes and controls its effect, but also puts forward a new idea for traffic research in large cities.

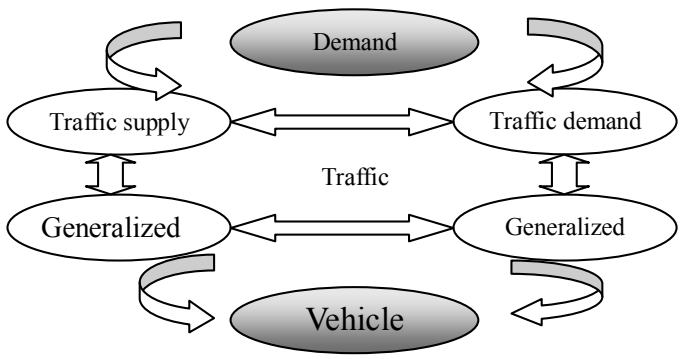

Figure 1. Traffic demand vehicle circulation efficiency analysis

In the city roadway system, the traffic unit includes vehicles, non-vehicles and pedestrians. When vehicle and non-vehicle use road resources, pedestrians usually use the walking system. Compared with the vehicle system, the walking system uses limited road resources. This paper considers traffic demand produced by the walking system alone. In the passenger transport structure, the transfer from pedestrian traffic mode to others should be calculated by founded models.

Vehicle demand model. The framework of our urban passenger transport is

quite complex. In general, different cities have different frameworks and different traffic mode proportions. Using a large city as a research object in this paper, vehicles are classified as: bus, commuter cars, car, private car and taxi. The production of urban traffic demand relates the traffic gross and intensity, the total traffic quantity of the *i* kind traffic model is $Q_{Mi} = P \cdot Y \cdot P_i \cdot D_i$.

Where, Q_{Mi} is the total traffic quantity of the i^{th} kind traffic model, person-time．km; P is the total urban passenger transport quantity, person-time; Y is traffic intensity, time/(person．day); M_i is traffic model, except walking traffic; P_i is the traffic proportion of the i^{th} kind traffic model, $\sum_i P_i = 1$; D_i is the average traffic distance of the i^{th} kind traffic model, km.

Then in the road system, the total traffic quantity means the summation of all kinds of traffic model, except walking, and is defined as $Q = P \cdot Y \sum P_i \cdot D_i$. Traffic quantity in unit time relates to urban scale, urban development degree and so on, calculated method: $Q_t = Q / T$.

This index reflects the traffic demand in unit time. In general, this index has the same rule with the resident traffic which changes following time. In peak hours, this index affects urban traffic demand directly, and can be obtained by stating the traffic data in a different period of time(Yam et al, 2000). In order to accomplish this, traffic needs some kind of traffic mode with a stated speed and must complete the traffic within the traffic distance. Owing to traffic should use some road resources in urban traffic systems and the walking traffic uses fewer resources than vehicles. For research convenience, this paper researches the walking system separately: $VEH_i = K_i / C_i$

Changing different traffic mode passenger transport quantity into equivalent car, then generalized passenger transport demand measure model:

$$M = PEO \cdot Y \sum_i \frac{P_i \cdot D_i \cdot K_i}{C_i \cdot V_i \cdot T} \qquad (1)$$

where, M is Generalized total passenger transport demand, veh/min-1; C_i is the average patronage of No. *i* transportation, people; V_i is the average trip speed of No. *i* species mode of transportation, km/h; k_i is vehicle model converted coefficient.

The meaning of generalized passenger transport demand of per unit time is the multiplication of the various traffic generated equivalent amount of car travel with the product of the sum of travel time. Vehicles must occupy some space resources of the road network. This model has the same dimensionless approach as the generalized road network capacity, if the generalized traffic demand is assigned to the road network, and we can analyze the operational efficiency of motor vehicles traffic in the city road network.

Supposing $a_i = D_i K_i / C_i V_i$, the type of number *i* traffic relationship with the traffic demand is calculated as follows:

$$M_i = a_i P_i + \frac{(1-P_i)P_1 a_1}{1-P_0} + \cdots + \frac{(1-P_i)P_{j-1} a_j}{1-P_0} + \cdots \frac{(1-P_i)P_{j+1} a_{j+1}}{1-P_0} + \cdots + \frac{(1-P_i)P_n a_n}{1-P_0}$$

$$= a_i P_i + \frac{(1-P_i)}{1-P_0} \sum_{j \neq i} P_j a_j \qquad (2)$$

N is the passenger transport form of the quantity, p_i is the proportion of type number i transport mode for the mode of transportation in the status quo, it can be seen that the impact of the volume demand in various ways is different. Order $b_i = P_i D_i K_i / C_i$, so the average trip speed and demand model:

$$M_i = b_i / V_i + \sum_{j \neq 1} b_j / V_j \qquad (3)$$

This indicator reflects the level of city traffic load. On the whole, the volume demand increases as the speed decreases, but with different modes of travel, the extent of the impact is different. When a certain mode of travel's travel speed is 0, the traffic demand is considered infinite; when road traffic jams occur, consider the local traffic demand as infinite. Vehicles parked in the road system occupy time and space resources, but without travel.

Foot traffic demand model. Traveling by walking uses a shorter distance, and speed is comparatively stable. So, as a separate model to study, use the above analysis methods to set up the foot traffic system demand model:

$$M_p = PEO \cdot Y \frac{P_p \cdot D_p}{T \cdot V_p} \qquad (4)$$

Where, p_i is the traffic-sharing ratio of walking, %; D_i is the average trip distance of foot traffic, km; V_i is the average travel speed of foot traffic, km / h.

Foot traffic through the walking system provides an analysis of the total supply. The current problem of the walking system in our country is the Humanized Design of the foot traffic system which enhances the level of the motor city but reduces the proportion of trips by foot traffic.

EXPERIMENT TEST

Taking a certain city as an example, the model application is analyzed and the data from the 2004 year's investigation results is used. The data of passenger traffic structure, average travel time, average travel distance, et al. have been shown as Table 1. As the city is not building a rail transit system, the value of this index is 0.

Based on the model in Table 1, traffic demand output and speed is set up. In the model of traffic mode, assume that certain traffic mode is changed, and the relative proportion of other is unchanged. The calculation result is shown in Table 2. Model results show the unit of quantity but the numerical magnitude only expresses the change law of demand but not mean actual value.

Table 1. Statistics of Basis Data

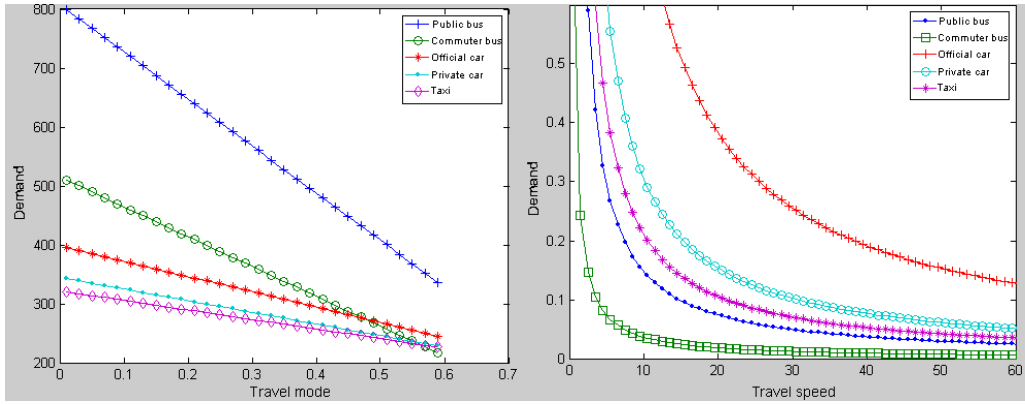
Traffic mode M_i	Public bus M_1	Commuter bus M_2	Official car M_3	Private car M_4	Taxi M_5	Rail transit M_6	Bicycle M_7
Proportion P_i (%)	0.428	0.106	0.166	0.062	0.037	-	0.200
Travel distance D_i (km)	12.4	6.9	13.8	14.7	14.3	-	3.4
Travel speed V_i (km/h)	25	28	30	30	28	-	10
Passenger Capaity C_i (P)	72	40	3	3	2.5	200~1000	1
Vehicle conversion coefficient K_i	2	2	1	1	1	-	0.2

Table 2. Vehicle Out-driving Demand Model

Traffic mode	Public bus M_1	Commuter bus M_2	Official car M_3
Travel speed model	1.4753/v	0.3657/v	7.6544/v
Traffic mode model	-1084.3p+1092.9	-688.1p+697.7	-456.3p+594.3
Traffic mode	Private car M_4	Taxi M_5	bicycle M_7
Travel speed model	3.0576/v	1.3607/v	-
Traffic mode model	-371.8p+518.8	-331.2p+491.4	-409.4p+579.4

As can be seen from Figure 2 (a), when the proportion of one certain traffic mode increased, the total demand decreased. The demand of various modes changed sensitivity from big to small followed by the order: public bus, commuter bus, official car, private car, taxi. With the proportion of public transport, when commuter traffic increased, generalized traffic demand reduced significantly. The reason is that the quantity of passengers transported by public bus and commuter bus is large so that the total number of travelers per capita road resource is less.

Figure 2 (b) shows that the traffic demand of different traffic modes will decrease with its average speed increasing. And in the social vehicles, when the travel speeds of official cars and private cars increases, obviously the generalized traffic demand reduces. Therefore, the official cars and private cars in city traffic occupy the largest proportion of the composition.



a) Traffic mode **b) Velocity**

Figure 2. Total demand change with different conditions

By the equation (4), we can see that when the average travel distance increases, the demand increases, but for a specific city, the spatial average travel distance of various traffic modes will not vary much in general. In the analysis of this factor, by increasing the accessibility of various travel modes, the individual travel residence time in the road resource will be decreased in order to reduce the total production of generalized traffic demand.

CONCLUSIONS

Through traffic generated by the process, a broad indicator of the traffic demand is presented, and the corresponding measurement model determined. Through analyzing the relationship between a variety of factors and the demand generated, the most obvious factors influencing generalized urban passenger traffic demand are: the structure of the proportion of passenger traffic and motor vehicle travel speeds, in which the increase ratio of buses and commuter cars lead to a reduction of the most obvious travel; community bus vehicles' and private cars' increased speed is equivalent to a reduction in car travel. This analysis of major cities in the process of traffic demand not only provides a basis to urban transport development policy making, but also analyzes the efficiency of a city's transport system.

ABSTRACT

According to the characteristics of traffic accidents of long highway tunnel, this paper proposes a method to identify black spots based on improvable accident of tunnel environment. On the basis of the relationship of traffic accident and long highway tunnel system components, including the driver, the vehicle and the tunnel environment, accidents are classified into seven categories, and this paper only considers four categories relating to tunnel environment. The degree of membership of each accident in the tunnel environment component is used to represent the ability of accidents by tunnel environment improvement. Each accident is weighted by its ability. Then, the method of the equivalent of accident frequency and accident rate is used to identify black spots. Finally, the Kaoyishan tunnel in Beijing-zhuhai freeway in China was applied to analyze black spots using this method. The results show that the proposed method is useful to improve the safety of long highway tunnel.

KEY WORDS Traffic safety; Long Highway Tunnel; Black Spots; Tunnel Environment;

INTRODUCTION

The sustainable fast economic development in China for the past 10 years has greatly inspired the construction of new highways particularly long highway tunnels. Long highway tunnels play an important role in developing highway networks and the number of long highway tunnels in China has continually increased rapidly over past several years. Long highway tunnels have some advantages, such as reducing vehicle-miles of travel, saving travel time, reducing the emissions, and so on.

Therefore, the construction of long highway tunnel has brought large social and economical benefit. However, as a special structure type, the transportation environment in highway tunnel makes the tunnel section as black spots (Amundsen and Ranes, 2000; Luo, et al., 2006; Zhang, et al., 2007). Consequently, for the agency of tunnel management, it is an economical and effective way to identify black spots, analyze the causes of accidents and propose safety improvement measures. Especially, when the funding is limited, it is beneficial to improve the safety in black spots of long highway tunnels.

Many identification methods of black spots were proposed by researchers domestic and abroad, such as accident frequency method, accident rate method, matrix method, equivalent number of total accidents method, quality control method, the critical rate method, accident cumulative frequency curve method, and so on. (Pei and Wang, 2004). Recently, many researchers proposed some new methods, such as the identification method based on traffic conflict technique, the equivalent of accident frequency and accident rate method, outstanding factor method, fuzzy evaluation method, improved quality control method, and so on (Zhou and Luo, 2000; Zhu and Lu, 2002; Liu, et al., 2003; Shao, et al., 2004; Pei and Ding, 2005; Pei and Dai, 2005; Pei, 2006). However, since black spots include many accidents that cannot be avoided by road improvements, thus the location identified by these methods may not be truly accident-prone locations from a highway agency's point of view.

Accidents caused by three components of highway tunnel system or any of these components or a combination of them shown in Figure 1: the driver, the vehicle and the tunnel environment. From the view of tunnel management, drivers and the vehicles contributed little while the tunnel environment contributed mostly to accidents. Therefore, the identification of black spots should be related to identify the factors contributing to accidents in the tunnel environment.

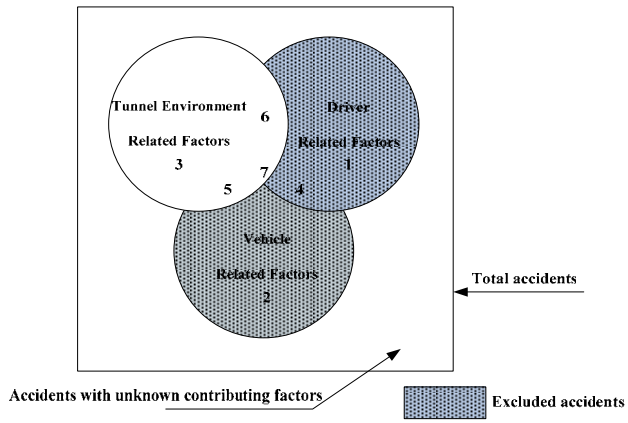

Figure 1. Classification of accidents according to causes

The work reported in this paper describes a method to identify black spots

based on an assessment of factors that contribute to accidents in long tunnels. Accidents that do not belong to the tunnel environment group are excluded from the identification of black spots. Then the equivalent of accident frequency and accident rate method is used to identify black spots. Finally, the Kaoyishan tunnel in Beijing-zhuhai freeway in China is used to analyze black spots by the method.

IDENTIFICATION METHOD OF BLACK SPOTS

The basic idea of identification method is to classify accidents by the contribution to accidents according to their patterns and contributing factors into one of the three groups in the tunnel system or a combination of these groups. Accidents that do not belong to the tunnel environment group are excluded from the identification of black spots. Then the equivalent of accident frequency and accident rate method is used to identify black spots. The steps for the identification method of black spots in this paper can be described as follows:

Step 1. The equivalent of accident frequency related to tunnel environment of each accident was calculated.

Step 2. The equivalent of accident frequency and accident rate related to tunnel environment of each section was calculated.

Step 3. The average equivalent of accident frequency and accident rate related to tunnel environment of the whole long highway tunnel was calculated.

Step 4. The upper limit of the equivalent of accident frequency and accident rate related to tunnel environment at a 0.05 significant level was calculated.

Step 5. The equivalent of accident frequency and accident rate of each section compared the upper limit at a 0.05 significant level. If both the equivalent of accident frequency and the equivalent of accident rate are not less than the upper limit at a 0.05 significant level, the section is identified as black spots.

Calculation of the equivalent of accident frequency related to tunnel environment

Firstly, accident data were analyzed and sorted, and accident data related to tunnel environment were only considered according to the classification shown in Figure 1, named category 3, 5, 6 and 7.

Secondly, according to the influence of the accidents severity on society and individual, the accident severity is calculated by giving a certain weight to deaths and injuries, and the formation was as follows:

$$ER_{ij} = W_j(K_1 F_{ij} + K_2 J_{ij} + 1) \quad (1)$$

where ER_{ij} is the equivalent of accident frequency related to tunnel environment for jth traffic accident in section i; W_j is the weights of jth traffic accident related to tunnel environment; F_{ij} is the fatalities of jth traffic accident related to tunnel

environment in section i; J_{ij} is the injuries of jth traffic accident related to tunnel environment in section i; K_1 and K_2 are the weights of fatal and injured accident.

Calculation of the average equivalent of accident frequency and accident rate related to tunnel environment

For all the selected sections, the formation of the equivalent of accident frequency and accident rate of t years in section i were as follows:

$$ER_i = \sum_{j=1}^{m} W_j (K_1 F_{ij} + K_2 J_{ij} + 1) \quad (2)$$

$$ER_{fi} = \frac{ER_i \times 10^6}{365 \times t \times L_i \times AADT} \quad (3)$$

where ER_i is the equivalent of accident frequency related to tunnel environment in section i; m is the number of accidents occurred in t years in section i; ER_{fi} is the equivalent of accident rate related to tunnel environment in section i; t is the statistical time; L_i is the length of section i; $AADT$ is annual average daily traffic volume of tunnel.

According to the equivalent of accident frequency and accident rate of different section, the formation of the average equivalent of accident frequency and accident rate were as follows:

$$ER_m = \frac{1}{n} \sum_{i=1}^{n} (ER_i / L_i) \quad (4)$$

$$ER_{fm} = \frac{\sum_{i=1}^{n} ER_i \times 10^6}{365 \times t \times \sum_{i=1}^{n} L_i \times AADT} \quad (5)$$

Where ER_m is the average equivalent of accident frequency related to tunnel environment; n is the number of sections; ER_{fm} is the average equivalent of accident rate related to tunnel environment.

Determination of black spots

According to quality control method, the upper limit of the equivalent of accident frequency and accident rate were calculated based on the average equivalent of accident frequency and accident rate at a 0.05 significant level. The formations are listed below:

$$\overline{ER_m} = ER_m + k \times \sqrt{\frac{ER_m}{M} + \frac{1}{2M}} \quad (6)$$

$$\overline{ER_{fm}} = ER_{fm} + k \times \sqrt{\frac{ER_{fm}}{M} + \frac{1}{2M}} \quad (7)$$

where, $\overline{ER_m}$ is the upper limit of the equivalent of accident frequency related to tunnel environment; $\overline{ER_{fm}}$ is the upper limit of the equivalent of accident rate related to tunnel environment; k is the statistical constant (1.96); M is the number of vehicles through tunnel in statistical time. According to matrix method, the equivalent of

accident frequency and accident rate were combined to identify black spots in this paper. The equivalent of accident frequency and accident rate of different sections were compared to the upper limit of the equivalent of accident frequency and accident rate. If ER_i is not less than $\overline{ER_m}$ and ER_{fi} is not less than $\overline{ER_{fm}}$, the section i is identified to black spots.

EXPERIMENTAL RESEARCH

The proposed method was applied to empirical analysis at Kaoyishan tunnel in Beijing-Zhuhai freeway in China. Kaoyishan tunnel is a two-way tunnel, and the study scopes of the left line and right line are ZK144+644~ZK147+825 and YK144+666~YK147+815. In this paper, the weights of fatal accidents K_1 and injure accident K_2 are equal to 2 and 1.5 separately. The weights related to tunnel environment are shown in Table 1(Ma, 2004).

Table 1. The weights related to tunnel environment

Category	Weights	Value
3	The weights related to tunnel environment	0.49
5	The weights related to vehicle and tunnel environment	0.32
6	The weights related to driver and tunnel environment	0.14
7	The weights related to driver, vehicle and tunnel environment	0.05

In this paper, 0.2km is taken as the standard length. Traffic accidents occurring in Kaoyishan tunnel during 2003-2004 were considered, and the equivalent of accident frequency and accident rate related to tunnel environment of different sections were calculated. Then, according to Equation (4) and (5), the average equivalents of accident frequency and accident rate related to tunnel environment were calculated, which were 2.52 times per kilometer and 0.12 times per million vehicle-miles respectively. Finally, the upper limit of the equivalent of accident frequency and accident rate were also calculated, which were 3.23 times per kilometer and 0.29 times per million vehicle-kilometers. Therefore, if ER_i is not less than 3.23 and ER_{fi} is not less than0.29, the section i is identified to black spots, and the situation of black spots are shown in Table 2.

Table 2. Black spots of Kaoyishan tunnel

Location	Length (km)	Accident frequency	Injured	Killed	ER_i (km)	ER_{fi}(/ million vehicle-kilometers)
ZK146+044~K146+244	0.2	1	0	2	8	0.38
ZK146+825~K147+025	0.2	4	3	0	10	0.47
ZK147+425~K147+825	0.4	6	3	0	8.4	0.4
Summation	0.8	11	6	2	8.6	0.41

CONCLUSION

For different analysts, key components of researches are different, so the identification of black spots is also different. In terms of the agency of tunnel

management, black spots in long highway tunnel should be located where traffic accidents occurred intensively due to the deficiencies of tunnel environment. Therefore, this paper attempts to propose a new method to identify black spots based on tunnel environment. The identification of black spots is the first step in the tunnel-safety-improvement project, and the further study will focus on analyzing the cause of accidents occurred in long highway tunnel and proposing improved measures for black spots accordingly.

ABSTRACT

In order to quantitatively describe the complexity of the traffic flow system, this paper analyzes the traffic flow complexity on a road based on introducing statistical complexity and its properties. Taking traffic flow on three typical road sections in Nanjing, by comparing and analyzing the relationship between traffic flow complexity and traffic conflict rate on different sections, the paper draws out the regression model of traffic flow complexity and traffic conflict rate. The results show that: The characteristic complexity is an effective measure of the random and non-linear systems and the relevance between traffic flow complexity and non-serious traffic conflict rate is better enough to measure and analyze the traffic flow complexity, which brings a new idea in studying the complexity of traffic system.

Traffic flow complexity; Traffic conflict rate; Statistical complexity; Regression analysis

INTRODUCTION

A traffic system is an open and complex giant system and at the same time is a dynamic non-linear composite system. In cities especially in urban centers, traffic systems often show such characteristics that are complex and non-linear. As one element of the traffic system, traffic flow also shows a non-stationary, complexity, and is non-linear. Therefore non-linear analysis methods may help to better reveal the characteristics and mechanism. In recent years, with the development Lempel-Ziv algorithm, it is possible to quantify the complexity of traffic engineering through approximate entropy and statistical complexity methods.

Statistical complexity was first proposed by Lopez-Ruiz in 1995. The paper analyzes the traffic flow complexity on the road based on introducing statistical complexity and its properties. Take traffic flow on three typical road sections in Nanjing, by comparing and analyzing the relationship between traffic flow complexity and traffic conflict rate on different sections, draw out the impact of traffic conflict rate on the complexity of traffic flow in order to provide new ideas in studying the complexity of traffic systems.

STATISTICAL COMPLEXITY

Currently the depiction of characterization of traffic flow system complexity, fractal dimension, Lyapunov exponent and the measure entropy characteristic quantities etc. are usually adopted. These characteristic quantities can partly depict the complexity of the system, but they are facing two problems in the application: 1) the calculation of these characteristic quantities requires a long time series, the measured data is very difficult to meet their requirements; 2) these methods can only draw out the complexity criterion, but cannot do comparison between different locations, different time slots of the traffic flow system, that is to say, those methods can only resolve the problem of whether or not the system is complex but cannot resolve the problem of the extent the complexity of system arrivals. Therefore, it is necessary to realize the comparable measure of the complexity of traffic flow system. In this paper, I introduce the statistical complexity of nonlinear dynamic theory which is put forward in recent years to try to measure the complexity of traffic flow based on such a theory.

Foundation of the statistical complexity is information theory, which is mainly used to study how the shannon entropy of continuous expansion subsystem converges to the entropy density of whole system which is a measure of components of system regularity.

Assuming a discrete random variable Y with N-state y, the $P(Y)$ is the probability when random variable Y equals y, then the statistical complexity C is

$$C(Y) = H(Y)D(Y) \tag{1}$$

$$H(Y) = -\sum P(Y)\log_2 P(Y) \tag{2}$$

$$D(Y) = \sum 2\left[P(Y) - \frac{1}{N}\right] \tag{3}$$

Where: H is information entropy; D is the non-equilibrium item which shows the dispersion between Probability $P(Y)$ and the uniform distribution.

In C expression, the contributions that randomness and disorder make to the complexity of the statistics are considered, but $H(Y)$ and N are relevant, while the $D(Y)$ and N are not relevant, thus the contribution of which are in different ways, so the calculation of statistical complexity with formula (1) is not so unreasonable.

Based on what has been shown above, Feldman etal. [8] use the information distance of non-equilibrium distribution $P(Y)$ and balanced distribution $P(\hat{Y})$ in place of the non-equilibrium $D(Y)$ of formula (1), and give a modified formula:

$$DFC(Y) = \sum P(Y)\log_2 \frac{P(Y)}{P(\hat{Y})} = \sum P(Y)\log_2 \left[NP(Y)\right] \tag{4}$$

Where： DFC is the extensive quantity.

Thus, the calculation formula of statistical complexity has been modified to

$$C(Y) = H(Y)DFC(Y) \qquad (5)$$

For systems with complete rules and orders, it has $H(Y) = 0$, $C(Y) = 0$; for complete White Noise system, it has $P(Y) = \frac{1}{N}$, $DFC(Y) = 0$, $C(Y) = 0$. The advantages of formula (5) are: it meets the boundary conditions of order and randomness, and can clearly measure such chaotic system as neither completely random nor completely orderly, which makes it more scientific to depict the complexity of the system and less data are required. But it also has two disadvantages: 1) when calculating the complexity of two-dimensional array, they are required to be changed into a higher dimensional array firstly, which is rather complicated and excessively fine-grained; 2) Measurement is established on statistical significance so that some minor structural complexity of the system will inevitably get neglected.

According to the model checking, when samples are taken between 400~ 1000, complexity tends to be stable, and the complexity values of white noise within the system and the cycle of systematic statistical errors are very small, thus there exists a great gap compared to the statistical complexity of the chaotic regional logistics and the Henon system which shows statistical complexity meets the boundary conditions of order and randomness, and can be used to express the complexity of a nonlinear structure well.

MEASUREMENT OF TRAFFIC FLOW COMPLEXITY

Headway is used to calculate the complexity of traffic flow, because headway can reflect a large amount of information such as the traffic volume, speed and traffic density etc., and is also easy to investigate.

Collection of Traffic Flow Data

The following investigation locations were chosen: Nanjing Taiping North Road (R1), Beijing East Road, (R2) and the Zhujiang Road (R3). The investigation times are Wednesday's 8:00-9:00 (morning peak MP) ,10:00-11: 00 (morning platy MN) ,12:00-13: 00 (noon peak NP) ,15:00-16: 00 (noon platy NN) ,18:00-19: 00 (evening peak EP) and 20:00-21: 00 (evening platy EN), from above 18 series of Headway times are received, the sample volume is 500. Not only Headway but also the corresponding traffic conflicts are investigated. Figure 1 shows headway investigated from the R1 road mining sections of MP time.

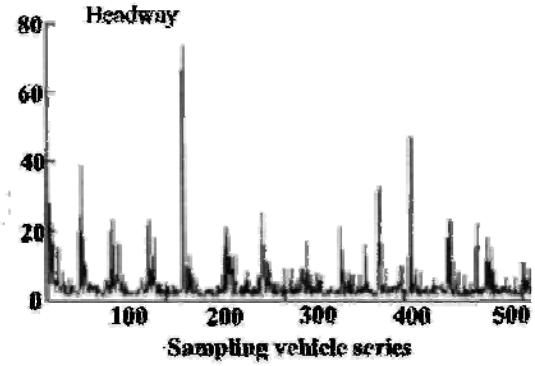

Fig 1. Variation of time-distance of sampling vehicle.

Measurement Based on the Statistical Complexity

In Combination with 30 traffic flow sequences from the result of the survey, we measured them by the statistical complexity method; the results are shown in Figure 2.

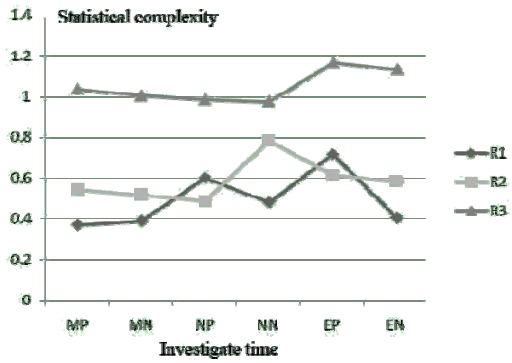

Fig 2. Statistical complexity of three roads.

As can be seen from the chart:

（1） The peak of complexity of the traffic flow in various sections are almost in the peak periods, but as traffic flow increases to a certain extent, it becomes gradual and orderly, the complexity gradually becomes smaller.

（2） The complexity of Zhujiang Road is the largest. Taiping North Road and Beijing East Road are similar, which is related to the road hierarchy, traffic flow composition and traffic volume. Zhujiang Road is a residential road located the central area of electronic distribution in Nanjing, traffic composition flow is rather complicated, on which the cross-section is a piece of board, and traffic flow is more seriously out of order. Taiping North Road and Beijing East Road are arterial roads, and channelization facilities are perfect, relatively speaking, traffic flow is in order, that is, complexity is relatively small.

（3） Complexity values are much greater than the cycle system and the white noise that illustrates traffic flow system is neither cyclic nor a completely

random system, but it is a dynamic system with a non-linear structure , moreover the non-linear structure can generate chaos.

REGRESSION ANALYSIS

Traffic Conflict Rate

Traffic conflicts are divided into serious conflicts and non-serious conflicts.

The traffic conflict on the section is mainly relevant with the traffic volume and the length of the sections, so the traffic conflict rate of each section is different in different time.

$$I = \frac{C}{Q \times H} \qquad (6)$$

$$I = I' + I'' \qquad (7)$$

Where: I is traffic conflict rate, I' is traffic non-serious conflict rate, I'' is traffic serious conflict rate, C is traffic conflicts, Q is traffic volume, H is the length of the sections.

Tab.1 traffic conflict rate of each section.

	MP		MN		NP		NN		EP		EN	
	I'	I	I'	I	I'	I	I'	I	I'	I	I'	I
R_1	4.53	5.49	3.98	4.63	4.34	5.35	5.36	6.33	6.95	7.89	3.12	4.07
R_2	6.78	7.87	5.76	6.45	6.54	7.52	7.29	8.03	8.76	10.51	4.55	5.42
R_3	11.85	13.54	9.56	10.79	10.89	11.72	8.25	9.51	13.43	14.89	7.89	9.26

Modeling

A regression analysis of the traffic flow complexity of three sections and the corresponding traffic conflict rate wereperformed using SPSS software. After fit, the complexity of traffic flow of the sections and traffic non-serious conflicts rate have better relevance.

$$C = 4.891I'^2 + 0.080I' + 4.511 \qquad (8)$$

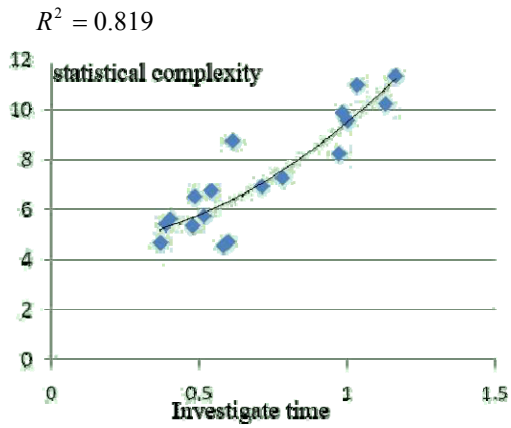

Fig3. Regression of traffic flow complexity and non-serious traffic conflict rate.

It was indicated that complexity of traffic flow and the corresponding sections of the serious traffic conflict rate are poor as shown by regression analysis. On the one hand, the source of serious conflict data collection is much less than the non-serious conflict data and it is difficult to draw out the correlation between them because in a short period of time it is difficult to observe a serious conflict. On the other hand because the complexity is used to measure the randomness of traffic flow, to a large extent, a serious conflict is determined by man-made factors or road facilities.

A regression analysis was made about complexity of traffic flow and the corresponding traffic conflict rate. The correlation coefficient is $R^2 = 0.759$, which can meet the demand. The formula is as follows:

$$C = 0.002I^2 + 0.118I - 0.089 \qquad (9)$$

From what has been analyzed above, we can see that non-serious traffic conflict rate and the complexity of traffic flow are directly proportional, but the increased rate is gradual. In practical applications we can analyze the factors which impact traffic flow complexity through comparison of non-serious conflict rates to compare with different complexity of traffic flow, and achieve a fundamental understanding about characteristics of the traffic flow.

CONCLUSIONS

1) Complexity of Traffic flow systems and chaotic systems are closer which shows traffic flow systems are highly stochastic, with non-linear structure and may produce chaos.

2) The peak of complexity of traffic flow of various sections are almost in the peak periods, but as traffic flow increases to a certain extent, it becomes gradual and orderly, complexity gradually becomes smaller.

3) Non-serious traffic conflict rate and the complexity of traffic flow are well correlated. In practical application we can analyze complexity of different traffic flows through comparison of non-serious conflict rates.

ABSTRACT

Shallow tunnel may inevitably disturb ground soils during the construction. process, The disturbance will certainly produce different levels of surface subsidence, and thus it will cause some unfavorable influence on the safety of construction and surrounding structures. Therefore, it's necessary to determine the control index of surface subsidence scientifically and reasonably, which can relieve, eliminate and avoid the unfavorable impact. The underground passage of Changchun railway station in the south and north squares lies in the soft soil layer, and was dug through the station yard, and thus its construction is very difficult. In the construction process, firstly, a suitable strict control and monitoring system is designed to detect the surface subsidence. Then the collected data from the monitoring system is analyzed and fed back, and the construction is dynamically managed. Finally the construction work is ensured to keep on going smoothly and safely.

Key words：*existing railway; shallow tunnel; surface subsidence*

With the rapid development of our economy, the urban traffic becomes increasingly busy. Many crossings of highway and railway need to be replaced by overpasses, and mainly underground excavation form or culvert advancing into hole form. When a tunnel under the railway is excavated, it will inevitably cause some disturbances to its adjacent structures, and the disturbance will lead to the rail irregular operations. Meanwhile as the train passes the place, it will produce impact force, and increase the surface subsidence.It turns out great vulnerabilities of the system. Therefore, it is vital to study the surface subsidence of the shallow tunnel. Alleviation of the surface subsidence is of great significance to ensure the safe operation of railway and the tunnel construction. .

A BRIEF DESCRIPTION OF THE PROJECT CONSTRUCTION

The project introduction

The underground passage under the north and south squares of the Changchun station is about 274m long, heading north from LiaoNingLu, and stop at the Changchun freight station, including a main channel, a building connecting the south and north hall, and the escalator section. Construction of the south and north hall part adopts the cut and cover method, and the main channel adopts the subsurface excavation method, with the mileage from DK0+063.279 to DK0+218.679, and its span approximately equal to 155.4m. The subsurface excavatione is supported with a structure of two columns and three arches. Middle part for pedestrian passage is 8 m wide, and both sides of the commercial development zone are 3m wide. The total excavation is 16.2 m wide, the excavation is 7.3 m deep, and the tunnel has a largest covering of 5 meters. The main channel crosses Changchun station yard 14 strands

operation orbits and part of hump lines, also four passenger platforms and four postal channels; In construction area, the underground pipelines distribute densely, which made the construction environment very complex.

The construction method

The station goes through the shallow soft soil stratum, and large spanned. Thus the shallow depth excavation edge hole method is adopted, with its main construction procedures shown in Figure 1. The entire construction sequential is described as follows, firstly carry on the tunnel edge hole's excavation support construction using the short steps obligate core method. The distance between the upper and the lower steps is 5 m apart, and each excavation is 0.5 m. Then the excavation of left pilot tunnel is performed after the right side hole's initial support closed 5 m long, excavate the core cave after the left side hole's initial support closed 5 m long, using the short steps core soil with CD reserved method. The right and the left sections of upper step are apart from 5 m, in the middle adding up temporary support by I_{16} beam, and the distance between the upper and the lower steps is 5 m. After the whole section excavation is done, the secondary lining is to be installed together, carry on the two sides span's second lining, then break the initial supporting of two sides hole, and carry on the lining of the middle arch, in order to becoming an organic whole with the two sides span second lining, eventually dismantle the rest of initial supporting of both sides hole and the second lining slab. As soon as finish two sides span lining, begin the sides decorate construction. The middle arch's decoration is carried on after completing the midspan vault lining.

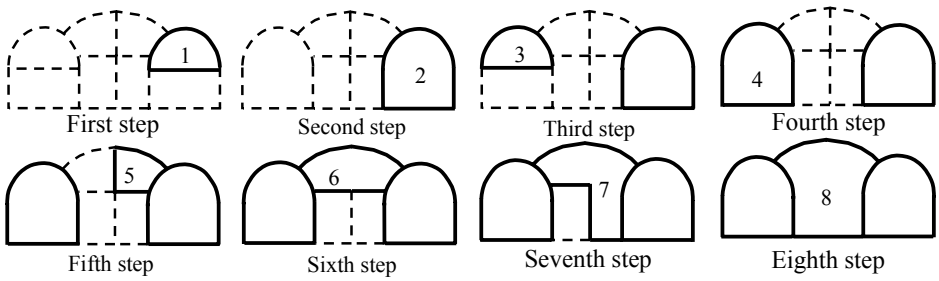

Figure1. edge hole construction's step schematic diagram

MONITORING MEASUREMENT

Definition of settlement control benchmark

The harmful settlement must be controlled in the shallow tunnel construction. The most important problem is how to setup the settlement control benchmark, and use the control benchmark to monitor the existing building above ground、surface subsidence in the construction process under the guidance of the theoretical analysis, and subsequently manage tunnel construction based on the monitoring data.

The horizontal surface subsidence may adopt the normal probability curve to analyze, which was proposed by Mexico scholar Peck and British scholar Reilly. When excavated single hole equation is as follow:

$$S = S_{\max} \exp\left(-\frac{x^2}{2i^2}\right) \qquad (1)$$

In the equation, x stands for the distance measured from tunnel center, S *is* the surface subsidence of the point with distance x from the tunnel center, S_{max} is the

maximum settlement, and *i is* the coefficient of the width of the settled tank.

The building foundation types and its stiffness directly affect the building deformation, which is caused by the surface subsidence. And different foundation types have different adaptabilities to the foundation deformation.

Table 1. The allowable surface subsidence of the channel construction

Section equivalent radius(m)	Coating thickness (m)	Internal frictional angle(°)	Bath setting width coefficient（mm）	Allowable computed settlement (mm)			
				Underground	pipeline	Postal channel	Railway line
7.11	5.0	19	6.78	86.7		66.2	13.6

The main channel at Changchun station crosses 14 strands operation orbits and part of hump lines , also four passenger platforms and four postal channels. If the same benchmark is used, it would be conservative in some areas, and non-conservative in others. Therefore, the control standard of different type buildings should be set up separately. The allowable maximum differential settlement should meet their safety needs to the best in their engineering practice. The allowable surface subsidence benchmark is shown in Table 1, which meets the normal requirement of underground pipelines, underground postal channels and railways.

Design of the monitor measuring system

In connection with the engineering practice of the tunnel at Changchun station, the surface subsidence is measured at every 5 ~ 15 m of a measurement section as shown in the measurement layout. There are 11 ~ 15 points at each section, and 2 monitoring sections at the four postal channels at the north and south sides, setting up the surface subsidence measuring-points at the canopy pillars, which is shown in Figure 2. The measuring-points of vault sink and headroom are placed for every measurement section of 5-15 m, and each measurement section has three vault sink points and three headroom convergence lines. The measuring-point arrangement is shown in Figure 3.

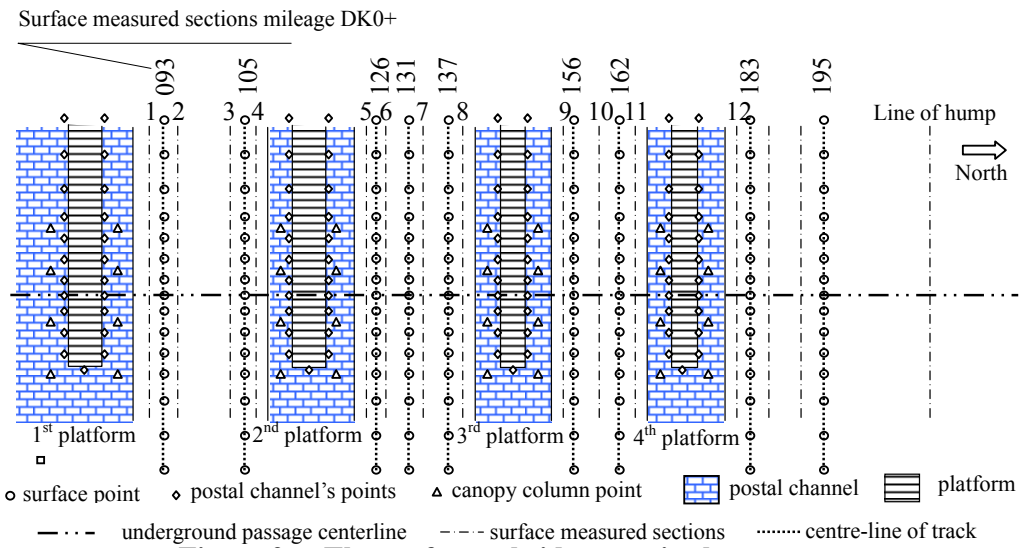

Figure 2. The surface subsidence point layout

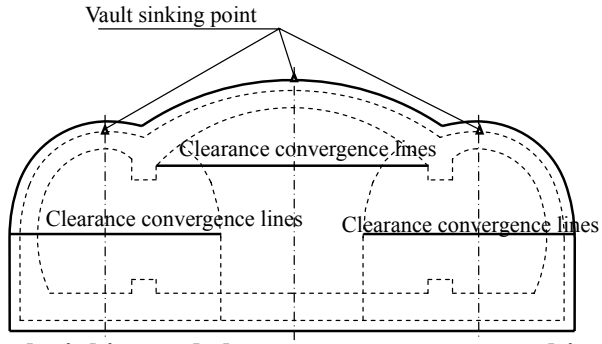

Figure 3. The vault sinking and clearance convergence multipoint arrangement

SUBSIDENCE CONTROL MEASUREMENT DURING THE CONSTRUCTION

Construction measures for the rail traveling soil stratum

When the passage crosses the railway, some auxiliary measures are adopted to reduce the surface subsidence, in order to keep the subsidence of the railway base within the permitted range. To maintain the normal operation of the railway, a big pipe is grouted ahead of preliminary support, anarch radial grouting is applied to the small catheter to reinforce the soil stratum, and locks are added up at the arch foot and on the lateral brace.

Construction measures for railway postal channels stratum

The underground passage crosses the railway postal channel four times. When passing through the channel, the benching tunneling method is applied, with the construction principle of "short footage, quick closure, and strong support." Because the postal channel has only a 1.5 m of headroom, some auxiliary measures are adopted. For instance, a preliminary support is provided by densely grouting the small catheter, the reinforced postal channel bottom and the tunnel vault soil are grouted , in order to ensure the safety of the vault soil and channel, fast going through the area.

Technique of Buckling the rail reinforcement

Because the shallow tunnel construction causes substantial surface subsidence, which will make the rail track distortion, and affect the train's passage. To ensure the train's moving unaffected, the reinforcement technique of beam buckling rail is feasibly adopted to strengthen the track structure, in an attempt of maximizing the line's overall stability in order to prevent the collapse that is potentially caused by the tunnel construction. In addition, in order to eliminate the track distortion caused by the excessive subsidence, variations of the surface subsidence is monitored for the three tunnel construction stages: pre-precipitation and with the edge hole supporting completed, the middle hole supporting completed, and the entire project completed.

CONSTRUCTION EFFECT AND DATA MONITORING

Monitor processing and data analysis

Surface subsidence

The measured data indicates that the maximum surface subsidence, with its value of 60.26 mm at the eighth point at the center channel, occurred at the section of DK0+195. The surface subsidence records at the transverse sections of DK0+183 and DK0+195 are plotted in Figure 4. The maximum surface subsidence is 24.7 mm,

of the postal channel occurred at the eighth point of the fourth platform south of 4# postal channel. The surface subsidence at the 1st and 2nd platform of the postal channel is shown in Figure 5. Here give the surface settlement and time curve of a maximum surface subsidence, 1st platform's canopy 4# column point surface subsidence time curve is shown in Figure 6.

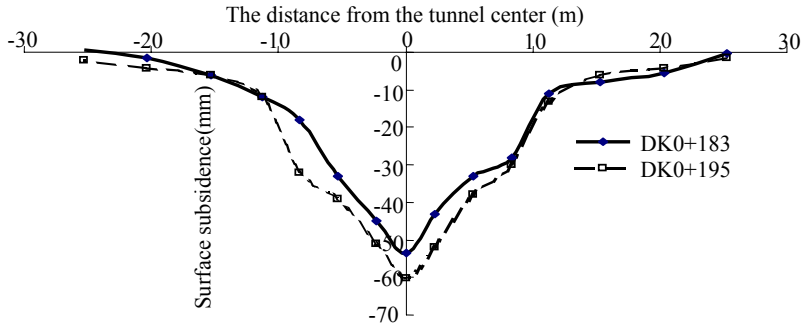

Figure 4. DK0+183, 195 measurement sections surface subsidence's transverse curve

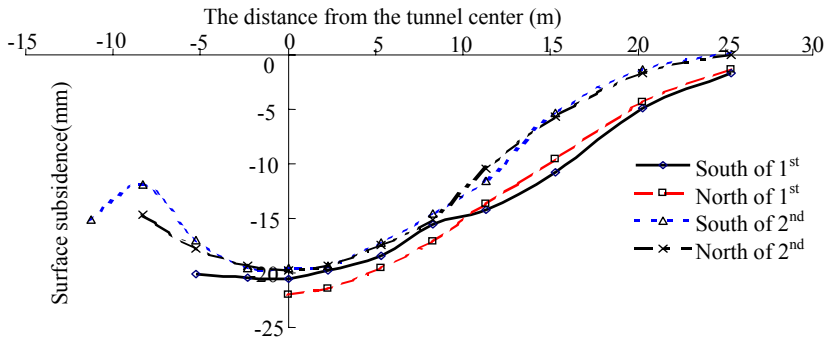

Figure 5. 1st and 2nd platform postal channel sections surface subsidence's transverse curve

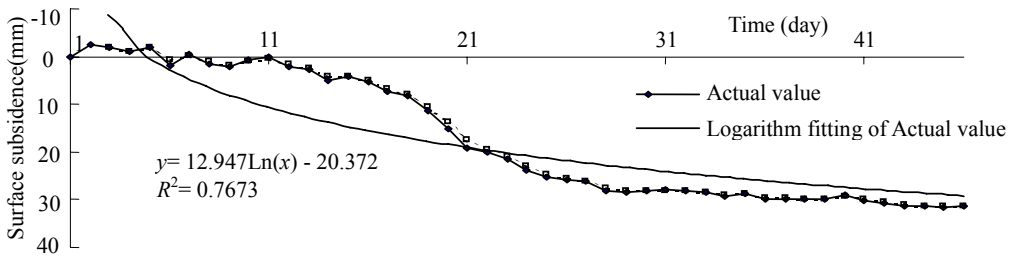

Figure 6. 1st platform's canopy 4# column point surface subsidence's time curve

Vault settlement and headroom convergence

Due to the two columns-three arche structure for the underground passage, every vault settlement's and every headroom convergence's measurement section also has three vault sink points and three lines, which are set with every hole's excavation. The vault settlement time curves of DK0 + 093 section center hole、east hole 、west hole are shown in Figure 7~9.

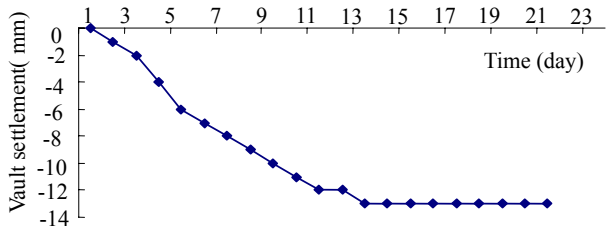

Figure 7. DK0 + 093 section center hole's vault settlement time curve

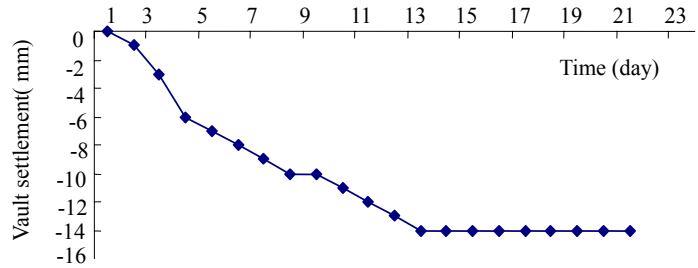

Figure 8. DK0 + 093 section east hole's vault settlement time curve

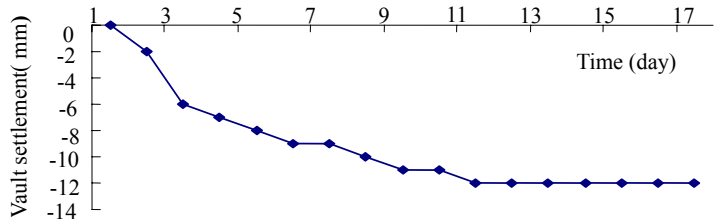

Figure 9. DK0 + 093 section west hole's vault settlement time curve

The vault settlement and headroom convergence are smaller than the surface subsidence. Because the vault measuring-points are built-in after the excavation, there is no vault prophase displacement.

Effect of the implementation

Monitoring of the construction process indicates that the subsidence of channel center is between 38.25 mm and 60.26 mm, with its maximum of 60.26 mm occurring at the DK0+195 section. The measured settlement is in the allowable range. Current track surface subsidence is limited to 13.6 mm. Based on the subsidence requirement, the construction will become extremely difficult, or the engineering cost will be greatly increased.

In consideration of the ground track and bed maintenance characteristics, and the monitoring results of track deformation, the tunnel builder should apply the rail buckling reinforcement to the original rail, and perform in stages the construction work, fill the ballast and keep a good maintaining job for the track base to limit that maximum settlement of rail top surface less than 13.6 mm, and make the railway work normally.

CONCLUSION

1) Construction of the underground passage of Changchun station strictly follow the construction requirements, which read "pipe advancement, strict grouting, short excavation, strong support, quick sealing and frequent measurement". A series of plans are implemented to effectively minimize the surface subsidence, and ensure the safety and stability of the above and underground structures. These plans are integrated with the long shed-pipe and pre-grouting with tubule for preliminary support. After the short-step excavating two edge holes then center hole with the short steps core soil with CD reserved method, reinforcing the stratum of rails and postal channels, buckle rail reinforcing, sorting out the rail in stages and so on.

2) Settlement measurement plays an important role in the shallow tunnel construction. According to the monitoring feedback , the observational management can be employed for the construction work. If the monitoring data exceeds the standard or alerting value, the construction scheme should be timely adjusted, and the supporting reinforcement measure should also be rectified to ensure the construction process undisturbed.

ABSTRACT

Based on calculation of load stresses at both the middle of the longitudinal joint and the slab corner with various degrees of voids between the slab and the base layer, critical loading load transfer location of slab with voids could be analyzed. According to these data, we have analyzed the effect of voids beneath cement concrete pavement service life. In addition we came out with a void classification standard. Our research shows that, once the pavement has been void, as the void is expanding, the maximum loading position would transfer from the middle of the longitudinal joint to the corner. When the void size L_v is larger than 0.7m, the boundary of void area and no void area becomes the most unfavorable load position. So our void classification standard is as follow: slight degree void when L_v is 0～0.4m, moderate degree when L_v is 0.4m～0.7m and severe degree when L_v is larger than 0.7m.

KEYWORDS

Pavement engineering; cement concrete pavement; void; classification standard; service life

INSTRUCTION

In engineering, common judgment methods to determine the existence of void mainly include the falling weight deflectometer (FWD), the ground penetrating radar, and acoustic-vibration method and so on. Voids can also be judged by empirical methods. It is proposed that all the deflection values, which are more than 0.2mm, are identified as the slabs containing voids by the Chinese national standard. Establishing a division standard for the void grade is very important to evaluate the CCP slab void accurately. Therefore, we put forward the division standard of the CCP void beneath based on the fatigue life influence coefficient ε in order to guide the actual treatment of slab void (Chen, 2008) (Huang, 1993) (Wang et al., 2008).

THE FATIGUE LIFE INFLUENCE COEFFICIENT ε

The fatigue life influence coefficient ε is defined as the ratio of residual

fatigue life between void and no-void. We establish the division standard of CCP void beneath by analyzing ε. We give research on the load stress in the middle longitudinal edge and in the slab corner under different void sizes, as well as the most unfavorable loading position transfer law of concrete slab (Zhao, 2004).

LOAD STRESS IN THE MIDDLE LONGITUDINAL EDGE UNDER VOID SLAB CORNER

We assumed different slab corner void sizes in ANSYS and calculated the maximum load stress in the middle longitudinal edge. We have established calculation model of elastic half-space concrete slab. Void isosceles triangle region is set up in the slab corner, and the right-angle is L_V. The influence of the void beneath on slab loading stress is not obvious, which can be omitted in the structure calculations by analysis (Han et al., 2006) (Luo et al., 2001) (Zhou et al., 2004).

Comparing the void with no-void under the maximum load stress, we define the void stress correction coefficient ε_σ as follows:

$$\varepsilon_\sigma = \frac{\sigma_y}{\sigma_w} \tag{1}$$

Where: σ_y is the maximum load stress under the void (MPa); σ_w is the maximum load stress under no-void (MPa).

The calculation of ε_σ in the middle longitudinal edge under slab corner void is shown in Figure 1. We can see a better relationship between ε_σ of Winkler and void size. Regression formula can be expressed as follows (Zhou et al., 2007):

$$\varepsilon_\sigma = 1.85e^{-\frac{L_v}{3.525}} - 0.816 \tag{2}$$

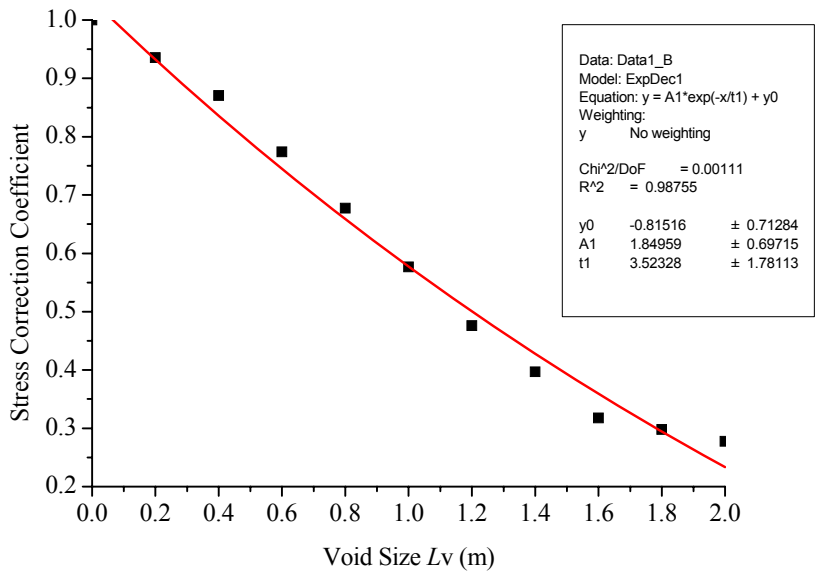

Figure 1.The fitting curve of load stress in the middle of the longitudinal joint in different void size.

LOAD STRESS OF THE SLAB CORNER LOADING POSITION UNDER VOID

When the slab corner void appears, the void regions can be approximated as an isosceles triangle, and the triangle AOB is shown in Figure 2. Assumed that the void critical section AB is fixed，OB and OA are unrestrained, the flexural stress of void critical section AB can be obtained by formula (3) subject to standard single axle load .

$$\sigma_{lj} = \frac{3\pi pa^2}{h^2 L_V}(L_V - 2a) \tag{3}$$

Where: σ_{lj} is the max flexural stress of single standard axle load in the critical section *AB* (MPa); *p* is the load pressure, taken 0.7 MPa.

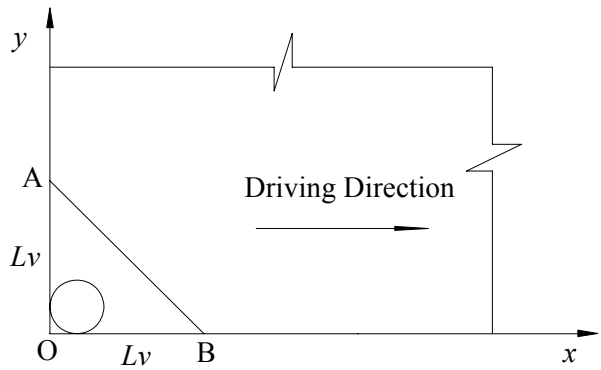

Figure 2.The critical load position in the void region.

We calculated different sizes of void σ_{lj} with a slab thickness of 0.25m. The results are shown in Figure 3. We can find that the flexural stress in the void critical section increases gradually with increase of the void size.

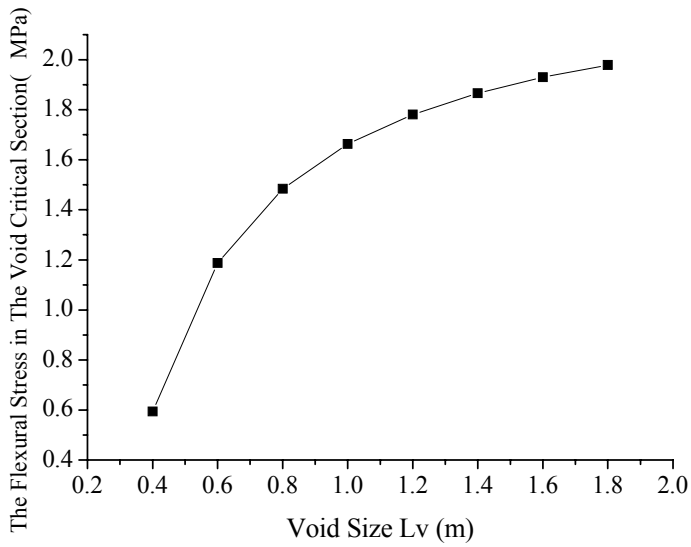

Figure 3.The flexural stress in void critical section.

Figure 4 compares the stress in the critical section of the slab corner void and the stress in the middle longitudinal edge (foundational response modulus k =200MN/m^3). As it is shown in the figure, we can know that when the slab corner void size $L_v \leqslant 0.7$m, all the maximum flexural stress in the section on AB is less than or close to that in the middle longitudinal edge under the standard axle load 1.325MPa. When $L_v > 0.7$m, it is more than 1.325MPa (Tang, 1992) (Tan et al., 2003).

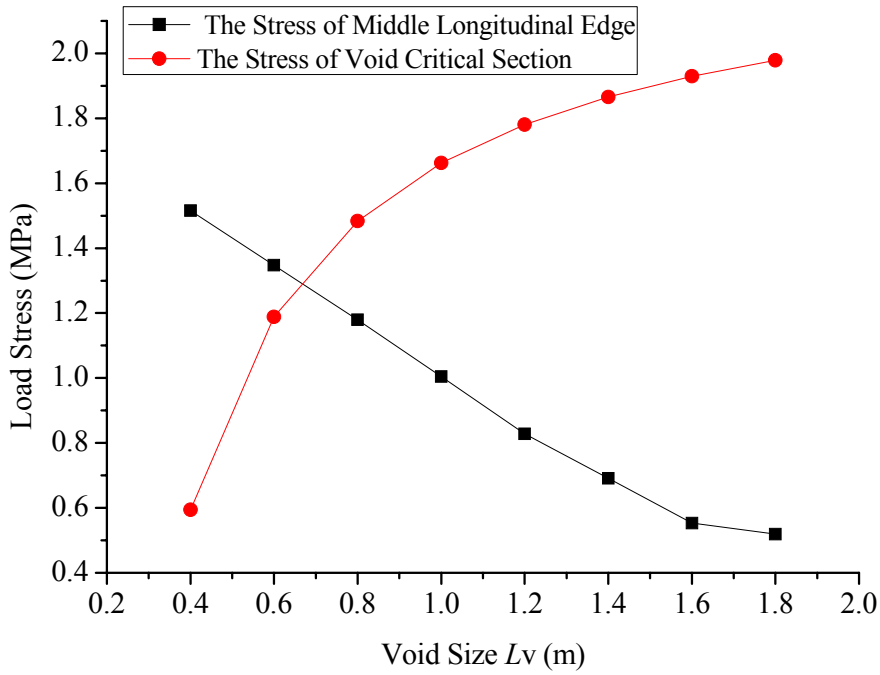

Figure 4.The transfer of critical loading position under the void slab corner.

CALCULATION OF VOID SLABS FATIGUE LIFE AND CLASSIFICATION STANDARD

The fatigue life of void concrete slabs N_f can be calculated based on the fatigue damage equation in "Concrete Pavement Design Specification" (JTG D40-2002). We can obtain N_f using formula (4). The results are shown in Table 1.

$$N_f = 10^{12.26-12.978\frac{\sigma}{f_m}} \tag{4}$$

Where: N_f is the effect numbers of cumulative standard axle loading when fatigue damage; σ is flexural tensile stress (Temperature stress is not taken into account in this paper); f_m is the flexural strength, taken 5 MPa.

Table1.The Calculated Results of Service Life.

Void Size L_v (m)	0.4	0.6	0.8	1	1.2	1.4	1.6	1.8
N_f (10^6)	211.38	577.98	255.93	87.80	43.37	26.10	17.80	13.28

Comparing N_f under void and no-void, we can get the fatigue life influence coefficient ε. The result is shown in Figure 5.

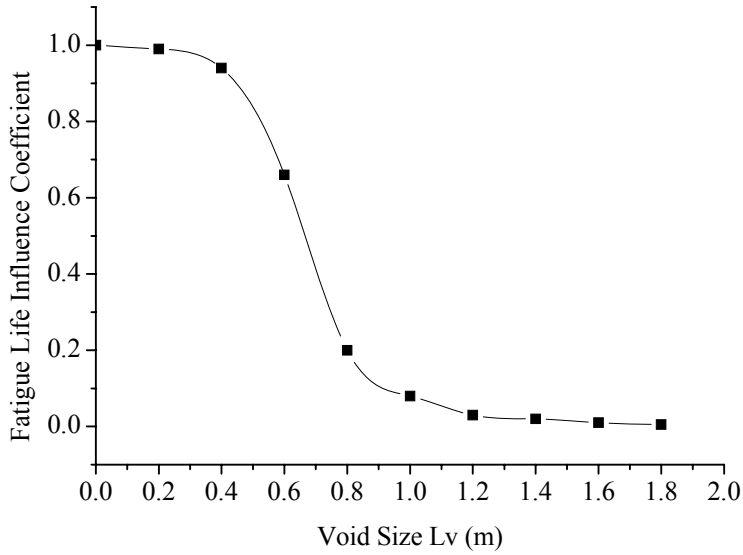

Figure 5. ε in different void size.

We can see from Figure 5 that ε reduces obviously with increase of voids at the slab corner. When void size increases to 0.4m, the trend of curve become downward significantly, and fatigue life also reduces. Then it needs to use reinforcement processing immediately, or else it will present early rupture. When the void size reaches 0.8m, ε will drop to 0.1m. As a result of critical loading position transferring to slab corner, concentration stress will be in void slab critical sections. Void size continues to increase, and curve drops to flat. However, fatigue life influence coefficient ε has been reduced very slightly at that time. Since L_V=0.7m is the critical void size of the critical loading position transferring, in view of this we can define that L_V=0.4m and L_V =0.7m are the division boundaries of void grade. According to the analysis above, we can establish the classification standard of the CCP void, as shown in Table 2.

Table 2.The Void Classification Standard of Cement Concrete Pavement.

Void Size in the Slab Corner L_V (m)	0～0.4	0.4~0.7	>0.7
Void Classification	Slight	Moderate	Severe

CONCLUSIONS

1. The modified coefficient of void stress under the loading in the middle longitudinal edge can be represented as an exponential attenuation function for the void slab corner. The stress in the middle longitudinal edge reduces as the void size increases, which indicates that the critical loading position of slab beneath transfers rapidly to the slab corner.

2. When the void size L_V>0.7m, the boundary of the void and no-void region in the slab corner becomes the most disadvantageous location. As a result of repeated loading, fracture will occur with the limiting fatigue stress. It impacts the service life of the pavement slab.

3. According to the analysis, the void size L_V=0.4m and L_V=0.7m should be the division boundaries of the void classification.

ABSTRACT

A three-dimensional (3D) virtual simulation system was developed in this paper for reappearance of the visibility and validation of road traffic signs. The system combined subjective and objective evaluation methods to reconstruct and optimize traffic signs design. Based on the system perspective of driver-vehicles-road, a 3D interactive simulation model was proposed and developed, including driver functional model, vehicle type select model, vehicle generation model, 3D road scene, and road network building model. This system has solved the shortages of static testing method and the complicated problems of dynamic testing method. And this system has provided a straight forward and reliable on-line analysis and simulation platform for pre-design, post-optimization and transformation work for road traffic signs system.

Keywords: Road, Traffic Signs, Virtual Simulation, Visibility, Safety Evaluation, 3D

1 INTRODUCTION

Road traffic sign is one of the important traffic safety infrastructures, which is to protect the safety of road transportation (Ministry of Science and Technology Highway, 1999, Chu 2005). Past research showed that most traffic accidents happened on some sections of highway where traffic signs are not visible and not properly designed. In recent years, a three-dimensional transportation network has formed with the rapid development of highway construction. In reality, the service level of traffic signs has lagged far behind. The common problems include no design standard, improper visibility, and so on (see Fig 1).

Figure 1. The Actual problems of traffic signs

Presently there are two evaluation methods for the visibility and validation of

[1]road traffic signs. One is static laboratory testing method, the other is real dynamic vehicle testing methods. Static laboratory testing method is in the lab room. Although the process of the method is very simple and easy to implement, test results do not entirely reflect the influence factors, such as during driver recognition of road traffic signs, he must be affected by the moving vehicle at high speed. Real dynamic vehicle testing method is to test the visibility and validation for traffic signs in actual vehicle, and this method is implemented on highway. So its testing results most accord with realities. But the testing process is in a typical road environment can not fully cover common road environments in reality. The task of the testing method is heavy and the cost of the testing method is very high (Chu, 2005) As a result, a comprehensive evaluation for traffic signs visibility and validation is developed based on virtual reality techniques (VR), which not only solve all kinds of traffic problems recently in our country but also is an import way to optimize the design of traffic signs [3].

2 ANALYSIS OF TRAFFIC SIGNS VISIBILITY IMPACT FACTORS

The primary characteristics of traffic signs is Easy-visibility and understandable. In order to realize the evaluation and optimization the visibility and validation for road traffic signs, we should study some crucial factors which impact drivers' visibility on traffic signs. Based on the system perspective of driver-vehicles-road, we can divide these factors into subjective and objective factors, as is shown in table 1. These factors are interactive each other, which make the qualitative and quantitative evaluation for road traffic signs very complicated (Yi, 2004).

Table.1 Influencing Factors

Influencing Factors		Specific Index
human	driver	Sexual ，, age, driving skills, etc
vehicle	speed	Driver seat high, eye height and speed
road	Road characteristics	Road width, linear, slope, etc
environments	weather	Rain, snow, fog light
Physical Characteristics of traffic signs	design	shape, color, symbols, characters and size, fonts, spacing, and stroke thickness of traffic sign
	set	Distance from lane center, height, order, tilt angle set model

2 DESIGN OF SYSTEM FUNCTION MODELS

After Specific the subjective and objective factors of road traffic signs, some function models of system has been designed separately in this paper, based on five

Supported by : West Transportation Construction Technology Projects (2004 318 223 33-10)

aspects such as driver, vehicle, roads, environments and traffic signs, physical characteristics.

2.1 DRIVER: FUNCTION DESIGN OF DRIVER MODELS

Driver function models are designed mainly from perspective, visual distance and eye height of driver. There a lot of factors influence driver identify traffic signs information, including driver's seat, Vehicle rear-view mirror and the front of the vehicle former perspective and so on. So considering these factors, the driver function models designed in this paper have some special functions, such as the driver can adjust his view angel, also can control keyboard (up, under, left and right, etc.) to make the vehicle speed up, slow down or turning.

2.2 VEHICLES: VEHICLE GENERATION AND TYPE SELECT MODELS

By using of Multi-Agent techniques, dynamic behavior models of vehicle have been designed. This model can control vehicle's driving behavior according to the setting parameters. And vehicle control rules of travel speed and direction are established. Such as speed up, slow down or turn (Chen, 2007). The function setting interface for vehicle type and driver's view angel is shown in figure 2.

Figure 2. Setting Interface for Vehicle Type and Driver's View Angel

2.3 ROAD: 3D ROAD NETWORK AND ENVIRONMENT MODEL

Through this model we can quickly and easily building a 3D road network scene by using data of road linear mapping and road design information. These data is mainly from field mapping, Google earth and aviation pictures. Through interactive dialogue interface, these data can be input into the computer. Function model including as follows:

1. Road models

This model can generate a road automatically and some properties of road can be set conveniently by users interactive with setting interface. The properties of road including soil road shoulder, road surface, hard shoulder, center isolating marked line, roadbed slope, drainage, road side of isolation facilities, road surface materials, surface slope, the number of lanes, lane width, safety barrier, outline of the signposts

and other safety devices (Yang, 2005). The alignment and surface construction interface of road as shown in Figure 3.

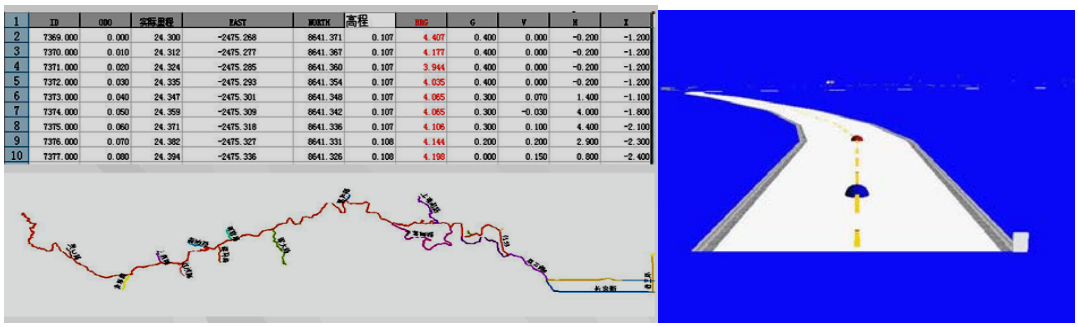

Figure 3. Interface for road alignment and road surface construction

2. Road intersection model

Grade intersection model is an independent model, which can describe the situation of two roads or more than two roads crossing. Such as grade intersection model and 3D-intersection model. User can through mouse and keyboard select intersection's type. Road cross in the intersection can connecting automatically after the intersection type selected.

3. Bridge and tunnel models

Bridge and tunnel models are also designed as Independent unit. The length, width and height of bridge and tunnel can be input into the computer by keyboard. Then the road surface properties can be generation automatically. Lighting and traffic safety facilities can be seated accurately. And the seated position of bridge and tunnel can be layout through mouse.

4. Simulation model of road Scene

The simulation model of road scene provides users some function menus. Through these menus users can be selected vary kinds of scenes to form a simulation road. The simulation effect of road scene as is shown in figure 4.

Figure 4. Simulation effect of road scene

3 3D-DIMENSIONAL MODELS DYNAMIC DESIGN OF TRAFFIC SIGNS

3D-dimensional models of traffic signs are designed dynamically for four

major kinds of road traffic signs (warning signs, ban signs, indication signs and guide signs). The functions of these traffic signs models mainly include location, type selection, support pattern, dynamic editing for traffic signs size and information. 3D-dimensional models of traffic signs dynamic design structure is shown in Figure 5.

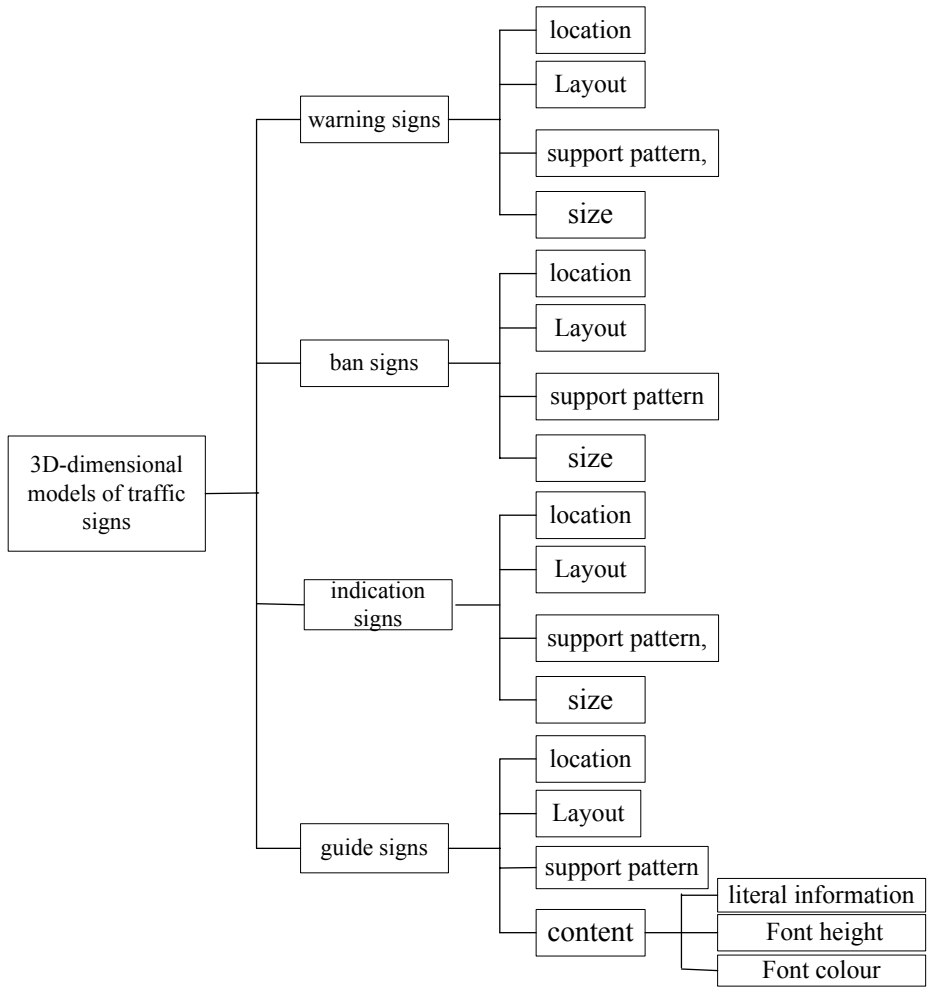

Figure 5. The structure of 3-Dimensional models for traffic signs

The Function implementation steps of traffic signs 3D-dimensional models as follows:

1. Firstly, after determined the location of traffic signs, user can place a selected traffic signs on the road surface through a mouse click or enter mileage of road.

2. Select a kind of layout for traffic signs by traffic menus.

3. Select a kind of support pattern for traffic signs by traffic menus. This model provides some common support patterns. Such as pillar pattern, single cantilever pattern, dual cantilever pattern, door frame pattern and attached pattern. And traffic sign board can automatically position at proper location on the road. Then, according to the traffic information determines the size of traffic signs board.

4. Finally, based on the job completed, users can edit traffic signs' information dynamically and real-timely.

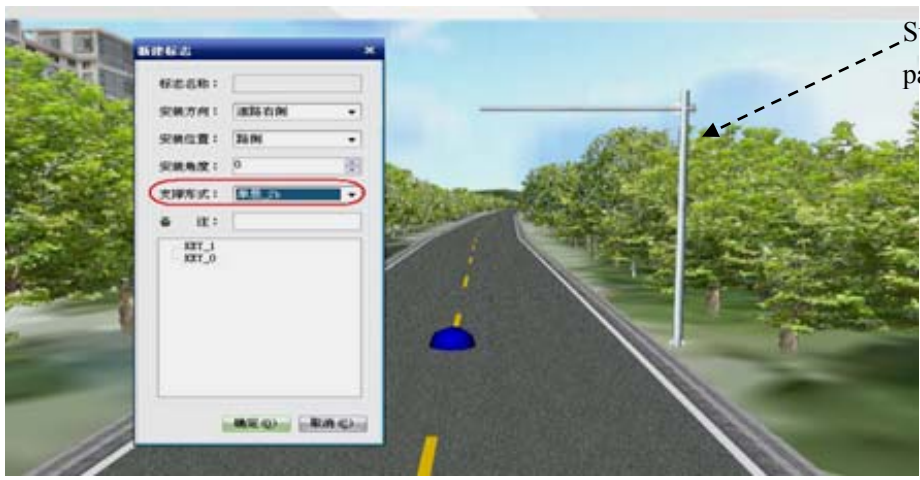

Figure 6.Traffic signs support pattern select interface

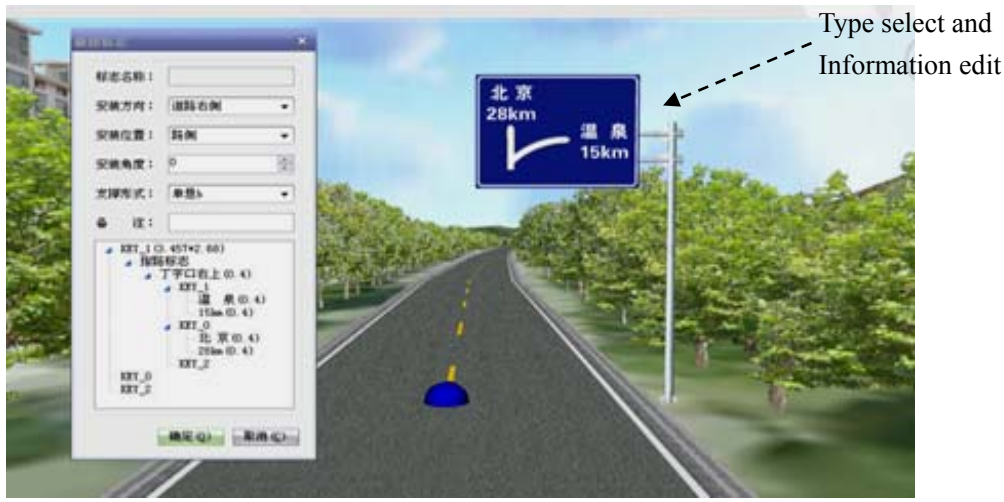

Figure 7.Traffic signs type select and information edit interface

As is shown in figure 6 and figure 7, the install location, support pattern, install angel, type and content information of traffic signs can be designed dynamically and modified real-timely on the road sides.

4 EVALUATION METHODS AND INDEX OF TRAFFIC SIGNS

Based on the 3D road network model, traffic signs model and vehicle model are completed above; we can evaluate the visibility and validation of traffic signs in accordance with the evaluation methods and index. The evaluation methods take into account objective index and subjective index. Due to different traffic signs have different functions; evaluation methods should according to the main function of different type traffic signs to classify and to establish. For example directional traffic

signs and guide traffic signs emphasize understandability, warning traffic signs and prohibition traffic signs emphasize validity.

For example established evaluation index for directional traffic signs and guide traffic signs as follows:

1. Running time. Evaluator departs from the starting point until the evaluators found the test traffic signs. This period counted as the running time of the evaluator.

2. Error rate. Calculation method is shown in formulate 1. Error understanding number divided by total number of evaluations of a certain sample evaluators we can calculate error rate. The total number of evaluations is the sum of the error understanding number and the proper understanding number of evaluation. That is,

$$\text{Error rate} = \frac{\text{error understanding number}}{\text{The total number of evaluations}} \times 100\% \quad (1)$$

Considering environment impact on the visibility of traffic signs, this system has developed some function models to set and display sun light, rain, snow and fog weather features, which will to ensure the authenticity and validity of evaluation results. The 3D virtual simulation system for road traffic signs has been applied in Men-Tou ditch of 109 National Road. The section of evaluation function simulation interface as shown in Figure 7. Visibility and validation of road signs and markings on the Men-Tou ditch of 109 National Road has been evaluated by subjective evaluation methods. By these methods, about ten bad visibility and improper-set traffic signs and markings have been found on the road. These traffic signs can easily leads to various types of traffic accident. And finally, these traffic signs and markings have been improved by Traffic Management Department. This is helpful to ensure the traffic safety on the road.

Fig.7 evaluation function simulation interface of 109 national road

5 CONCLUSIONS

Based on human factors, a set of 3D virtual simulation platform was developed for traffic safety. And the 3D interactive modeling and simulation was developed for drivers, vehicles and road. This system can assist Pre-evaluation and Post assessment of the visibility and actual implementation for various traffic signs on classified highway. The evaluation results can help reduce the unreasonable and unscientific traffic signs design scheme. In theory, the 3D virtual simulation platform developed in this paper will enrich and improve the existing traffic signs research results.

Using VISSIM to Calculate the Capacity of Urban Expressway Interchange

X. Zang[1,3] and W. Zhou[2]

ABSTRACT

Traffic flow at urban expressway interchanges is unique, and researchers have used the VISSIM simulation model to calculate the capacity of such interchanges. In this paper, in order to calibrate and validate VISSIM, the measures of effectiveness (MOE) are put forward, the confidence intervals of parameters chosen in the VISSIM are calculated, and then the factors in the interval are fine tuned to meet the accuracy of MOE, which is the percentage of error between the simulated and observed values. At last, the capacity of an urban expressway interchange in Guangzhou is calculated based on the proposed method. The validation results show that the approach to calibration and validation is feasible.

INTRODUCTION

An interchanges is a key joint of urban expressways. It determines the capacity of connecting urban expressways, and it may become the bottleneck if its operation is unreasonable. At present many urban interchanges in China become quite congested, so it is necessary to study the capacity of urban expressway interchanges. But how to define the interchange capacity is difficult because there is not a general concept of interchange capacity. In this paper, we define the concept as the maximum volume of traffic that an interchange can serve under the definite conditions. This concept must be different from the capacity of weaving area, merge area, diverge area, or basic section area.

The urban expressway interchange is a complex traffic system. Generally, there are diverging, weaving, and merging areas in one interchange, and the traffic flow is greatly disturbed.. It is difficult to analyze the traffic flow characteristics using statistical and theoretical methods to calculate the capacity of an interchange (Zhou et al. 2007). Using computer simulation to calculate the capacity is feasible because the computer simulation has repeated characters, real-time characters, continued characters and easily controlled characters (Zhong et al. 2006). It can simulate the traffic flow under different conditions and analyze the vehicle characteristics, driver characteristics, traffic flow characteristics, and so on. This paper will calculate the capacity of an urban expressway interchange based on VISSIM after calibration and

validation.

THE TRAFFIC FLOW CHARACTERISTICS

There are various types of interchanges on urban expressways. Their lane numbers and traffic composing and geometrical conditions are different, and their capacity values are different, too. In diverging, s or weaving, or merging areas, the traffic flow is disturbed. The traffic flow in the weaving area is disturbed by that in the diverging area, and the traffic flow in the merging area is disturbed by the weaving area. This occurs because the distance between the diverging area and weaving area or between the weaving area and merge area is too short, and the vehicles cannot return to their natural condition after being influenced, and its time headway distribution is not determined.

Figure 1 is an illustration of time headway distribution, and it is drawn based on the actual survey data from an urban expressway interchange in Guangzhou city. From Figure 1, we can see that with the increased distance from the end of the weaving area to the start of the merge area, the mean time headway decreases, but traffic flow volume increases. This occurs because in the weaving area, the straight running vehicles will change lanes from the outside to the inside lane to avoid the disturbance. The vehicle volume in the outmost lane is low, and after the weaving area, many vehicles change lanes from the inside lane to the outmost lane.

Moreover, the distribution of time headway in the outmost lane in the merge area does not accord with the exponential distribution, M3 distribution, or Erlang distribution, but alterable parameters WEIBULL distribution. All these distributions demonstrate that the traffic flow characters in interchange are different from those in another place, for example in the base segment or merge area of an expressway. So we must consider these characters and build feasible calibrating methods when we calibrate the VISSIM.

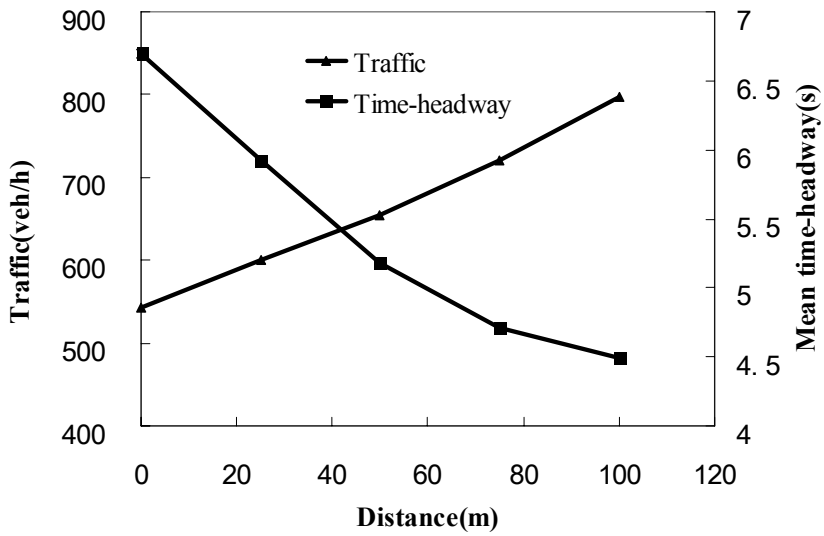

Figure 1. The relations of traffic and time headway with distance.

CALIBRATION of VISSIM

The meaning of calibration. Calibration is the adjustment of parameters in a model so as to represent local conditions (Cohen, 2004). The reliability of any simulation software depends on its ability to produce results close to reality (Liu et al. 2008). The process of determining whether the simulation model is close enough to the situation being simulated is generally achieved through an iterative trial-and-error process involving calibration of the model parameters, comparing the model to the actual system behavior, and using the discrepancies between the two to improve the results until the accuracy is judged to be acceptable (Hourdakis, et al. 2003).

Selection of calibration parameters. In VISSIM, there are many parameters, including fixed parameters and adjustable parameters. The fixed parameters include road condition factors and controlled condition factors, for example, lane width, curve radius, gradient, and so on. The adjustable parameters include driver character factors, lane change time, minimum time-headway, and so on(Sun et al. 2007). The fixed parameters can be obtained by survey, and the adjustable parameters need research and are analyzed based on the record and data surveyed. In interchanges, because traffic flow characteristics are particular, the greatest difference from other facilities is the driver characteristic, so we choose the emergency stop distance, expected lane change distance, minimum time-headway, observed front vehicle, additional safety distance, and minimum and maximum acceleration as the main calibration parameters.

The measures of effectiveness (MOE) and the goodness of fit measure. In an interchange, the measures of effectiveness must express the traffic flow characters synthetically, so the variables chosen for MOE aretotal time, interzone mean velocity, and traffic volume in the downstream of mainline. The goodness of fit measure calculates the difference between the simulated and observed values(Merritt, 2003). The test measure is as follows:

$$P = \frac{V_S - V_O}{V_O} \times 100\% \qquad (1)$$

Where p is the percentage of error between the simulated and observed values, V_S is the simulated value of all the MOE, and V_O is the observed value of all the MOE.

The confidence interval of the MOE. After much research and analyzing the survey data, researchers concluded the following: the emergency stop distance is related to velocity, a driver's reaction time, and the friction of the road surface. The expected lane change distance is shorter than the other area because the traffic flow in interchange is disordered, and the driver is more cautious than in other facilities. The minimum time-headway within an interchange is smaller than that in the other facility because the drivers are tensional, and they do not want be stopped but to go through the interchange sequentially. According to the actual survey data, the researchers calculate the 95 percent confidence interval of above factors. The value is shown in Table 1. The value of calibration parameters should be within the interval.

Table 1. The 95% cConfidence interval of calibration parameters.

Parameters	Diverge area		Weaving area		Merge area	
the emergency stop distance(m)	18	21	16	19	18	21
expected lane change distance(m)	135	165	130	160	132	162
the minimum time-headway(s)	0.9	1.2	0.9	1.2	0.9	1.2
additional safety distance(m)	1.5	2.5	1.5	2.5	1.5	2.5
minimum acceleration(m/s^2)	-1	-1.2	-1	-1.2	-1	-1.2
maximum acceleration(m/s^2)	-4	-4.6	-4	-4.6	-4	-4.6

Methodology for practical calibration. In VISSIM, there are too many parameters and the calibration is very difficult. Many scholars consider that the calibration process is an optimization problem (Chu, 2004). Many methods have been used, for example, genetic algorithm, the gradient approach algorithm, genetic simulated annealing algorithm. For interchanges, using the methods above will not be feasible because the traffic flow states are varied, and the calibration result is not unique. That is to say there will be many different combinations for calibrating factors by only the optimizing method. The calibration result in one condition may be not fit for every condition. We must then calibrate VISSIM by combining the actual data with optimization methods. The steps are as follows:

1) Survey the calibration parameters chosen above in the interchange.

2) Analyze the confidence intervals as calculated in Table 1.

3) Program based on the circular calculation algorithm.

4) Adjust the parameters in the confidence interval to meet the target that the $P < 5\%$ after an iterative trial-and-error process.

5) Adjust the other parameter except the parameters at step 4 if the target of step 4 cannot be achieved.

6) Validate the calibrated VISSIM based on the data that is different from the data used for calibrating, but it should be the same as the traffic conditions. Detail is included in the next chapter.

7) Calculate the capacity of an interchange by using a calibrated VISSIM.

VALIDATION OF VISSIM

Validation is a comparison of the measures of effectiveness as computed by a model and as observed in field data under the same traffic flow conditions. In order to ensure the validity of the calibrated VISSIM, the data used for validation must be different from the data used for calibration. The measure of goodness-of-fit we used for evaluating the calibrated simulation model is the Mean Percentage Error (MAPE), which can be calculated by:

$$MPE = \frac{1}{n}\sum_{i=1}^{n}((M_{oi} - M_{si}) / M_{oi}) \qquad (2)$$

Where M_{oi} is the observed values, M_{Si} is the simulated values, and n is the minimum number of replications for the required accuracy. It is calculated by:

$$N = (\frac{st_{a/2}}{uE})^2 \quad (3)$$

Where u and s are estimates of the mean and standard deviation of the MOE, E is the required accuracy, $t_{a/2}$ is the critical value of the t-distribution at significance level a. If $MPE < 5\%$, we can use the calibrated VISSIM to predict the capacity of an urban expressway interchange.

A SIMULATION EXAMPLE

According to the steps above, we calculated the capacity of an urban expressway half-cloverleaf interchange in Guangzhou city. The circumstance is as Figure 2, which was plotted according to the GPS data. The parameters calibrated are as Table 2, and the processes are as the section of **Methodology for practical calibration**. The validated results of MOE are shown in Figure 3 (only given a demonstration of interzone mean velocity, the others is elided). In Figure 3, the interzone mean velocity is the mean velocity from the beginning of the weaving area to the beginning of the merging area, which begins in lane 1 under the different traffic conditions. Figure 3 shows that the change of velocity in the interchange is violent, and the chaos is serious. And one line is the actual data line, the other line is the simulation data line. The difference between the two lines shows the calibrating effect. From Figure 3 we can see the two lines are very close, so the calibrated VISSIM is effective. Then based on the calibrated VISSIM, we calculate the capacity of an interchange in a single direction in KEYUN road is 7490 (pcu/h) (total 4 lanes) under the conditions that the ratio of weaving volume to total volume is 15 percent, the ratio of diverging volume to total volume is 10 percent, and the ratio of merge volume to total volume is 10 percent. In an interchange, the traffic characteristics are complex, and too many factors influence the capacity of the interchange. So the researchers' conclusion only fits particular conditions. However, the method to calibrate the VISSIM is helpful when studying the interchange capacity extensively.

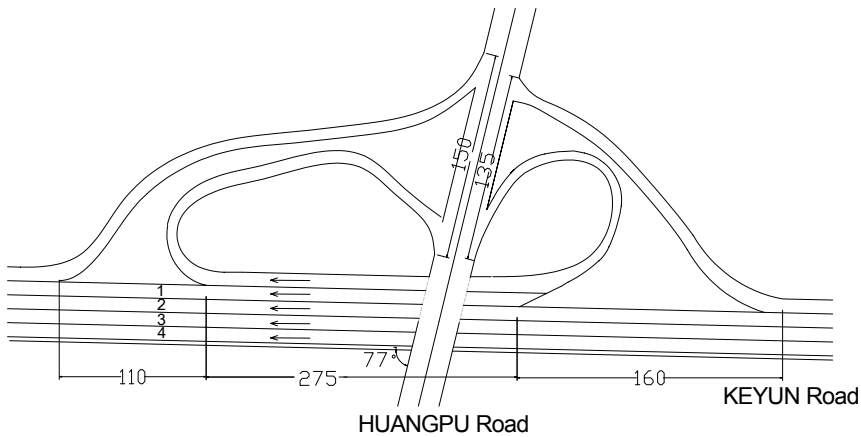

Figure 2. The circumstance of interchange chosen.

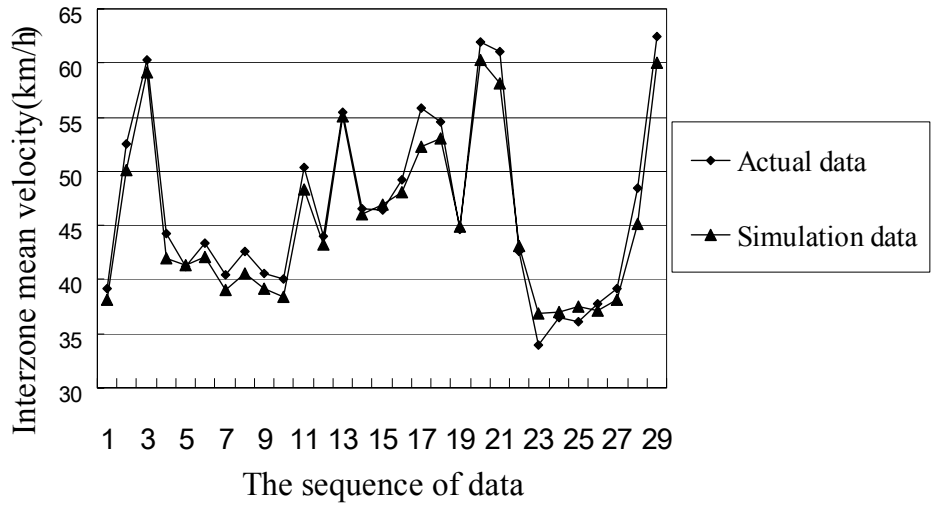

Figure 3, The comparison between the actual data and simulation data.

Table 2. The value of MOE calibrated.

Parameters	Diverge area	Weaving area	Merge area
the emergency stop distance(m)	20	17	20
expected lane change distance (m)	145	135	135
the minimum time-headway(s)	1.05	1.05	1.05
additional safety distance(m)	2	2	2
minimum acceleration(m/s^2)	-1.1	-1	-1
maximum acceleration(m/s^2)	-4.2	-4.2	-4.2

CONCLUSIONS

The study shows that the calibration of VISSIM at an interchange is different from that in other facilities because the traffic flow characteristics are particular. In order to calibrate the parameters in VISSIM, we make certain the confidence interval is based on the actual data surveyed, then the parameters are tuned to satisfy the goodness of fit best. If the accuracy cannot be obtained, then tune the other parameters slightly. The simulated results demonstrate that this calibrating method is feasible, and the accuracy is sufficient. However, the interchange models are varied in different nations or districts, and the traffic characteristics are also different. It is difficult to ascertain the universal interchange capacity, so the research results in this paper are limited. The calibrating method is also fit for other kinds of interchanges.

In this paper, six parameters are calibrated, but many parameters concerning vehicles are not calibrated. More research is needed in capturing all the vehicle parameters.

ABSTRACT

During the red-light time, when pedestrians walk to the zebra line, the presence between pedestrian and vehicle is one of the main problems for pedestrian counting. Common approaches including edge detection, histogram of gradient, and segmentation based on histogram of intensity gradient are not feasible. After the review of the general pedestrian counting methods, a new algorithm for pedestrian counting from the crowd RGB picture is proposed in this paper. Firstly, using the sequential frames with differential color threshold as based templates of human head and shoulder detection for preliminary counting db3 wavelet is used for retrieving the features. and K-mean cluster is used for the centroid detection of feature points clusters. Additionally, the track of centroid is used for the filtering of pedestrians not walking towards the camera. The algorithm is applied in pedestrian alerting system of Eshan Road and Dongfang road in Shanghai. In 1000 alerting events, the error is below 22% and the related analysis result is presented.

1. INTRODUCTION

Pedestrian detection and counting in urban traffic is one of the key issues in Intelligent Traffic System (ITS) and traffic safety research. Based on the background subtraction methods in the image process, Single Edge Detection (Haritaoglu,1998), Histogram of Oriented Gradient(Dalal,2005), and Intensity Histogram base Region Division methods(Michael Girard,1985) were used in single frame based pedestrian detection and counting. For the sequential frames of video stream, it is proposed to use Biology Movement (Shafique, 2005), self-adapt background subtraction (Nixon.,1999), etc. methods for pedestrian contour retrieve and recognition. These methods were not feasible in crowded scenario. One method to solve this problem in current research is to detect, retrieve, and track the feature points of human head and face, thususe these data for pedestrian counting. Viola (2001) proposed the traditional

technique of base human-face detection . The method can be used in real time detection. However, the application of Adaboost classifier in his method requires large number of face pictures for positive and negative classifier training.

The key point of this project is not to recognize and match; hence, it proposed a new human counting algorithm for crowded scenario during day period based on RGB pictures showing in the following sections

2. SYSTEM FRAMEWORK

Based on the region-detail synthesis, the detection sequence is shown in Figure 1: Pedestrian contour →Face region→Face feature points→Centroid of feature points→Moving direction.

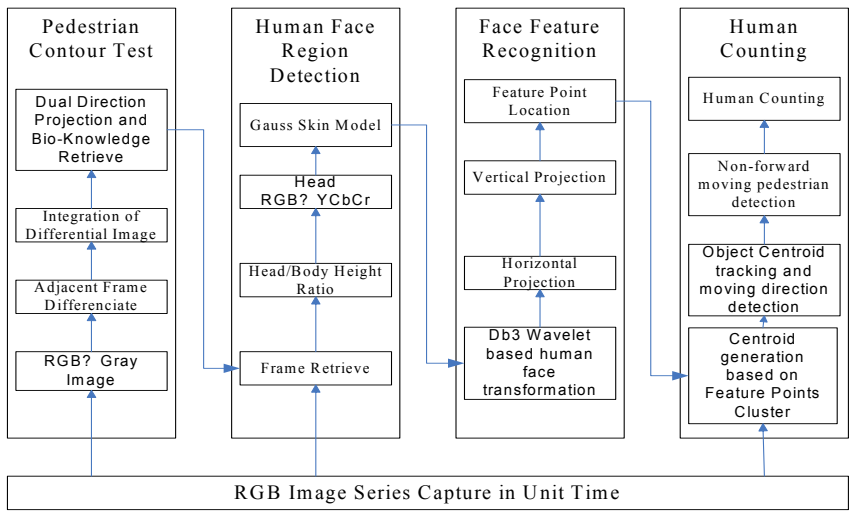

Figure 1. Statistic of Pedestrian Red Light Violation in a Crowded Scenario

3. ALGORITHMS FOR PEDESTRIAN STATISTIC IN RED LIGHT TIME

3.1 Gray-level Image Differentiation based Pedestrian Contour Detection

Different with the conventional background subtraction method, the algorithm applied here only record the moving objects in the camera scene. Roadside camera is setup facing zebra line vertically; the *i*th frame can be presented as:

$$f_i(u,v) = f_{P_i}(u,v) + f_{V_i}(u,v) + f_{B_i}(u,v) + f_{N_i}(u,v), i = 1,2,3,\cdots$$

Where,(u,v)-pixel coordinates, $f_i(u,v)$-gray level of point(u,v), $f_{Pi}(u,v)$-gray level of pedestrian in the frame, $f_{Vi}(u,v)$-gray level of vehicles, $f_{Bi}(u,v)$-gray level of background image, $f_{Ni}(u,v)$-gray level of image noise, follow zero mean Gauss Distribution.The *j*th differential frame can be written as:

$$I_j(u,v) = \left| f_{i+1}(u,v) - f_i(u,v) \right|, i = 1,2,3,\cdots, j = 1,2,3,\cdots$$

Where $I_j(u,v)$ is the difference of two adjacent frames, when the sample time closing to zero, $f_{Bi}(u,v)=f_{Bi+1}(u,v)$. In a frame sequential with M images, the sum of M-1 differential frames is:

$$I_{\Sigma}(u,v)=\sum_{j=1}^{M-1}I_j(u,v)=\sum_{i=1}^{M}\left|f_{P_{i+1}}(u,v)-f_{P_i}(u,v)\right|+\sum_{i=1}^{M}\left|f_{V_{i+1}}(u,v)-f_{V_i}(u,v)\right|+\sum_{i=1}^{M}\left|f_{N_{i+1}}(u,v)-f_{N_i}(u,v)\right|$$

Where the background is subtracted and the left is the block information of pedestrian, vehicle tracks, and point noise under Gauss distribution. The erosion process is used to eliminate the point noise with minimum damage to block information, the result is image $I'_{\Sigma}(u,v)$. The vertical projection of pedestrian moving track maybe present as:

$$V(u)=\sum_{v=1}^{H}I'_{\Sigma}(u,v),u=1,2,\cdots,W$$

Where, W-image width, H-image height, V-the histogram with multi-peak values, *x*–the number of pixel values, which correspondent to the pedestrian number, use the α (decide by M) *W_p (pedestrian width) region on both sides of peak value to estimate the vertical track of pedestrian, it gives *x* regions. S_k stands for the *k*th vertical region for the projection of histogram in vertical direction.

$$S_k(v)=\sum_{u=a_k}^{b_k}I'_{\Sigma}(u,v),v=1,2,\cdots,H$$

Where, a_k-the start point of *k*th vertical region, b_k-the end point of *k*th vertical region. S_k-the histogram close to square wave, use the distance from start point of square wave to β (decided by M)*H_p(Average Height of Pedestrian) as the horizontal region estimation of the *k*th pedestrian's track, the descending side of square wave is not used here considering the occlusion of vehicles in the scene. Hence, after the projection of the eroded image, any pedestrian contour of the original images is located within the rectangle area decided by the projection results.

3.2 Gauss Skin Color Model in YC_bC_r Space

Considering the both presence of human, vehicles during the red-light scenarios, based on the pedestrian contour location, the human head, body height ratio is used for the detection of human face in the head/shoulder region, which only keeps the pedestrians facing the camera and counts the pedestrian numbers accurately being tracked.

Using Gauss Skin model and YCbCr space (Phung, 2002) to divide the estimated human face region. Since the captured image is in true color, the RGB conversion to YCbCr can be achieved by the following equation:

$$\begin{bmatrix} Y \\ C_b \\ C_r \end{bmatrix} = \begin{bmatrix} 16 \\ 128 \\ 128 \end{bmatrix} + \frac{1}{256} \begin{bmatrix} 65.481 & 128.553 & 24.966 \\ -37.797 & -74.203 & 112 \\ 112 & -93.786 & 18.214 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix}$$

The statistic result shows the skin color of human face is within the certain region. The center of this distribution can be calculated by the samples. The mean and variance of the distribution are calculated as follows:

$$\mu = [156.56 \quad 117.43], C = \begin{bmatrix} 160.13 & 121.143 \\ 121.143 & 299.46 \end{bmatrix}$$

The similarity of one pixel to the skin is counted base on its distance to this center, as follows:

$$P(C_r, C_b) = \exp(-0.5(x-\mu)^T C^{-1}(x-\mu)), x = [C_r \quad C_b]^T$$

The empirical result showing a good result may be achieved using 0.65 as the threshold in image binarization:

$$F(u,v) = \begin{cases} not & P(C_r, C_b) > 0.65 \\ yes & P(C_r, C_b) \le 0.65 \end{cases}, \quad u,v \text{ is pixel coordinate within the head region}$$

3.3 Human Face Feature Recognition and Locating with Wavelet

The separated face region data need to be distilled for real time based tracking, the feature based recognition, and location is used here based on the wavelet methodology (Satyanadh, 2004). Assuming we have 2D scatter signal of human face image $\{X_{m,n}\}_{m,n \in Z} \in Z$, with $C_{0,m,n}=X_{m,n}$, the wavelet based deduction is:

$$\begin{cases} C_{j,m,n} = (H \otimes H)(C_{j+1})_{m,n} = \sum_{k,l} C_{j+1,k,l} h_{k-2m} h_{l-2n} \\ D^1{}_{j,m,n} = (H \otimes G)(C_{j+1})_{m,n} = \sum_{k,l} C_{j+1,k,l} h_{k-2m} g_{l-2n} \\ D^2{}_{j,m,n} = (G \otimes H)(C_{j+1})_{m,n} = \sum_{k,l} C_{j+1,k,l} g_{k-2m} h_{l-2n} \\ D^3{}_{j,m,n} = (G \otimes G)(C_{j+1})_{m,n} = \sum_{k,l} C_{j+1,k,l} g_{k-2m} g_{l-2n} \end{cases}$$

Where, H and G equal to the low/high frequency filter of db3 wavelet in Daubechies group. D^1 is the vertical direction wavelet parameter, D^2 is the horizontal direction wavelet parameter, *and D3* is wavelet parameter on diagonal direction.

The details in vertical edge of original frame is well remained after the second layer wavelet transformation in high frequency image, which may efficiently recognize human face features such as eyes, nose, and mouth, the location of these features may be easily calculated with the integral of horizontal/vertical gray level projection.

3.4 Fuzzy Based K-Mean Clustering

The tracking of pedestrian requires the identification of one pedestrian with his feature points; here the Fuzzy K-Mean methodology is used to locate the centroid of pedestrian face feature points in original frame, for pedestrian identification. FKM algorithm gives out the cluster centroid within the human face feature points clustering process.

3.5 Tracking

The empirical result shows that most of the pedestrian walks through the zebra lines with a constant speed, and the adjacent frames got minor difference. The binary principle to tell the centroid of ith frame ($u_{i,k}$,$v_{i,k}$) in the i+1 frame ($u_{i+1,l}$,$v_{i+1,l}$) belongs to the same pedestrian is:

$$d = \sqrt{(u_{i+1,l} - u_{i,k})^2 + (v_{i+1,l} - v_{i,k})^2}, k = 1,2,\cdots, l = 1,2,\cdots, sign(d) = \begin{cases} 1 & d \le \delta \\ 0 & d > \delta \end{cases}$$

Where δ is decided by the sample frequency and pedestrian moving speed.

Sample M frames in unit time, the *k*th pedestrian moving direction can be:

$$Direction = \begin{cases} \text{moving towards the camera} & v_{M,k} - v_{1,k} > 0 \\ \text{moving away form the camera} & v_{M,k} - v_{1,k} < 0 \\ \text{moving vertically to the camera facing direction} & v_{M,k} - v_{1,k} = 0 \end{cases}$$

4. APPLICATION AND ANALYSIS

The algorithm is applied in pedestrian alerting system at Eshan Road and Dongfang road inShanghai. In one thousand alerting events, the error is below 22%. An example is presented here. 15 frames (768×576 pixels) are processed per second. Figure 2 listed the original RGB image series.

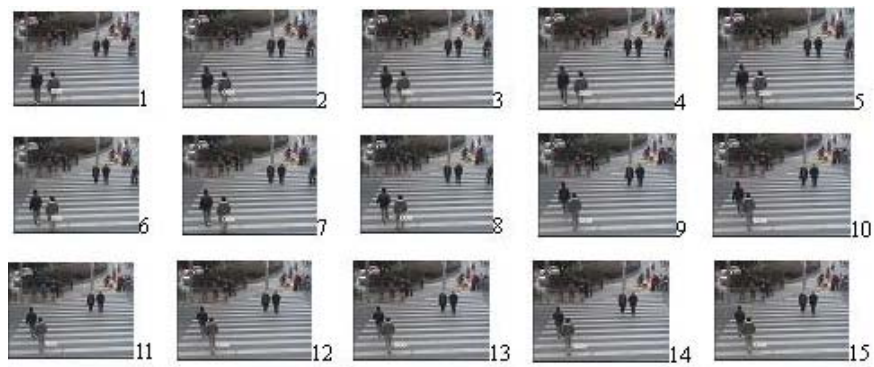

Figure 2. Original image series

Figure 3 showed the sum of 14 gray differential frames..and Figure 4 showed the pedestrians' contours of the original imageslocated within the rectangle area

Figure 3. The sum of 14 gray differential frames

Figure 4. The result of pedestrians' contour detection

The result of the point locations by face feature for the 15th original image is shown in Figure 5. By obtaining the face feature points of 9 sequent original frames, the clustering result is shown in Figure 6. The number and the direction of the men moving forward the camera can be detected easily.

Figure 5. The face feature point location

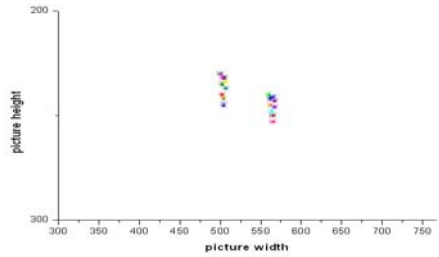

Figure 6. The clustering result

5. Conclusion and Future Work

After the review of the general pedestrian counting methods, a new algorithm for pedestrian counting in crowd RGB picture is proposed in this paper. The algorithm is applied in pedestrian alerting system of Eshan Road and Dongfang road in Shanghai. A perfect result is obtained. The new algorithms and research approach for night period will be developed in the future work.

Impact of Posted Speed Limits on Operating Speed in Urban Expressways

H. Wang[1], X. Sun[1], B. Li[1], and Y. He[1]

[1] Beijing Key Lab of Transportation Engineering, Beijing University of Technology, P.O.Box 100124, 100# Pingleyuan, Chaoyang District, Beijing; PH (86) 67391597; FAX(86) 67391597; email: wanghuarong@emails.bjut.edu.cn

ABSTRACT

The relationship between posted speed limits and operating speed is one of the main factors in determining appropriate speed limits in a speed zone. In this research, 19 sites were randomly selected from the 3rd, 4th, and 5th Express Ring-Road in Beijing, and the spot speed and headway data were collected at these sites. Then, free-speed data were reduced from the original data, and the 85th percentile speeds were computed as each site's operating speed. Deviation analysis of operating speed at the 3rd and 4th site shows that there were no obvious distinctions between these two types of road facilities. The regression analysis of posted speed limits and operating speed shows that there exists a strong linear relationship between these two speed terms. The percentage of operating speed exceeding posted speed limits increases with the speed limit value. The relationships between speed limits and operating speed established here may be expected to provide some quantifying basis for transportation agencies to set posted speed limits in speed zones. Results of this study may help the Department of Transportation and its districts quantify the speed limits and provide more objective insights for setting speed limits.

Keywords: posted speed limits; operating speed; deviation analysis; regression analysis

INTRODUCTION

According to the Fatality Analysis Reporting System (FARS) released by the National Highway Traffic Safety Administration (NHTSA) in the U.S., over one third of all fatal crashes in the years from 1988 to 2006 were related to speeding, that is, exceeding the posted speed limit or traveling too fast for the existing conditions (NHTSA 2006). In China, 10.2 percent of all fatal crashes were related to speeding in 2007 (TMRI 2008). Speed management is a very important tool for improving road safety. Posting speed limits as one of the speed management practices is often understood as a tool to control vehicle speeds and to mitigate accident risks referred to crash statistics. The final report on speed management (Milliken et al. 1998) stated that current approaches for setting speed limits in the U.S. consist of two main methods: maximum statutory speed limit and speed zoning. In determining a legislated speed limit, such factors as design speed, vehicle operating speed, crash history, and enforcement experience are taken into consideration. While the 85th percentile speed under a free-flow condition is the most decisive factor used in setting speed limits in speed zones, the numeric value of a speed limit may be adjusted by

additional factors such as crash rate, roadside development, and roadway geometry, parking, and pedestrian level. The speed limit setting practices in China mainly consider the design speed of certain roadways, ignoring the fact that most drivers have an understanding of a reasonable speed and operate their vehicles at a speed they consider appropriate for the roadway geometry and environment regardless of speed limits. Initially, it is necessary to discover the relationship between posted speed limits and operating speed in China. Here, several segments located in the 3rd, 4th, and 5th Urban Express-Ring Road of Beijing were selected to collect field speed data and speed limits information in October 2007 to make following research.

SPEED DATA COLLECTION

Site Selection Criteria

Here, sites were selected based on the following criteria:

- Sites were selected to represent a basic segment, that is, a reasonable distance from accesses, ramps, and weaving sections to prevent speed data from having any immediate influences by such features.
- Sites were selected to provide a good typical location where speed limit signs could be easily recognized.
- Sites were selected to make sure there was no automated enforcing instrument, such as photo radar, in use.

With these sites selection criteria, a hypothesis was made: drivers of these sites select their speed based only on the speed limits signs and their perception of the driving environment. Accordingly, there were 8, 3, and 8 sites, respectively, selected from the 3rd, 4th, and 5th urban Express Ring-Road of Beijing.

Data Treatment and Reduction

The raw video traffic flow data were exported from Autoscope 2004 to Microsoft Excel and saved as event data. The information includes detecting time, lane, speed, and vehicle length. The 85th percentile speed (a renowned operating speed representation and the primary basis to set speed limits) should be measured under free-flow conditions (NHTSA 2006). A number of studies defined the free-flow speed as similar to selecting those vehicles that have a substantial headway and are not impeded by other vehicles or other factors. It is usual to set a minimum headway between vehicles in the traffic flow of 3 seconds to measure free speed, but a time gap of at least 4 seconds is preferable (Geneva 2008). Here, a time gap of 4 seconds was selected as free speed. In this research, the proportion of truck, bus, or other large vehicle is little than 5 percent, so large vehicles were ignored, and only passenger cars were considered. Then, 8,198 free speeds were reduced from 22,475 originally collected data of 19 different sites during this study. The detailed information of each investigating site, such as posted speed limits, original sample size, and free-speed sample size was shown in Table 1.

ANALYSIS AND RESULTS

Operating Speed

As mentioned above, the 85th percentile speed is a renowned representation of operating speed. Accordingly, we extracted each free-speed sample's 85th percentile speed using the statistical method as each site's operating speed. Table 2 presents a summary of the site statistics, including the mean, standard deviation (SD), maximum and minimum speed, and 85th percentile speed. The site No. in Table 2 corresponds to that in Table 1.

Table 1. Information of investigating sections.

Investigating Location	Site No.	Posted Speed Limits /kph	Original Sample Size	Free-speed Sample Size
3rd Urban Express Ring Road	1	80	349	264
	2	80	592	326
	3	80	375	241

Making contrast between posted speed limits value in Table 1 and the 85th percentile speed value in Table 2, it can be seen that almost all of the 85th percentile speeds exceed its corresponding posted speed limits. The relationship between posted speed limits and 85th percentile speed will be investigated later in depth.

Relationship between Posted Speed and Operating Speed

Deviation Analysis

As shown in Table 1, the posted speed limit at the sites we selected from the 3rd and 4th Express Ring-Road was 80 kph, and we formulated a regression analysis without separating these two parts. To discover whether there are obvious distinctions among a sample's distribution from these two sites, we formulated a deviation

analysis about the 85th percentile speed of the 3rd and 4th Express Ring-Road. The deviation analysis results are shown in Table 3.

The *p* value in the last column of Table 3 is 0.8658 and greater than 0.05, which means that there are no obvious differences between the mean values of the 85th percentile speed in the 3rd and 4th sites. The result shows that the operating speed data obtained from the 3rd and 4th Express Ring-Road can be seen as one sample, thus we can make a regression analysis.

Table 2. Summary statistics for investigating sites.

Site No.	Mean/kph	SD/kph	Min./kph	Max./kph	85th percentile speed/kph
1	85.14	18.49	30	156	98
2	93.88	21.38	37	146	110
3	100.03	16.77	54	156	110
4	73.48	15.75	36	147	87
5	85.3	18.62	35	146	101
6	75.53	10.57	58	140	86
7	70.35	11.88	44	115	80
8	63.32	15.08	22	128	77
9	85.42	14.52	55	147	98
10	84.21	14.37	30	144	98
11	76.83	13.40	40	141	89

18	94.44	19.53	47	158	113
19	86.16	19.10	28	154	105

Table 3. Deviation analysis.

Origin of Deviation	Degree of freedom	Sum of Sq	Mean of Sq	F value	Pr (>F)
Factor	1	4.12	4.12	0.0302	0.8658
Residual	9	1227.88	136.43	—	—
Sum	10	1232.00	—	—	—

Regression Analysis

It is generally acknowledged that 85th percentile operating speeds exceed posted speeds (Parker 1997). Many of these reports have also demonstrated that the 50th percentile operating speed either is near or exceeds the posted speed limit (Fambro et al, 1997). Figure 1 illustrates the differences between rural two-lane highways and suburban/urban (S/U) roadways in the U.S. (Fitzpatrick et al. 2003). It can be seen from Figure 1 that 85th percentile speeds of urban and suburban roadways exceed existing posted speed limits more often than rural arterials in the U.S. As stated in part 1, little research was conducted on the relationship between operating speed and posted speed limits in China. Figure 2 is drawn by the data obtained from each site's posted speed limits in Table 1 and its corresponding 85th percentile speed in Table 2. It can be seen from Figure 2 that when the posted speed limits increase from 80 kph to 100 kph, the percentage of 85th percentile speeds exceed the posted speed also increase, i.e., increasing from 91 percent to 100 percent.

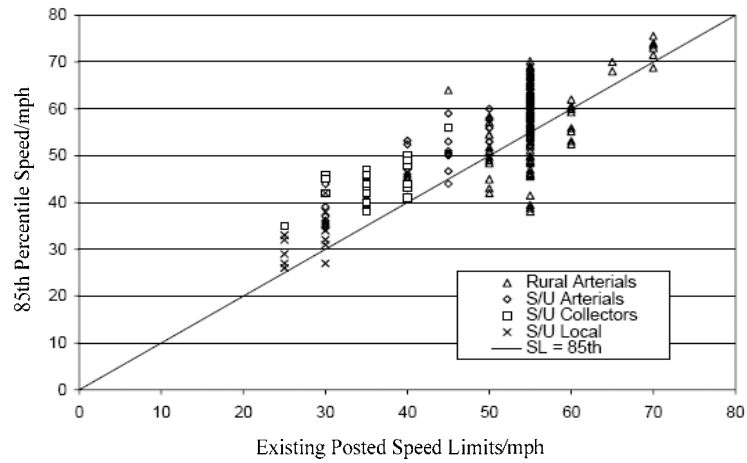

Figure 1. 85th percentile speed versus posted speed from NCHRP, Texas, and FHWA data.

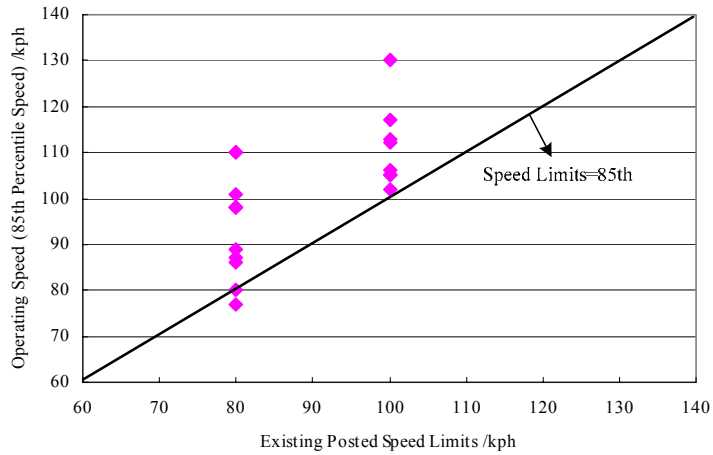

Figure 2. 85th percentile speed versus posted speed in Beijing Express Ring-road.

The linear regressing analysis results between 85th percentile speed and existing posted speed limits obtained by statistical R programming are shown in Table 4. From Table 4, we can draw the linear relationship between 85th percentile speed and posted speed limits as following: $y = 0.8625x + 25$, Where x is existing posted speed limits and y is 85th percentile speed.

The R square of equation (1) is 0.4321. In Table 3, x variable's P-value is little than 0.01, which means that there is strong linear relationship between 85th percentile speed and posted speed limits. This result is identical to the conclusion drawn from the NCHRP Report 504.

Table 4. Linear regression results between 85th percentile speed and existing posted speed limits.

	Coefficients	Standard error	t-Statistic	P-value	Lower 95%	Upper 95%
Intercept	25	21.33768	1.171636	0.257503	-20.0186	70.01858
x Variable	0.8625	0.239828	3.596325	0.002227	0.356507	1.368493

DISCUSSION

It can be seen from Figure 2 that among 19 investigating sites, only one site's operating speed is below its posted speed value. According to the speed limits setting guidelines of speed zone, does this mean that existing speed limits are not reasonable and should be raised? However, it was doubtful that all speed limits on the urban highways where the numerical value of speed limits are lower than the operating

speed must be raised (Park 2003). Numerous studies of travel speeds on rural interstate highways have shown that 85th percentile speeds increased when speed limits were raised and then continued increasing. The 85th percentile is not a stationary point. It is rather a moving target that increases when speed limits are raised. If speed limits are raised to meet a current 85th percentile speed, a higher new 85th percentile speed will soon result. As noted before, raising speed limits also requires considering other factors such as traffic safety and enforcement level, which should be investigated independently in detail.

CONCLUSIONS AND RECOMMENDATIONS

It would be possible to develop mathematical models for other classes of roadways, such as limited-access freeways and rural two-lane highways based on the approach proposed in this research to investigate the relationship between their operating speed and posted speed limits. In order to find the relationship of these two speed variable's relationship more appropriately, periodic investigations on the effects of newly set speed limits on operating speed and safety are necessary. Moreover, the investigating sites should be added to collect data including most types of roadway and various level of posted speed limits information in later research, thus providing a good basis for other related research.

ACKNOWLEDGEMENTS

This research was conducted at the Beijing University of Technology and was funded by the Western Region Transportation Science and Technology Projects under Grant: 200731800027.

ABSTRACT

Compared with parametric analysis method, nonparametric method is more robust and widely used. In order to make different safety policy of various kinds of time and reduce traffic crashes, this paper wisely and reasonably uses nonparametric tests models, such as Mann-Whitney, and Shapiro-Wilk, to analyze traffic crash date. After testing of normality, this paper discusses timely distributions of traffic crashes --hourly, monthly and yearly distributions of traffic crash data by nonparametric tests. So some right models for suitable timely distribution are given. Finally, analysis of related crashes data in America and China is carried out.

Keywords: nonparametric analysis, timely distribution, traffic crash

INTRODUCTION

Many countries invested so much money, human resources, and advanced equipments to study traffic crashes, especially driving fatality (Richard A. Retting et al., 2003; Dominique et al., 2008; Wen et al., 2005). It is necessary to take great effort to reduce the number of crashes and improve the environment of traffic safety (Marc Graudry and Sylvain Lassarre, 2000). So far, there are some shortcomings of parametric statistical approaches and models. For example, when using parametric test, some presuppositions, such as independently observation, normality of population, consistent standard of population and so on, should be met. If the data is not appropriate for parametric approaches, it is reasonably to consider using nonparametric method and models rather than parametric ones (S, Siegel, 1986; Brian et al., 2002). The reason why some nonparametric statistics is suitable for some situation is that they are not stringed by presupposition of parametric (i.e., they

are more freely). In addition, nonparametric analysis is unique for interval data of crashes (W.J Conover, 2006). In order to make some safety policies and regulations for different timely distributions of crashes, it is clearly that the law and characteristics of hourly, daily, monthly and yearly crashes distribution ought to be studied.

APPROPRIATE NONPARAMETRIC METHODS FOR TIMELY DISTRIBUTION OF CRASHES

It is reasonable to consider using nonparametric statistic model to analyze timely distribution of crashes (Pei Yulong and Wang Wei, 2007). Timely distribution of traffic crashes is the statistic characteristic during different time. It is commonsense that variation of characteristic of traffic fluid is big within different hour, day, month, or year. The location, climate, traffic infrastructure and culture would affect the crashes. Sometimes, in order to make sure that the average number of monthly crashes has changed, it is usually to use the t test, which is a kind of parametric method, to test the difference (Shen Feimin and Zhang Ronggui, 2006). If the data is appropriate for parametric approach, it is wisely to considering using parametric ways. However, in the real observed data, there is seldom situation fit the requirement of parametric ways. So it is reasonably considering usage of nonparametric method. In addition, some situations that would be discussed below are fit to apply three nonparametric tests of crashes. Mann-Whitney test is the first one. It is effective to test the difference of average and median of crashes, particularly deviation of them is so small that even expert in this field have no confidence to get conclusion from his experience. And it is used fitly for test for effectiveness of some safety improvement, which has been made before. Secondly, Cox-Stuart test can be used to detect the trend of two groups. So it is quite reasonable to apply to test the trend of the crashes in two years or months. Finally, One sample χ^2 test can be used for test the random distribution of crashes in different phrases. The basic idea is that when the null hypnosis is right, observation and expectation are very closing to each other,

$$\chi^2 = \sum_{i=1}^{k} \frac{(o_i - e_i)^2}{e_i} \tag{1}$$

Where o_i stands for the number of item i observation;

e_i stands for the expectation of item i when null hypnosis H_0 is right;

$\sum_{i=1}^{k}$ stands for the sum of all item.

NONPARAMETRIC ANALYSIS OF TIMELY DISTRIBUTIONS

A. Normality fitness and standard deviation test

It is necessary to take some normality fitness and standard deviation test

before analysis of data of crashes. The reason is that the parametric test is more powerful and more information from data then nonparametric test. That is mean parametric method is the first choice. This paper collects alcohol-related crash fatalities of 52 states from 2006 to 2007 in the U.S.A (A Brief Statistical Summary, 2008).It is easier to decide whether the sample fit to the normality from a Quantile-Quantile (QQ) Plot. QQ Plot is a kind of scatting one, in which quantile of standard normal is the horizontal axle and value of the sample is the vertical axle (Huang yan and Wu ping, 2005). If the data distribute around a line in QQ plot (see Figure1), then sample is fit to the normal distribution. In addition, P-values of Shapiro-Wilk and Kolmogorove-Smirnov are smaller than 0.01(significance level). In sum, this alcohol-related crash fatality cannot satisfy the requirement of parametric method. It is wisely to considering using nonparametric ways.

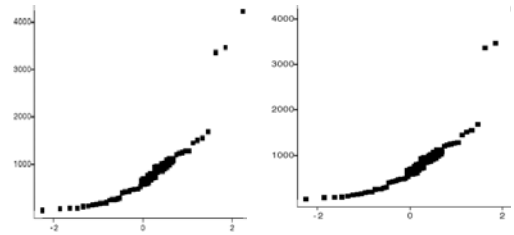

Figure 1 QQ plots of alcohol-related crash fatalities of 52 states in the USA from 2006 to 2007

***B.* Nonparametric Analysis of hourly Distribution of Traffic Crash**

Table 1 is the hourly distribution of crashes in Heilongjiang China since 2006 to 2007. Based on roughly estimation, it seems that the hourly crash distributions of highways are different. In order to demonstrate the hypnosis, Mann-Whitney test was used and processes are as followed.

Table 1 Hourly distribution of crashes in Heilongjiang China (2006-2007)

Phrase / Year	0~2	2~4	4~6	6~8	8~10	10~12	12~14	14~16	16~18	18~20	20~22	22~24
2006	132	122	230	522	625	610	748	859	888	894	730	374
2007	156	130	236	519	689	642	656	837	900	825	783	343

1) Null hypnosis--H_0: the hourly crash distributions in Heilongjiang from 2006 to 2007 are almost same. Alternative hypnosis H_1: the hourly crash distributions of crashes in Heilongjiang are different;

2) Method: It is used by the Mann-Whitney bilateral test, because date is from different independent samples (2006 and 2007), small samples (only 12 phrases), and ordered scale of measurement;

3) Significance level: $\alpha < 0.05$;

4) Statistical value: $T = \sum_{i=1}^{12} R(x_i)$.

Where $R(x_i)$ is the rank of the random variables and T is the sum of rank of the random variables;

5) Rejection region: because of two-tailed test, when H_0 is satisfied, one-tailed p-value<0.025;

6) Inference: the paper using Statistical Assistant System (SAS) to process the data, the result showed that P-value>0.05. This p-value suggested that from material that is collected there is no reason to reject the null hypnosis and accept H_0: the hourly crash distributions in Heilongjiang from 2006 to 2007 are almost the same.

***C*. Nonparametric Analysis of monthly Distribution of Traffic Crash**

Table 2 is the statistical monthly distribution of crashes in Heilongjiang in China from 2006 to 2007. From estimation, it seems that the monthly crash distributions are trend to rise. In order to infer the trend, Cox-Stuart test was used and processes are the same as followed. Firstly, pair the random variables as (x_1, x_{1+c}), (x_2, x_{2+c}), (x_3, x_{3+c}),…, $(x_{n'}, x_{n'+c})$, Where $c = (n'+1)/2$, n' is the number of reordered variables; If $x_i < x_{i+c}$, then use "+" stand for the paired random variable; If $x_i > x_{i+c}$, then use "-" stand for the paired random variable. It is reasonablely to use the Cox-Stuart test, because date is from different independent samples (from 2006 to 2007), small samples (only 12 months), and ordered scale of measurement. At last, the result showed that T=8, P-value>0.05 (n=12, p=1/2, T=8). This result suggested that there is no reason to reject the null hypnosis from material collected and it had to accept H_0: the monthly crash distributions will trend to rise in 2008.

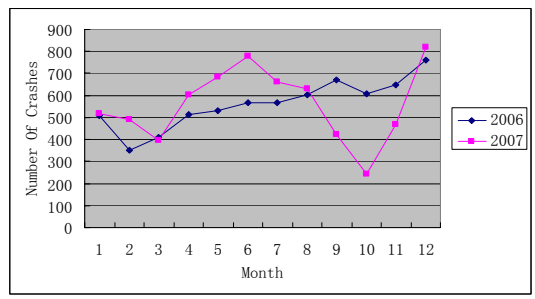

Figure 2 Curve of number of crash in Heilongjiang, China (2006-2007)

Table 2 Monthly distributions of crashes in Heilongjiang, China (2006-2007)

Month / Year	1	2	3	4	5	6	7	8	9	10	11	12
2006	508	351	408	514	532	567	566	603	669	609	647	760
2007	519	489	397	601	683	777	660	629	425	245	470	821

***C*. Nonparametric Analysis of yearly Distribution of Traffic Crash**

Figure 3 is a histogram of alcohol-related crash fatalities from 2003 to 2007 of 52 states in the U.S.A. From the Figure 2, it is suitable to use nonparametric methods. The yearly alcohol-related crash fatalities from 2003 to 2004 of 52 states in the U.S.A are different. In order to demonstrate the hypnosis, Mann-Whitney test were used and processes are as followed.

1) Null hypnosis--H_0: the yearly alcohol-related crash fatalities from 2003 to 2004 of 52 states in the U.S.A remain almost same or had the decreasing trend. Alternative hypnosis –H_1: the yearly alcohol-related crash fatalities from 2003 to 2004 of 52 states in the U.S.A had a rising trend;

2) Method: it is used by the Mann-Whitney bilateral test, because date is from different independent samples (52 states in the U.S.A), small samples (only 52 states compared with themselves), and ordered scale of measurement.

3) Significance level: $\alpha < 0.05$;

4) Statistical value: $T = \sum_{i=1}^{52} R(x_i)$, where $R(x_i)$ is the rank of the random variables, T is the sum of rank of the random variables.

5) Rejection region: because of one-tailed test, when H_0 is satisfied, one-tailed p-value<0.05.

6) Inference: the result shows that T=-11.76 (P-value <0.05), this result indicates that the yearly alcohol-related crash fatalities from 2003 to 2004 of 52 states in the U.S.A has a rising trend.

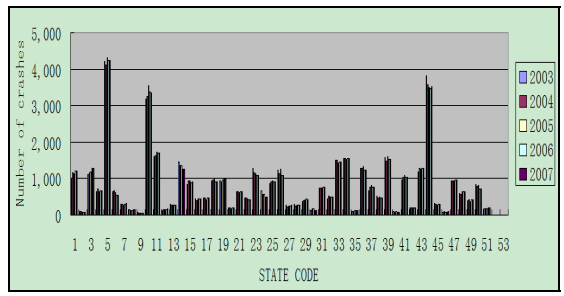

Figure 3 Histogram of alcohol-related crash fatalities of 52 states in the U.S.A

In fact, Department of Transportation Administration in America had realized the trend and made great effort to reduce the number of crashes in whole country in 2005. The result of statistic crashes is declining compared with past two years (2003 and 2004). In addition, universities and training agents provided some programs to make the youths and drivers realize the great hazard of driving after drinking alcohol. Finally, in order to predict the trend of crashes in 2008, the paper used result of crashes statistical 2006 and 2007. Mann-Whitney test were used and processes are the result showed that T=-0.1031, (P-value>0.05). That meant that management of crashes in the U.S.A is successful and the trend of crashes would be declining.

CONCLUSIONS

This paper reviews parametric test and nonparametric method and models. In some situation, nonparametric statistical is suitable because they are more freely. Three nonparametric models, such as Mann-Whitney test, Cox-Stuart test and so on, are used in timely distribution of crashes. Secondly, the paper uses Mann-Whitney

test for the yearly alcohol-related crash fatalities from 2003 to 2004 of 52 states in the U.S.A, a result shows that this result indicated that the yearly alcohol-related crash fatalities from 2003 to 2004 of 52 states in the U.S.A had a rising trend. In fact, Department of Transportation in America had realized the trend and made great effort to reduce the number of crashes in whole country since 2005. The result of statistic crashes was declining compared with past two years (2003 and 2004). In addition, universities and training agents provided some programs to make the youths and drivers realize the great hazard of driving after drinking alcohol. Finally, the paper predicts the trend of crashes in 2008 through analysis of the yearly alcohol-related crash fatalities from 2006 to 2007 of 52 states in the U.S.A. Result meant that management crashes in the U.S.A in 2008 would be declining. Although nonparametric analysis is very useful, there are still some drawbacks and restrains for its prevailingly use in crashed analysis. In addition, it is significantly robust, but it would lose some power of test.

ABSTRACT

The purpose of this study is to prevent and reduce fire at highway tunnels. This paper systematically analyzes the influence factors for the safety system of highway tunnels, establishes a risk assessment model for tunnel fire based on analytic hierarchy process and multi-grade fuzzy evaluation, and introduces a risk factors assessment system for tunnel fire in details. Using this model, the risk of a specific highway tunnel fire has been assessed. The research results show that this evaluation method is in accordance with the actual situation. Therefore the model is recommended to put into practical applications.

1 PREFACE

With the rapid development of Chinese economy and improvement of people's daily lives, all sorts of highway tunnels have been built and China has become a country which owns the world's top highway tunnels both in scales and in distance. Consequently the numbers and frequencies of tunnel fire accidents appear to rise yearly, resulting in huge losses of life and property. In order to prevent and reduce the occurrence of fire, risk analysis and evaluation are essential to identify the potential hazards and take corresponding measures to improve the safety levels of these traffic tunnels. Due to the diversities of the hazards which may lead to a fire and the ambiguous interactions among them, Analytical Hierarchy Process(AHP) and Fuzzy Comprehensive Evaluation Method are introduced for comprehensive risk evaluation on the highway tunnel fire, to facilitate a quantitative description of the impacts of these factors on tunnel safety.

2 SETUP OF RISK ASSESSMENT SYSTEM OF TUNNEL FIRE

2.1Establishment of assessment index system

Tunnel fires are usually caused by a number of factors that interact each other. The four main influence factors are: (1) Vehicle. To a large extent a tunnel fire is caused by this factor, therefore checking dangerous vehicles and limiting them into the tunnels is essential to prevent fires. (2) Fire safety management system. The safety responsibility system, the fire evacuation plan and the periodic inspection are the best ways to reduce fire hazards. (3) Fire protection facilities. Completed fire

detection and alarm system, appropriate fireproof structures and emergency ventilation system are very helpful to prevent fire escalating in its early stage. (4) Tunnel structure. Tunnel wall and internal combustion properties have important influence on flame control. Each primary factor above consists of several secondary indices for assessment as shown in table 1.

Table 1. Risk assessment index system for highway tunnel fire.

	Primary Indices	Secondary Indices
Highway tunnel fire risk assessment index system U	Vehicle （U_1）	Fire caused by vehicle crash（U_{11}）
		Flammable loads on fire（U_{12}）
		Vehicle electrical equipment on fire（U_{13}）
		Vehicle braking equipment on fire（U_{14}）
	Fire safety management system （U_2）	Fire safety responsibility system（U_{21}）
		Fire safety awareness （U_{22}）
		Fire safety training（U_{23}）
		Fire evacuation plan（U_{24}）
	Fire protection facilities （U_3）	Automatic fire detection and alarm system （U_{31}）
		Sprinkler systems（U_{32}）
		Hydrant system（U_{33}）
		Smoke control systems（U_{34}）
		Lighting Systems（U_{35}）
	Tunnel structure （U4）	Tunnel construction（U_{41}）
		Tunnel fire safety evacuation facilities （U_{42}）
		Tunnel wall decoration（U_{43}）
		Tunnel Design（U_{44}）

2.2 Weight determination of each assessment index

AHP is applied for weight determination, which compares the indices in pairs on a scale of 1 to 9 to set judgment matrix and calculate its maximum eigenvalue and eigenvector, and then obtain relative weights of the indices in a certain level related to their corresponding indices in upper level, to form a set of weighted aggregative index numbers. The detailed calculation procedure is shown below:

2.2.1 Setting judgment matrix A.Calculation of geometric mean of each row in the judgement matrix

$$\overline{\omega}_i = \sqrt[n]{\prod_{j=1}^{n} a_{ij}} \qquad i=1,2,3,\ldots,n \qquad (1)$$

2.2.2 Normalized $\overline{\omega}_i$

$$\omega_i = \frac{\overline{\omega_i}}{\sum_{j=1}^{n} \omega_j} \qquad i,j=1,2,3,\ldots,n \qquad (2)$$

$\omega=[\omega_1, \omega_2, \ldots, \omega_n]^T$ which is the eigenvector.

2.2.3 Calculation of the maximum eigenvalue

$$\lambda_{max} = \sum_{i=1}^{n} \frac{(A\omega)_i}{n\omega_i} \qquad (3)$$

2.2.4 Consistency check

Consistency test is based on：

$$CR = \frac{CI}{RI} \qquad (4)$$

which，$CI = \frac{\lambda_{max} - n}{n-1}$，RI is the average random consistency index. When CR<0.1, the matrix has satisfactory consistency. The results shown in table 2~6

Table 2. Matrix A and weight of index

3 FUZZY COMPREHENSIVE EVALUATIONS

3. 1Establishment of the comment set of evaluation indicator

As per the scientific standard of the Ministry of Public Security （2001BA803B02－09），fire hazards are categorized into five levels for severity evaluation. In this paper the hazardous indices leading to tunnel fire are also categorized into five levels to form a comment set *V*. And *V* = { light risk V_1, low risk V_2 , ordinary risk V_3 , high risk V_4 , severe risk V_5 }。For a centesimal grading system, V_1 = 95, V_2 = 85, V_3 = 70, V_4= 50, V_5 = 30.

3. 2Single factor fuzzy evaluation

Single factor fuzzy evaluation evaluates all kinds of factors within evaluation indicators. The function of membership grade is established based on the requirement of evaluation indicators and evaluation standard, then the membership grade of evaluation schemes are given for evaluation indices. Finally, the membership grade matrix is obtained by combination of each single factor. The single factor fuzzy evaluation of tunnel fire risk is determined by expert panel, in another word, membership grade matrix R_i of all factors in U_i.

$$R_i = \begin{bmatrix} r_{i11} & r_{i12} & r_{i13} & r_{i14} & r_{i15} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ r_{ij1} & r_{ij2} & r_{ij3} & r_{ij4} & r_{ij5} \end{bmatrix} \qquad (5)$$

3. 3Multi-grade fuzzy comprehensive evaluation

Many factors that may induce tunnel fire are ambiguous, and these factors can be divided into many layers. A single-grade comprehensive evaluation often results in relatively small numerical values in the fuzzy evaluation matrix due to too many factors being involved. In this situation, it is hard to sort various factors in a preferential order and unlikely to obtain a meaningful evaluation result. However, multi-grade fuzzy comprehensive evaluation with stepwise approaches is able to highlight the main factors without eliminating other factor, therefore its evaluation results can reflect the overall features of the objects being assessed.

$$B = A \cdot R \qquad (6)$$

A---Weight sets of evaluation indicator; "·"--- Fuzzy operator;

R---Matrix of membership degree.

3.4 Example

3.4.1 Establishment of evaluation matrix

Taking a highway tunnel for an example, an evaluation matrix R_i of membership degrees is setup based on every evaluation indicator graded by 10 experts according to the level of evaluation indicator. The grades of the primary index 'fire safety management (U2)' are shown in Table 7.

Table 7

Evaluation indicator	Weight	Level of evaluation indicator				
		V_1	V_2	V_3	V_4	V_5
U_{21}	0.473	4	3	2	1	0
U_{22}	0.258	3	2	3	1	1
U_{23}	0.202	2	3	2	2	1
U_{24}	0.067	2	3	3	2	0

And the evaluation matrix of fire safety management is

$$R_2=\begin{bmatrix}0.4 & 0.3 & 0.2 & 0.1 & 0.0\\ 0.3 & 0.2 & 0.3 & 0.1 & 0.1\\ 0.2 & 0.3 & 0.2 & 0.2 & 0.1\\ 0.2 & 0.3 & 0.3 & 0.2 & 0.0\end{bmatrix}$$

Similarly：$$R_1=\begin{bmatrix}0.3 & 0.3 & 0.2 & 0.2 & 0.0\\ 0.2 & 0.3 & 0.1 & 0.3 & 0.1\\ 0.3 & 0.2 & 0.2 & 0.2 & 0.2\\ 0.2 & 0.2 & 0.3 & 0.2 & 0.1\end{bmatrix}$$

$$R_3=\begin{bmatrix}0.3 & 0.3 & 0.2 & 0.1 & 0.1\\ 0.4 & 0.2 & 0.2 & 0.2 & 0.0\\ 0.3 & 0.3 & 0.3 & 0.1 & 0.0\\ 0.2 & 0.3 & 0.2 & 0.2 & 0.1\\ 0.2 & 0.2 & 0.3 & 0.1 & 0.1\end{bmatrix}$$

$$R_4=\begin{bmatrix}0.3 & 0.3 & 0.2 & 0.2 & 0.0\\ 0.3 & 0.2 & 0.3 & 0.1 & 0.1\\ 0.2 & 0.3 & 0.2 & 0.2 & 0.1\\ 0.2 & 0.2 & 0.3 & 0.2 & 0.1\end{bmatrix}$$

3.4.2 **Multi-grade fuzzy comprehensive evaluation**

For many risk evaluation objects of highway tunnel fire, ordinary addition and multiplication model is chosen for calculation to obtain reasonable evaluation results. One-grade fuzzy evaluation is shown as following.

$B_2=A_2 \cdot R_2=$（0.292，0.289，0.226，0.149，0.045）

Similarly：

$B_1=A_1 \cdot R_1=$（0.247，0.273，0.181，0.226，0.073）

$B_3=A_3 \cdot R_3=$（0.275，0.275，0.225，0.145，0.080）

$B_4=A_4 \cdot R_4=$（0.233，0.244，0.255，0.189，0.079）

By considering the evaluation matrix B_i of each primary indicator U_i as its one-grade evaluation result, the risk evaluation matrix B of tunnel fire is obtained through two-grade fuzzy comprehensive evaluation of $R=(B_1, B_2, B_3, B_4, B_5)^T$, as shown below:

$$R=\begin{bmatrix}R_1\\ R_2\\ R_3\\ R_4\end{bmatrix}=\begin{bmatrix}0.247 & 0.273 & 0.181 & 0.226 & 0.073\\ 0.292 & 0.289 & 0.226 & 0.149 & 0.045\\ 0.275 & 0.275 & 0.225 & 0.145 & 0.080\\ 0.233 & 0.244 & 0.255 & 0.189 & 0.079\end{bmatrix}$$

Two-grade fuzzy comprehensive evaluation is listed as following:

$$B=A\cdot R=(0.429, 0.214, 0.214, 0.143)\begin{bmatrix}0.247 & 0.273 & 0.181 & 0.226 & 0.073\\ 0.292 & 0.289 & 0.226 & 0.149 & 0.045\\ 0.275 & 0.275 & 0.225 & 0.145 & 0.080\\ 0.233 & 0.244 & 0.255 & 0.189 & 0.079\end{bmatrix}$$

=（0.261，0.273，0.211，0.187，0.069）

3.4.3 Evaluation of fire hazard level

The risk evaluation score for highway tunnel fire is calculated based on the linear weighted average model, and the fire hazard level is determined thereafter as a recommendation reference for appropriate safety measures .

$$F = \sum_{i=1}^{5} b_i \times e_i = 95\times0.261+85\times0.273+70\times0.211+50\times0.187+30\times0.069=74.19$$

The fire hazard of the highway tunnel falls in the category of 'ordinary risk'. In this situation, fire can be triggered by any problem in certain links, and the corresponding safety measures shall be taken to eliminate fire hazards.

4 CONCLUSIONS

Fire hazards can be revealed and fire can be consequently reduced via nonscheduled fire safety evaluation of highway tunnels. By using analytic hierarchy process and fuzzy comprehensive evaluation, fire hazards of highway tunnel can be comprehensively assessed from all aspects of their influence factors, which is helpful for the relevant department to take certain safety measures to reduce the risk of fire.

The Analysis of Rural Road Safety and Its Strategies

Sun Feng

College of Transport and Vehicle Engineering; Shandong University of Technology; Zibo 255049; China; Email: sunfeng0904@sina.com

ABSTRACT

This paper presents the main features of traffic accidents on rural roads by detailed statistical analysis of traffic accidents, modes of vehicles, time, driver behaviors and other related factors about traffic accidents occurred on Huantai County rural roads from 2005 to 2007. The root causes of accidents were obtained by applying traffic engineering principles to the current situation of rural road construction and transport development. This paper proposed strategies to reduce deaths and injuries resulting from traffic accidents on rural roads from the aspects of traffic management system, safety education, safe facilities, vehicle management, etc., which will be applied to the field of traffic safety management on rural roads.

INTRODUCTION

With the rapid development of China's rural economy, the demand for transport of both passengers and cargoes has been on the increase. It is also true for the rural road mileage and its traffic flow. However, traffic accidents on rural roads have been increased year by year. So how to take effective measures to improve China's rural road safety has become an urgent issue in the field of traffic safety. At present, researchers mainly concentrate on studying the safety of freeways, highways and urban roads. But few studies on the safety of rural roads have been made. Since rural roads greatly differ from them in road conditions, transport components, characteristics of transport participants' travel, it is significant to propose effective strategies to reduce deaths and injuries resulting from traffic accidents through analyzing the characteristics of rural road accidents and deeply studying the problems about traffic safety existing on rural roads. This paper has put forward several countermeasures based on the deep study of the problems about rural road traffic safety by taking Huantai County rural roads in Zibo as an example.

CURRENT SITUATION OF TRAFFIC DEVELOPMENT

Rural roads mileage. With the rapid development of industry and agriculture in Huantai County, the demand in transportation is growing, the construction of county and township roads is being accelerated, and the traffic mileage is also growing rapidly. Based on statistics of 2008, the total mileages of county roads and township roads in Huantai County are 139.388km and 190.756km respectively. According to the 11th Five-Year Plan of the Rural Roads in Huantai County (2005), Huantai County will rebuild five county roads covering 36.6km, seven township roads which are 58.4 km long and three tourism roads with the length of 25.5km, and build 14-kilometre-long new township road by 2010.

Motor vehicles and drivers. In recent years, the number of motor vehicles and drivers is increasing steadily. The details are clearly set out in Table1. Table1 shows that the growth rate of motorcycles has slowed down, however, the possession of

motorcycles still account for the largest quantity. There are 62658 motorcycles, which constitute 73.6% of all motor vehicles possession. Meanwhile, the number of people who own private cars is on the rise with the fantastic development in economy in rural areas in China. In 2007, the increased number of cars accounted for 40.7% of all the new vehicles. With the rapid increase of private cars, the growth of drivers appears to be accordingly accelerating.

Table 1. Quantity of New Motor Vehicles and Drivers .

Year	Trailer	Oversize vehicle	Car	Motorcycles	Quantity of drivers	Growth rate
2003	58	196	1912	6472	52192	——
2004	71	308	1877	6107	53075	1.69%
2005	55	135	2149	5619	54117	1.96%
2006	122	191	2638	4239	55009	1.65%
2007	188	310	3082	3940	58127	5.67%

Passenger and cargo transportation . From Table2, it can be seen that in recent years, transportation volume of both passenger and cargo in Huantai County is increasing rapidly, especially in 2007, its transportation volume of passenger increased by 143% compared with 2006. The transportation volume of cargo in 2007 was up 342% over the previous year (HCSY, 2002~2007).

Table 2. Transportation Volume of Passenger and Cargo in Huantai County .

Year	Transportation volume of passenger (million passenger)	Passenger miles (million passenger-kilometer)	Transportation volume of cargo (million ton)	Rotation volume of freight transport (million ton-kilometer)
2002	476.0	17703	309.0	26083
2003	438.0	17151	343.0	30815
2004	433.0	16750	387.0	35643
2005	378.0	17010	358.0	36398
2006	842.0	35057	426.0	46600
2007	1534	85279	2487	206159

Analysis of current situation . Through the above statistics, it can be seen that Huantai county road mileage, number of motor vehicles and drivers, and transportation volume of both passenger and cargo are in a period of rapid growth. But, it is worthwhile to note that in the light of the experience of foreign countries, it is also a period of sharp increase in traffic accidents (Mao Li-zeng and Duan Li-ren, 2007).

STATISTICS AND ANALYSIS OF TRAFFIC ACCIDENTS

Overview on rural road traffic accidents . This paper analyses the 609 traffic accidents occurring on the rural roads in Huantai County, Zibo City between 2005 and 2007. Figure1 presents that there is an increasing tendency for the traffic

accidents which happened on rural roads in Huantai County between 2005 and 2007.

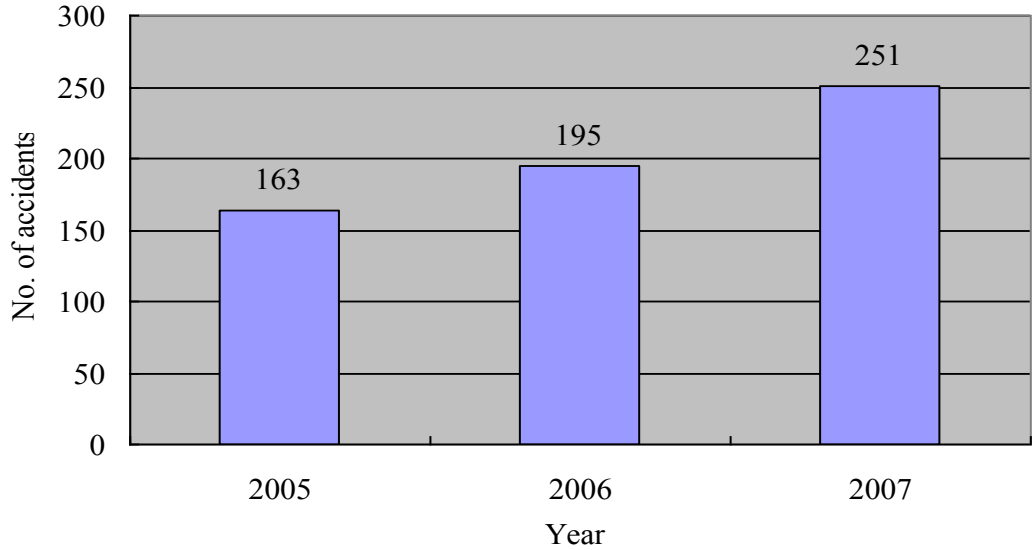

Figure1 . The Traffic Accidents Happened on the Rural Roads in Huantai County (2005~2007).

Time distribution of traffic accidents and number of deaths. From Figure2, we can see that a high number of traffic accidents on rural roads mainly happen between 15:00 and 22:00, and the most of the accidents involved death happen at night, where 18:00~21:00 is the critical point and the deaths during this period account for 31.1% of all deaths. This means that it is prone for the accidents to happen at night, which not only brings about high accident risk but also involves serious injury or loss of life. Sleepiness is now recognized as being a significant accident causation factor at night. Research has shown sleep-related crashes tend to occur at night and to be more severe due to higher impact speeds. They tend to involve drivers who are at work or driving company cars (Maycock, 1996, 1997) and younger male drivers (under-30) are particularly at risk (Reyner et al, 2001).

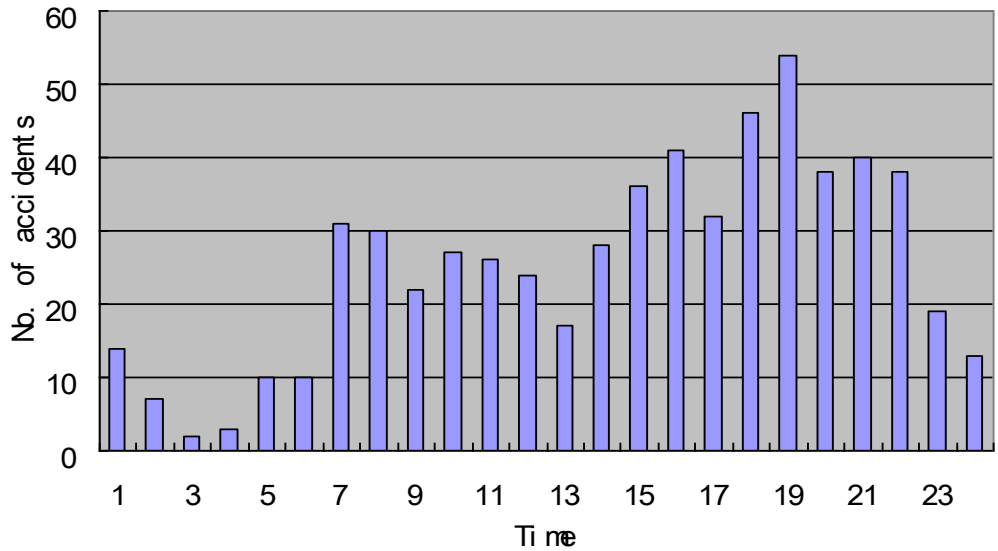

Figure 2. Time Distribution of Traffic Accidents on Rural Roads

Distribution of types of vehicles involved in traffic accidents. Table 3 shows

the proportion of vehicles involved in road accidents. It can be seen that the proportion of two-wheeled motor vehicles involved in accidents is considerably the largest, which accounts for 31.48% of rural accidents. It is mainly the inadequacy of buses that results in the high level of motorcycle ownership in the rural townships, accounting for 73.6% of all motor vehicle ownership. Through the analysis of motorcycles that contributed to accidents, we concluded that the motorcyclists who drive without a license account for 43.07% of accidents, the illicit motorcycles account for 15.66% and driving under the influence of alcohol account for 15.66%, which is attributable to the motorcyclists' poor safety awareness and the backward management system for motorcycles. The second most common vehicle involved in traffic accidents is the car, which is reported in 21.64% of rural accidents.

Table 3. List of Vehicle Types Involved Traffic Accidents on Rural Roads.

Vehicle type	No. of traffic accidents	Percentage
Two-wheeled motor vehicle	288	31.48%
Car	198	21.64%
Truck	130	14.21%
Pick-up	65	7.10%
Three-wheeled motor vehicle	61	6.67%
Medium-size truck	57	6.23%
Farm vehicle	53	5.79%
Tractor	31	3.39%
Medium-size car	23	2.51%
Large bus	9	0.98%

Distribution of types of drivers' violation involved in traffic accidents. Through qualitative surveying over traffic accidents happened on rural roads in Huantai County between 2005 and 2007, we concluded that the proportion of driving without a license, the illicit motorcycles, failing to look properly and driving under the influence of alcohol is the higher, taking 23.84%、14.08%、13.64% and 9.76% respectively in terms of the relative importance of all the drivers' violation contributed to rural accidents.

ANALYSIS OF PROBLEMS ABOUT TRAFFIC SAFETY

Based on the above qualitative survey, along with current situation of Huantai County transportation, the paper points out various road safety problems existing on rural areas of Huantai County, which is also prevalent in rural areas in China.

Rural communities' low awareness of traffic safety. Rural communities' traffic safety awareness is relatively low, for instance, it's not uncommon for peasants not to watch out for cars when crossing the road and not to dodge the other vehicles when going around the curves in the road. It is quite common for the motorcyclists to violate traffic regulations, mainly include driving without a license, not wearing protective helmets, speeding, driving under the influence of alcohol, and so on.

Relatively backward public transportati on. In rural areas, the development of public transportation is relatively backward, which makes the rural communities

inconvenient to travel out, so more and more families purchase agricultural vehicles, electric bicycles, motorcycles to meet the demand of production and livelihood. However, the poor management of vehicles in rural areas indicates that there exist potential safety hazards.

Imperfect traffic safety infrastructure . While rural roads are gradually increasing, the traffic safety infrastructure is not perfect, such as traffic signs are not sufficient, road traffic markings are not conspicuous and improvement and maintenance of roads is not in time which causes damage to rural roads. In addition, the inadequate street lights especially in the areas through rural village, result in the high incidence of accidents late in the afternoon.

Weak supervision on rural roads. The rural road has the characteristics of multipoints and large size, but at present its supervision is very weak. So far it is administered only by traffic department. As rural traffic becomes complicated, traffic police's supervision on the rural roads will be constrained by the shortage of police.

Backward in management system of motor vehicle and driver. As the number of private cars increases , the number of novice drivers is rising quickly. However, the novice drivers are a vulnerable road user group and prone to traffic accidents because of their inexperienced driving skills and lack of driving experience. By surveying the traffic accidents between 2005 and 2007 in Huantai County, it is found that the accidents caused by the drivers with driving experience under 3 years are about 35.1% of all the traffic accidents.

COUNTERMEASURES TO IMPROVE RURAL ROAD SAFETY

Based on the above problems concerning the rural road safety, this article puts forward the most effective countermeasures to improve the rural road safety.

Clarify responsibility and strengthen rural road safety. According to the Highway Law and Law on Road Traffic Safety, the township (town) people's government is in charge of the construction and maintenance of rural highway, and the road traffic safety management department takes in charge of rural highway traffic safety. They have to perform administrative duties, attach great importance to road traffic safety management and add the rural road traffic safety management to the agenda under the unitary leadership of the county government.

Publicize traffic safety of rural road and create a good atmosphere . All the township (town) people's governments with relative departments should initiate education campaign about Law of The People's Republic of China on Road Traffic Safety, and widely publicize the related knowledge about traffic safety. The theme of traffic safety publicity is "safety comes first while traveling" and its purpose is to popularize knowledge about traffic safety and educate people by taking serious accidents as an example to improve rural communities' road safety and law-abiding awareness.

Accelerate the development of bus. Accelerating bus developments of urban and rural integration can make bus extend to rural areas, provide facilities for rural communities to travel out and reduce their cost of travel out, which can restrict the increase of motorcycles at essence and gradually reduce the proportion of traveling out by motorcycles.

Develop and perfect transport facilities. Accelerate the development of traffic safety facilities on rural highways to guarantee orderliness and safety the traffic.

While a highway is under new construction, renovation or expansion, traffic safety facilities should be designed, constructed and tested at the same time. Further more, it is necessary to improve lamp lighting facilities on the rural roads, especially in the areas through rural village and town.

Increase the number of traffic police and guarantee expenditure. Ensure the normal operation of traffic management through enriching traffic police, and all the township people's governments should guarantee expenditure of traffic police, improve infrastructures including vehicles and telecommunications and provide high technology equipments to relieve traffic police's pressure from work and effectively solve the problem of insufficient traffic police.

Strengthen administration of agriculture vehicles and motorcycles. The traffic administrative department and agricultural machinery department shall join efforts and closely cooperate with each other while acting in accordance with the division of their functions and duties, to strengthen the administration of agriculture vehicles. It is essential to organize rural police stations to participate in specialized administration of motorcycles.

Step up evaluation and administration of drivers. It is helpful to introduce traffic safety information system about vehicle drivers to record drivers' traffic violations, their traffic scores for breaking rules and regulations, traffic accident conditions. The records about drivers' traffic safety can offer the reference for employers to recruit drivers and insurance company to handle the insurance business. In addition, it is also essential to strengthen the evaluation and administration of driver training school, standardize the teaching process, and ensure the novice drivers to possess the quality of safety driving.

CONCLUSION

In this paper, by detailed statistics of rural road traffic accidents occurred in Huantai County from 2005 to 2007, combing the current situation of rural road construction and transport, the root causes of the accidents are concluded. Based on the above analysis, this paper proposed strategies to reduce deaths and injuries resulting from traffic accidents on rural roads from the aspects of traffic management system, safety facilities, transport development, etc., which will be applied to the field of traffic safety management on rural road.

ABSTRACT

This paper analyzes the characteristics of three cars continuous collision accidents by dividing them into different processes. The relation model between vehicles during the impact process is established, and the physical models of each vehicle before and after the impact based on principles of kinematics are established. In this way, according to the stop location, stop states of the vehicles as well as the marks left on the road, the whole movement process of three-car continuous collision and any transient movement state of each car are computed and reconstructed by using reverse analytical calculation method.

1. INTRODUCTION

A great deal of research work of issues recurrence for simulated traffic accident at home and abroad has been done and brought some results so far. The more representative one was the car on car collision accident simulation recurrence research in 1995 by Xi'an Highway University and Japan Automobile Research Institute (WEI, 2000a). Later, they also did the further research for the two cars in a collision after collision occurring in the second issue, established the analytical calculation model, and validated the correctness of the model through examples (WEI, 2000b,WEI, 2000c).But the analysis, calculation, as well as recurrence technology for many vehicles involved in collisions in a row are still in a blank state. This type of traffic accidents takes a large proportion of total. As a result, this thesis does research on three consecutive car collision pattern and reproduction technology in the traffic accident.

In the continuous collision of three cars, the movement states of vehicles are different, and the analytical methods used in the process of analysis and solution also vary. Therefore, this article studies the accident patterns of the car A and B collision, and then car B and C collision, and car B didn't not lose the stability after the first collision.

2. THE MODEL ESTABLISHMENT

Collision process in accordance with the above-mentioned characteristics of its movement can be divided into five phases. The dynamic models involved in the five stages include: vehicle lateral dynamics model; vehicle vertical dynamic model; tire dynamic model and vehicle dynamic model of the collision process. These

models don't take roll-over accident into consideration. Next the models mentioned above will be separately established.

2.1 Vehicle longitudinal and lateral dynamics model

Simplified vehicle longitudinal and lateral dynamics model in the process of movement is shown in Figure 1. XOY in the map is the coordinate system fixed on the ground, $\xi o\gamma$ is the coordinate system fixed on the vehicle's centroid, and ξ is the driving direction. Thus obtained:

$$\delta_m m\dot{V}_{o\xi} = F_{HL\xi} + F_{HR\xi} + F_{FL\xi}\cos\delta + F_{FR\xi}\cos\delta - F_{FL\upsilon}\sin\delta - F_{FR\upsilon}\sin\delta - F_R - F_L \quad (1)$$

$$m\dot{V}_{o\gamma} = F_{HL\gamma} + F_{HR\gamma} + F_{FL\upsilon}\cos\delta + F_{FR\upsilon}\cos\delta + F_{FL\zeta}\sin\delta + F_{FR\zeta}\sin\delta \quad (2)$$

$$\begin{aligned} m\rho_0^{\,2}\dot{\omega} = {} & (F_{FR\upsilon} + F_{FL\upsilon})\cos\delta L_V - (F_{HR\gamma} + F_{HL\gamma})L_H + (F_{HR\gamma} - F_{HL\gamma})\frac{S_H}{2} \\ & + (F_{FR\zeta} + F_{FL\zeta})\cos\delta\frac{S_F}{2} + (F_{FR\upsilon} - F_{FL\upsilon})\sin\delta\frac{S_F}{2} + (F_{FR\zeta} + F_{FL\zeta})\sin\delta L_V \end{aligned} \quad (3)$$

The meaning of symbol above formulas is in Figure 1.

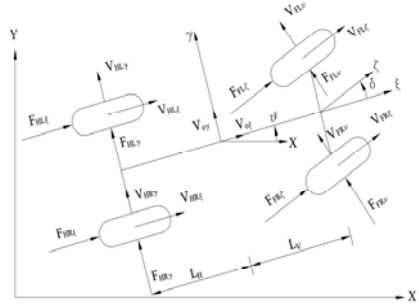

Figure 1.Vehicle dynamics model (longitudinal and lateral).

2.2 Vehicle vertical dynamics model

Simplified vehicle vertical dynamics model in the process of movement is shown in Figure 2. The resultant vertical vehicle dynamic model equation is:

$$\begin{aligned} m\ddot{z}_2 = {} & -C_{2FR}(z_{2FR} - z_{1FR}) - D_{2FR}(\dot{z}_{2FR} - \dot{z}_{1FR}) - C_{2FL}(z_{2FL} - z_{1FL}) - D_{2FL}(\dot{z}_{2FL} - \dot{z}_{1FL}) \\ & - C_{2HR}(z_{2HR} - z_{1HR}) - D_{2HR}(\dot{z}_{2HR} - \dot{z}_{1HR}) - C_{2HL}(z_{2HL} - z_{1HL}) - D_{2HL}(\dot{z}_{2HL} - \dot{z}_{1HL}) \end{aligned} \quad (4)$$

$$m_{1FR}\ddot{z}_{1FR} = C_{2FR}(z_{2FR} - z_{1FR}) + D_{2FR}(\dot{z}_{2FR} - \dot{z}_{1FR}) - C_{1FR}(z_{1FR} - z_{0FR}) \quad (5)$$

$$m_{1FL}\ddot{z}_{1FL} = C_{2FL}(z_{2FL} - z_{1FL}) + D_{2FL}(\dot{z}_{2FL} - \dot{z}_{1FL}) - C_{1FL}(z_{1FL} - z_{0FL}) \quad (6)$$

$$m_{1HR}\ddot{z}_{1HR} = C_{2HR}(z_{2HR} - z_{1HR}) + D_{2HR}(\dot{z}_{2HR} - \dot{z}_{1HR}) - C_{1HR}(z_{1HR} - z_{0HR}) \quad (7)$$

$$m_{1HL}\ddot{z}_{1HL} = C_{2HL}(z_{2HL} - z_{1HL}) + D_{2HL}(\dot{z}_{2HL} - \dot{z}_{1HL}) - C_{1HL}(z_{1HL} - z_{0HL}) \quad (8)$$

$$\begin{aligned} J_Y\ddot{\psi} = {} & C_{2FR}(z_{2FR} - z_{1FR})L_F + D_{2FR}(\dot{z}_{2FR} - \dot{z}_{1FR})L_F + C_{2FL}(z_{2FL} - z_{1FL})L_F \\ & + D_{2FL}(\dot{z}_{2FL} - \dot{z}_{1FL})L_F - C_{2HR}(z_{2HR} - z_{1HR})L_H - D_{2HR}(\dot{z}_{2HR} - \dot{z}_{1HR})L_H \\ & - C_{2HL}(z_{2HL} - z_{1HL})L_H - D_{2HL}(\dot{z}_{2HL} - \dot{z}_{1HL})L_H + ma_x h_g \end{aligned} \quad (9)$$

$$\begin{aligned} J_X\ddot{\varphi} = {} & C_{2FR}(z_{2FR} - z_{1FR})\frac{S_F}{2} + D_{2FR}(\dot{z}_{2FR} - \dot{z}_{1FR})\frac{S_F}{2} - C_{2FL}(z_{2FL} - z_{1FL})\frac{S_F}{2} \\ & - D_{2FL}(\dot{z}_{2FL} - \dot{z}_{1FL})\frac{S_F}{2} + C_{2HR}(z_{2HR} - z_{1HR})\frac{S_H}{2} + D_{2HR}(\dot{z}_{2HR} - \dot{z}_{1HR})\frac{S_H}{2} \\ & - C_{2HL}(z_{2HL} - z_{1HL})\frac{S_H}{2} - D_{2HL}(\dot{z}_{2HL} - \dot{z}_{1HL})\frac{S_H}{2} - G_a a_y h_g \end{aligned} \quad (10)$$

The meaning of symbol above formulas is in Figure 2.

2.3 Tire dynamics model

The analytic analysis of vehicle lateral dynamics model is related to wheel

lateral force. The wheel lateral force is not only related to the wheel-side angle, but also is related to the tire characteristics and vertical loads on the wheels. In order to take into account the analytical precision of analysis and to calculate the workload of the two factors, in this option of analysis by using the Fiala tire model. The mathematical expression of the model:

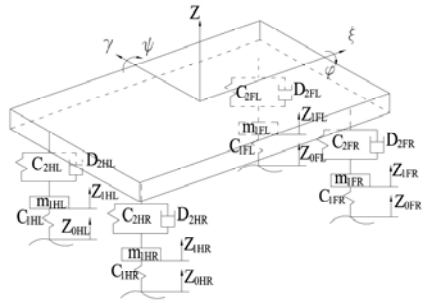

Figure 2.Vehicle dynamics model (vertical).

$$C_y = k_y W L_R^{\,2} / 2 \tag{11}$$

$$\phi = C_y \tan\alpha / F_Z \tag{12}$$

$$\phi_0 = \phi - \phi^2/3 + \phi^3/2 \tag{13}$$

$$F_Y = \phi_0 \mu F_Z \tag{14}$$

Where k_y -Fetal crown lateral rigidity of imprinted Tire Rubber unit surface area; L_R -Imprinted Tire length; W -Imprinted Tire width; α -Tire declination; μ -Ground attachment coefficient; F_Z -Vertical wheel load.

2.4 Dynamics model in the collision process

Instantaneous states of the collision of two vehicles are shown in Figure 3. Two vehicles in the collision process are in line with the law of conservation of momentum, so two vehicles dynamics model in the collision process are obtained(that is, the model whit the relationship between speed and angular velocity of two cars before and after collision) ,which are as follows:

$$m_A(V_{g\eta A} - V_{q\eta A}) + m_B(V_{g\eta B} - V_{q\eta B}) = 0 \tag{15}$$

$$m_A(V_{g\tau A} - V_{q\tau A}) + m_B(V_{g\tau B} - V_{q\tau B}) = 0 \tag{16}$$

$$m_A\rho_A^{\,2}(\omega_{gA} - \omega_{qA}) + \tau_A m_A(V_{g\eta A} - V_{q\eta A}) - \eta_A m_A(V_{g\tau A} - V_{q\tau A}) = 0 \tag{17}$$

$$m_B\rho_B^{\,2}(\omega_{gB} - \omega_{qB}) + \tau_B m_B(V_{g\eta B} - V_{q\eta B}) - \eta_B m_B(V_{g\tau B} - V_{q\tau B}) = 0 \tag{18}$$

The meaning of symbol above formulas is in Figure 3.

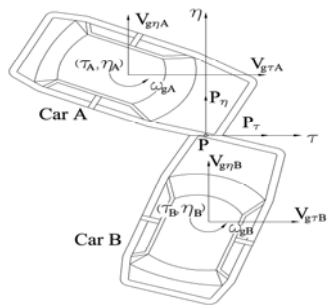

Figure 3.Vehicle impact dynamics model.

3. ANALYSIS OF MOVEMENT PROCESS

As in the accident analysis, the movements of the vehicles are based on the location of the vehicle stopped, and the stop state of vehicles on roads, marks left by the vehicles, as well as marks left in the collision process on the vehicle and on the roads, using reverse analytical method of calculation to obtain. Therefore, modeling and analysis process with the reverse resolution process consistent.

3.1 Simulation phase V

After the collision of car B and C, it is confirmed that two vehicles in the collision instant location from the ground traces and traces of vehicle collisions in the collision. When the collision after the end, car B and C is in a state of freedom of movement and, ultimately, is stopped. Taken use of vehicle lateral dynamics model, vehicle Vertical dynamics model, As well as relations between the two coupling, and taking the tire dynamic model into account, According to car B, car C parking location and state; the ground marks of movement process and the location of instantaneous parameters of vehicle collision, it is confirmed that the car B's and car C's centroid velocity and angular velocity of rotation in the end of collision through the reverse analysis method.

In the calculation process, this paper chooses the coordinate of the car B stopped location as the initial point of iterative calculation. At this time as a vehicle in a static state, by setting the corresponding initial parameters, this paper chooses the coordinate of the car B stopped location as the termination point of iterative calculation. Carry out iterative calculation by using vertical dynamics equation and horizontal dynamics equation. At the end of iterative process, calculated car B's speed and the rotation angular velocity at the beginning of this movement, It is also the car B's speed and the rotation angular velocity at the ending the moment of collision $V_{g\eta B}$, $V_{g\tau B}$ and ω_{gB}.

Taking use of the completely similar process, car B's speed and the rotation angular velocity at the ending the moment of collision $V_{g\eta C}$, $V_{g\tau C}$ and ω_{gC} are calculated.

3.2 Simulation phase IV

The collision process of car B and C by using the collision dynamics model above is calculated. As mentioned earlier, this paper only discusses the case of car B does not lose stability after the first collision in a three car collision course. Therefore, car B was in a controllable state before the second collision, when the rotating angular velocity of car B was $\omega_{qB} = 0$. Similarly, car C was also in a controllable state before the second collision, when the rotating angular velocity of car C was $\omega_{qC} = 0$.From substituting these conditions as well as the previous step calculate of car B's and car C's speed and angular velocity $V_{g\eta B}$, $V_{g\tau B}$, ω_{gB}, $V_{g\eta C}$, $V_{g\tau C}$ and ω_{gC} in the moments after the collision into the collision dynamics model, the velocity $V_{q\eta B}$, $V_{q\tau B}$, $V_{q\eta C}$, $V_{q\tau C}$ of car B and C before the collision can be calculated.

3.3 Simulation phase IIV

This phase includes three parts, which are: the movement of car A after the

first collision to stop state; the movement of car B before the second collision and the normal movement of car C before the collision. Separately calculate here.

3.3.1 Simulation of car C's movement before the collision

Car C was completely controllable before the collision. According to the situation of the ground traces, it is estimated whether the driver has taken braking measures before the collision, by which the values of simulation variables are determined. When braking measures absence: $F_{FL\zeta} = F_{FR\zeta} = F_{HR\xi} = F_{HL\xi} = 0$; when there is braking measures: $F_{FL\zeta} = \mu F_{FLZ}$, $F_{FR\zeta} = \mu F_{FRZ}$, $F_{HL\xi} = \mu F_{HLZ}$, $F_{HR\xi} = \mu F_{HRZ}$;the car C's instantaneous velocities before collision which are calculated by the previous step, $V_{q\eta C}$, $V_{q\tau C}$, are chosen as the initial value in the iterative calculation $V_{q\eta C0}$, $V_{q\tau C0}$. The collision location coordinates are chosen as the initial point of the iterative calculation, choose a key point coordinates on the vehicle trajectory by road signs as the end point of the iterative calculation, iterative calculate by lateral dynamics equation and vertical dynamics equation, finally get car C's instantaneous movement state value before the collision.

3.3.2 Simulation of car B's movement before the second collision

As already mentioned above, this paper discusses car B at the controllable state from the first collision to the second collision. According to the situation of the ground traces, whether the driver had taken braking measures between the two collisions of car B is estimated, by which the values of variables of this simulation process are determined. The car B's instantaneous velocities before the second collision which calculated by the Previous step, $V_{q\eta B}$, $V_{q\tau B}$, are chosen as the initial value in the iterative calculation $V_{q\eta B0}$, $V_{q\tau B0}$. This thesis chooses the second collision location coordinates as the initial point, choose the first collision location coordinates as the end point of the iterative calculation, iterative calculate by lateral dynamics equation and vertical dynamics equation, finally get car B's each instantaneous movement state value from the first collision to the second collision and the instantaneous movement state value after the first collision.

3.3.3 Simulation of car A's movement after the first collision

After the first collision of car A, two vehicles' instantaneous locations are determined from the ground traces and traces of vehicle s' collisions in the collision. Car A was in a freedom movement state after the collision, And, ultimately, is stopped. Car A's parking location and status are taken as the initial iteration point, take the ground marks of the movement process and the instantaneous location parameters of the vehicle collision into account, iterative calculate by lateral dynamics equation and vertical dynamics equation, finally get car A's instantaneous centroid velocity and angular velocity of rotation after the first collision.

3.4 Simulation phase

The collision process of car A and B is calculated by using the collision dynamics model above. As car A and B are in controllable states before the first collision, the rotation angular velocity of car A and car B are zero at this time, that is $\omega_{qA} = 0, \omega_{qB} = 0$. Substituting these conditions, as well as instantaneous speed and angular velocity of car A and car B $V_{g\eta A}$, $V_{g\tau A}$, ω_{gA} and $V_{g\eta B}$, $V_{g\tau B}$, ω_{gB} ,which are

calculated by the previous step into the collision dynamics model, the speed of car A and B before the collision $V_{q\eta A}$, $V_{q\tau A}$, $V_{q\eta B}$, $V_{q\tau B}$ can be calculated.

3.5 Simulation phase

Car A and C are in the controllable states before the collision. According to the situation of the ground traces, it is estimated whether the driver has taken braking measures before the collision, by which the values of simulation variables are determined. This article chooses the car A's and car B's instantaneous velocities before collision which are calculated by the previous step at the same time $V_{q\eta A}$, $V_{q\tau A}$, $V_{q\eta B}$, $V_{q\tau B}$ as the initial value in the iterative calculation $V_{q\eta A0}$, $V_{q\tau A0}$, $V_{q\eta B0}$, $V_{q\tau B0}$. This paper chooses collision location coordinates as the initial point of the iterative calculation, chooses a key point coordinates on the vehicle trajectory by road signs as the end point of the iterative calculation, iteratively calculates by lateral dynamics equation and vertical dynamics equation, and finally get car A's and car B's instantaneous movement state value before the collision.

4. CONCLUSION

This paper chooses one form to research on recurrence technology on the basis of the analysis in the three car collision process. First of all, the whole process is divided into five stages by its movement characteristics. Then, it establishes dynamics equations of each stage, and gives the boundary conditions for analysis and calculation of each stage. Finally, by taking use of reverse analytical method for calculation, it acquires the ideas of cars' movement states in the whole collision process and calculation process of three vehicles involved collisions, and provides a theoretical foundation of recurrence technology study in three car collision accident.

Study on the Preventive Maintenance Time for Asphalt Pavement

Ying Ronghua, Wu Ting, Wang Lijuan and Hou Zhaoguang
(School of Traffic and Transportation Engineering, Changsha University of Science & Technology)

Abstract: Through the MTS of mid-point trabecular bending fatigue test about asphalt mixture, a fatigue life equation is obtained, and the relationship between the fracture length and N/N_f is analyzed. Based on this, we determine the fatigue life of asphalt pavement under standard axle load combined with the actual road conditions and fatigue failure is predicted quantitatively. Aimed to the law of fatigue damage of the asphalt pavement performance, the asphalt pavement preventive maintenance time has been studied, and we suggest a method to determine the best preventive maintenance time in the asphalt pavement based on the fracture length.

Key words: Preventive Maintenance; MTS of Trabecular Bending Test; Fatigue Life; Fracture Length; Maintenance Time

1 Introduction

In recent years, how to prevent and delay the emergence of diseases in high-grade highway has been paid great attention by our highway worker. However, we usually carry out the maintenance and repair after the roads are broken, it is easier to identify and determine the timing of maintenance and repair, but the preventive maintenance is that taking measures when the roads is still in good condition, which makes pavement preventive maintenance face a difficult issue, that is, the timing of the preventive maintenance? (Yu, 1993)

Before carrying out the preventive maintenance, the trend of the pavement damage must be made clear; because the asphalt pavement structure is always under the circulating effect of traffic and temperature loads, and its destruction is mainly fatigue failure. In this paper, the timing of preventive maintenance in asphalt pavements is put forward based on fatigue failure.

2 Fatigue test of asphalt mixture with large stone (LSAM)

Gradation is determined as follows through the optimization:

Table2.1 Mineral aggregate gradation

Gradation	31.5	26.5	19.0	16.0	13.2	9.5	4.75	2.36	1.18	0.6	0.3	0.15	0.075
	90	76	55	48	41	31	26	14.5	10.5	7	5	3.5	1.5

Use the Marshall method to determine that the optimum asphalt content of dense framework structure of LSAM is 4.1%.

In this paper, during the fatigue study, apply the material testing machine of MTS for the LSAM, and use the repeated bending load fatigue test of mid-point loading with the sample size of 50.0mm × 63.5mm × 381mm.

According to the results of bending fatigue test, and the corrected fatigue equations of asphalt mixture are:

$$N_f = 3612434(\frac{1}{\sigma})^{1.8237} \quad (5\text{Hz}) \tag{2.1}$$

$$N_f = 1220113(\frac{1}{\sigma})^{2.056} \quad (10\text{Hz}) \tag{2.2}$$

$$N_f = 420318(\frac{1}{\sigma})^{2.1036} \quad (50\text{Hz}) \tag{2.3}$$

Through observing the cracks, correlation formulas of crack length with N / N_f are obtained, and the correlation coefficients are more than 0.98.

3 The service life prediction of asphalt pavements based on fatigue test

3.1 Asphalt pavement structure

In order to estimate the fatigue life of asphalt pavement, it is necessary to analyze the structure of asphalt pavement to obtain internal stress distribution of asphalt pavement under loading. Taking into account the actual situation and the analysis convenience, this paper selects a typical asphalt pavement structure to analyze:

Upper layer	AC-13	1600 Mpa	μ=0.25
Lower layer	AC-20	1400 Mpa	μ=0.25
LSAM		μ=0.25	
Semi-rigid Base	lime-fly ash concrete	850Mpa	μ=0.35
Soil Base		40Mpa	μ=0.35

3.2 Prediction of fatigue life of asphalt pavements

Through fatigue life equation (2.3), carrying out the standard axle load conversion using standard load of BZZ-100, tire pressure of 0.707MPa, load radius of 10.65cm, distance of double round of 31.95cm, and static modulus used in the structure design system in our country.

In this study, calculate the layer bottom tension stress of base course in the above pavement structure by BISAR procedure under the standard axle load. The results are as follows:

In the pavement structure, tensile stress of large stone asphalt stabilized macadam base of 12cm is 0.13946Mpa, which is substituted in the fatigue life equation (2.3) to attain the action times of approximately 6.9×10^7 in the entire fatigue life.

If the daily average action times of standard axle load N_1 = 18000 times / d in such a typical flexible base asphalt pavement structure with an average annual growth rate of 6%, 6 lanes and lane coefficient of 0.4, the service life is 18 years in accordance with the formula $N_e = \frac{N_1[(1+\gamma)^t - 1]\times 365}{\gamma}\eta$

.

3.3 The prediction based on fatigue failure

By observing the cracks in fatigue test, we can see that crack length is related to N / N_f, in accordance with the formula with maximum correlation coefficient to quantitatively predict the fatigue failure of asphalt pavement, and the formula is as follows (Zheng, Zhou, Zhang, 2003):

$$y = 56.461x^{5.9221}$$
$$R^2 = 0.987 \tag{3.1}$$

When $N / N_f = 0.5$, and the service life is 18 years in the above typical structure under the standard loading, the crack length is about 0.93mm by using the formula (3.1), in other words, at

the ninth year of pavement usage, we can see that the cracks appear according to the test, and the crack length of each year can be predicted by the formula (3.1).

4 Determination of the timing of the preventive maintenance based on fatigue failure

In this paper, because fatigue failure is one of the main damage types of asphalt pavement, we quantitatively determine the indicator of maintenance timing. Because fatigue crack length and speed change with the age of road changing, until the cracks have reached a certain level, the road enters into the severely failure state, in accordance with laboratory test integrated with decay condition of practice pavement to determine that the indicator of maintenance timing for fatigue failure is the crack length, then apply the method of cost-effectiveness ratio to determine the maintenance timing of the road condition after preventive maintenance.

In this paper, the example in the former chapter is used to determine the timing of preventive maintenance.

(1) The preventive maintenance scheme

Because this paper is to study the maintenance timing selection, so select slurry seal as the only maintenance measure.

(2)Road condition indicator

By the formula (3.1) we can obtain the length of fatigue cracks in different road condition, so select the crack length as the road condition indicator. In order to simulate the failure condition of the practical pavement, according to the entire pavement service life of 18 years, converse the relationship between N / N_f and fatigue cracks to the crack length of each year that is:

$$Y=2*10^{-7}*e^{1.3645x} \tag{4.1}$$

Making the maintenance timing in accordance with the road condition attenuation law: at the 5th, 6th, 7th and 8th year, the pavement crack length of practical pavement is respectively 0.00796mm, 0.02812mm, 0.08175mm and 0.20602 mm.

(3) The lowest acceptable level

The lowest acceptable level of performance index (Dong, Sun and Peng, 2005) when taking preventive maintenance measures is the maximum or minimum limits of the Y-axis of performance index when calculating the effect area, to the performance index curve which decreases with the age of road growing, lowest acceptable level of the performance index is the lower limit, the area over the lower limit of performance indicators will not be counted as part of the effect when calculating the effect area. According to the test results, we can see that when the crack length is 20mm, the failure rapidly increases, so we can determine the crack length of lowest acceptable level is 20mm. The figure is as follows:

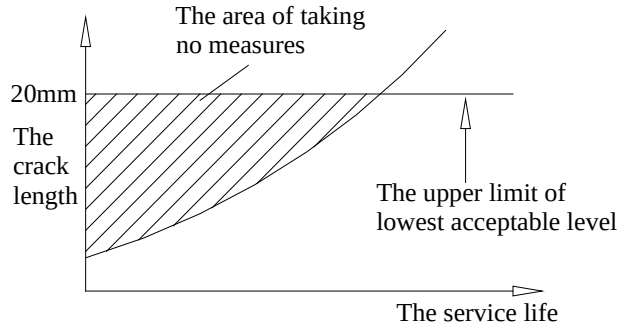

Figure4.1 The lowest acceptable level

(4) The decay condition of pavement cracks after preventive maintenance

According to the changes of the decay curves of pavement condition after preventive maintenance provided in the reference (Ren, 2006), the decay curves after micro surfacing are as follows through similarity analysis in this article:

Table4.1 Performance curve equations after taking preventive maintenance measures

The age of road when taking preventive maintenance measures	The decay curve equations of crack length
5	$y=2*10^{-7}e^{1.6818x}$
6	$y=2*10^{-7}e^{1.3154x}$
7	$y=2*10^{-7}e^{1.3933x}$
8	$y=2*10^{-7}e^{1.6039x}$

(5) The age to the lowest acceptable level

Table4.2 The age of road achieving to the lowest acceptable level when taking maintenance measures at different timing

The decay curves	The x value to the lowest acceptable level	The age of road to the lowest acceptable level
$y=2*10^{-7}e^{1.3645x}$	13.5	13.5
$y=2*10^{-7}e^{1.6818x}$	11.00	16.00
$y=2*10^{-7}e^{1.3154x}$	14.00	20.00
$y=2*10^{-7}e^{1.3933x}$	13.22	20.22
$y=2*10^{-7}e^{1.6039x}$	11.48	19.48

(6) The calculation of the effectiveness index

$$DRR = S_1 - S_0 = \frac{(P_B - P_D)}{q} - \frac{(P_B - P_A)}{p}$$

By $PJ = PB - PC$ and we can obtain the performance jump and reduction of deterioration rate as follows:

Table4.3The parameters of effectiveness model

Maintenance year	P_A	P_B	P_C	P_D	p	q	PJ	DRR
5th	0	0.00796	0.0000002	19.410845	5	11	0.0079598	1.762307
6th	0	0.02812	0.0000002	19.470981	6	14	0.0281198	1.384089

7th	0	0.08175	0.0000002	19.922058	7	13.22	0.0817498	1.489101
8th	0	0.20602	0.0000002	19.989926	8	11.48	0.2060198	1.697584

From the results of calculating the effectiveness index we can see that: at the 8th year the performance jump is the best, at the 5th year the effect of reduction of deterioration rate is the best.

(7)Maintenance effect

1) Calculating the effect area when maintenance measures are not taken

When preventive maintenance measures are not taken, the integral area of the performance curve which has reverse tendency is as follows:

$$AREA_{+} = \int_{x_0}^{x_1}(UBC - EQ_{DN}) = \int_{0}^{13.5}(20 - 2\times10^{-7}\, e^{1.3645x})dx = 253.697$$

2) The calculation of the effect area after maintenance measures are taken

As can be seen from Table 4.2, in the first scheme the road reaches the lowest acceptable level of preventive maintenance measures at the service life of 16 (computed from the 5th year)years (which is the first year to achieve minimum acceptable), so we use 16 years as the analysis period. Calculate the effect area in accordance with maintenance measures as follows:

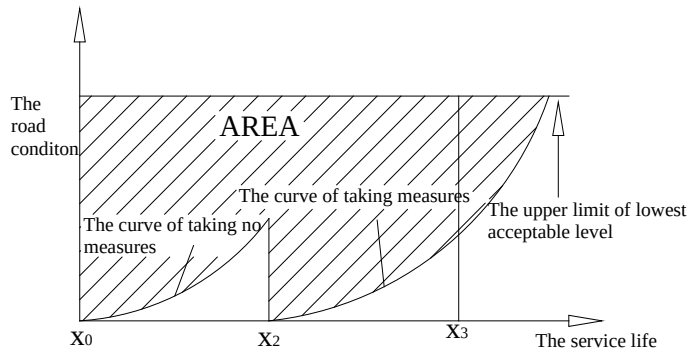

Figure4.2 Determination of the area of performance index

$$AREA_{PT(+)} = \int_{x_0}^{x_1}(UBC - EQ_{DN}) + \int_{0}^{(x_2 - x_1)}(UBC - EQ_{PT}) \qquad (4.2)$$

Table4.4 The calculation of the effect area after maintenance measures are taken

The age of road when taking preventive maintenance measures（year）	5	6	7	8
Effect area	319.397	319.978	319.934	319.814

3) The calculation of effect

There are four maintenance schemes in which taking the maintenance measure of micro-surfacing at the age of 5, 6, 7and 8 years, the effect area of each scheme is calculated in terms of Figure 4.2.

Calculating the effect according to the following formula:

$$BE = (AREA_{BE})/(ARER_{DN-TOT})\times100\% \qquad (4.3)$$

Table4.5 Results of effect calculating after taking the preventive maintenance measures

The age of road when taking preventive maintenance measures（year）	5	6	7	8

Effect（%）	26.897	26.126	26.109	26.062

(8) Maintenance cost

1) Costs of preventive maintenance measure

Because we are to make the cost analysis of the maintenance item in this highway, and the initial construction costs are the same, we can assume that the initial construction costs are zero, only the costs of preventive conservation measures are different. Based on local experiences and quota calculation, thickness of micro-surfacing of domestic modified asphalt is 1cm with its costs of 296,750 million yuan / km.

2) Pavement residual value

Calculate the pavement residual value at the end of the analysis period according to the ratio of residual life to its service life.

$$SV = (1 - \frac{L_A}{L_E})C_r \tag{4.4}$$

For the first scheme, its service life is 11 years computed in accordance with its performance index decay equation of road condition and the lowest acceptable level, at the end of the analysis period it has been used for 10 years. According to the calculation model set up by the above formula the pavement residual value of the first scheme is:

SV= (1-10/11)*29.675=2.6977million yuan

For the second scheme, its service life is 14 years, and at the end of the analysis period it has been used for 9 years, thus its residual value is as follows:

SV= (1-9/14)*29.675=10.5982million yuan

For the third scheme, its service life is 13.22 years, and at the end of the analysis period it has been used for 8 years, thus its residual value is as follows:

SV= (1-8/13.22)*29.675=11.7174million yuan

For the forth scheme, its service life is 11.48 years, and at the end of the analysis period it has been used for 7 years, thus its residual value is as follows:

SV= (1-7/11.48)*29.675=11.5805million yuan

3) Calculating cost present value

Costs can be calculated by the present value, cost present value of PC is computed as follows:

$$\text{PC} = \sum_{t=1}^{n} (CO)_t \ (\text{P/F,i,t}) \tag{4.5}$$

In the four schemes of this article, the expenditure at different times during the analysis period is conserved to the present value according to the discount coefficient (let the first year as the datum year), and the discount rate is7%.

The calculation results are shown in Table 4.6.

Table4.6 Calculation Table of cost present value

Time of taking preventive conservation	Preventive maintenance costs (million yuan/km)	Residual value (million yuan/km)	Total cost (million yuan/km)
5	21.1579	0.7874	20.3705

6	19.7737	3.0935	16.6802
7	18.4801	3.4202	15.0599
8	17.2711	3.3802	13.8909

Note: The total cost = Preventive maintenance costs - Residual value

(9) Determination of the best maintenance timing

According to the increment method, the calculating results of cost-effectiveness ratio are in Table 4.7.

Table4.7 Cost-effectiveness ratio

Time of taking preventive conservation	Effect（%）	Total cost (million yuan/km)	Cost-effectiveness ratio （%）
5	25.897	20.3705	0.01271
6	26.126	16.6802	0.0157
7	26.109	15.0599	0.01734
8	26.062	13.8909	0.01876

From Table 4.7, we can see that when taking the measure of micro-surfacing at the pavement life of 8 years, the cost-effectiveness ratio of preventive maintenance measure is the biggest, just look at the effect, at the 6th year is the best, just look at the total cost, at the 8th year is least; at the 5th year the effect is the least and the costs is the most, so it is excluded. Then optimize plan according to the increment method optimization program: comparing the latter two options, costs are increased by 11,690 yuan / km but the effect is only increased by 0.047%; then comparing the schemes of the 8th year and the 6th year, the costs are increased by 27,111yuan/km but the effect is only increased by 0.064%, so it is considered that the increase of the effect is less, finally the best maintenance timing is to take the maintenance measure at the 8th year.

5 Conclusion

In this paper, we obtain the law of fatigue damage by interior trabecular fatigue test to determine that the maintenance timing indictor of the fatigue failure is the crack length, then using the method of cost- effectiveness ratio to calculate the best timing of preventive maintenance. However, there still exist some problems and deficiencies, requiring further study.

ABSTRACT

Precision Level is widely used to measure road elevation. The measuring process needs several cooperating people to complete. The measuring error is not easily to be controlled due to the artificial influence. A wavy road elevation measurement method is proposed in this paper based on the principle of inertia. This equipment mainly consists of a gyro, a three-axis accelerometer and a photoelectric encoder. When moving on the road at a high speed, it can real-timely measure the running speed and the pitch angle of the car, from which the road elevation can be obtained by data processing. The advantage of this method is simple, high speed and easy to achieve, it can be applied to measure the wavy road elevation.

KEYWORDS: road elevation; inertia; gyro; three-axis accelerometer

INTRODUCTION

Elevation refers to the distance along the plumb line direction from a point to the absolute base, which is always called the absolute elevation and short for elevation (RUMMEL R et al. 1998). Elevation is one of the elements which determine the location of terrestrial points. At present, the most commonly used methods to measure the elevation are the leveling (YANG Jun-zhi et al. 2008) and trigonometric leveling (YE Jian-hua**,** 2006). The leveling can calculate the elevation by using the equipment providing the level of sight (such as LEVEL) to measure the height difference between two terrestrial points; whereas trigonometric leveling obtains the height difference through the observation of the zenith distance (or elevation angle) and the horizontal distance between two points. Compared with the leveling, the trigonometric leveling is easy to observe, free from restrictions on terrain conditions, and is the basic method to obtain elevation. However, in geodesy, effects of the earth bending and atmospheric vertical refraction must be considered since the length of side is long.

To improve the accuracy of elevation measurements and reduce the difficulty, a simple and reliable wavy road elevation measurement method is proposed based on the principle of inertia.

WORKING PRINCIPLE OF SYSTEM

The main parts of this equipment are a gyro, a three-axis accelerometer and a photoelectric encoder. When moving on the road at a high speed, it can real-timely measure the running speed and the pitch angle of the car, from which the road elevation can be obtained by data processing.

Gyro

Gyroscope (GUO Su-yun, 2006) is a device to sense and maintain the direction, which is designed based on the theory that angular momentum is undiminished. The gyros have two characters: one is inertia or rigidity, and the other is precession that the detection system only uses. The precession of the gyros produces inertia when the gyroscope rotor rotates at a high speed. It helps rotation axis of the gyroscope rotor maintain a fixed direction in space and prevent and antagonize any forces which may change the direction of rotor at the same time.

Install one gyroscope in the inspection car and make sure that the rotation axis of the gyroscope rotor is consistent with the forward direction of the car. When the gyro is energized, the output voltage is proportional to the changing rate of the angular velocity. Based on this principle, when the inspection car is running on the road, gyroscope can real-timely measure the angle (θ) between the forward direction of the car and the horizontal direction according to changes of its own rotating angular velocity. As shown in Figure 1.

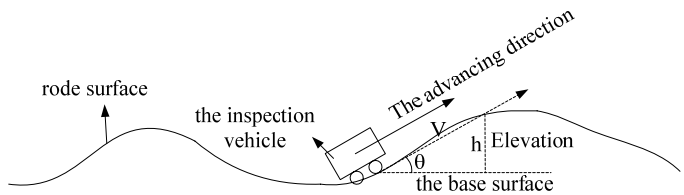

Figure 1. Working Principle of System

Three-axis Accelerometer

When the inspection car is stationary or running with no changes in the direction, the gyroscope rotor is stationary or uniformly running and the output value of the gyro is zero. This, however, prevents the device from measuring the pitch angle of the car, for which we have introduced three-axis acceleration (MENG Wei-guo, 2007)

to make up for this deficiency. Name the three axis of the three-axis accelerometer: A-axis, B-axis and C-axis. When installing, make sure that one of the three axis of the acceleration is consistent with the forward direction of the car (say A-axis). When the inspection car is stationary or running with no changes in the direction, the components of the gravitational acceleration at A axis, B axis and C axis will be measured by the three-axis acceleration, so that the angle between the direction of the gravitational acceleration and A-axis (that is, the forward direction of the car) will be obtained, from which the initial pitch angle (θ_0) of the car can be gained. As shown in Figure 2.

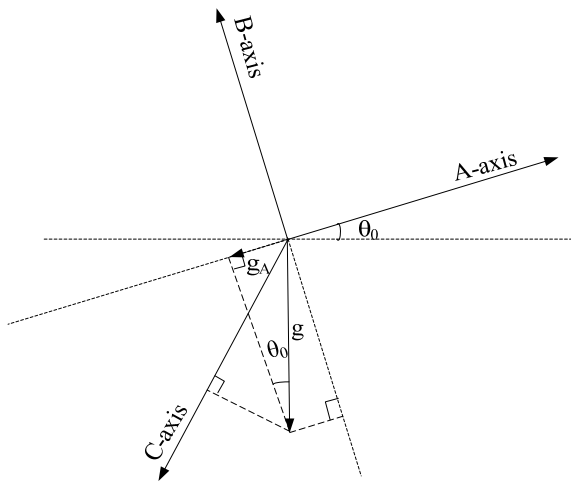

Figure 2. Principle of three-axis accelerometer

Photoelectric Encoder

With real-time pitch angle of the car, the elevation of the pavement can be measured as long as the real-time speed of the car is known. To that end, the speed of car will be obtained by the photoelectric encoder. Photoelectric encoder is a device used to measure the speed and it is classified as single-output encoder and dual output encoder (Yang Wen-yuan. 1994). A single-output encoder is used in the system, and the single-output means that the encoder output is a set of pulses. The photoelectric encoder is installed at an appropriate location of the inspection car. Through accumulating the number of the output pulses during a period, the speed signal could be gained (ZHAO Yan, 2003).

DATA PROCESSING

The Obtaining of Detect car's Pitch Angle

Suppose an inspection car is running with changes in the direction. The pitch angle of the car is θ_0 at a time t_0, and the pitch angle is θ, when the time reaches t_1. Assuming that the variable quantity of gyroscope rotor's angular velocity is ω from the time t_0 to t_1, the pitch angle θ will be obtained from the following formula (1):

$$\int_{t_0}^{t_1} \omega dt = \theta \qquad (1)$$

Equation 2 is an alternative of Equation 1 provided (t_1- t_0) is small enough.

$$\theta = \theta_0 + \omega(t_1 - t_0) \qquad (2)$$

In the calculation, θ_0 corresponds to the initial state of the pitch angle, which is hard to get by reading the gyroscope output when the inspection car is stationary or running without changes in the direction. However, it can be obtained by reading the output of the three-axis acceleration. Three axis of the acceleration are perpendicular to each other, which compose a three-dimensional coordinates system. From Figure 2, assuming that the component of gravitational acceleration (g) at A-axis reading from the three-axis acceleration is g_A, the relationship between gravitational acceleration and pitch angle is expressed as follows:

$$g \sin \theta_0 = g_A \qquad (3)$$

So, by combining formula (2) and (3), the pitch angle of the inspection car at any time can be obtained.

The Obtaining of Inspection Car's Speed

Assuming that the circumference of the inspection car's wheel is L and the number of the output pulses of the photoelectric encoder is N, when the wheel finishes one revolution. When a pulse signal is captured, the progressive journey (s) of the inspection car will be obtained by the formula (4) as follows:

$$s = L / N \qquad (4)$$

The pulse signals are put into the microcontroller which is set to run with interrupts. By recording the time (T) and signal number (n) between two interrupts, speed of the car will be obtained by the formula (5) as follows:

$$V = \frac{L \times n}{N \times T} \qquad (5)$$

The Obtaining of Elevation

With the speed and pitch angle of the car, elevation could be calculated by choosing a base surface. From Figure 1, the base surface where the inspection car

begins to run is selected as the base level. Hence, road elevation could be obtained by the following formula (6):

$$h = \int V \sin\theta dt \qquad (6)$$

EXAMPLES OF VERIFICATION

Vehicle-mounted surface measurement has been carried out on two roads by using the algorithm in this paper and the results are compared with those measured by the leveling. The results are plotted in Figure 3 and 4 (blue curve for the Leveling measurement results, the green curve for the results of this method of measurement).

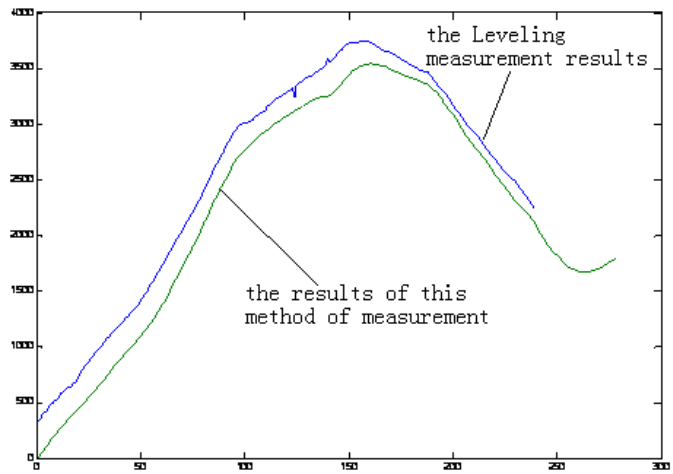

Figure 3. Comparison Result 1 (Horizontal axis: Length - m, Vertical axis: Height - mm)

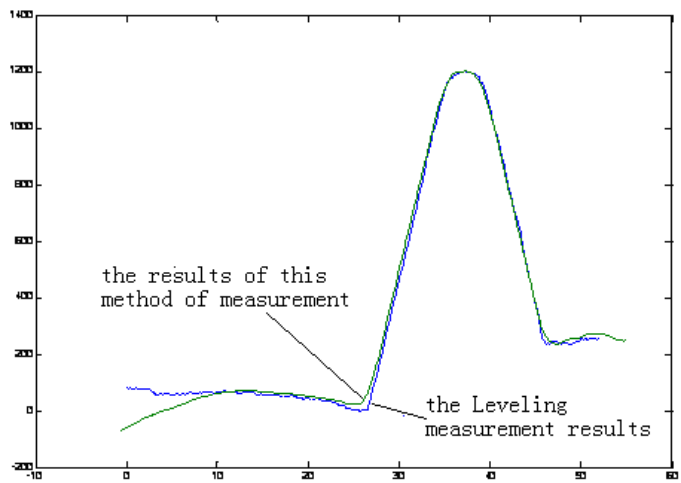

Figure 4. Comparison Result 2 (Horizontal axis: Length - m, Vertical axis: Height - mm)

Therefore, it shows that the road pattern measured by this method is close to the facts and available, and that the overall measurement error is less than 5%. However, if the road is flat and with little wave, the measurement error is big enough when little angle is measured, for the reason that the accuracy of the angular rate measured by the selected MEMS gyroscope is limited. According to this situation, it can improve the measurement accuracy by choosing high-precision fiber optic gyro sensor.

CONCLUSION

A wavy road elevation measurement method based on the principle of inertia is proposed in this paper. The technical innovation point of this method is using the most advanced gyroscope to measure pitch angle of car real-timely as well as using three-axis gyroscopes to compensate for the acceleration that can not be detected when the gyroscope rotor is stationary or uniform running. This method only requires the car running on the road to be measured. The elevation could be measured through data processing. The method is simple, quick and easy to achieve. Since the accuracy of the angular rate measured by the selected MEMS gyroscope is limited, the measurement error is big enough when little angle is measured, so the equipment can be applied only to measure the big wavy road elevation. How to use it in the road where is flat and with little wave needs to be further studied.

ABSTRACT

While it is generally agreed that operational conditions have an effect on traffic safety, their relationship has not been well defined at a level of detail that adequately supports operation and planning performance measurements. Signalized intersections are the most complex locations on the roadway network, and they are vital to the efficiency and safety of transportation systems. Based on the data collected at 164 four-legged signalized intersections in the State of Florida, this study investigated the relationship between level of service (LOS) and safety at signalized intersections. The LOS was calculated for three time periods: a.m. peak, midday, and p.m. peak. The crash count data models were applied to fit crash frequency models for total crashes in order to investigate LOS and safety relationship. Overall, the LOS indicator is a significant factor for predicting crash occurrence at intersections. However, the models show that the operational condition itself (by only including the LOS indicator) is not sufficient to predict the safety status. LOS "D" is a desirable level which is associated with less total crashes.

Keywords: operational condition, safety status, level of service (LOS), signalized intersections

INTRODUCTION

Signalized intersections are the most complex locations on the roadway network, and they are vital to the efficiency and safety of transportation systems. Level of service (LOS) is a measure of operational condition for speed and travel time, freedom to maneuver, traffic interruptions, comfort, and convenience (HCM, 2000). Researchers believe that operational condition has an effect on safety. On the other hand, safety is an integral part of intersection operations, which in turn will affect operational condition of signalized intersections. However, the relationship between operation and safety is not clear. Congestion might reduce the number of crashes because of lower speed on congested roads. In some cases, crash statistics show that the number of crashes is reduced when the road is less congested.

At signalized intersections, there is a clear relationship between traffic volume and crash frequency. Higher volumes usually correspond to a larger number of crashes because the probability of a crash occurring is generally greater when there are more vehicles (Hauer et al., 1988; Wang and Abdel-Aty, 2007; Wang and Abdel-Aty, 2007). However, higher volumes do not definitely equate to increased congestion, and there is little research on the relationship between intersection operational conditions and safety (Persaud & Nguyen, 1998). Because safety is not explicitly considered in operational measures to define LOS, beginning with HCM 1994, "safety" was removed from the LOS definition (Zhang & Prevedouros, 2003). The objective of this study is to investigate the relationship between LOS and safety at signalized intersections. Crash data at Signalized intersections and other intersection-related information were collected. The LOS was calculated. The crash frequency modeling technique was applied in this study to facilitate the analysis.

LITERATURE REVIEW

Only a few studies investigated the relationship between safety performance and various LOS measures for signalized intersections. Persaud and Nguyen (*1998*) explored the relationship between LOS and safety for four-legged signalized intersections. Data from rural areas in Ontario, Canada were used. These consisted of a sample composed of 107 four-legged signalized intersections and 970 associated crashes over 6 years (1988-1993). Only a.m. and p.m. peak period data were considered in the analysis. It was assumed that two peak periods did not differ much in model parameters. The required intersection peak hour average stopped delay, capacity, and LOS were calculated using the Highway Capacity Software (HCS) based on HCM 1994. Two sets of models were estimated for the analysis: one that uses flow and delay as variables and the other uses LOS as a categorical variable. The analysis suggested that the best models for these two sets are those having separate calibrated parameters for a signalized intersection's major and minor flows. They found that the expected number of accidents during the peak periods is larger for LOS D and E than it is for LOS B and C.

Hall and Polanco de Hurtado (*1992*) inspected 445 urban signalized intersections in Albuquerque, New Mexico, and selected about 260 for the analysis. Crashes from 1987 to 1989 were included for those occurring at intersection and intersection-influenced locations (i.e. occurring within 200 ft of an intersection), and then converted to crash rate. Weekday one-hour peak period intersection volumes from 1989-1990 were used for calculating LOS and v/c ratios using the procedures from HCM 1985. The 60-minute peak hour periods considered were morning (beginning either at 7:15 or 7:30 a.m.) and afternoon (beginning at 4:30 p.m.). They found that accident rate exhibited a small but positive correlation with the amount of traffic entering the intersection. However, the authors concluded that equations developed for estimating accident rates as a function of v/c had such high standard errors that they could not be used for any practical purpose. This could be due to the use of accident rate and ordinary linear regression for intersection safety analysis (Hauer, 2002).

It can be noted that some common limitations can be encountered when trying to explain the LOS-safety relationship. Persaud and Nguyen (*1998*) recommend the

use of larger data sets for this type of analysis in future studies. Furthermore, crash rate is still being used, as well as linear regression when analyzing it (Hall and Polanco de Hurtado, *1992*). The investigation of how operational conditions affect safety is still at the exploratory phase.

DATA PREPARATION

The study was based on a sample of 164 regular four-legged signalized intersections in Orange and Hillsborough Counties of Central Florida. The intersections are located in suburban areas. The data collected for the selected intersections include signal timing, 24-hour approach volume, turning movement count, intersection geometry design features, and crash data. Both counties have turning movement count for the selected intersections for three time periods: a.m. peak, p.m. peak, and midday.

Levels of service (LOS) and related operational measures, i.e. delay, lane group capacity, and volume to capacity ratio (v/c), were calculated for the selected intersections using the Highway Capacity Software (HCS), which is based on the 2000 version of the Highway Capacity Manual (HCM, 2000). The study considers three time periods (a.m., midday, and p.m.). The process started by entering the required geometric design features into the software, which include the number of out-flowing lanes and receiving lanes for all approaches, whether these are shared or exclusive, and queue storage lengths for each approach. These main features were determined with aerial imagery captured by GoogleTM Earth and verified with the information in the intersection's respective signal timing plan. Other input data considered were traffic volumes and peak hour factors (PHF). These were calculated on each approach based on the available turning movement counts and the peak 15-minute volumes for each time period.

Collisions over 6 years (2000 - 2005) were collected for the selected intersections from the Crash Analysis Reporting (CAR) system maintained by the Florida Department of Transportation (FDOT) Safety Office. Crashes included are those occurring "at intersection" or "intersection-related".

METHODOLOGY

Negative Binomial regression provides a common tool for modeling cross-sectional count data like crash frequencies at signalized intersections (Poch and Mannering, 1996). In this study, for each selected intersection, there are observed crash frequencies for three time periods. Multiple observations on the same intersection are most likely to be correlated because of the common unobserved characteristics of intersections. Generalized Estimating Equations (GEEs) provide an extension of generalized linear models (GLMs) to the analysis of clustered data, which account for the temporal correlation among the repeated observations for a given intersection. GEE comes from specifying a known function of the marginal expectation of the dependent variable as a linear function of covariates, assuming that the variance is a known function of the mean, and specifying a "working" correlation matrix for the observations for each intersection (Zegeer et al., 2008). GEE is proved to be a promising modeling approach for temporal or clustered crash frequencies. Lord and Persaud (*2000*) applied GEE for a 6-year period of data for 868 four-legged

signalized intersections. Wang et al. (*2006*) and Abdel-Aty and Wang (*2006*) conducted temporal and spatial analysis for signalized intersections.

MODELS FOR TOTAL CRASHES

Crash frequencies of the selected intersections were extracted and plotted by LOS of the entire intersection for a.m. peak period as shown in Figures 1. The figure shows that more congested intersections correlate with higher frequency of collisions. For the a.m. peak, the highest number of crashes occurred at intersections with LOS F.

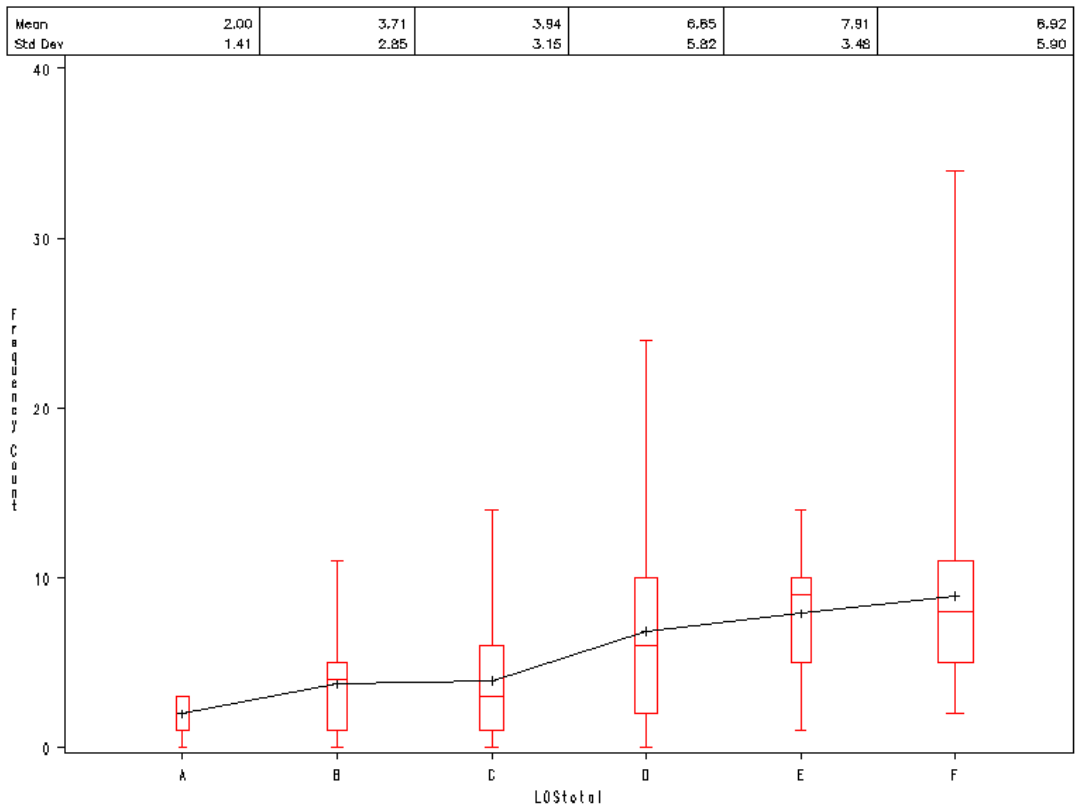

Figure 1. Crash frequency distribution by LOS in a.m. peak

GEE Negative Binomial regression was used for fitting the total crashes in the a.m. peak, midday, and p.m. peak periods (see Table 1) to account for temporal correlation among the repeated observations for a same intersection. In Model 1, total crashes in each time period were fitted by only including LOS indicators, which were treated as categorical variables. Compared to the base case (LOS A), the positive coefficients and low p-values indicate that worse LOS conditions are significantly correlated with more crashes. In addition to LOS indicators, Model 2 included intersection traffic flows, geometric design features, as well as traffic control and operational features. The LOS indicators are still significant in the model 2.

Observations per intersection	3			3		
Maximum Absolute Value	11.4368			5.2267		
P-value	0.0002			0.4311		

Lin et al. *(2002)* proposed a Cumulative Residuals method based on the cumulative sums of residuals for checking the model overall goodness-of-fit. For a GEE model, the distribution of the stochastic processes under the assumed model can be approximated by the distribution of certain zero-mean Gaussian processes whose realizations can be generated by simulation. Each observed residual pattern could then be compared with a number of realizations from the Gaussian process. A p-value larger than 0.20 indicates that the null distribution in Kolmogrov-type supremum test is not violated (*2002*). Model 1 has a large Maximum Absolute Value (11.4368) and a

small p-value (0.0002) for the Cumulative Residuals test; this indicates that the model's overall goodness-of-fit is not acceptable and that only using LOS for modeling crash frequency is not sufficient. On the other hand, Model 2 has a relatively small Maximum Absolute Value (5.2267) and a large p-value (0.4311). Incorporating additional parameters had the desired effect of improving the model's overall goodness-of-fit.

Similar to the box-plots in Figure 1, Model 1 crash frequency increases as LOS deteriorates. However, in Model 2, LOS "E" is the worst situation since it has the highest positive coefficient among the LOS parameters. LOS "D" is significantly better than LOS "C", "E", and "F" in terms of safety. As expected, the model predicts that the p.m. peak experienced more crashes than other periods. As a measure of exposure, higher traffic volumes on major and minor roadways are significantly associated with more crashes; this indicates that under the same operational level intersections with higher traffic volumes will have more crashes. It was found that providing zero or positive offset on minor roads reduced total crashes. Joshua and Saka (*1992*) pointed out that the minimum value of the offset can be zero, but cannot be a negative value in practical design, which would results in unsafe conditions. A higher speed limit on minor roadways is associated with more crashes (coef. = 0.011; p-value = 0.0541). An interesting finding in the model indicates that both positive and zero left-turn lane offsets have a significant benefit in safety. It was also found that the sign of the coefficient for the skid resistance at intersection is negative as expected, which means that higher skid resistance is associated with fewer crashes.

SUMMARY AND DISCUSSION

The crash frequency models show the following relationship between the operational condition and safety:

- Overall, LOS indicator is a significant factor for predicting crash occurrence at signalized intersections. However, the models with only LOS indicator are not significant. It shows that the operational condition itself is not sufficient to predict the safety of signalized intersections.
- Generally, as congestion increases, the crash frequency increases. However, there is a desirable level LOS "D" associating with less total crashes. At LOS "D", operational condition produces a desirable balance between safety and congestion. This phenomenon is obscured when the LOS indicator is used as the only predictor in the models or by only looking at crash frequency distribution trends among different LOS levels.
- The time period factor, with three levels in this analysis, i.e., a.m. peak, midday, and p.m. peak, is significant in the models for total crashes. It indicates that the crash mechanism is different in different times of a day.
- Average delay was tested as a continuous variable but it was found to be insignificant. A six-level LOS indicator is better than average delay in the crash frequency models. It indicates that the relationship between crash frequency and average delay is not linear. The unit change of delay at different congestion levels does not have the same effect on safety. This is shown by the different coefficients for LOS indicators.

Abstract

With the development of computer science and geographic information system (GIS), the graphic-attributes integration system which depends on graphic data and structured data is applicable to aviation accident investigation. Combined with graphics, text and multimedia, Web GIS technology is the core content of Web GIS graphic-attributes integration system. This article is on the basis of clarifying the concept of Web GIS graphic-attributes integration, and introduces the characteristics and framework of system of Web GIS based on B/S mode, and focuses to discuss the function integration, implementation process and key techniques, which provides a guarantee for analyzing aviation accidents.

1. Introduction

The traditional GIS can't meet the requirement of information management due to lack of the consideration of the information media's diverse feature. Hence, it is necessary to create a MIS based on the graphic-attributes integration, leveraging visualization to manage and make a decision (Yao, Jan., 2008). This article introduces a way of leveraging on Web GIS technology as well as the advantage of GIS to the geo-spatial data management, to solve the problem of lacking data integrity of the accident investigation. It realizes the consolidation of graphic-attributes integration under network and provides a display platform of 3-D information for the aviation accident investigation.

2. Web GIS based on B/S Mode

GIS is a system of access, store, query, consolidation, analysis which can also display the geo-spatial data and the related information (Yao, May, 2008). Accident investigation needs to refer to the terrain landform, airport, road, architecture, land, etc. It provides the evidence to determine the accident site and causes through a technology of graphics processing, mapping and visualization.

2.1 Web GIS definition

The Web GIS is a GIS system based on Internet and Client Application, running under Internet WWW protocol. It uses Web pages as users' interface. From

any WWW dot, the user can browse and access the data, index, and analyze, it makes the user be able to interact。

2.2Web GIS features

The traditional GIS has many disadvantages, like high development cost, inefficient operation and multi-accessing net bottleneck, it is difficult to ensure the integrity and also hard to operate and release. Table1 list the advantages of Web GIS based on B/S, comparing with the traditional GIS：

Table 1.The comparison of the two different GIS.

	Traditional GIS	Web GIS
Development Cost	High	Low
Response Time	Slow	Fast
Platform of Client Cerver	Weak	Powerful
User Interface	Simple	Rich
Tools of the Development and Support	Rich	Rich and Widely Used
Typical Platform and Product	ArcGIS, MapInfo,...	Google Earth, World Wind(NASA), UrMap,...

3. The function of Web GIS graphic-attributes integration

3.1 The conception of Web GIS graphic-attributes integration

Various sources needed to be collected in the aviation accident investigation, which includes wreckage and data of the accident site and all kinds of photos, flight data, satellite images, aerial photos, geographic data, AIP data, etc(ICAO,2001). Although the information needed to be examined varies, it can be categorized into graphic data and structured data, in which the graphic data can be divided into image and vector data. Web GIS graphic-attributes integration system refers to seamless integration between the graphics and structured information based on computer technology, then access to and develop the information, display and input between graphics and structured data can be achieved in this system(CHENG, 2008). It makes the image match the vector data in the accident investigation, and then incorporate with the structured data like flight data, which not only overcomes the drawback of simply dependent on the vector data applied to accident analysis, but connects more information.

3.2 The function integration

The accident reconstruction technology based mainly on flight data recordings, cockpit voice recordings, radar data, witness information involves many aspects of accident investigation, including field investigation, causes analysis, accident rating determining, safety recommendations, etc. It can mark related information on the flight path (Li, 2007). According to the thinking of Web GIS graphic-attributes integration, the accident reconstruction includes accident site reconstruction and digital AIP charts.

3.2.1 Accident site reconstruction

An overall description should be made in the accident investigation to determine and mark the first impact point between the aircraft and obstacle (terrain) and main scattered objects in follow-up track and flight path. It also determines the basic state of the aircraft wreckage and reconstructs the accident site by photos and

videos for the scene of accident. This system which makes the landform of accident site as background can describe wreckages by legends and localize them by latitude & longitude. Reconstruction of the site involves several steps as shown in Table 2:

Table 2. Five steps in reconstruction of the accident site.

Step Number	Contents
Step.1	Establish the wreckage legend library
Step.2	Use latitude & longitude to determine wreckage distribution, finish reconstruction and define for wreckage point object
Step.3	The position and size of wreckage legends are fit for accident site by rotating and conducting scaling
Step.4	Define the first impact point, the main scattered objects in flight path and other significant features
Step.5	Finish the reconstruction of wreckage distribution on accident site

3.2.2 The application of digital AIP charts

The Figure.1 is a schematic drawing according to actual air traffic control of an airport. Located in the runway at both ends of the oval-shaped surfaces are holding areas which are defined by IAP; Lines are routes; English letters are designators and names which represent radio aids; Numbers are channel frequency. This three dimensional demonstration platform takes the real airport terrain landform as background, overcomes the drawback of simply dependent on the vector data applied to express information, and adopts image combining vector data to intuitively reflect the departure/arrival procedures which need to follow during take off and land. Moreover, it can use Web GIS latitude & longitude timely to define (refresh) information of the marked point, and promptly reflect the deviation. In this way, it is facilitate to investigator for position of the accident site and the process of anomaly.

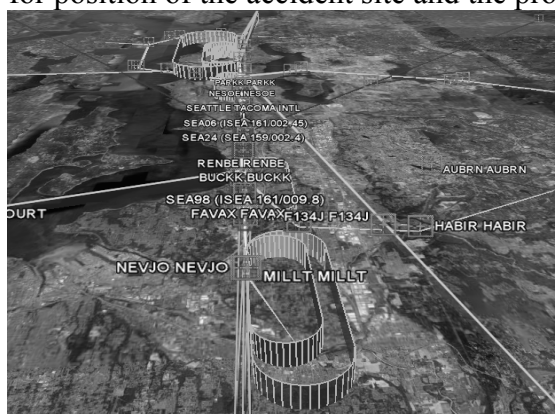

Figure.1 Digital AIP charts.

4. Implementation of system and key technique

4.1 Implementation of graphic-attributes integration

4.1.1 Introduction of Google Earth

Traditional GIS data uses two-dimensional platform to display. It can not rotate, nor show the depth of field, and sometimes can not distinguish the different colors (SUN, 2007). Therefore, we can not observe the crash point from different angles, nor can different levels are set up to analyze the flight path, so the visual part of the target has been greatly constrained. Google Earth provides global landform and

3D data, and creates the conditions for three-dimensional dynamic display.

4.1.2 KML language

KML(Keyhole Markup Language), developed by Google, is standard data based on XML grammar and file format which is used to describe and preserve the geographic information such as points, lines, planes, 3D models etc.

The functions can be illustrated as follows:

1. Distinguish locations with legends and marks
2. Designate clear visual angles for each view to set up different close-ups
3. Designate description based on easy HTML grammar for each feature, and support hyperlinks and embedded pictures.
4. Load KML file from local or remote network address dynamically.
5. When the Google Earth client view changes, send automatically view information to the specified source server and obtain useful information.

4.1.3 Expression and function of data of KML in Google Earth

Google Earth provides global physiognomy, and adds different layers in Google Earth by creating KML files to integrate display of graphics and structured data. Table 3 introduces six types of display provided for adding GIS data in Google Earth：

Table 3. Six kinds of data type for the addition in Google Earth.

Data Type	Application
Placemark	Locate what you want to search
Path(Lines)	Depict route, flight path and other related segments
Polygon	Outline the contours and shape features
GroundOverlay	Use the local information affixed to the corresponding region
ScreenOverlay	Match with GroundOverlay to describe position
3D Data	Set 3D model to directly show geographic images

Geo-spatial data model only deals with real entities and graphic images in coding. The thought of graphic-attributes integration should not only match images and vector data on the information platform of accident investigation, but also add structured data to the KML marked points, which include the property name, type and related flight parameter. KML uses kml, Document, Folder, Placemark as a root tag of KML file to organize information and inherits the implementation of geographical expansion of the target property value.

4.2 Data management

This Figure 2 shows the framework of Google Earth system development which is based on B/S. This mode takes Google Earth server as a center, and establishes Http transmission protocol of the three-tier. The first one: Google Earth Browser layer, it can provide map browsing and three-dimensional demonstration platform, and also output the interactive final query results between users and server. The second, Google Earth Server layer, it stores plenty of GIS data, including images, KML files, etc. This server also responds to the users' requests and simultaneously executes the related inquiry operation and data communication. The third one, User Server layer, it not only publish can the map and additional GIS data, display them on Google Earth Browser by user application software, but also may read those data from the application software and save it in user server.

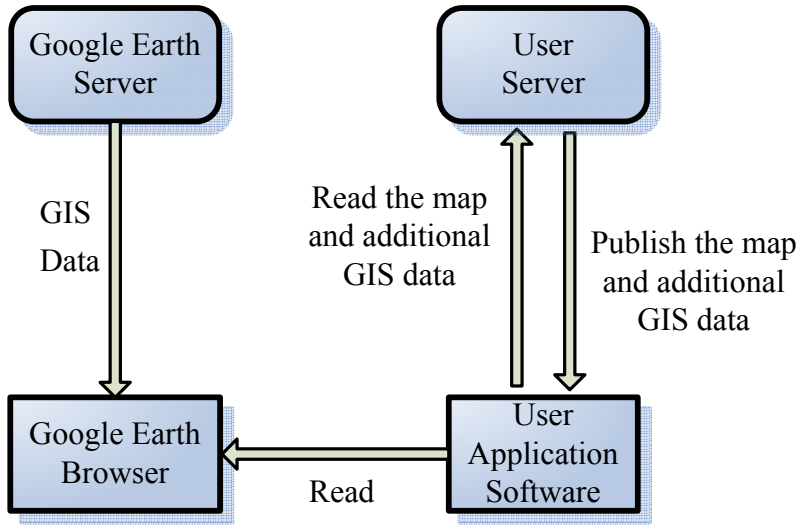

Figure 2. The general framework of Google Earth system development.

The graphic-attributes integration system involves graphic data, entity attribute, and photos, files, video, audio and other multimedia data. This technology must firstly deal with how to carry out the centralized management of various data. With the rapid development of object-oriented relational database technology, all of the commercial databases, such as oracle, SQL Sever, provide support for large binary object type to meet the feature that the spatial data dynamic growth in non-structure, which make it possible for the spatial data to save in relational database. Figure 3 shows the mode of object—relational database management, it makes geo-spatial data and their attribute mixed in the background large-scale relational database to manage them uniformly (Wu,2002).

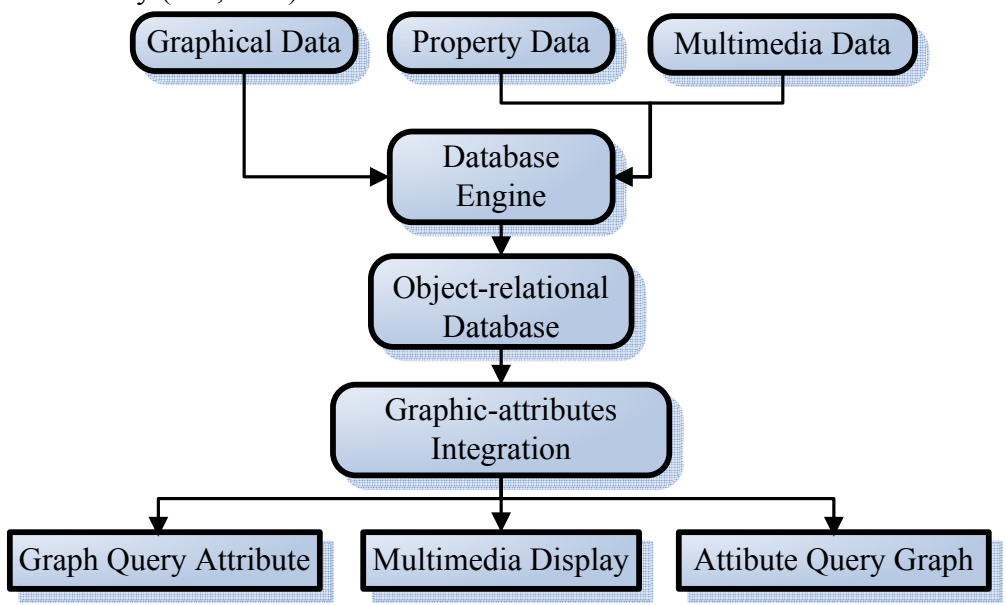

Figure 3. Object-relational database management mode.

5. Conclusions

This article presents a new design of Web GIS graphic-attributes integration system for aviation accident investigation, and discusses the major technologies of the function integration, implementation process, data management model. The system creates a platform enabling multi-layer, three-dimensional, visual display of information, and combines GIS graphic data and structured data, and therefore realizes real "graphic-attributes integration". With the rapid development of computer technology and GIS, further theoretical research and practical development is in great demand, so as to better fulfill the demand of aviation accident investigation.

ABSTRACT:
Tire mark intelligent identification and comparison is a key procedure in determining and tracing the violating vehicles at traffic accident scene survey, but in some cases the acquired JPEG image is hard to recognize due to the low contrast and the nonuniform background brightness. This paper puts forward image enhancement algorithm based on the JPEG decoder and develops a software system by Visual C++6.0 for this purpose. The histogram equalization (HE) and adaptive histogram equalization (AHE) are used to improve the global and local image brightness and contrast individually in image enhancement algorithm. The application results show that this system is effective to tire mark image enhancement, which lays the foundation for intelligent comparison and identification of tire mark.

INTRODUCTION

Tire mark is important evidence in accident investigation. It can be used to presume the impact locations and driver's behaviors as well as vehicles' heading, minimum speeds before the collision, and post collision trajectories, etc., in accident reconstruction. Especially, it can be used to identify the possible tire involved and reduce the scope of vehicles' investigation in the case of hit-and-run accidents. In practice, tire marks can be recognized by investigators or policemen using a simple skill such as the vehicle heading from the drivers' description, the position of the stopped vehicles and the tire-marks etc. Being a high complexity of accident scene such as multi-cars accident, and new and old tire marks irregularly distributed on the roadway. Therefore, it is necessary to develop an intelligent identification system to aid the traffic accident investigation and analysis. The evidences mainly resulted from JPEG image of tire mark taken by DC at accident scene. It is very important to acquire good quality images, but in practice a significant percentage of acquired images are of poor quality due to some environmental factors or user's body condition. The poor quality images of tire mark cause that many details may be ignored. Therefore, it is a great help to develop an image enhancement algorithm of tire mark to improve quality of accident appraisal.

Image enhancement algorithms have been designed to process a given image so the results are better than the original image for their applications or objectives [Jae, 1999]. Image enhancement has as main task to improve the visual quality of an

image from the human perspective. It uses several techniques, such as histogram equalization, contrast stretching, and slicing, that were initially developed for grayscale images. However, several attempts have been made to generalize the aforementioned techniques to color images. The generalization has been proven to be rather complicated due to the various color models and the relationships between the color components.

IMAGE ENHANCEMENT OF TIRE MARK

JPEG decoder of tire mark image

The JPEG image standard is by far the most popular method for storing and exchanging photographic image files. The term 'JPEG' actually covers a wide range of related methods developed by the Joint Photographic Expert Group in the late 1980s. JPEG includes standards for both lossless and the more common lossy compression, as well as progressive rendering techniques for encoding images to be sent over slow transmission lines (such as the Internet).

JPEG is a popular image compression standard, representative of discrete cosine transform (DCT) methods used in many image and video compression algorithms. JPEG includes a variety of techniques, but baseline sequential color decoding is by far the most popular and is the technique considered in this implementation. JPEG can be compressed with different quality factors (Price1999).

In JPEG compression, pixels are usually represented using 8-bit luminance (Y) and red (Cr) and blue (Cb) chrominance component values. The basic unit of compression is an 8x8 set of component values. Because the human eye is most sensitive to luminance, it is typical to sample the Y value four times for every chrominance pair. The original image is divided into minimum-coded unit (MCU) regions, where each MCU includes all component blocks necessary to reconstruct that region. In the typical case with down sampled chrominance values, each MCU would contain four luminance blocks and two chrominance blocks representing a 16x16 pixel region in the original image. MCUs are processed from left to right and top to bottom to reconstruct the image. When compressing, each block is DCT transformed into the frequency domain, and the frequency values are quantized to reduce the information, with many of the higher frequency coefficients becoming zero. The coefficient values are zigzag ordered to maximize runs of zeros, and the values are run-length and Huffman encoded.

The decode flow (see Figure 1), begins by reading the header information to determine the JPEG type and the number and composition of MCUs. Tables needed for decoding and dequantization are read in. The remaining stream contains the compressed values for all the MCUs in left-right, top-bottom order. As the stream is read in, the values are Huffman decoded and expanded to recover each MCU's coefficients. Because of the Huffman codes, the amount of bits required to be read from the stream varies between MCUs. Each 8x8 block within the MCU is scaled by the appropriate array of quantization values, and then run through an inverse DCT

transform to recover an approximation of the original Y, Cr, or Cb component values. Once all component blocks have been recovered, the chrominance values may need to be upsampled, and each YCrCb pixel is converted to RGB representation.

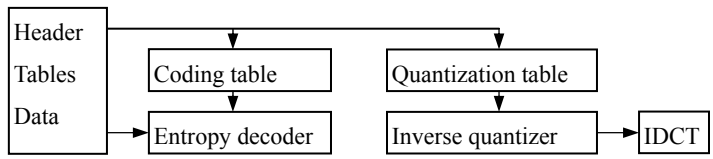

Figure 1. The JPEG decoder

Brightness and contrast enhancement of tire mark image

The image enhancement of tire mark includes brightness correction and contrast optimization adjustment. Equalization of color images can be realized by applying the grayscale image equalization method separately to the Red, Green and Blue components of the RGB color values of the image. Still, it should be noted that applying the same method on the Red, Green, and Blue components of an RGB image may yield changes in the image's color balance since the relative distributions of the color channels change as a result of applying the algorithm. Brightness and contrast enhancement includes: linear stretch, histogram equalization (HE), adaptive histogram equalization (AHE) (Sherrier1987), and multi-scale enhancement (Jian, 1994) and etc. This paper adopts the HE for the global brightness and contrast enhancement, and AHE for local tire mark.

The HE algorithm is used to image handling, and its expression is as follows:

$$cdf(v) = round(\frac{cdf(v) - cdf_{\min}}{(M \times N) - cdf_{\min}} \times (L-1)) \quad (1)$$

Where $cdf(v)$ is the equalization value of cumulative distribution function;

$cdf_{\min}$ is the minimum value of the cumulative distribution function; and

M × N gives the image's number of pixels and L is the number of grey levels used.

$cdf(v)$ is defined by:

$$cdf(v) = \sum_{j=0}^{i} p(x_j) \quad (2)$$

Where $p(x_j)$ is the probability of an occurrence of a pixel of level i in the image.

AHE is a local enhancement technique mapping based on small overlapping areas of an image. There are the cases in which it is necessary to enhance details over small areas in an image. In AHE rectangular, sub image of an input image is first defined. Histogram of that block is obtained and Histogram Equalization function is determined. Finally, processed sub images are represented together with bilinear interpolation (Gonzalez, 2002).

A description of the function algorithm implemented for AHE follows (Kearfott, 1996). First, a contextual region of size k pixels is used to define a neighbourhood centered ground some given pixel. The local histogram of gray levels, h(n), is then determined. The rank is computed at the center pixel for a region I having size by k using:

$$r(i) = \sum_{n=0}^{k} h(n) \tag{3}$$

The set of ranks is normalized so that $0.0 < r'(i) < 1.0$. A value of the enhancement factor, $0.0 < A < 1.0$, is chosen for stretching the maximum and minimum toward the ends of gray level distribution function.

The enhanced pixel value, $g(x,y)$, is obtained from the following, which yields a nearly uniform histogram of output image:

$$g(x,y) = [r'(i) * (i_{\max} - i_{\min}) + i_{\min}] * A \tag{4}$$

Where the derived local maximum and minimum, i_{max} and i_{min}, are specified for the contextual region. For an entire image, composed of an array of perceivable gray values, one computes the expected information that any pixel contains, or the image entropy, from:

$$H = -\sum_{x=0}^{M} p(x) \log_2 p(x) \tag{5}$$

Where *P(x)* is the probability of occurrence of intensity x in the image, with $0 < x < M$, where M is the maximum gray level. It has been shown that the information content and entropy are maximized when all signal levels are equiprobable.

Brightness and contrast adjustment of tire mark image

In Microsoft visual c++6.0, brightness and contrast adjustment of tire mark image can be realized by matrix transformation, see the equation (6) and (7).

$$[R_B] = [R][T_B] \tag{6}$$

$$[R_C] = [R][T_C] \tag{7}$$

Where $[R_B]$ is modified brightness matrix; $[R_B] = [R_B \quad G_B \quad B_B \quad A_B \quad 1]$, $[R_C]$ is modified contrast matrix; $[R_C] = [R_C \quad G_C \quad B_C \quad A_C \quad 1]$; $[R] = [R \quad G \quad B \quad A \quad 1]$; b is the brightness; c is contrast.

$$[T_B] = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ b & b & b & 0 & 1 \end{bmatrix} \quad [T_C] = \begin{bmatrix} c & 0 & 0 & 0 & 0 \\ 0 & c & 0 & 0 & 0 \\ 0 & 0 & c & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0.5(1-c) & 0.5(1-c) & 0.5(1-c) & 0 & 1 \end{bmatrix}$$

IMPLEMENTATION AND RESULTS

The JPEG image enhancement of tire mark (JIETM) is one of the most important parts of the intelligent identification of tire mark. The functional flow chart of the JIETM system is shown in Figure 2. Since the system is an independent

software which can't be dependent on any other software, such as Photoshop, CorelDraw … etc, it is developed by using Microsoft Visual C++6.0. It consists of JPEG decoder, brightness correction and contrast enhancement, brightness and contrast adjustment and JPEG save (encoder).

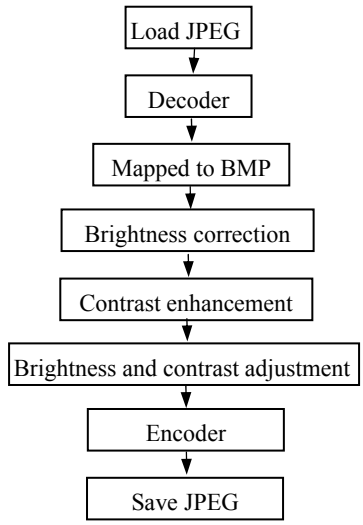

Figure 2. Flow chart for image enhancement of the tire mark

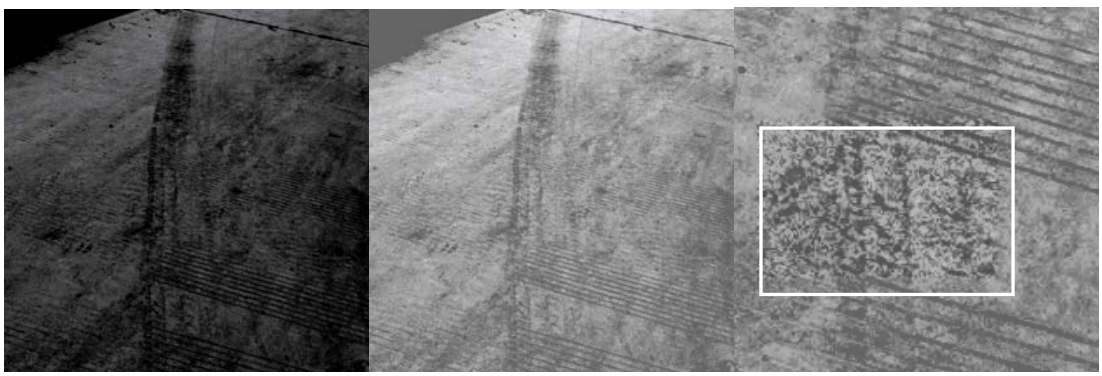
To verify the effectiveness of the proposed method and robust of developed system, experiments were performed with many JPEG image with nonuniform brightness levels and low contrast levels from the actual accident scene. Figure 3 shows handling results of an image obtained from the real accident scene located in Sichuan province by applying the software. The results show that the software gains the better visual effect both in global range and local image. According to the application results of many other images, it is found that the software has high practicality and effectiveness in improving incorrect exposure, but in some cases, when the pavement texture color and tire mark had no significant difference, it is hard to remarkably improve the image quality.



(a) Original. (b) Brightness correction. (c) Contrast enhancement.

Figure 3. Test image of tire mark on accident scene

CONCLUSION

In this paper, a computer implementation based on visual c++6.0 has been presented for image enhancement of tire mark. It deals with JPEG images by decoder and encoder, determines the brightness and contrast of image by HE and AHE algorithms, and adjusts the pixel by matrix transformation. The global adjustment is performed by HE algorithm, and local adjustment can be executed by AHE algorithm. The results show that the system produces good visual effect with shorter time consuming, and the method proposed using HE and AHE has achieved the better performance for low contrast and nonuniform brightness images. The system lays the foundation for intelligent identification and comparison of tire mark, and can be applied directly to handling color JPEG photos taken in the accident scene. But, the system is only effective in some case because of the difference of road surface and interference from other mark. In the future, and in order to achieve better effects, the different enhancement algorithms should be studied.

ABSTRACT

There is a phenomenon of traffic accident migration in the highways after used for some period, especially those that have been improved for traffic safety. In order to make sure the hypostasis and causes of the phenomenon, the character of this phenomenon was analyzed and induced, based on the investigation of traffic accident data of 5 years occurring in a freeway in South China. Then the possible causes of traffic accident migration were researched. And some potential causes of traffic accident migration was analyzed by studying accident causes and analyzing the variation of infrastructure and safety measurements of the freeway.

INTRODUCTION

The accident migration is a phenomenon which is found when accident data was statistically analyzed along a highway. The phenomenon was a puzzle whether the measurements of traffic safety improvement adopted in a black spot positively impacted the traffic safety of the whole highway. The accident migration was suggested that may indeed exist after intersections were converted to multiway stop control (Persaud, 1986). A migration of accidents from one location to another was distinctly found as an effect of adding an additional non-standard mixed-flow lane to a freeway in a restriping and reconstruction projects (Levine et al, 1988). And a potential for accident migration was showed through micro-simulation to application of variable speed limits on I-4 in Orlando, Florida (Abdel-Aty et al, 2006).

There were two viewpoints about the causes of the accident migration. One was that the statistical analysis deviation caused the phenomenon of accident migrations. Some researchers found there was a bias in the before and after comparison of accident frequencies in sites due to impropriety of the process of dividing the whole highway into some sections by a kind of rules (such as equidistance). The bias and its causes was proved by presenting a new probabilistic hypothesis and analysis of simulation result (Maher, 1987). And a bivariate negative binomial model was established to explain traffic accident migration (Maher, 1990).

The other was that the driver's risk compensation effect caused the accident

migrations. The drivers escaped from the potential threat of traffic accident owing to the safety improving measurements in the sites the measurements bringing into effect. And consequently they would be less aware of the dangerous during driving. The reduction of vigilantness may continue for a long distance and increase the risk of traffic accident in neighborhood sections of the sites, which is called the risk compensation. On the basis of this, the authenticity of accident migrations was verified and the scope of the migrations was researched (Boyle et al, 1984).

Although some evidences and research have proved the presence of accident migration, and its causes were analyzed, there is still some controversy over whether or not this effect actually exits. And there are no established techniques yet available to estimate such a effect for a particular site (PIARC, 2003). In this paper, new cases of accident migration were presented and their character and causes were analyzed based on road traffic accident data in China.

GENERAL INFORMATION ABOUT THE G4 FREEWAY

The G4 National Freeway is an important and busyness highway corridor from North China to South China. The section which was discussed was about 109 kilometers long in South China. There are many sharp turns, long and abrupt longitudinal gradients, grand bridges and long tunnels in the section when it goes through the natural calamitous mountain area of South China, which caused the high risk of traffic accident, macroscopically.

Table 1. Design Guide Line of The Section of The G4 Freeway.

Design Guide Lines	Unit	Value	
		Hilling Terrain	Mountain Terrain
Design Speed	km/h	100	80
Subgrade Width			
Entirety	m	24.5	23.0
Separate	m	2×12.5	2×11.75
Least Radius of Horizontal Curve	m	1000	500
Maximal Longitudinal Gradient	%	2	5
Least Radius of Vertical Curve			
Protruding	m	10000	8000
Concave	m	12611	8000

The section is a bidirectional freeway with four lanes. different criteria is adopted in hilling terrain segments (from K0 to K13 and from K85 to K109) and mountain terrain segment (from K13 to K85) of the section. The design guide lines of the two kind of terrain was shown as Table 1. The section was open to traffic in April, 2003. And two phases traffic safety improvement projects were implement in 2004 and 2005 because of severity of traffic accident.

BLACK SPOTS ANALYSIS

More than 2200 traffic accident have occurred during the period from April,

2003 to December, 2007 in the section of the G4 freeway. And there are 557 severe traffic accident one of which leads at least one death or three grievous bodily harm. Based on analysis on spatial distribution of the severe traffic accident, the black spots of the section were found by means of cumulative relative frequency (Pei Yu-long, Wang Wei, 2004).

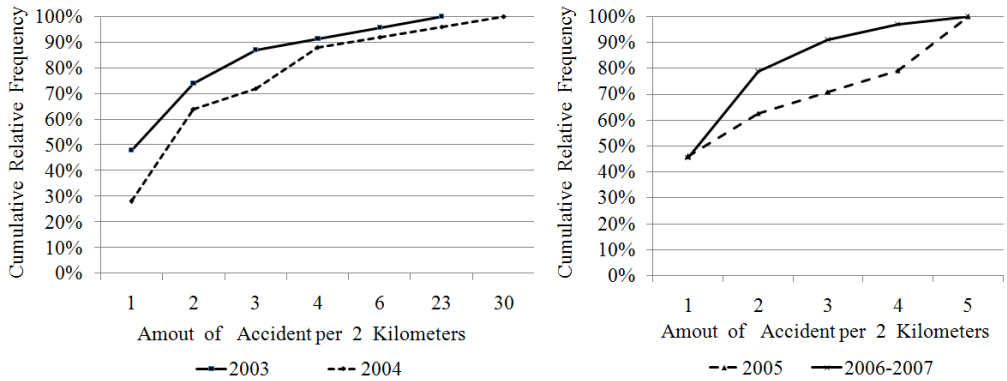

Figure 1. Cumulative relative frequency curves (downwardness).

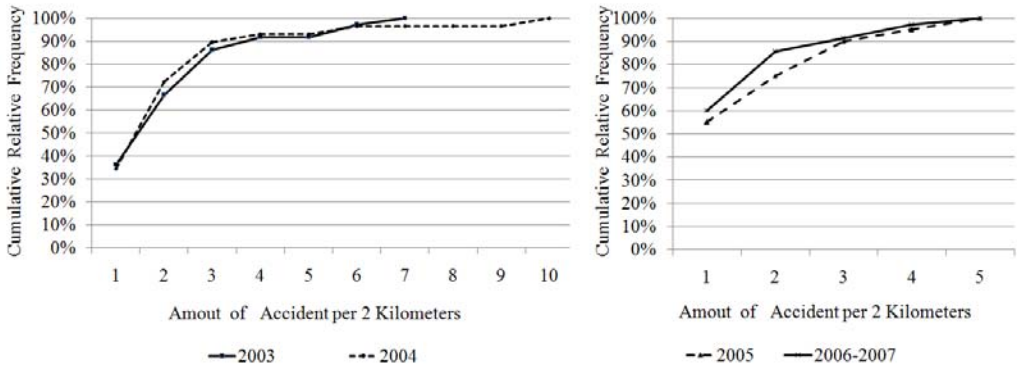

Figure 2. Cumulative relative frequency curves (upwardness).

Table 2. Number of Black Spots.

Period	Direction	Criteria	Number of black spots
2003	downwardness	3	6
	upwardness	3	11
2004	downwardness	4	7
	upwardness	3	7
2005	downwardness	5	9
	upwardness	3	5
2006-2007	downwardness	3	3
	upwardness	3	5

The accident data was disparted into two parts by different direction of upwardness (from South to North) and downwardness (from North to South). The traffic accident occurring frequency was counted in the freeway segment per 2 kilometers. Then the cumulative relative frequency curves was drawn every year

from 2003 to 2007 by counting the frequency of sites where the amount of accident was the same (seeing Figure 1 and Figure 2). The year of 2006 and 2007 were considered as one period of time for the safety improvement projects were accomplished in 2005.

The threshold filtering black spots was confirmed, according to cumulative relative frequency curves. The sites where the amount of accident was equal to or more than the value in the inflexion of the curves or in the point of cumulative relative frequency being greater than 85% (seeing Table 2).

CHARACTER ANALYSIS OF THE ACCIDENT MIGRATION

A kind of chart can be drawn to describe the spatial relationship of black spots in different periods by labeling the black spots with a coordinate of mileage (x axle) where the sits located and year (y axle) when the sits were considered as a black spot. And the size of the points in the chart represents the amount of accident occurring in the site. This kind of chart was drawn according to analysis of black spots of the two directions in order to find the phenomenon of accident migration (seeing Figure 3 and Figure 4).

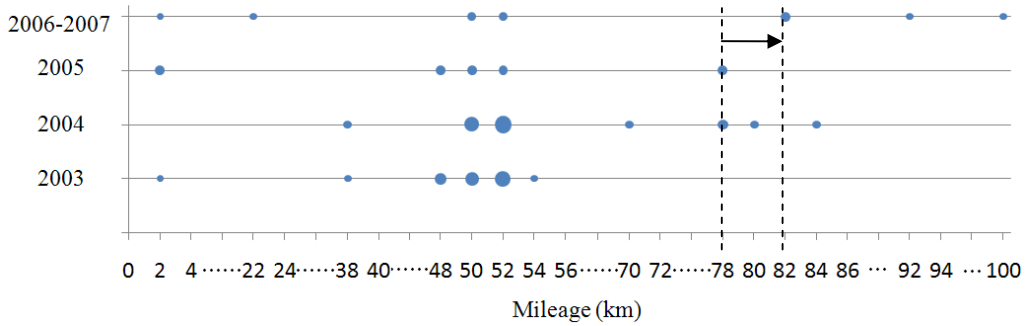

Figure 3. Spatial relationship of black spots (downwardness).

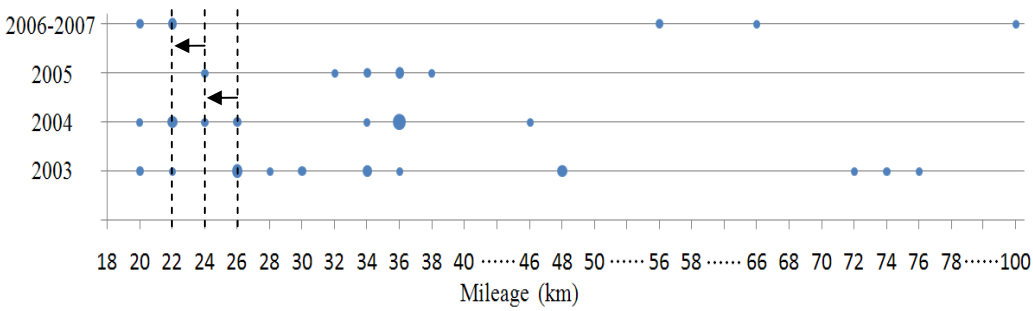

Figure 4. Spatial relationship of black spots (upwardness).

By analyzing spatial relationship of black spots, an accident migration from the segment of K76 - K80 to that of K80 - K82 can be found after the safety improvement of 2005 in downward direction. And an accident migration can be found in the segment of K20 - K26 in upward direction.

The downward Segment of K76 - K82. A spatial relationship of accident

which occurred in the downward segment of K76 - K83 was drawn by labeling the actual mileage of the accident, by which a more accurate spatial relationship was described (seeing Figure 5). So accident congregating in the segment of K77 - K79, especially nearby the site of K78, can be found in 2004 and 2005. Contrastively, there was only one accident occurring in site of K78 during the two years period from 2006 to 2007. And the four accident occurring in the site of K82 (where severe accident seldom occurred before 2006) indicate a new black spot during the period from 2006 to 2007. So the accident migration can be concluded from the segment of K77 - K79 to that nearby K82.

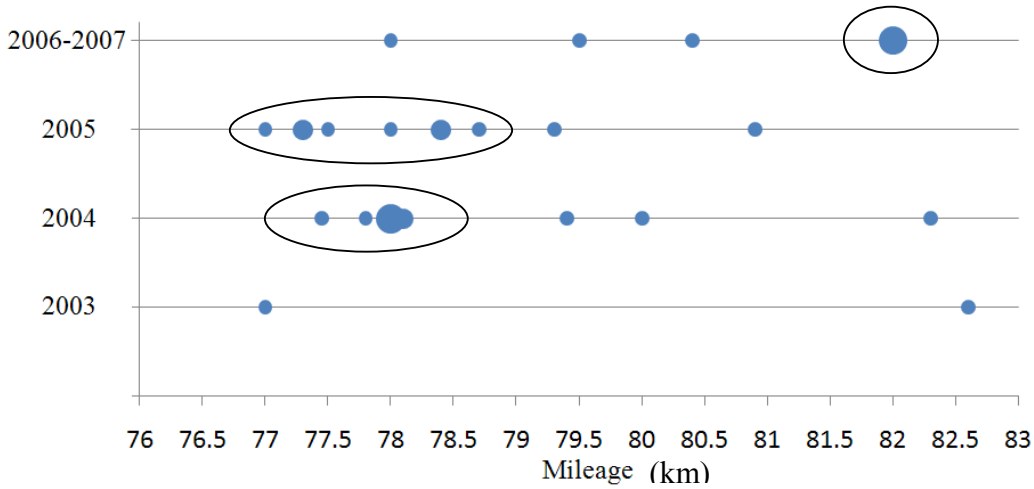

Figure 5. Spatial relationship of accident (downward Segment of K76 - K82).

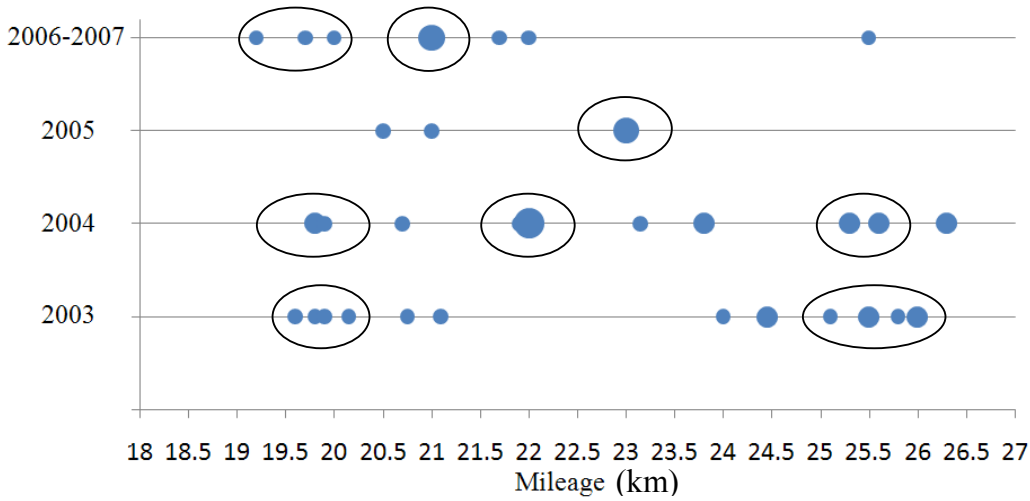

Figure 6. Spatial relationship of accident (upward Segment of K20 - K26).

The upward Segment of K20 - K26. There was a seeming macroscopical trend which the accident-congregating sites migrated from the segment of K25 - K26 to north (direction of mileage decreasing). But the segments of accident

congregating during the period from 2006 to 2007 were also site where accident congregate in 2003 and 2004 (seeing Figure 6). So it was unable to conclude the existence of accident migration from segment of K25 - K26 to that of K20 - K21.

CAUSES ANALYSIS OF THE ACCIDENT MIGRATIONS

The design and safety improvement countermeasure of the segment of K76 - K82 and K20 - K26 was investigated in order to find the causes of the migration perhaps occurring in the two sites. And the character of migrations was defined farther by analyzing the causes.

The downward Segment of K76 - K82. There are two tunnels in this segments with horizontal curves. The first tunnel located in the segment of K76 - K78 is more than 2,100m long with the alignment combined with two curves whose radius is 1,900m and 1,000m respectively and one straight line about 800m long. There was about 16 rear-end accident occurring in the tunnels because of the bad sight distance and overspeed according to analysis of the accident data. Speed control devices, sight guidance device and enhancing enforcement of police were implemented in the process of safety improvement projects during the period from 2004 to 2005. Then little accident occurred in this tunnel in 2006 and 2007. However, there is another tunnel in the segment of K81 - K82 which just locates in the lower reaches of the first tunnel. The alignment of the second tunnel is also combined with two curves whose radius is 2,300m and 1,560m respectively. Four accident occurred in the second tunnel in 2006 and 2007. Contrastively no severe accident occurred in the second tunnel before 2006.

So the accident migration from the segment of K77 - K79 to that nearby K82 can be explained by the theory of the risk compensation.

The upward Segment of K20 - K26. There is a continuous long downgrade just in upper reaches of this segment which is more than 10km long with average gradient of 3%. On the one hand, the accident occurring in this segment was mainly due to brake heat fade and lose control of vehicles impacted by the continuous long downgrade. Truck escape lanes and service zone were rebuild at the end of the continuous long downgrade during the process of safety improvement in 2005. On the other hand, there is a long straight line from K20 to K22 and the average gradient of downgrade in this segment is almost 4%. Partly because of the existence of the long steep downgrade straight line, there was rear-end accident in almost every years during the period from 2003 to 2007, and there was more than 10 accident in the segment at the end of the long straight line (nearby K20) during the past 5 years, according to the analysis of accident data.

So it was different of the main causes of accident occurring in the segment of K25 - K26 and that of K20 - K22. And the causes of accident occurring in the segment of K20 - K22 had existed before the safety improvement implement.

Therefore it was difficult to define the accident migration from the segment from segment of K25 - K26 to that of K20 - K21, although the traffic was also impacted by the continuous long downgrade in upper reaches of K26.

CONCLUSION

A case of traffic accident migration was presented based on freeway accident data in China. The phenomenon of accident migration was found by means of drawing and analyzing a kind of chart of spatial relationship of accident. And the facticity of two accident migrations was analyzed and distinguished.

Causes analysis of the accident migrations was done by comparing the accident data before and after the safety improvement effort and analyzing the alignment of the freeway. It was proved important that paying more attention to the segment of lower reaches when traffic safety of a site was improved according to the case of accident migration.

The existence of accident migration was proved again according traffic accident data in China. However, the causes of the accident migration, for example risk compensation, still need to be approved by some research based on direct data.

ABSTRACT

In order to arrange the route of hazmat transportation reasonably and reduce the harm brought by hazmat accidents, influencing factors including transportation cost, environmental risk, rescue capability, road accident risk, population risk, and traffic condition in hazmat transportation under time-varying conditions are analyzed. The urban road network in Changchun city was selected as the research object, an optimum model of transportation route under time-varying conditions was established based on ArcGIS and evaluated and analyzed using real data. The results show that the route optimized under time-varying conditions of the model is reasonable, and the graphics description is valuable for supervisors.

Key words: *Hazmat transportation, Urban road network, Route optimization, Time-varying, ArcGIS*

0 INTRODUCTION

In recent years, with the increasing of hazmat transportation volume year by year, traffic accidents related to it have also been increasing. Because the hazmat traffic accidents happen often accompanied by disasters (leakage, combustion, explosion, poisoning, etc.) so that the after effects and influence are serious. Therefore, the scientific and reasonable measures of hazmat transportation in all aspects of management are very necessary, while route optimization is the most important part of hazmat transportation.

From the existing research (Miaou et al. 1991), most of the hazmat transportation routes optimizations are single-objective, just for transportation costs, distance, time and risk etc., and the hazmat transportation is reduced to the shortest route problem (Revelle et al. 1991; Sung et al. 2000), and the majority are focused on the theoretical analysis (Wu et al. 2004), and less practical (Wang et al. 2009).

In this paper, a route optimization model of hazmat urban transportation under the time-varying conditions is created based on a GIS platform.

1 MODELING

1.1 Analysis of modeling target

Generally, in hazmat transportation, three of the most typical objectives are considered: cost, risk and equity.

1.2 Analysis of influencing factors

The influencing factors include transportation cost, environmental risk, rescue capability, accident risk, population risk, and traffic conditions. The first three do not have time-varying characteristics, while the latter three do.

- Transportation Cost - includes two elements: distance and time.
- Environmental Risk - the harm of hazmat transportation accidents to the surrounding environment.
- Rescue Capability - evaluated by the distance between the accident location and the surrounding rescue facilities.
- Accident Risk - The accident risk value of hazmat transportation route is the sum of all of the sections of the road. The accident rate is different at different times of the day.
- Population Risk - There is no obvious difference among the threats brought by the hazmat leakage to the separate individuals in the region within a certain distance. Therefore, the spots with dense population are chosen as the centers in this paper, sub-divided into three different regions according to the different distances, named as buffer that is the high-concentration zone (zone 3), the middle-concentration zone (zone 2), low-concentration areas (zone 1), concentration is changed with distance. When section of road lies in the 1,2,3-class buffer zone, risk of population exposure is low, middle and high separately.
- Traffic Condition – Forbidden pass or restricted pass etc. in technology or by law, as well as traffic jams, delay etc. need to be considered in route choice of hazmat transportation.

1.3 A Time-varying Route Optimization Model

$$R = \left[\sum_{c=1}^{n_c} \left[w_c \sum_{cf=1}^{n_{cf}} w_{cf} s_{cf} \right] \right] \tag{1}$$

where c is risk type; n_c is the number of risk type; w_c is the percent weight of c; cf is the factor of c type; n_{cf} is the number of the factor of c type; w_{cf} is the percent weight of the factor of c type; s_{cf} is the level of the percent weight of the factor of c type.

Formula (2) is comprehensive cost at the time-varying conditions, where,

w_f is the weight of each factor.

$$Cost_{t_m,route} = w_{tra_cost} \times F_{TC}\begin{Bmatrix} t_l_{t_m,route} \\ t_t_{t_m,route} \end{Bmatrix} + w_{acc} \times F_{AR}\left\{r_a_{t_m,route}\right\} + w_{pop} \times F_{PR}\left\{r_p_{t_m,route}\right\}$$
$$+w_{entir} \times F_{ER}\left\{r_e_{route}\right\} + w_{succor} \times F_{RC}\left\{s_c_{route}\right\} + w_{traffic} \times F_{TC'_{t_m,route}} \quad (2)$$

Get the optimal route of urban hazmat transportation under the time factor, as:

$$Route_{t_m}^{opt} = \min Cost_{t_m,route} = \min \sum_{t_m,arc} Cost_{t_m,arc} \times arc \quad (3)$$

$Cost_{t_m,route}$ is the comprehensive cost of hazmat transportation route at t_m time segment; $Cost_{t_m,arc}$ is the comprehensive cost of road section at t_m time segment; $Route_{t_m}^{opt}$ is the optimal route of hazmat transportation route at t_m time segment; t_m is the period of the time hazmat vehicle run in ; $m = 1,2,\cdots\cdots,24$; arc is 0 or 1.

2 APPLICATION AND EVALUATION OF THE MODEL

2.1 Assumption and the initial conditions of data

The accident statistical data from the traffic police department are regarded as an objective reflection of the actual accidents; section of road is the object in the calculation of accident risk analysis, and the range of the road section is defined in [0, 5] km ; only the delay of a typical intersection is analyzed.

- Accident risk - Hourly distribution of yearly road traffic accidents is based on the statistical urban accident data from the traffic command center in Changchun City, as shown in Figure 1:

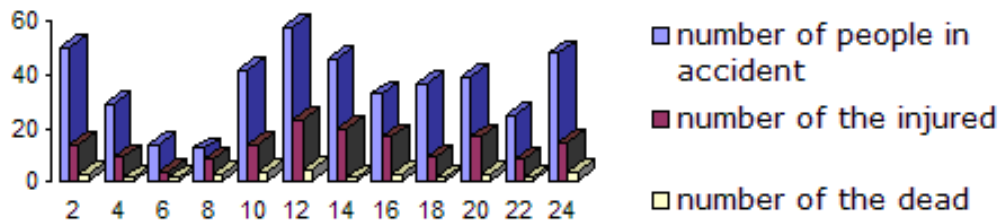

Figure 1. Hourly distribution of yearly road traffic accidents.

The frequency of historical accidents that happened in a certain period of time is regarded as the modifying coefficient of the accident risk.

$$risk_acc_{t_m,route} = \sum_{t_m,arc} (a_{t_m,arc} \times acc_prob_{arc} \times acc_level_{arc} \times leak_prob_{arc}) \times arc \quad (4)$$

where, t_m is the time period of hazmat transportation vehicle，$m = 1, 2, \cdots\cdots, 24$；$A_{t_m}$ is the number of accidents occurred in the period of time t_m；$risk_acc_{t_m, route}$ is the accident risk of hazmat transportation in the period of time t_m.

- Population Risk - The schools, malls, restaurants and recreation grounds are chosen to be analyzed, and the population distribution of such location is shown in Figure 2. Here, 10:00~14:00 is selected as period T1 (malls and restaurants as the main consideration); 14:00~18:00 as period T2 (malls and schools as the main consideration); and 20:00~24:00 as period T3 (recreation grounds as the main consideration) to analyze the transportation route.

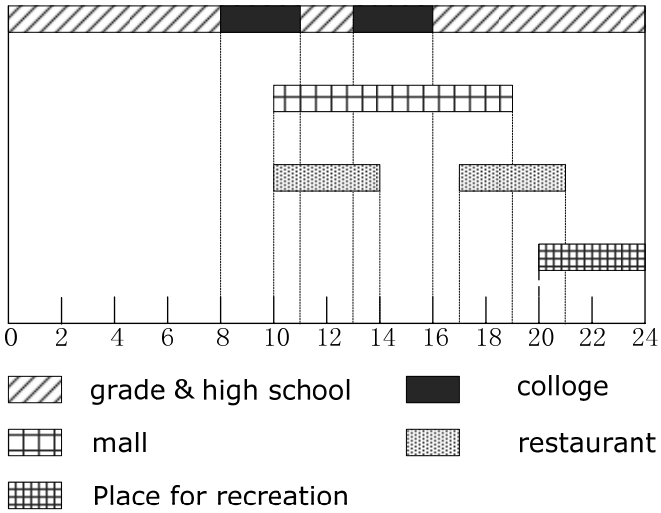

Figure 2. The period of high-density population distribution.

- Traffic Condition - In this paper, Gongnong Square is chosen as a typical intersection. Representative data is obtained via point-sample observation.
  The total waiting time: $T = 297 \times 15 = 4605\ Veh.S$ (5)
  The average waiting time on the entrance road per vehicle:

$$T_{wait} = {}^{4605}\!/_{469} = 9.8\ S \quad (6)$$

  Others waiting time is zero.

2.2 Weighting Factors

The weights are calculated by the way of the expert marking，as shown as Table 1.

Table 1. Weighting factors.

Influencing Factors	Layered Index	Weight
Traffic Condition	Time	0.144
	Distance	0.176
Accident Risk	/	0.230
Population Risk	/	0.193
Environmental Risk	/	0.097
Rescue Capability	Hospital	0.064
	Fire Protection	0.038
	Police	0.058

2.3 Time-varying Route Optimization

The crossing of Jilin road and the East Ring Road is selected as the origination of the transportation，the crossing of Huolinhe Road and West Ring Road as the destination. The analysis results based on the GIS are shown as figure 3~5.

- The route analysis in period of T_1
- The route analysis in period of T_2
- The route analysis in period of T_3

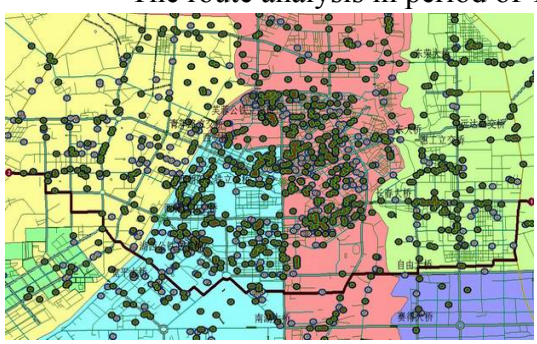

Figure 3. Route in period of T_1.

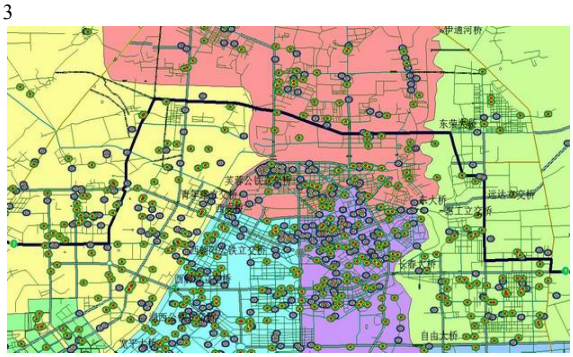

Figure 4. Route in period of T_2.

- The route analysis in period of T_2

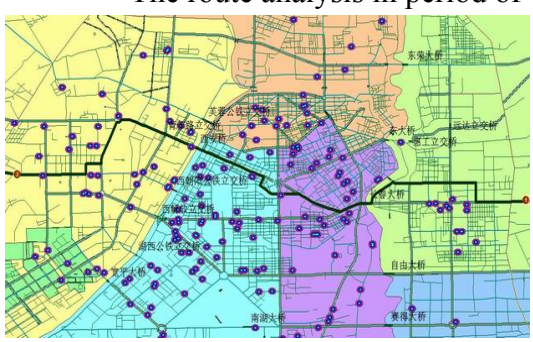

Figure 5. Route in period of T_3.

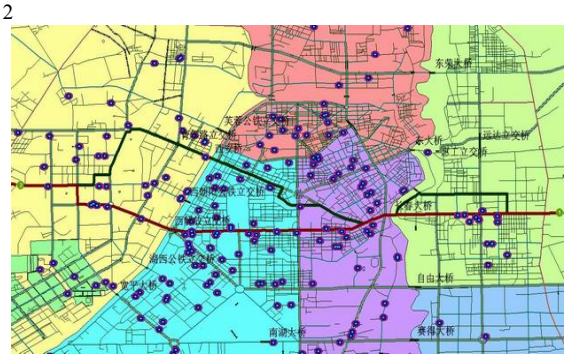

Figure 6. The contrast A(T_1)& B

2.4 Evaluation of the Route Optimization Result

Assume that A is the route of the model, B is the shortest route. The above result comes from the integrated evaluation, but in reality, the route choice is generally made by transportation cost, so that most of the drivers choose the shortest distance route, the contrast is as follows (Figure 6 through Figure 8).

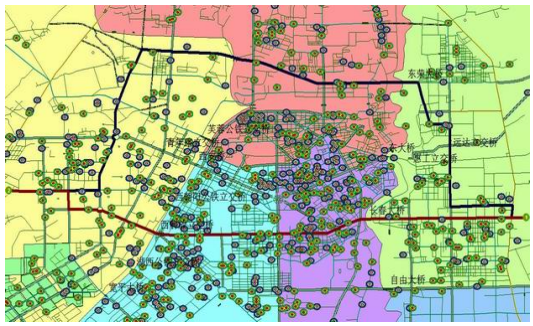

Figure 7. The contrast A(T_2)& B

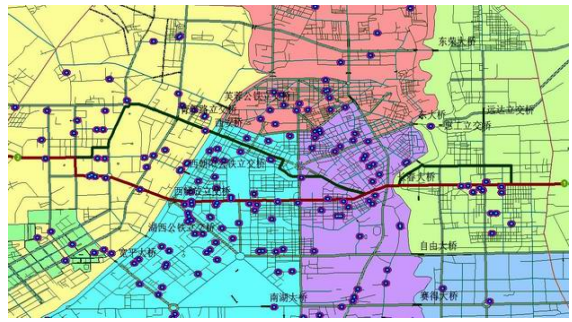

Figure 8. The contrast A(T_3)& B

The result of the contrast analysis can be summarized from Table 2, as follows:

- The number and the risk degree of the high-density population region that A goes through are both much less than B.
- Although B is less than A in distance, the integrated cost of B is obvious.
- Hazmat transportation has strong time-varying characteristics.

Table 2. Index contrast between the shortest route and the route of the model.

Period of time	T_1		T_2		T_3	
Index	Integrated Cost	Distance	Integrated Cost	Distance	Integrated Cost	Distance
Shortest Route	98.25	15598.26	74.23	15598.26	57.33	15598.26
Route of the Model	48.03	18172.49	55.06	21941.17	23.53	16868.98
Multiple / Difference	2.10	2574.23	1.39	5342.91	2.52	1270.71

3 CONCLUSION

In this paper, a route optimization model of urban hazmat transportation under the time-varying conditions is created and evaluated by real data. In the model, the integrated influence of multiple factors is regarded as the final target. The results show that hazmat transportation has strong time-varying characteristics; the model is valuable for supervisors, and the practicability and maneuverability in the route

choice of urban hazmat transportation will be improved.

ABSTRACT

For problems in the process of limiting speed of a vehicle for urban road, safety benefits and traffic benefits are regarded as the assessment indicator, and a decision-making model of speed limit optimization is proposed. Combined with the characters of hazardous material transportation, the model is revised based on AHP and fuzzy comprehensive evaluation methods, a speed limit model of vehicles for urban road hazardous material transportation is established and verified via the real vehicle. The results show that the dispersion degree of vehicle speed running at the speed from speed limit model is obviously reduced, and the model has a significant feasibility and practicality.

Key words: *Hazardous material transportation, urban road, speed limit*

1 INTRODUCTION

Velocity is an important factor to induce road traffic accidents. For the transportation of hazardous material, excessive speed is the main reason leading to transport accidents (Guo et al. 2006); and because of the specificity of the transportation of hazardous material, reasonable speed limits is essential for ensuring their safety (Suo et al. 2005).

As seen from the existing research, there are few studies on running speed for urban roads, and the factors are not considered across-the-board (Watanatada et al. 1987; Leisch et al. 1977); speed limit is unreasonable, and there are few quantified models for speed limits (Abishai et al. 2000); I have not yet found the research on speed limits for the transportation of hazardous material.

Based on the AHP and the fuzzy logical reasoning, for the social benefits and traffic benefits, a speed limit model for urban hazmat transportation is created in this paper, which provides an effective way to decrease the accident rate.

2 THE ESTABLISHMENT OF A SPEED LIMIT MODEL OF URBAN HAZMAT TRANSPORTATION

2.1. The speed limit model for general goods transportation

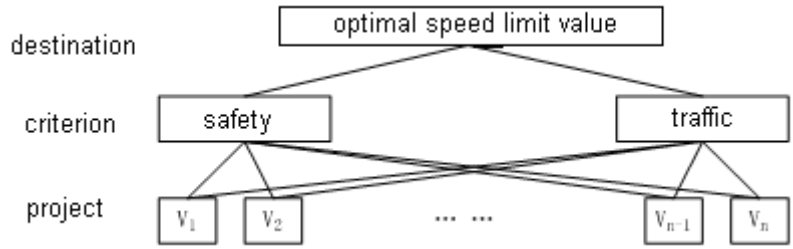

Figure 1. Optimal speed limit model.

2.1.1. The weight of criterion layer to destination layer

The weight of "safety benefits" and "traffic benefits" in the process of determining speed limit usually depends on type of road function, road location and the development level of the region along the road. The weight $\omega^{(2)} = [\alpha_1, \alpha_2]^T$ of "safety benefits" and "traffic benefits" is obtained in different statuses of traffic via Delphi.

2.1.2. The weight of project layer to criterion layer

- The determination of the project layer to weight of "safety benefits" - the weight of project layer on the "safety benefits" is obtained through calculation of authority vector $\omega_1^{(3)}$.
- The determination of the project layer to weight of "traffic benefit" - the weight of project layer to the "traffic benefit" is obtained through the calculation of the weight vector $\omega_2^{(3)}$.

2.1.3. The weight of project layer to destination layer

The combined weight ω of project layer to destination layer is used to indicate the membership degree of speed included in speed domain.

$$\omega = \left[\omega_1^{(3)}, \omega_2^3\right]^T \cdot \omega^{(2)} \tag{1}$$

2.2. The speed limit model for hazmat transportation

2.2.1. The indicator system for evaluating environment of hazmat transportation

The evaluation indicator system model for transportation environment impacts on safe speed of the hazmat transportation. As shown in Figure 2.

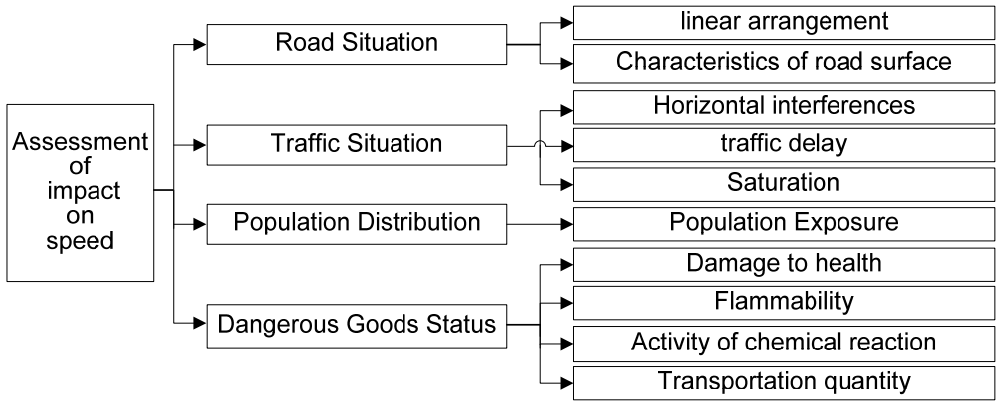

Figure 2. Evaluation indicator system.

2.2.2. The determination of weight of indicator

(1) Evaluation method

- Delphi method - Based on the Delphi method, this paper carries out that the qualitative evaluation indicator is converted into the quantitative. According to the evaluation system of impact on speed of hazardous material transportation, the Expert Opinion form is made.
- Fuzzy overall evaluation method

(2) Weight Calculation

According to the returned expert opinion form, the specific evaluation scores are determined, and then the weight of each indicator is calculated via AHP.

①Starting from road situation, traffic situation, population distribution, hazmat status, via the consulting experts' opinion for three rounds, finally the scorings of above three key factors are calculated, and it shows that they distribute at 3,8,5,6.

②Calculating the geometric mean of all elements of the same line of Judging matrix, $\varpi = (0.5791,1.5444,0.9652,1.1583)^{T}$

③ϖ_i Normalization，$W = (0.1364,0.3636,0.2273,0.2727)$

By referring to experts' advice, the following assessing grade and revising coefficients are determined, as shown as Table 1.

Table 1. Assessing grade and revising coefficient of transportation environment.

Scoring	Description	Coefficient
100-85	Almost no risk	1.0
75-85	Little risks	0.9
60-75	Heavy risks	0.7
60	Transportation prohibited	0.0

3 APPLICATION OF SPEED LIMIT MODEL OF URBAN HAZMAT TRANSPORTATION

In this paper, Yatai Street (an express road) in Changchun city is selected as the route. There are residential areas, schools, commercial areas, etc. along the road, so the traffic condition is complex. Divide the road into different sub-sections.

3.1 Speed limit of general goods transportation

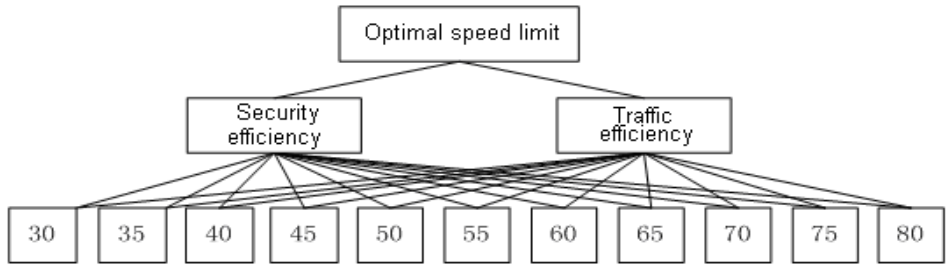

Fig 3. Decision-making model for determining speed limit of Yatai Street.

Through the questionnaire survey among experienced drivers, 80 questionnaires were collected, including 46 taxi groups, 24 private cars groups, and 10 other groups. The decision-making model for the optimal speed limit is built as shown in Figure 3:

(1) Determination of the weight of "safety benefit" and "traffic benefit" to decision-making of speed limit $\omega^{(2)} = \begin{bmatrix} 0.75 \\ 0.25 \end{bmatrix}$

(2) Determination of the normal speed membership degree of each speed

The normal speed subjection degrees are calculated, as shown as Table 2:

Table 2. Normal speed membership degree of each speed.

Speed km/h	30	35	40	45	50	55	60	65	70	75	80
Membership Degree	0.24	0.25	0.84	0.79	0.93	0.64	0.63	0.14	0.11	0.01	0.01

(3) The weight $\omega_1^{(3)}$

$$\omega_1^{(3)} = (0.0519,0.0546,0.1831,0.1721,0.2022,0.1393,0.1366,0.0301,0.0246,0.0027,0.0027)$$

(4) The weight $\omega_2^{(3)}$

$$\omega_2^{(3)} = (0.0495,0.0578,0.0661,0.0743,0.0826,0.0909,0.0992,0.1074,0.1157,0.1239,0.1322)$$

(5) Combined weight of project layer to destination layer

$$\omega = \left[\omega_1^{(3)}, \omega_2^{3}\right]^T \bullet \omega^2 \tag{2}$$

(6) The optimal speed limit

Integrated weight of speed is included in the speed field $V=\{30,35,40,...,80\}$, as shown as Table 3. The weight of 50 km/h is highest. Therefore, the optimal speed limit of Yatai Street is 50 km/h.

Table 3. Integrated **weight of every speed (km/h).**

Speed	30	35	40	45	50	55	60	65	70	75	80
Weight	0.04	0.04	0.14	0.13	0.15	0.11	0.10	0.02	0.02	0.00	0.00

3.2 Speed limit of hazmat transportation

Take a 10t LPG truck as an example. According to experts' advice, marks of the first section are shown in Table 4.

According to the evaluation of the hazmat status, the fuzzy assessing matrix of hazmat status is as follows,

$$Q_n = A_n \bullet [Q_{n1} \quad Q_{n2} \quad Q_{n3} \quad Q_{n4}]^T \tag{3}$$

$$Q_1=[0.3864 \quad 0.3134 \quad 0.1431 \quad 0.1570],\ Q_2=[0.1678 \quad 0.2461 \quad 0.1778 \quad 0.4083]$$

$$Q_3=[0.2924 \quad 0.3698 \quad 0.1581 \quad 0.1798],\ Q_4=[0.6292 \quad 0.2434 \quad 0.0159 \quad 0.1116]$$

Table 4. Evaluation of the first section.

Indicator for different layer	Assessment			
	Best	Better	Good	Bad
Reasonability of linear arrangement	0.6	0.2	0.2	0.0
Characteristics of road surface	0.7	0.2	0.1	0.0
Horizontal interferences	0.6	0.3	0.1	0.0
Traffic delay	0.4	0.4	0.2	0.0
Saturation	0.4	0.4	0.2	0.0
Population Exposure	0.3	0.2	0.3	0.2

According to the experts' advice, the weight W of the evaluation Q are as follows,

$$W_1=100 \quad W_2=80 \quad W_3=60 \quad W_4=40$$

$$S_{\text{authority}} = \sum_{j=1}^{5} q_j \bullet W_j \tag{4}$$

$$S_{\text{authority1}}=78.5808,\ S_{\text{authority2}}=63.4661,\ S_{\text{authority3}}=75.4959,\ S_{\text{authority4}}=87.8033$$

Combining with the evaluation level and revising coefficients in Table 3, speed

limits for every subsection for hazmat transportation are established as: 45 Km/h, 35 Km/h, 45 Km/h, 50 Km/h.

3.3 Result analysis

(1) "Consistency Test" evaluation

As shown in Figure 4, the speed limit and the overall trend of speed and average speed of every section are consistent. It shows that the speed limit is reasonable.

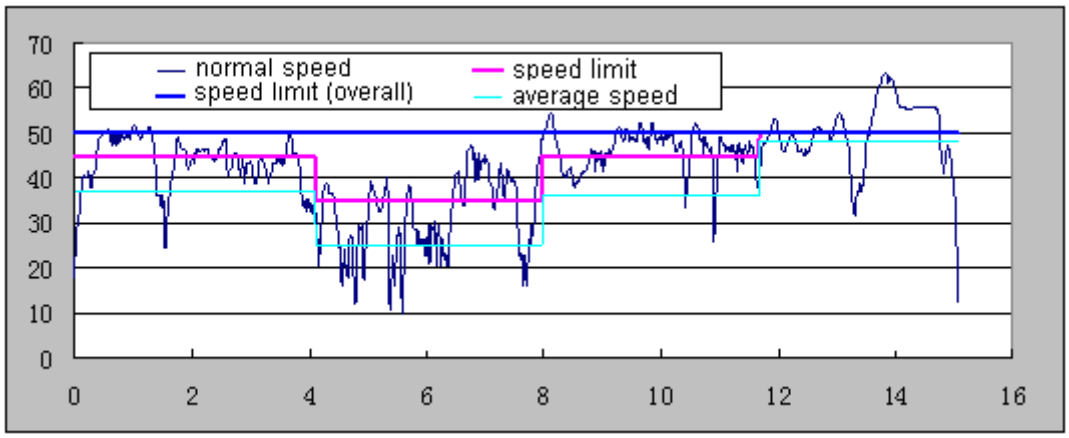

Figure 4. Speed comparison chart excluding the impact of the road intersection.

(2) Evaluation of the variance and standard deviation of speed

The various parameters of speed before and after amending of the sections are shown as Table 5. When the speed limit is implemented, each subsection and the overall standard deviation gets better except for the fourth section (influenced by traffic lights). Namely, the frequency and amplitude of speed decline. For hazmat transportation, both impact and risk decline.

Table 5. The statistical data of the speed with 95 percent confidence.

Subsection	First		Second		Third		Fourth		Overall	
variance	133	117	127	81	221	82	85	129	209	145
standard deviation	12	11	11	9	15	9	9	11	15	12
average	37	36	25	22	35	28	48	39	34	30
survey	397	413	549	533	375	355	256	312	1578	1614

4 CONCLUSION

The results show that: the dispersion degree when the car runs at the speed from speed limit model is obviously reduced, and the model has a significant feasibility and practicality.

ABSTRACT

Based on the influence of road operation safety under atrocious weather, a risk assessment research is presented from four aspects (i.e. climate environment, road condition, traffic environment, road maintenance and repair) to analyze the risk grade of road facilities operation environment. According to the operation environment analysis, the paper establishes a set of evaluation indexes and evaluation criterion for risk assessment of road operation environment. At the end, the lowest evaluative criterion of road operation environment is given to improve the design of road facilities and intensify operation environment safety of basic road facilities.

1 INTRODUCTION

Road facilities are an important carrier of highway transportation in our country. However, the geological and ecological environment in our country is very complex. Many meteorological disasters such as rainstorms, flooding, drought, cold damage and snow disasters occur frequently on interlaced highway line (Yuchun Yao et al. 2004). The disaster climate causes the road operation environment to be worse and influence the road facility's function and vehicle safety.

Vehicle travel safety depends largely on the security of the road operation environment. Road operation environment includes climate environment, road environment, transportation environment and management environment. Disaster climate has different influences on the road, traffic and management environment. Therefore, research of risk assessment of road operation environment under atrocious weather conditions has the important meaning in guaranteeing the operation safety of road facility and the vehicles.

2 RISK ANALYSIS OF ROAD OPERATION ENVIRONMENT UNDER

ATROCIOUS WEATHER CONDITIONS

The road operation environment is subject to many factors. Under the disaster weather's influence, adverse weather (rain, snow, freezing, etc.) have many disadvantageous impacts on the roadbed and road surface. Landslides and mud-rock flows caused by meteorological disasters will damage the road structure. Therefore, carrying on the real-time monitoring of inclement weather and geological environment is conducive to make the safeguard mechanisms respond promptly, thus improving the road operation environment security.

At the same time, the structural design of roads and the reasonableness of the geometric conditions are the basic premise to ensure the road operation environment safety. Evaluation of the road alignment, line-of-sight, roadbed, pavement performance will help us to determine the anti-risk level of road facilities. On the other hand, rain, snow, fog and other adverse weather conditions disturb the normal operation of traffic flow and cause traffic jams, traffic disruption, even lead to traffic accidents and seriously affect the operation of road traffic safety. When disaster weather occurs, prompt clean-up, maintenance and rehabilitation of the road infrastructure is very important to protect the road facility function and improve road operation environment safety.

In this paper, the risk assessment of road operation environment is researched from four aspects including the natural environment monitor condition, the road condition evaluation, risk degree of traffic environment and road administration maintenance situation.

3 RISK ASSESSMENT OF ROAD OPERATION ENVIRONMENT UNDER ATROCIOUS WEATHER CONDITIONS

3.1 Assessment of Climatic Environment Monitoring

Climatic environment monitoring mainly includes the meteorological condition monitoring and the geological condition monitoring. The function of meteorological condition monitoring lies in the prompt, accurate monitoring of heavy weather. The geological condition monitoring involves the real-time monitoring of the roadbed, road surface and the side slopes in special areas where disasters occur frequently so we can strengthen the prevention of the geological disasters region, draw a plan of pre-disaster early warning and rapid post-disaster recovery repairs to improve the road operation safety.

Climatic environment monitoring puts emphasis on the preparation, availability and emplaced rationality of the meteorology and the geological condition monitoring equipment. Through the environmental monitoring equipment, we can gather exhaustive information of meteorology, geology and natural environment of the road facility. According to the results of data processing, preliminary plans can be made to improve road operation environment safety.

Assessment indexes

1. Meteorological and geological condition monitoring facilities equipped
2. Monitoring equipment layout
3. Monitoring equipment intact ratio
4. Harmonization with road management and maintenance

Assessment contents

1. Establish at least one set of climatic environment monitoring equipment (CEME) on the main line at each road. The quantity and installation location of the CEME should be reasonably selected at the place where weather disasters frequently happened.
2. Establishment suggestion, related department implementation plan, progress report and effect evaluation of the climatic environment monitoring audited by an expert group no less than twice per year.
3. Regular maintenance of CEME should be implemented to ensure the equipment is in good condition and the rate of effectiveness more than 90%. At the same time, the effectiveness and intact rate of CEME set in disaster-prone sections is 100%.
4. The information (including rain, snow, fog and other weather information, landslides, mud-rock flows and other geological disasters information) detected by CEME is timely and accurate available to the road management department, which play a role in early warning and prevention to ensure the road facilities safety.

Assessment requirements

Review and check the index. The related base data of CEME, the recommendations of the expert group, implementation plans of the relevant department and the effect evaluation data of the equipment should be provided (Dianye Zhang et al. 2005).

Assessment grade

Judge the corresponding level by determining the number of indicators which can meet the requirements based on the materials. Assessment grades are shown in Table 1.

Table 1. Assessment grade of climatic environment monitoring situation

Assessment grade	Ⅰ	Ⅱ	Ⅲ	Ⅳ
U_1 Index	Meet 4 requirements [85，100）	Meet 3 requirements [70,85）	Meet 2 requirements [55，70）	Meet 1 requirements [0，55）

Assessment standard of climatic environment monitoring situation

In the process of road construction, there are many differences in funding, technology and management, so the selection and layout of CEME is impossible to achieve the optimal standard. When the request cannot be satisfied, the road operation environment safety may be affected to a certain extent. Therefore, reference to past research results and experts' evaluation, the minimum standard of climatic environment monitoring situation is presented to ensure the road operating environment safety.

Minimum standard: Meet at least three assessment contents to achieve the second-level assessment criteria.

3.2 Risk assessment of road facility environment

The quality of road facilities environment depends on the level of road design and completeness of road related facilities. The level of road design standards has a direct impact on the safety of road operating environment. Under the effect of a weather disaster, a bad alignment or road structure design will bring the result of overall poor road quality, easy damage to the roadbed and pavement and difficulty of repairing. Therefore, a good design of road alignment, roadbed and pavement should be made to enhance the anti-risk ability of road facilities.

Reasonable road safety facilities can improve the road capacity, reduce traffic accidents and the incidence of secondary accidents, save economic cost, alleviate the degree of drivers' fatigue and improve the level of road service. So it is very important in the safety of road operating environment.

Assessment indexes

1. Risk of road alignment
2. Status of roadbed
3. Status of pavement
4. Road safety facilities equipped

Assessment contents

1. Assessment of road alignment risk: Include the combination of horizontal and vertical alignment, sight distance, resultant gradient, curve radius, drainage, etc (PRCMOT 2004). Evaluate the proportionality and rationality of alignment according to the relevant technical standards;
2. Assessment of roadbed status: Include roadbed height, section type, drain etc. Evaluate the intension and stability of the roadbed according to the relevant technical standards;
3. Assessment of pavement status: Including pavement structure, crown gradient, drain, skid resistance, etc. Evaluate the intension, skid resistance and stability of pavement according to the relevant technical standards;
4. Road safety facilities equipped: Include signage and marking, protection and separation, anti-glare, abduction, lighting and emergency assistance and so on. Select and lay out facilities according the requirement of highway engineering

evaluation standards by quality inspection. The facilities settled on the whole road should have the ability of defending bad environment; The highway department should master the facilities status of each road in a timely way and solve the problems quickly.

Assessment requirements

Review and check the index. The relative data of road design, landform and geology data along the road, and in the particular data of the facilities should be provided.

Assessment grade

According to the relevant technical standards, judge the corresponding level by determining the number of indicators which can meet the requirements based on the materials. Assessment grade is shown in Table 2.

Table 2. Assessment grade of road environment

Assessment grade	Ⅰ	Ⅱ	Ⅲ	Ⅳ
U_2 Index	Meet 4 requirements [85，100）	Meet 3 requirements [70,85）	Meet 2 requirements [55，70）	Meet 1 requirements [0，55）

Risk assessment standard of road facility environment

In the process of road design, there are many differences in funding, technology and geology conditions, so the design of road and facility is impossible to achieve the optimal standard. When the request cannot be satisfied, the function of road corollary facilities may be affected. Therefore, reference to past research results and experience, the minimum standard of road facility environment risk is presented to ensure the road operating environment safety.

Minimum standard: Meet at least three assessment requirements, achieve the second-level assessment criteria.

3.3 Risk assessment of traffic environment

The traffic environment is an important influencing factor in road traffic operation safety. Under the influence of weather disasters, the traffic accident event's occurrence frequency is high. The seriousness of the incident and traffic flow status impacts the traffic capacity, the real-time safety and the travel time over the road facility. Through analysis and evaluation of the traffic state, spatial influence and duration under the influence of the weather disaster, the safety of the traffic environment can be determined.

Assessment indexes

1. Traffic state
2. Spatial influence scope

3. Duration

Assessment contents

The operational status of traffic flow was judged based on the traffic volume, travel speed, traffic density, lane occupancy rates and other traffic parameters under influence of a weather disaster. Suggested values of traffic state assessment are listed in Table 3. In order to protect the traffic environment safety, the status of traffic flow should be unblocked.

Table 3. Suggested values of traffic state assessment

Grade	Traffic status
I	Free traffic flow, excellent state
II	Non-free traffic flow, unblocked state
III	Non-free traffic flow, traffic congestion state
IV	Traffic interruption

According to the road sections and road network connectivity, accessibility and capacity, spatial influence scope of traffic incident can be determined. Suggested values of spatial influence scope are listed in Table 4. In order to ensure the road connectivity, influence scope should be limited in small area.

Table 4. Suggested values of spatial influence scope assessment

Grade	Spatial influence scope
I	Only one or two lane blocked, good connectivity and accessibility
II	Partial lane blocked, good connectivity
III	Partial section or road network traffic blocked, bad accessibility
IV	Large-scale road network line blocked, road network traffic interruption

The impact of the Road Traffic Incident can be reasonable judged according to traffic events duration. Suggested values of duration are listed in Table 5.Traffic events' duration should be less than 3 hours to resume the traffic flow operation.

Table 5. Suggested values of duration assessment

Grade	Duration
I	Less than 1 hour
II	2～3 hours
III	4～8 hours
IV	More than 8 hour

Assessment requirements

Review and check the index. The related data of traffic state parameters, the recommendations of the expert group, implementation plans of the relevant department and the effect evaluation data of the equipment should be provided.

Assessment grade

Judge corresponding level by determining the number of indicators meeting the requirements based on the materials. The Assessment grade is shown in Table 6.

Table 6. Risk assessment grade of traffic environment

Assessment grade	Ⅰ	Ⅱ	Ⅲ	Ⅳ
U_3 Index	Meet 3 requirements [85，100）	Meet 2 requirements [70,85）	Meet 1 requirements [55，70）	Meet 0 requirements [0，55）

Assessment standard of traffic environment

In the process of road operation, there are many differences in local land form, physiognomy, climatic conditions and volume of traffic flow, so the assessment of the traffic environment is impossible to achieve the optimal standard. When the request cannot be satisfied, the road operation environment safety may be affected to a certain extent. Therefore, reference to experts' evaluation, the minimum standard of traffic environment is presented to ensure the road operation environment safety.

Minimum standard: Meet at least three assessment requirements, achieve the second-level assessment criteria.

3.4 Assessment of road management environment

Road routine maintenance and rapid repair are important to ensure the normal operation of road traffic under disaster condition. Besides the road routine maintenance, there should be stored necessary materials, machinery and equipments on important road section where climatic and geological disasters often happened.

Assessment indexes

1. Road maintenance, repair material and mechanical facilities equipped
2. Road maintenance staff equipped
3. Effective rate of routine maintenance

Effective rate of routine maintenance =

$$\frac{The\ \ number\ \ of\ \ road\ \ facility\ \ maintenance}{The\ \ number\ \ of\ \ road\ \ facility\ \ damage}$$

Daily maintenance work includes roadbed, road surface maintenance and road disaster prevention and so on. The assessment of highway maintenance quality may refer to《Highway evaluate standard by maintenance quality inspection》(JTJ 075-94)。Suggested values of daily maintenance effective rate are listed in Table 7.

Table 7. Suggested values of daily maintenance effective rate

Grade	Ⅰ	Ⅱ	Ⅲ	Ⅳ
Acceptable range	＞0.8	0.8～0.6	0.6～0.4	≤0.4

Effective rate of rapid repair after disaster

$$\text{Effective rate of rapid repair} = \frac{The\ \ time\ \ required\ \ for\ \ road\ \ repair}{The\ \ average\ time\ \ required\ \ for\ \ road\ \ repair}$$

Rapid road repair work after a disaster includes field cleaning, troubleshooting and repair of the roadbed, road surface, slope, etc. The definition of the repair completion is at least one lane that will allow buses or trucks to pass in case of an emergency situation (Zhang Yi et al. 2007). Suggested values of the effective rate are listed in table 8.

Table 8. Suggested values of repair effective rate after disaster

Grade	Ⅰ	Ⅱ	Ⅲ	Ⅳ
Acceptable range	≤0.4	0.4～0.8	0.8～1.2	＞1.2

Assessment contents

1. Establish at least a road maintenance station on the main line for each road. The outfit rate of road maintenance, repair material and mechanical facilities set in the disaster-prone section is 100%.
2. Highway maintenance staff has to master the maintenance knowledge and skills, each person should be provided with the necessary maintenance equipment and accept effective management.
3. Effective rate of routine maintenance may not be lower than the middle class which is shown in table 7.
4. Effective rate of rapid repair after a disaster may not be lower than the middle class which is shown in table 8.

Assessment requirements

Review and check the index. The related data of road maintenance and repair equipment, the recommendations of the expert group, implementation plans of the relevant department and the effect evaluation data of the equipment should be provided.

Assessment grade

Judge corresponding level by determining the number of indicators which can meet the requirements based on the materials. Assessment grade is shown in Table 9.

Table 9. Assessment grade of manage environment situation

Assessment grade	Ⅰ	Ⅱ	Ⅲ	Ⅳ
U_4 Index	Meet 4 requirements [85，100）	Meet 3 requirements [70,85）	Meet 2 requirements [55，70）	Meet 1 requirements [0，55）

Assessment standard of the road management environment

In the process of road maintenance and repair, there are many differences in funding, technology and management, so road maintenance and repair is impossible to achieve the optimal standard. When the request cannot be satisfied, the road operation environment safety may be affected to a certain extent. Therefore, refer to experts' evaluation, the minimum standard of road management environment is presented to ensure the road operating environment safety.

Minimum standard: Meet at least above two assessment requirements, achieve the third-level assessment criteria.

4 CONCLUSION

By assessing four aspects of road operation environment including climate, road, transportation and administration, it provides road facilities with such functions as early warning before accidents, feedback under emergency and rapid repair after the disaster, so the operating security of the highway is greatly improved (Yan Ma et al. 2007).

1. Function of early warning: According to the evaluation of meteorological and geological environment monitoring, each monitoring facility not only makes prediction and determination timely and correct, but also identifies and warns of the potential for catastrophic weather and road accidents.
2. Function of feedback: By risk analysis and assessment of road running environments, it determines the weakness during road design, analyzes deficiency in transportation management and control under catastrophic weather environments, and feeds back road and traffic information immediately, so as to provide the reference for fundamental research on road operation security.
3. Control function: Once the road traffic is blocked under catastrophic weather, it is able to respond rapidly, sets down a series of measures including recovery service, traffic control and guidance, coordinates and allocates personnel, materials and so on, aiming at repairing the road, opening up the congested traffic and ensuring the normal road traffic operation.

ABSTRACT: The article researches on the theory and practice of two-vehicle central collisions and two-vehicle eccentric impacts (collisions), proved that all kinds of complex two-dimensional collisions can transform into one-dimension collisions with theory analysis. Secondly, the article introduces collision parameters k and μ, established a vehicle speed model with a momentum equation and a momentum matrix equation, eliminated affection of impulsive force distributing coefficients by quadratic optimizing, and established accident reconstruction model of two-vehicle collision based on reverse-reasoning method, realized two calculate modes. Finally, the method was found to be effective and feasible by validating with actual cases. We also find that the two basic hypothesis of traffic accidents had effects on accident reconstruction, which need to be researched and optimized in the future.

KEY WORDS: traffic accident, accident reconstruction, reverse-reasoning method, accident dynamics

0. INTRODUCTION

Traffic safety is a major problem of national economy and society stability. Our country is facing the problem of traffic accidents, and how to deal with these traffic accidents is an important task. As a key point, since accident reconstruction involves reason analysis and responsibility cognizance of each accident, it can also improve the efficiency of dealing with traffic accidents.

1. THE CORE IDEA OF REVERSE-REASIONING METHOD

The kernel crash analysis method applied all over the world nowadays is the simulation method which is also called the positive-reasoning method. This method calculates the vehicle speed after crashing and simulates slipping and turning processing after crashing assuming a vehicle speed before crashing (Bruce et al. 1995). However the disadvantage of this method is avoiding solving a moment recovery factor of the universal face-to-face crash, and the disadvantage is the unknown vehicle speed and many parameters need to be assumed, and the stopping position after crashing is needed to be determined by simulating again and again (Daogao et al. 2005). Therefore the use of this method is often limited because of scarcity of initial computing parameters and time required to be spent on the simulation.

Facing the problem above, the universal face-to-face crash was transformed to a point-to-point crash, and the reverse-reasoning method was used for accident reconstruction. According to trails of vehicle slipping and turning after crashing, the reverse-reasoning method solves vehicle speed just after crashing and vehicle speed just before crashing. This method agrees with the form of traffic accidents better and can avoid solving for the moment recovery factor as well. And the parameters needed in computing for this method are far less than that in positive-reasoning method and are more easily obtained (Ward et al. 1999). Computational complexity in this method is better than that in positive-reasoning method. So reverse-reasoning method is more advantageous for simplifying computing and rapidly analyzing traffic accidents.

2. TWO-VEHICLE NON-CENTRAL AREA COLLSION TRANSFORMED INTO POINT COLLISION

In real life, the collision part of a traffic accident is not a particular point but an entire area (Knneth 1999). Take whichever O, the effect point, on the collision area , which at the same time needs a collision force-couple M. That is to say, besides P_n and P_x which act on O, it also needs M. Therefore a moment regain coefficient k_m is added when establishing an equation. When translating the effect line of normal momentum force for a distance e, it will absorb the collision force couple, thus the area-to-area crash was transformed to a point-to-point crash (Figure 1).

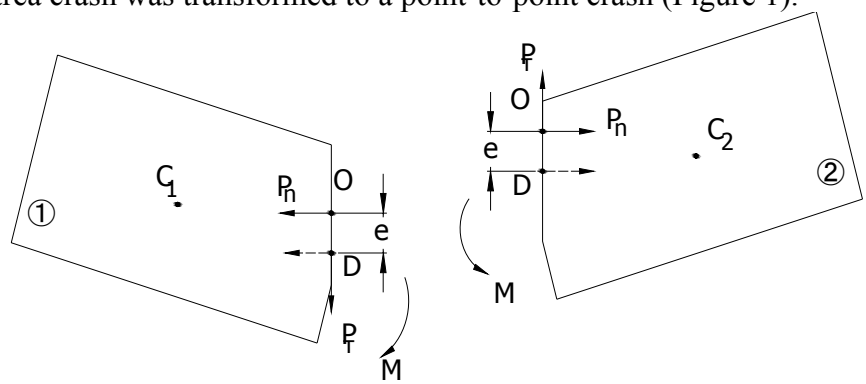

Figure 1. Sketch map of area collision transformed into point collision

3. ACCIDENT RECONSTRUCTION MODEL OF TWO-VEHICLE NON-CENTRAL COLLISION

3.1 Three Sets of Rectangular Coordinate system are Needed in Two-vehicle Non-central Collisions

The main characteristic of the non-central collision is that when the vehicles slide after collision, both translatory movement and rotation happen (WRA 2003). In order to establish the vehicle plane motion dynamic equation, three sets of rectangular coordinates are needed, as shown in Figure 2.

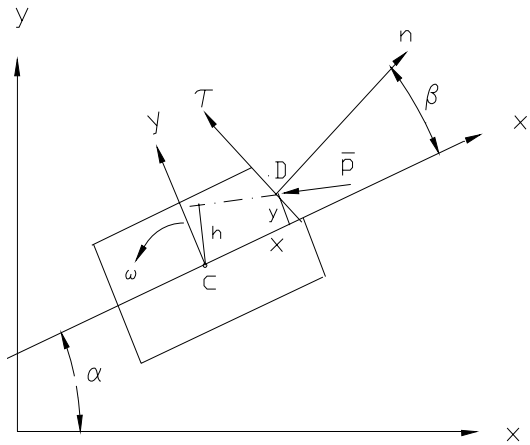

Figure 2. Three sets of rectangular coordinate system in Reverse-reasoning Method

(1) Vehicle body coordinate system XCY. Take vehicle body barycenter C as the origin of the coordinates, the vehicle body longitudinal axis as X, rotating the X axis 90° anticlockwise gets the Y axis. This vehicle body coordinate system is mainly used to ascertain the coordinate position of the collision point D compared to the barycenter.

(2) Normal coordinate system nDτ in the collision area. Take the collision area normal as n axis, 90° anticlockwise is τ axis. This collision-area normal coordinate is mainly used to decompose the collision momentum to the normal momentum P_n and tangential momentum P_x, and establish an equation along the normal and tangential directions, respectively.

(3) Earth-fixed coordinate system XOY. Usually take the direction of the accident-vehicle traveling path as the X axis, 90° anticlockwise is the Y axis, the origin O could be uncertain. The fixed coordinate system is mainly used to describe the driving parameters such as velocity, acceleration, skidding distance, and the direction angle between the two vehicles.

3.2 The Model of Two-vehicle Non-central Collision

The effect point of the collision momentum is known, so it is called a point-to-point collision. Figure 3 describes the collision pressure of both vehicle 1 and vehicle 2.

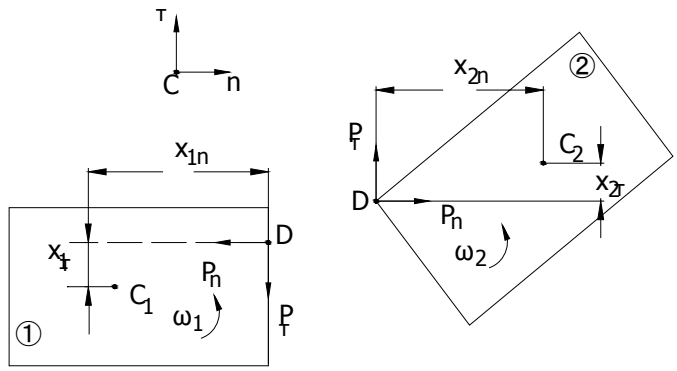

Figure 3. The force diagram of the non-central collision

Make the masses of the two vehicles as m_1 and m_2, the rotating inertia around the barycenter as J_1 and J_2 . The respective components of the two vehicles' speed before and after the collision in the normal coordinate are v_{1n}, $v_{1\tau}$, v_{2n}, $v_{2\tau}$ and v_{10n}, $v_{10\tau}$, v_{20n}, $v_{20\tau}$. The rotating angular velocities are ω_{10}, ω_{20} and ω_1, ω_2. Applying the impulse theorem and impulsive moment theorem and introducing an elastic recovery coefficient κ and a tangential fiction coefficient μ on the collision point D, then the accident reconstruction model is established:

$$[A_0]\{X_0\} = [A]\{X\} \tag{1}$$

Where:

$$\{X_0\} = [v_{10n} \quad v_{10\tau} \quad v_{20n} \quad v_{20\tau} \quad \omega_{10} \quad \omega_{20}]^T \quad \{X\} = [v_{1n} \quad v_{1\tau} \quad v_{2n} \quad v_{2\tau} \quad \omega_1 \quad \omega_2]^T$$

$$[A_0] = \begin{bmatrix} m_1 & 0 & m_2 & 0 & 0 & 0 \\ 0 & m_1 & 0 & m_2 & 0 & 0 \\ \frac{m_1 x_{1\tau}}{2} & -\frac{m_1 x_{1n}}{2} & -\frac{m_2 x_{1\tau}}{2} & \frac{m_2 x_{1n}}{2} & J_1 & 0 \\ -\frac{m_1 x_{2\tau}}{2} & \frac{m_1 x_{2n}}{2} & \frac{m_2 x_{2\tau}}{2} & -\frac{m_2 x_{2n}}{2} & 0 & J_2 \\ \mu & -1 & \mu & -1 & 0 & 0 \\ k & 0 & -k & 0 & -k x_{1\tau} & k x_{2\tau} \end{bmatrix} \quad [A] = \begin{bmatrix} m_1 & 0 & m_2 & 0 & 0 & 0 \\ 0 & m_1 & 0 & m_2 & 0 & 0 \\ \frac{m_1 x_{1\tau}}{2} & -\frac{m_1 x_{1n}}{2} & -\frac{m_2 x_{1\tau}}{2} & \frac{m_2 x_{1n}}{2} & J_1 & 0 \\ -\frac{m_1 x_{2\tau}}{2} & \frac{m_1 x_{2n}}{2} & \frac{m_2 x_{2\tau}}{2} & -\frac{m_2 x_{2n}}{2} & 0 & J_2 \\ \mu & -1 & \mu & -1 & 0 & 0 \\ -1 & 0 & 1 & 0 & x_{1\tau} & -x_{2\tau} \end{bmatrix}$$

3.3 Parameter Optimization of Reverse-reasoning Method

In order to enhance the reliability of the computed result, it needs to optimize some computed parameters in the accident reconstruction model.

3.3.1 Position Optimization of Collision Point

Take the initial collision point as the center, choose 5 points respectively along the two areas of the normal and tangent in the collision area as compute positions, 0.05m between every two points. According to the known model formula of the angular acceleration before the collision, use a computer to do circle calculations. Taking the minimum angle between the initial velocity direction and the known vehicle longitudinal direction before collision as the rule, compare the corresponding direction error of each calculation in order to find the minimum direction. Thus using the final result can get a collision position which is the prime collision point after adjustment.

3.3.2 Direction Optimization of Area Collision

Taking the initial normal of the collision area as norm, choose 5 directions respectively both clockwise and anticlockwise, with 2° between every two directions. Similarly, use the computer to do circle calculations according to the known model formula of the angular acceleration before the collision. Then taking the minimum angle between the direction of the initial velocity and the known angle of the vehicle longitudinal axis before collision as the rule, compare the corresponding direction error of each calculation to find the minimum direction. Thus using the final result can get a normal which is the best direction normal.

4. THE VERIFICATION OF THE TRAFFIC ACCIDENT CASE

The time of the case : 2004/04/16/14:45

The location of the case: The intersection of Pudong road and Suzhou north street in Changchun

Case outline：Jeep(1) driven along the Pudong road from east to west collided with truck(2) driven from south to north.

Inspection of the scene: As figure 4 shows, The roads are plane and straight with a good line of sight and bituminous pavement. The weather was sunny and there was no signal light in the intersection. The right front corner of truck (2) bumped into the left front area of jeep (1), both were damaged seriously. The data of the scene investigation is showed in figure 5.

Figure 4. General picture of accident (from west to east)

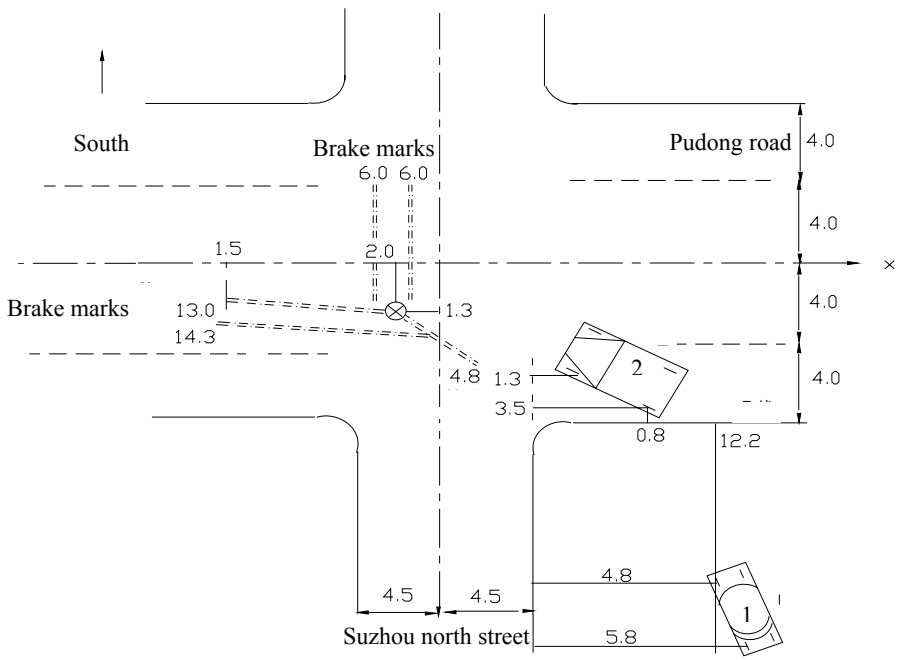

Figure 5. Scene of the two-vehicle collision on the intersection

The Collision Morphological Analysis and Reconstruction Calculation: This case should be processed as a general two-dimensional point collision because two vehicles crashed in the crossing and both were hit on the corner, which made them both rotated in a large angle. Take the Pudong road from east to west as the X axis,

jeep(1) as vehicle 1, truck(2) as vehicle 2. The calculated parameters of this case are showed in Table 1.

Table 1. Calculated parameter of two-vehicle collision on the intersection

Calculated Parameters	Jeep (1)	Truck (2)	Calculated Parameters	Jeep (1)	Truck (2)
Vehicle Quality (kg)	2330	2500	Slip direction angle(o)	-55	-41.8
Tread(mm)	1575	1410	Vehicle longitudinal axis angle before collision(o)	-2.2	-90
Wheelbase(mm)	2850	2515	Vehicle longitudinal axis angle after parking(o)	-68.5	-151
Collision point coordinates X(cm)	142.5	180	Equivalent Friction coefficient	0.58	0.7
Collision point coordinates Y(cm)	78	-70	Angular velocity before collision (degree/second)	0	0
Length of brake marks after collision(m)	22.7	10.5			

The calculate results before collision are as follows:

$v_{10} = 69.5(km/h)$, $v_{20} = 66.8(km/h)$

Drive speed calculation: The two results are initial collision speed rather than the drive speed before braking. We should calculate drive speed of the two vehicles before braking according to the length of the brake marks, because the two vehicles both braked before collision.

The length of brake marks before collision of Jeep1 is 14.3m, its collision speed is v_{10}=69.5 (*km/h*) =19.3 (*m/ s*). The drive speed v_1 before braking can be calculated as:

$$v_1 = \sqrt{v_{10}^2 + 2g\varphi_1 S_1} = \sqrt{(19.3)^2 + 2 \times 9.8 \times 0.7 \times 14.3} = 23.9(m/s) = 85.7(km/h)$$

The length of brake marks before collision of truck2 is 6.0m, its collision speed is v_{20} = 66.8(*km/h*)=18.5(*m/s*). The drive speed v_2 before braking can be calculated as:

$$v_2 = \sqrt{v_{20}^2 + 2g\varphi_2 S_2} = \sqrt{(18.5)^2 + 2 \times 9.8 \times 0.7 \times 6.0} = 20.6(m/s) = 74.3(km/h)$$

5. CONCLUSIONS

The paper confirms the validity and the feasibility of Reverse-reasoning Method by reconstruction of a real traffic accident. At the same time, it also discovered that the premise ("two basic hypotheses" of collisions) of its application influences the calculation accuracy, which should be further studied and optimized. Meanwhile, in view of the increasing severity of China's traffic safety situation, the author believes that it can help to enhance effectiveness, fairness and accuracy in traffic accident processing, and to propose transportation safety managing countermeasures if China independently researches and develops the traffic accident reconstruction model and applied software which agree with China's national condition.

ABSTRACT

This paper details research undertaken by the simulation laboratory at Faculty of Transportation, Kunming University of Science and Technology. The aim of this research is to compare the relative effectiveness of three kinds of median markings in undivided highway tunnels. The sample of the tunnels was selected from a real road in a mountainous area in Yunnan province as a test course and was reconstructed by computers on the driving simulator. Forty subjects participated in the experiment and the data were collected from the experiments. The study found consistently superior results for the Warning poles that can fall down and resume set on the centre of the undivided highway tunnel in comparison to common road markings and the enhanced visibility road markings in various measures of driving behavior. Questionnaires also give a higher evaluation for the Warning poles.

1 INTRODUCTION

With the increase in the number of tunnels, highway tunnels security issues are becoming increasingly apparent and attract more attention. Yunnan province is located in the mountains and there are a lot of undivided highway tunnels which have high risk of accidents. So many safety ensuring methods were designed for them.

The purpose of this research is to evaluate two kinds of median markings as well as a common road marking in undivided highway tunnels by using a driving simulator. One of the median markings is made of enhanced visibility quadrangles with a common road marking (see Figure1), (termed as ‘Visual marking’), another is Warning poles sitting on the center of the undivided highway with common markings in the tunnel (see Figure2). When vehicles hit these special warning poles, they fall down and subsequently resume (termed as ‘Warning poles’).

In order to reach the objective, experiments were organized based on Driving Simulator technology to obtain the behaviors of the vehicles passing through the tunnels. The speed, and its standard deviation, the track lateral position, and its standard deviation were used in the experiments to analyze and evaluate these three kinds of markings（Kay Fitzpatrick et al. 2000）. The purpose of the experiments is to see which markings help make the vehicles go smoothly and straightly.

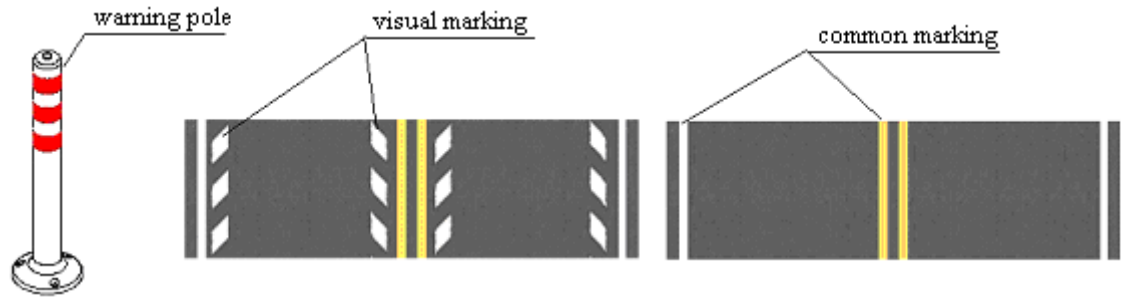

Figure1. Pattern of three median markings

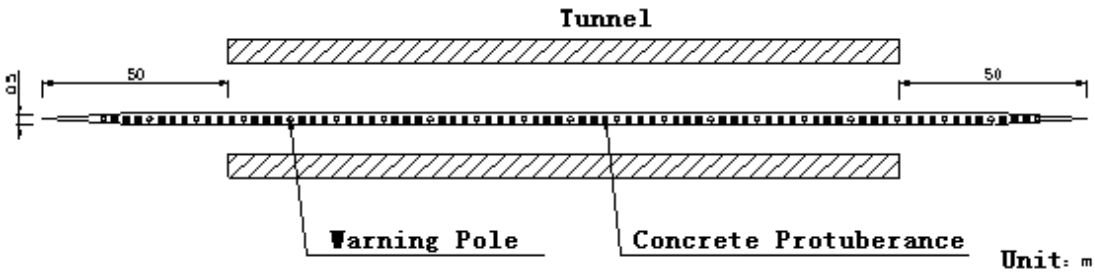

Figure2. Placement method for the warning pole in the tunnel

2 METHOD

To carry out the experiments on the Driving Simulator, it was first necessary to create a virtual experimental scenario exactly based on the sample road section (Berssenbrügge et al. 2006). Afterward, subjects (test drivers) were selected and trained to fit to the simulator (Nancy E. Laurie 2004). Before starting, preliminary testing and calibration are required to make the rig work well and the parameters of the vehicle dynamical model match with actual ones（Mats Lidström, 1998）. Finally, formal experiments were carried out and the data were collected. For further analysis and evaluation all parameters acquired from the simulator had to be treated and elaborated with respect to the exact position of the vehicle along the test course.

The driving simulator

The driving simulator (KMRTDS) was set up in the simulation laboratory at Faculty of Transportation, Kunming University of Science and Technology, which consists of following five subsystems: the computer system with an elaborate mathematical model of the vehicle, a visual scene creation system, the projection system which presents the visual environment on a 120-degree wide screen, a digital sound system, and a full scale cab with real operation room. The driving simulator is controlled by a platform in a control room, and all the experiments can be controlled for given conditions.

Experimental Scenario

The sample roadway was selected from a section of G213 (The National highway in China) located in a Yunnan province mountainous area. There were three tunnels in the 4-km long sample section, which were named T1, T2 and T3, and

similarly three kinds of markings were named M1, M2 and M3, respectively. The experimental scenarios are shown in table 1.

Table 1. Experimental Scenarios

Experimental Scenarios	The first tunnel(T1)	The second tunnel(T2)	The third tunnel(T3)
Scenario1	The first tunnel equipped with Warning pole (T1+M1)	The second tunnel equipped with Visual marking (T2+M2)	The third tunnel equipped with common marking (T3+M3)
Scenario2	The first tunnel equipped with Visual marking (T1+M2)	The second tunnel equipped with common marking (T2+M3)	The third tunnel equipped with Warning pole (T3+M1)
Scenario3	The first tunnel equipped with common marking (T1+M3)	The second tunnel equipped with Warning pole (T2+M1)	The third tunnel equipped with Visual marking (T3+M2)

Traffic flows were set in these three experimental scenarios, which were free flow and set on the opposite lane to avoid affects on drivers, but there were some cars in front of the subject in the driving lane with a higher speed so as not to affect driver's choice of speed.

a. The entrance to the tunnel **b. In the tunnel**

Figure 3. Experimental Scenario

Subject

In total, 40 subjects were selected with age from 28 to 48, 25 males, 15 females and all with driving experience over three years. Each subject participated in all the experiments based on above three scenarios.

Procedure

Before the experiments the driving simulator and its functions were

introduced to the subjects and preliminary tests were conducted to make them familiar with the simulator. After the experiments a questionnaire was required to be make as compensation.

The experiment data were collected from the vehicle dynamical model from each driver. The speeds of the vehicle and the track positions along the road were the main parameters for the study. Since all the collected parameters were with respect to time, they were transferred into location-based data so as to analyze a case at the site of the road. The data transformation can be figured out by locating every position of the moving vehicle on the test course as a coordinate system. Consequently the speed and other parameters of the vehicle were accurately located along the test course (speeds versus location).

3 DATA ANALYSIS AND EVALUATION

Data Analysis

Based on 40 drivers' data in the test course, an analysis gives rise to some results regarding the three kinds of markings.

Figure 4 shows the test result of the sample tunnel (1.78km long). From the figure it can be seen that the trends of mean speed profile of the three markings were nearly same and at the entrance and exit of the tunnel the speeds slow down under any marking condition.

Figure 4 also shows the standard deviations of the speed along the course. To clarify, entering, inner, and exit were set as three special segments for analyzing points. Table 2 shows the mean standard deviations at each segment. It can be seen in the table that at the entering and exit segments of the tunnel the speed deviations show little difference for the three markings, but at the inner segment the speed deviation for the common marking is much greater than warning poles and visual markings, and between warning poles and visual markings the former is smaller.

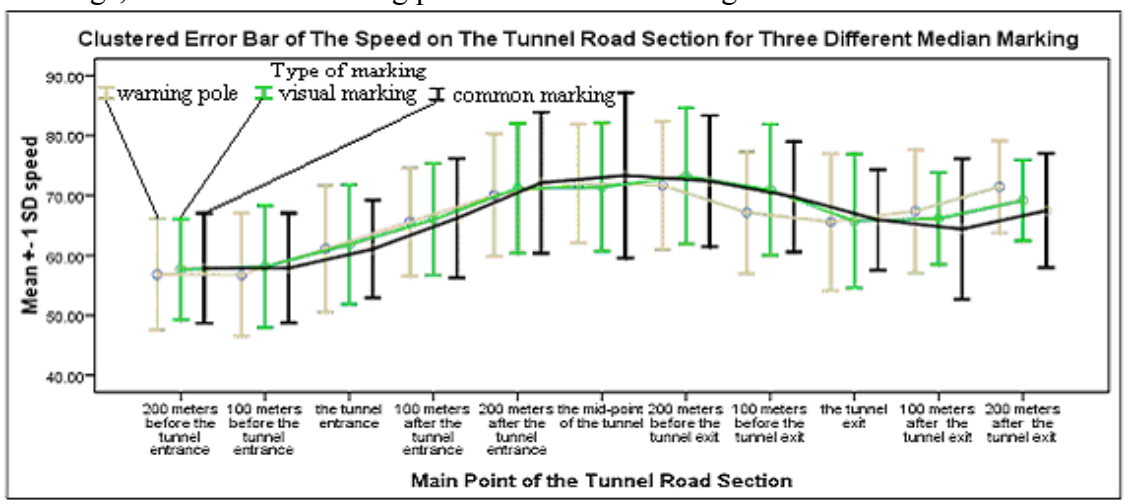

Figure 4. Clustered Error Bar of the Speed on the Tunnel Road Section for Three Different Median Marking

Table 2. The mean speed deviations on entering, inner and exit segment of the tunnel

Type of marking	Entering segment	Inner segment	Exit segment
Warning poles	9.49	9.90	9.82
Visual marking	9.78	10.70	9.57
Common marking	9.03	13.33	8.84

Like speed deviation, deviation of track lateral position along the test path and special segments are shown in Figure 5 and Table 3. From the figure, it can be seen that for the warning poles the mean distance between track and road center line is greater than visual marking and common marking. This means the vehicles in this case are each trying to avoid conflict with on-coming cars.

In addition the data of the table shows that the deviation of track lateral position in the warning poles condition is always greater than the others' at entering, inner and exit segment. The standard deviation of track lateral position shows how much a driver is able to maintain a constant track lateral position. In other words it is a surrogate of how much a driver 'weaved' along the road. Generally speaking, the less the deviation is, the better the vehicle's behavior (Tim Horberry et al. 2004).

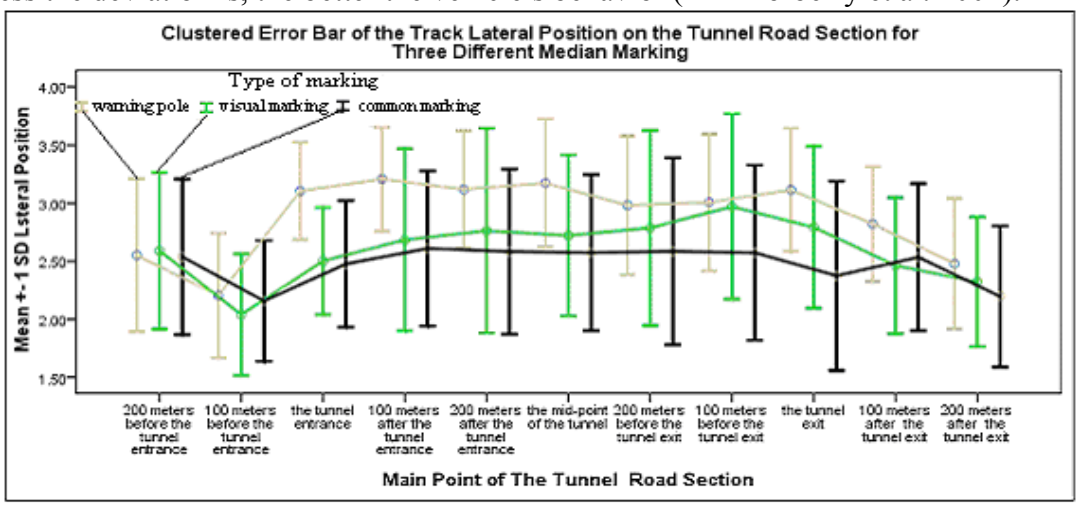

Figure 5. Clustered Error Bar of the Track Lateral Position on the Tunnel Road Section for Three Different Median Marking

Table3. The mean Track Lateral Position deviations on entering, inner and exit segment of the tunnel

Type of marking	Entering segment	Inner segment	Exit segment
Warning poles	0.55	0.53	0.53
Visual marking	0.66	0.77	0.68
Common marking	0.64	0.73	0.70

Note: The Track Lateral Position was the distance between road center line and track of the car.

4 CONCLUSIONS

- The three kinds of median marking in the tunnel have little impact on the speed of vehicles passing through the tunnel.
- Compared with visual markings and common markings, the warning poles make the vehicles go along a smoother and straighter path in the tunnel.
- The track lateral distance from road center line is greater than two others, so it is easer for the vehicle to avoid conflict with opposite cars.

5 ACKNOWLEDGMENT

This study was supported by the open fund from Key Laboratory of national highway traffic safety technology center. We also obtained the highway database from Yunnan Highway Design and Research Institute. To everyone involved, we express our sincere gratitude.

ABSTRACT

Numerical analyses of sound and vibration from the 225/50R17 smoothing radial tire, excited by surface load, have been carried out by using the FEM software, ANSYS, and the BEM software, SYSNOISE. The displacement frequency response of the tire which is respectively excited by radial contact force, tangential contact force and lateral contact force are calculated by using FEM. Then, the radiated sound power, radiation efficiency, and the directivity of sound in far field are given by using BEM in which the velocity boundary condition, are transformed from nodal displacements of FE modal.

INTRODUCTION

Sound radiation from a vibrating tire is a complex subject not only because of generation mechanisms, but also because the propagation of sound from the source to recipient is extremely complicated, which has attracted many scholars. Most research has been carried out experimentally and numerically, few aimed at radiated sound power, radiation efficiency, and the directivity of sound in far field.

Eberhardt [Eberhardt, A.C., 1981] concluded that sidewalls are not independent vibration radiators and that the contributions to emitted sound are about 10dB lower from the sidewalls than the tread. These conclusions are supported by Doan et al [Doan V.Q., Brackin D., Nishihata S. and Sauerzapf J., 1995], who considered side wall vibration as the most significant noise mechanism in the dominating frequency band 500-1000Hz. Ruhala [Ruhala, Richard, J., 1999] suggested that the sidewall region near the contact patch radiates more efficiently than the structural wave response along the tread band. Ulf Sandberg [Sandberg, Ulf and ejsmont, Jerzy A., 2002.] believed the tread band and the sidewall both contribute significantly to the radiation and also that belt resonance is the reason why the peak around 1kHz is observed in tire/road noise spectra for smooth or circumferential-grooved tires. R.A.G. Graf [R. A. G. GRAF, C.-Y. Kuo, A. P. Dowling and W. R. Graham., 2002] experimentally and numerically investigated the horn effect directivity. Some studies about tire/road noise directivity are summarized by Ulf Sandberg [Sandberg, Ulf and ejsmont, Jerzy A., 2002.], none of which can characterize clearly sound directivity resulting from tire vibration.

In this paper, the radiated sound power, radiation efficiency, and the directivity of sound in far field are studied. First, displacement frequency response of a smoothing tire which is respectively excited by radial contact force, tangential

contact force, and lateral contact force are calculated by employing finite element software ANSYS. Then, nodal displacements of FE modal are extracted and input into boundary element software SYSNOISE to calculate sound quantity. Some conclusions have been drawn from the numerical results.

NUMERICAL MODELS

Finite element model. Both the structure of the tire and the material at each part are complex, and the dynamic analysis on tire is emphasized in this paper. Three parts of a tire: the tread compound, the steel belt and the carcass ply are considered in order to highlight the computational efficiency and reduce the working load. Material parameters at each part are as follows: tread compound, ρ =1280 kg/m^3, EX =9.6×10^{6}N/m^2, $PRXY$ =0.49; steel belt, ρ =1500 kg/m^3, EX =1.1×10^{7}N/m^2, EY =1.3×10^{10}N/m^2, EZ =1.7×10^{7}N/m^2, $PRYZ$ =0.36; carcass ply, ρ =1100 kg/m^3, EX =2.94×10^{8}N/m^2, EY =1.5×10^{7}N/m^2, EZ =1.5×10^{7}N/m^2, $PRYZ$ =0.43. The tire is fixed at the wheel rim. Radial force, tangential force, and lateral force are respectively applied on the contact surface where tire and road meet. Because the vertical pressure at the leading edge is higher than that at the trailing edge [Sandberg, Ulf and ejsmont, Jerzy A., 2002], and both the tangential force and lateral force are proportional to vertical contact pressure. It is, therefore, assumed that the magnitude of the exciting force is linearly decreasing along the circumference from the leading edge to the trailing edge. Both the calculation frequency range is 10~1000 Hz, with the step of 10 Hz, aand the sound radiated from the tire vibration are nearly concentrated on the frequency range lower than 1000 Hz.

The ground contact length L =20cm and the tire contact width B =18cm are respectively determined by these two empirical formulas [Zhuang Jide, 1995]:

$$L = 2D\left(\frac{\delta}{D}\right)^s \tag{1}$$

and

$$B = B_0(1 - e^{-t\delta}) \tag{2}$$

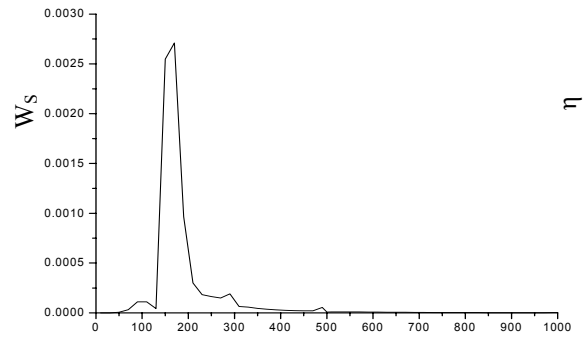
where $\delta = c_1 \dfrac{W^{0.85}}{S_0^{0.7} D^{0.43} p^{0.6}} K_0$ is the deformation of the tire along the radial direction on the contact surface; c_1 is a parameter related to tire design, c_1=1.15 for a bias tire and c_1=1.5 for a radial tire, W is the load applied on tire (daN), D is the tire outside diameter (cm), S_0 is the tire width (cm), p is the inflation pressure (100kpa), $K_0 = 15\times10^{-3} \times S_0 + 0.42$.

Boundary element model. Boundary element mesh is obtained through the FEM software, ANSYS, and the BEM software, SYSNOISE data interface technology. The velocity boundary condition is established by inputting displacement frequency response results which are acquired from FEM. Then,

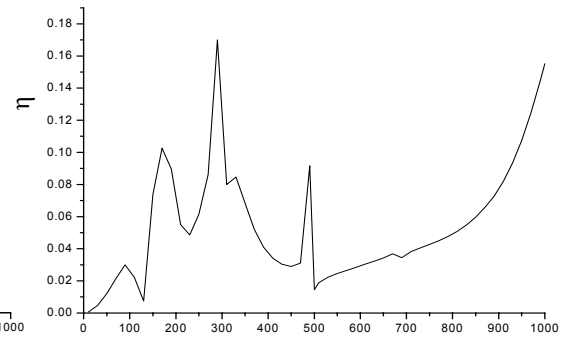
the calculation of the partial acoustic quantity is carried out by BEM. Air density is 1.225 kg/m^3 and the sound velocity in the air is 340 m/s.

NUMERICAL RESULTS AND CONCLUSIONS

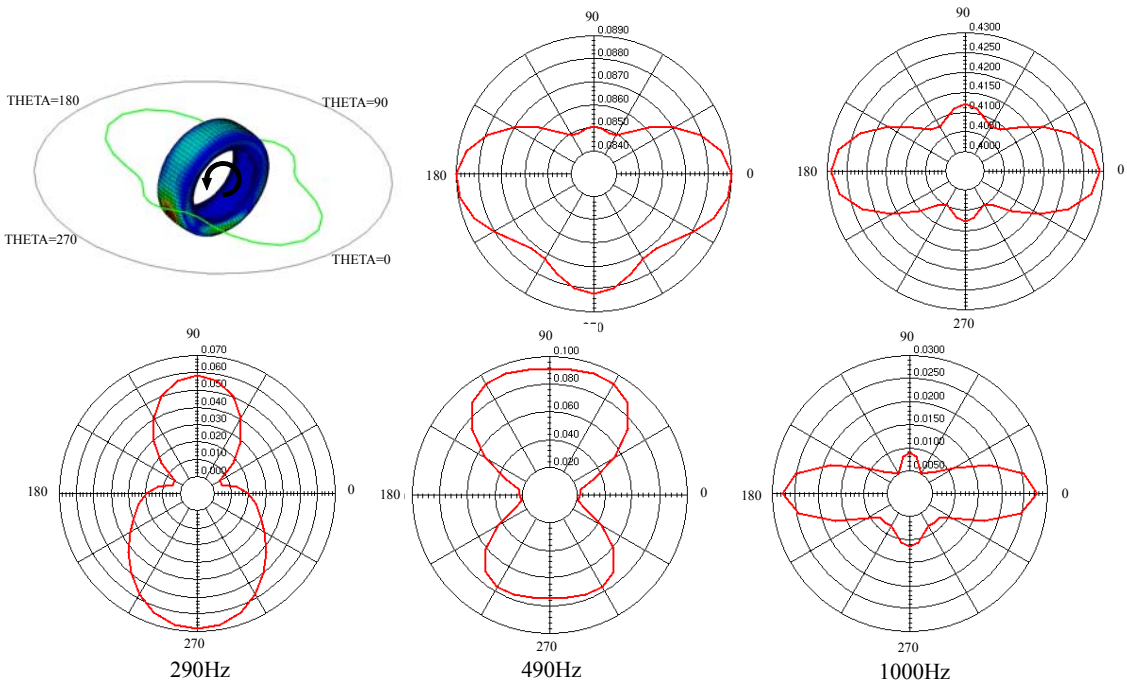
Figure1, Figure2 and Figure3 show BEM calculation results of radiated sound power, radiation efficiency, and directivity for a vibrating tire excited by radial force, tangential force and lateral fore respectively..



(a) Radiated sound power

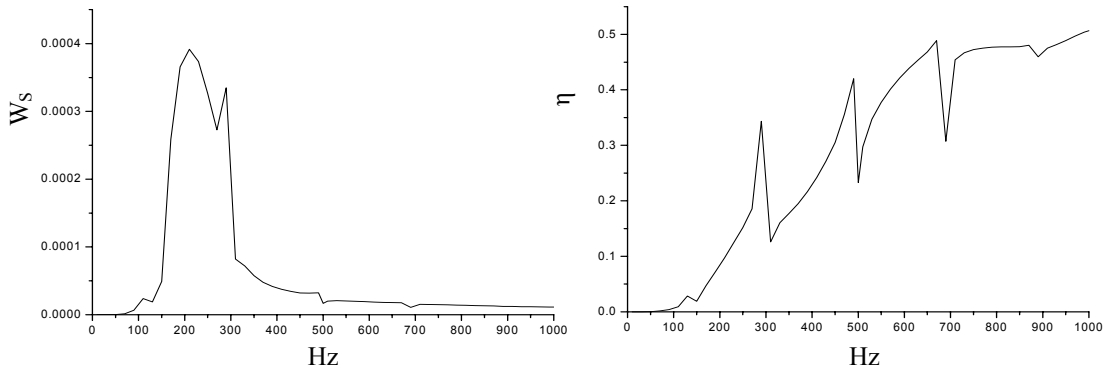


(b) Radiation efficiency

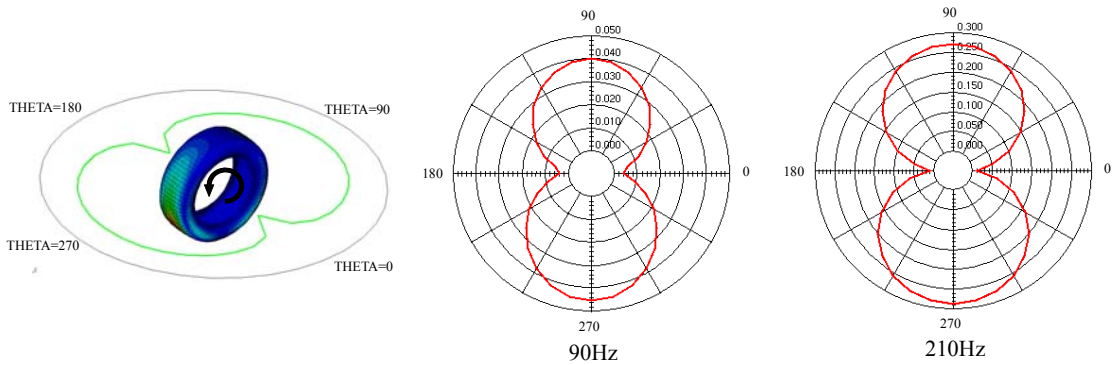


(c) Directivity of sound in far field

Figure 1. BEM calculation for a vibration tire excited by radial force.

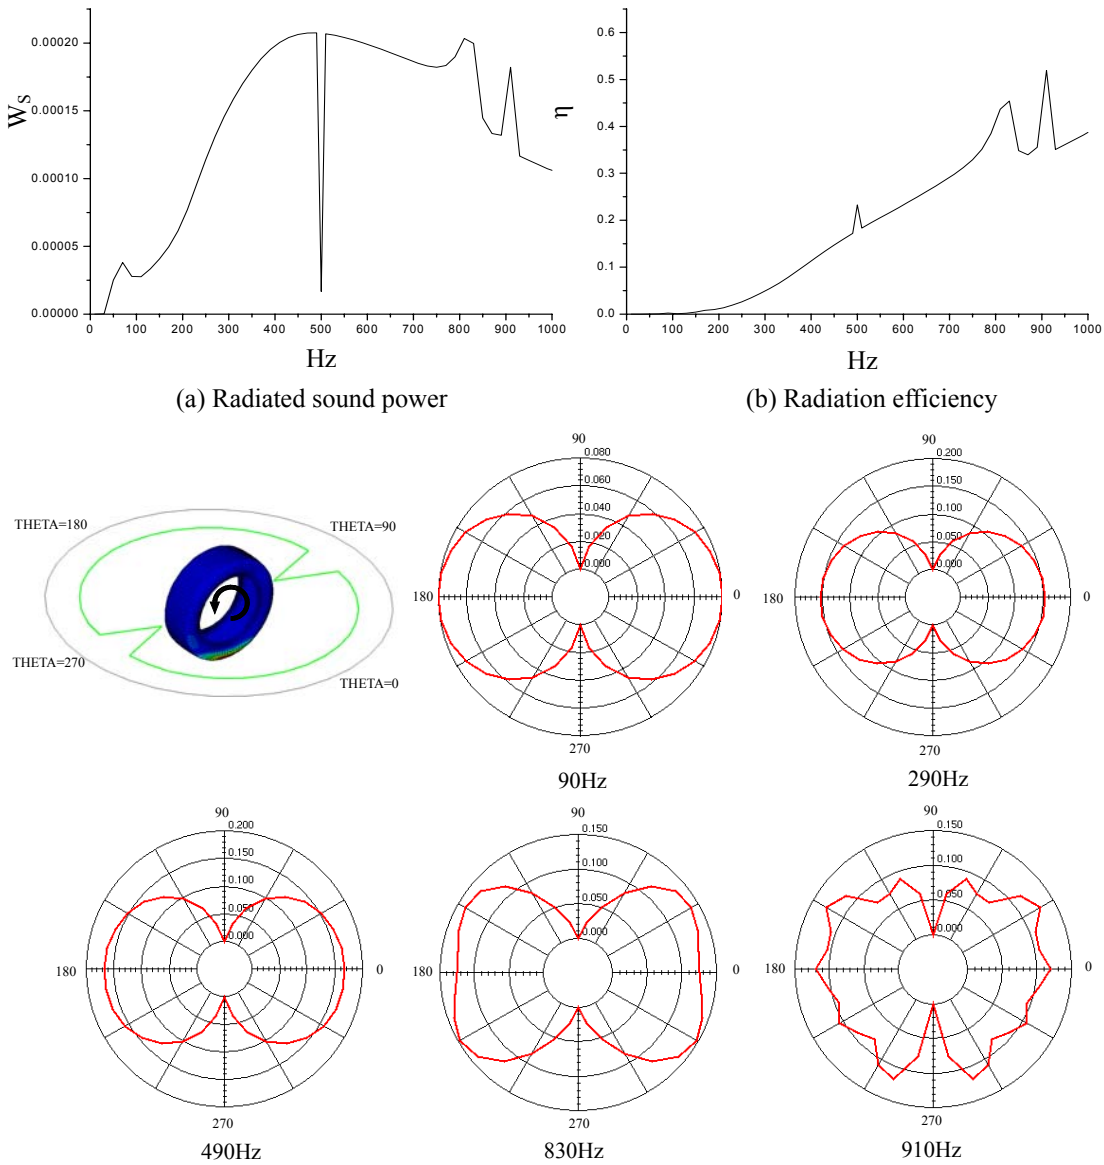


(a) Radiated sound power (b) Radiation efficiency



(c) Directivity of sound in far field

Figure 2. BEM calculation for a vibration tire excited by tangential force.



(a) Radiated sound power (b) Radiation efficiency

(c) Directivity of sound in far field

Figure 3. BEM calculation for a vibration tire excited by lateral force.

In Figure1, it is concluded that the peak value for radiated sound power of a vibrating tire excited by radial force occurs at 170Hz. Radiated sound power at a low frequency is higher than that at a medium frequency. At a low-frequency (10~500Hz), there are three peaks for radiation efficiency; however, at a medium-frequency (500~1000Hz), the radiation efficiency increases gradually. At different frequencies, the directivity of sound in far field shows different shapes. Sound levels are not substantially higher in the front and rear than that at the sides; although, levels may be lower, and the directivity of sound becomes complex with

increasing frequency.

In Figure2, it is concluded that the peak value for radiated sound power of a vibrating tire excited by tangential force occurs at 210Hz. Radiated sound power at a low frequency is also higher than that at a medium frequency. The general tendency of radiation efficiency increases with increasing frequency. Sound levels are higher in the front than in the rear and the sides.

In Figure3, it is concluded that the radiated sound power of a vibrating tire excited by lateral force distributes in a wide frequency range. The general tendency of radiation efficiency increases with increasing frequency. Sound levels are higher at the sides than in the front and rear, and the directivity of sound become complex with increasing frequency.

ABSTRACT

Based on vehicle collision safety technology, GPS technology and mobile communication technology, this paper offers a person-free operating Vehicle Collision Accident Self-alarm System. The thesis introduces the principle and the structure of the system, and offers the solution of the self-alarm. The system can solve problems in which the drivers or passengers injured in the vehicle collision accident can't alarm by themselves or they can alarm but don't know their accurate location. The system will alarm automatically in a timely manner.

KEYWORDS: collision accident; self-alarm; GPS; mobile communication; solution

1. INTRODUCTION

With the explosive development of the automotive industry and the increasing volume of automobiles, with cars going faster, traffic accidents are growing rapidly. If a car has a serious collision, the crew in the car cannot call for help by themselves because of shock, coma or their movement limitations; or they can alarm but don't know where they are. These factors can seriously delay rescue and cause unnecessary death. The thesis offered by this paper utilizes vehicle collision technology, GPS technology and mobile communication technology to devise a person-free operating Vehicle Collision Accident Self-alarm System ("The System" for short). This system can smooth over the faults of traditional manual alarm systems, and can efficiently solve the problems mentioned above. After the collision accident, the system can trigger the alarm system, locate the vehicle accurately then send information to the rescue service station, so the rescuers can act quickly which can reduce the death rate.

2. THE PRINCIPLE AND STRUCUTRE OF THE SYSTEM

2.1 The Principle

When a car meets a serious collision, the Airbag System will inflate the airbags, meanwhile, the inflation signal will also be sent to the ECU of the System; the mounted GPS Action Athena can receipt the signal from satellites to compile the current geographical information and then save it into the RAM of the mounted terminal; the communicating module will load the information and format a SOS short message (including the current geographical information of the vehicle) which is going to be sent to the Long-range Service Center; the servers contact with the vehicle and determine whether they need rescue.

2.2 Structure

The System is formed with Independent Power Supply, Airbag Module, GPS Signal Receiver, Electronic Control Unit, Communicating Module, and Fault Self-test Module. The parts inside the dotted line rectangle of Figure 1 are the formation of the Mounted Terminal.

(1) Airbag Module: This module is the standard configuration, so we don't need to design it in the System. The System only collects the ignition signal as a trigger signal.

(2) GPS Signal Receiver: Receipts the satellite signal timely, vehicle location identification, combined with existing electronic navigation software can achieve precise positioning vehicles.

(3) Electronic Control Unit (ECU): Control the modules work coordinately. Judge whether there is an ignition signal so as to control whether the System works or not. It collects the location data; edits distress message itself, and send the communication instruction to the communication module. Communication Module: Send distress messages to the Service Center according to the instruction of ECU; receive voice call and two-way call.

(4) Independent Power Supply: Can supply the whole System after the main power supply of the automotive break down.

(5) Fault Self-test Module: Can diagnostic the fault of the mounted terminal.

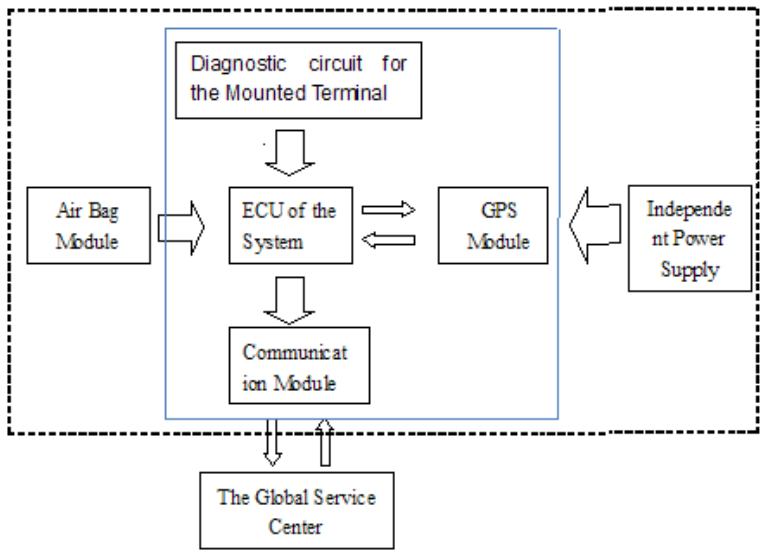

Figure 1. Structure of the System.

3. SYSTEM HARDWARE DESIGN

The design of The System mainly includes GPS Signal Receiver, Electronic Control Unit, Communication Module and Independent Power Supply.

3.1 GPS Signal Receiver

The GPS Signal Receiver can transform, amplify, and process the received navigation signal, so as to get the accurate location of the vehicle, then transmit the signal to the ECU. The System adopts a Chang-Tian GR-85 GPS Module from Taiwan China to get the original positioning data. Its structure is shown in Figure 2.

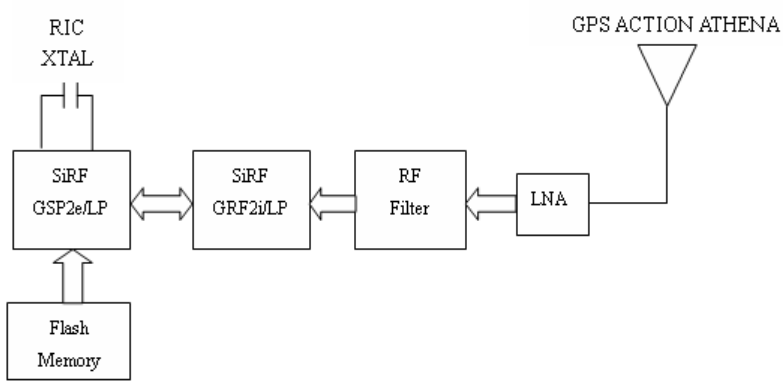

Figure 2. Structure of GR-85

3.2 Mounted Electronic Control Unit

The System adopts the embedded system which is timely, with high reliability and efficiency. The CPU of S3C44B0X is the 16/32-bit ARM 7TDMIRISC Processor (66MHz) with ARM7TDMI integrated Thumb code compression, on-chip ICE breakpoint debugging support, and a 32-bit hardware multiplier. S3C44B0X expands on a full range of common peripheral devices based on the ARM7TDMI core, which can greatly reduce the system circuitry in addition to the components outside the processor configuration, thereby allowing the cost of system to a minimum.

3.3 Communication Module

The System adopts GPRS Net as the communication platform, which has high transmission rate, high frequency utilization, almost zero error-bit rates, supporting multiple network protocols, and supports roaming.

The System uses the GPRS SIM300C module. The client model of the SIM300C system connector (60 pins) is IL-312-A60P-VF-A. This system connector is the interface between the SIM300C module and applications which mainly provides interfaces for the external power supply, RS-232 Serial Port, SIM Interface and Audio Interface.

Users can complete the operations to the module by AT commands through the serial interfaces provided by SIM300C, and can also access the internet by the GPRS functions offered by the module (GPRS network support required).

The module supports an external SIM card, and can be connected directly to a 3.0V or 1.8V SIM card. The module can monitor and automatically adapt to the type of the SIM card used. The designed circuit of the SIM card connection is shown in Figure 3.

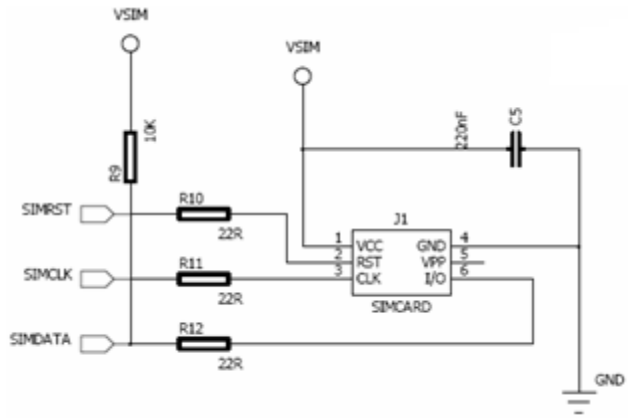

Figure 3. SIM card circuit

3.4 Power Supply

The Power Supply mainly provides power for the Communication Module, GPS Signal Receiver, the ECU, etc. In order to guarantee the reliability of the System, there is also a standby power supply. In this part, we only design the power supply to the Communication Module. Since the pulse emit can cause rapid changes of current consumption, the power supply must provide instantaneous peak current. Table 1 shows the reference value of current in different states.

Table 1. Reference value of current in different states.

Communication Status	Current (typical)
Free mode	4mA
In communicating(Circuit-switched mode, 1 slot receive, 1 slot emit)	250mA
In communicating(GPRS mode, 1slot receive, 2 slots emit)	500mA
In communicating－peak current	1700mA
GPRS mode, 3 slots receive, 2 slots emit	560mA
GPRS mode, 4 slots receive	125mA
Power-off	50uA

The Communication Module supply voltage range is 3.3V~ 4.6V, and the power supply should have 2A peak current output capacity. The 12V automotive power supply is regulated by the regulator chip MIC29302BU, and regulates to 3.3V~ 4.6V to properly operate the SIM300C module. When the DC supply voltage is lower than 3.3V, the module will switch to the standby power supply automatically, and in order to ensure the stability of the power supplied to the module, a regulator capacitor should be added to the input end of the power supply to the module, to stabilize the supply voltage for the module during the transmission.

The standby power supply is a Li-ion battery pack with a rated voltage between 3.6V~ 3.9V. It will be auto-charged when the voltage is lower than 3.6V, and stop charging when over 3.95V. The standby power supply does not need to supply power under normal operating conditions.

4 THE SELF- ALARM SOLUTION SCHEME

In order to alarm rapidly and efficiently, the geographical location, frequency of the SOS messages sent, the number calling from the Service Center and the time for waiting for the reply should be analyzed and processed. The location of the car is divided into three levels “A”, “B” and “C”, according to the GPS positioning information and the related electronic maps; level A for the traffic flourishing region; level B for the region whose traffic condition is over the average; level C for the traffic least developed region. We define “A” for the Good condition, “B” for the Medium condition and “C” for the Poor condition. The higher the level the lower frequency the alarm messages send. Starting with sending the collision signal, if there are no feedback calls from the service center with the passage of time, the alarm signal sending frequency will increase. That is to say, at the early stage, the lower sending frequency requires fewer alarm service resources; if there is still no feedback call when it reaches a certain period of time, raise the alarm signal frequency to call the greatest attention of the service station. The service station should carry out the voice calls to the car as soon as they receive the alarm messages. If there is still no reply after several calls, the service station will start rescuing.

The related parameters are defined as follows: the Mounted Terminal operation delay is t; the total number of alarm signal sending is n_1; the time interval between each message is T_c; the time for waiting for the feedback call is T_{cw}; the receiving and feedback delay is T_1; the voice calling delay is T_d; the time for waiting for the reply is T_s; the fixed time for waiting the reply is T_{s0}; the waiting time after hang up is T_w; the total number of voice calls is N_c; the fixed largest number of the voice calls is N; the voice calls can be connected is defined as Y=1, otherwise is Y=0; “Replied” is defined as R=1, otherwise is R=0. Enquiring if needing rescue, define Yes; if no, define No; the total communicating time is defined as T.

Step1 The Mounted Terminal will wait after sending the alarm message. If Tcw>Tc, then repeat Step 1.

Step2 If Tcw≤Tc, and there is a voice call, then stop sending alarm messages.

Step3 When Nc≤N,

1) If Y=1, then wait for the reply, the waiting time is Ts0:

a. If Ts > Ts0, and R=0, then hang up, wait time interval Tw, repeat Step3;

b. If R=1, then enquire instead of calling again; if Yes, then rescue, if No, hang up.

2) If Y=0, then hang up, wait a time interval Tw, repeat Step 3.

Step 4 If Nc>N, then judge to be Yes.

Step 5 Good:N=5. Medium:N=4. Poor:N=3. Tc＝10sec,Ts0＝30sec,Tw＝20sec.

Step 6 The total communicating time is $T \le t + (n1 - 1) \times Tc + T1 + Nc \times Td + (Nc - 1) \times Tw + Ts0 \times Nc$.

This scheme gives consideration to both cost and reliability of the whole system. It can help the Service Station work efficiently through the defined levels of the traffic condition. The flow-process diagram of the above tactics is shown in Figure 4. The System consists of the Self-Test subroutine, the Airbag Monitoring subroutine and

the Alarm Signal Sending and Feedback subroutine.

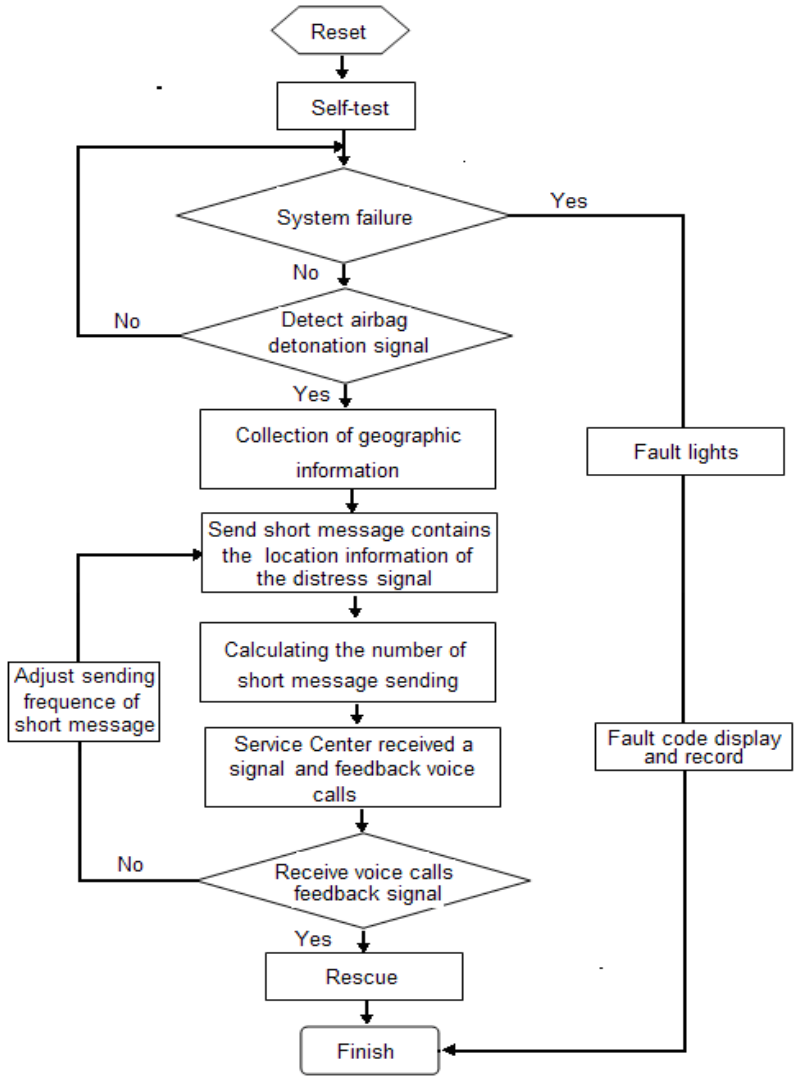

Figure 4. The flow-process diagram of theSystem software

5 SUMMARY:

Based on the study introduced above and design of the The System principles, we can solve the hard problems posed by some collision accidents in which the vehicle crew cannot alarm manually. This can shorten the rescue time and thereby reduce death rates and property loss. This study of the technology has great potential to improve the vehicle accident alarm system. The System still has some GPS satellites signal dead zones and the mobile communication signals, so in order to solve this problem, we still need more in depth study into alarm tactics.

ABSTRACT

Walking is one of the important traffic modes in Beijing central city, and should be given sufficient attention. This paper, through a large of field survey and literature review, analyzed and summarized the difficulties faced by walking traffic, including traffic infrastructure, traffic environment and pedestrian safety awareness and such issues under the rapid development of motorization and trip demand. A series of ensured measures were listed at the end to improve walking environment.

KEY WORD: Walking, Pedestrian Safety, Traffic Environment, Motorization

1 BACKGROUND

Along with the fast development of Chinese economy and motorization, there are 0.17 billion motor vehicles in China (0.127vehivle/person) by the end of June of 2008. Beijing, as the capital of china, motor vehicle grows rapidly in recent years, the traffic congestion has become an obstacle in Beijing development process. In order to deal with the serious traffic congestion, the vehicle lane is widened increasingly, while the walk space is sharply invaded. The conflict between motor vehicle and pedestrian become more and more and correspondingly the hidden accidents and real traffic conflicts have aroused the society's attention.

The <World Report on Road Traffic Injure Prevention>has point out the traffic accidents and death number will increase largely in middle and low income countries between the year 2000 and 2020. If we do not take the adequate measures, by the end of 2020, the road traffic injury will become the third reason for the global disease and injuries. Walking, as the necessary traffic mode to connect public transport trips, is a part of "New Beijing Transport System". Therefore it is needed to protect pedestrian right of way and provide a safe and comfortable traffic environment for walking to

perfect Beijing traffic.

2 DEVELOPMENT OF MOTORIZATION IN BEIJING

Beijing economy has kept continuously rapidly incensement since 2000, the year average increase rate is over 10 percentage. In 2007, the GDP had reached 935.5 billion, increasing 13.3% comparable with 2006. Now Beijing development is influenced by the international finance crisis, but with the China national, and Beijing Municipal government's high attention, Beijing economy will still keep about 8% yearly growth in the future

According to related reference, when GDP per person is over 3000 dollars, the vehicle amount will enter a swift growth period. In 2008 Beijing average GDP per person has reached 9000 dollars. The rapid growth of economic and the high living standard lead to a higher request to the traffic journey conformability; the car enters the ordinary citizen family rapidly.

In recent years, Beijing vehicle amount increases about 10% every year. By the end of 2008, Beijing vehicle grossed to 3.5 million, among them, the personal car is 2.3 million. The vehicle number per thousand persons is 207(Beijing Transportation Research Center, 2009). This symbolizes that Beijing entered the fast motorization "the automobile time", the car entering the ordinary family will soon achieve.

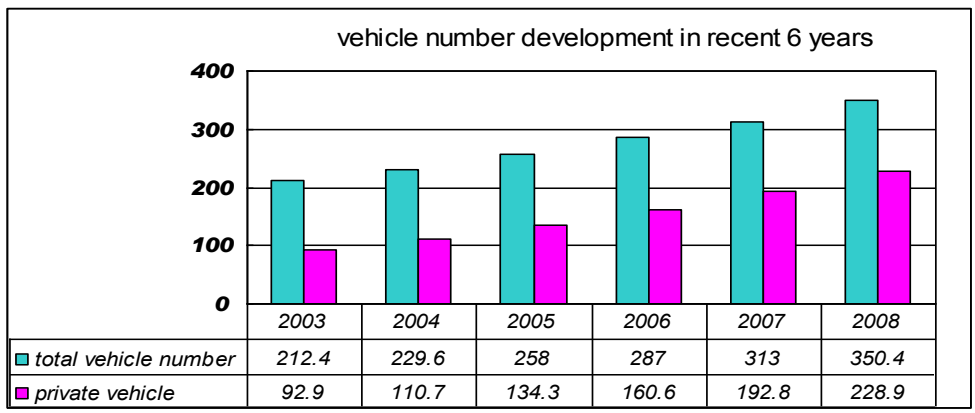

Figure 1 vehicle number development in recent years .

3 TRAFFIC ENVIRONMENT OF BEIJING

3.1 Air Environment

The vehicle rapidly growth has brought a series questions for the urban development, the most serious problem is the urban air pollution. Statistics show that 40-60% of suspended particle, 80% of hydrocarbons (HC) and 70-80% of nitrogen oxides (NOX) of Beijing air come from vehicle exhaust (Environmental Defense Fund, 2009). Beijing has taken a lot of measures to deal with the polluted environment, and the air quality has already improved in recent years, but there are still some index can not attain the standard. The pedestrian walks on the road, exposure in automobile exhaust with high concentration. It endangers people's health directly.

3.2 Traffic Infrastructure

The fast development of vehicle leaded to a more serious traffic congestion in Beijing. In order to alleviate it, more and more road space is occupied by motor vehicle, the walking and bicycle lane is continuously invaded, traffic infrastructure for walking does not consider pedestrian's demand, lead inconvenience and hidden conflict for pedestrians. To be noticed, this paper pays attention in Beijing central city, the suburban is out of consideration.

1) Sidewalk width insufficient

Some roads do not set sidewalk, passenger and motor vehicle mix in the same space. Some artery roads sidewalk width is less than 1 meter, during the peak hour passengers have to enter motor vehicle roadway, which extremely easy to cause traffic accident.

Beixiange street

Changshunjie street

The west ring road

Figure 2 Pictures of unreasonable sidewalk

2) Barrier on Sidewalk

Since a long period of time, there are no co-ordinate arrangements and the effective management of sidewalk. The sidewalk space is illegally occupied by different uses, such as municipal facilities, vehicle parking, bicycle running and parking, shopping and etc. those facilities and obstructs brought inconvenience and difficulties to pedestrian especially for the old, young, sick, disabled people and pregnant women

The investigation shows that 76% pedestrians disagree vehicle parking on the sidewalk; 81% pedestrians approve to widen sidewalk especially at the bus station (Beijing Municipal Institute of Planning and Design, Beijing Transportation Research Center, 2008.12)

3) Incomplete crossing facility

Pedestrian crossing facilities include crosswalk, overpass and underpass; it is a necessary part of walking system. The unreasonable interval of crossing facilities, vehicle interference, excessive overpass and underpass, over wide vehicle lane and etc, all those are for a goal, that is to provide high speed for motor vehicles. But what's for the pedestrian? They have to go up or down to cross a 8 or 10 vehicle-lanes street. For them the ground crossing is the best.

The investigation shows that 57% pedestrians feel crossing is inconvenient, only 5% pedestrian feel good for current crossing condition. The reason for inconvenience

is: detours too far (34%), the vehicle not give way to pedestrian (33%), overpass and underpass (24%) and too wide vehicle street (Beijing Municipal Institute of Planning and Design, Beijing Transportation Research Center, 2008.12).

4) Poor pavement and inconvenience for disabled people

Except for the new building roads, most of existing sidewalks and crossing facilities do not comply with disabled passing standard. The disabled people can not travel.

3.3 Traffic Accidents

Pedestrian, without any protection, is the vulnerable road user compare with vehicle driver. Once the pedestrian and vehicle conflict, the injured even dead must be the pedestrian. According to the statistics, pedestrian accounts for 25% of death in recent 20 years; it is the major vulnerable group (Duan Liren, 2006).

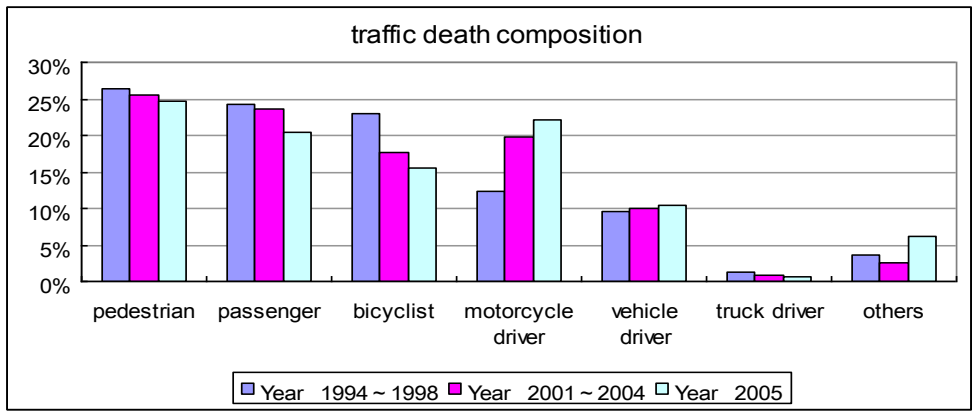

Figure3 Traffic Death Composition in China

4 DEVELOPMENT TREND OF WALKING

In order to alleviate the increasingly traffic congestion problem, Beijing government and many non-government organizations (NGO) carry out a number of activities to encourage less driving and more using public transport, bicycle and walking. 16th to 22nd of September 2007, Beijing held the first “China Urban Public Transport Week and Car Free Day” activity. And the activity continues. The theme of “car free day” of 2008 is “Human Street”.

After the successful Olympics. “Human Traffic” “High-tech Traffic” and “Green Traffic” become the strategic goal in the future of Beijing traffic development history. Walking, as an important component of the cityscape, reflects the fair, human and sustainability of Beijing traffic. It is an important component to build "New Beijing Transport System," and it will play an important role in integrated transport system in Beijing.

Whether the government or NGO have actively encouraged people to adopt green travel mode, walking is one of the most important component. Beijing walking policies should be to advocate walking and to implement walking priority. Beijing will provide a safe, smooth, convenient and comfortable walking environment for all

pedestrians including the disabled groups.

5 IMPROVEMENT MEASURES FOR WALKING SYSTEM

Europe's transport policy has been to encourage people to walk. In 1988, the European Parliament passed the "European Charter on the Rights of Walking." It brought forwards people should walk and ride in search of fun, and more attention should be pay to children, the elderly and disabled with their right. Those countries and regions developed a complete planning and construction guidelines; carried out scientific and careful designs; took the corresponding supporting policies; promoted government departments, business organizations and the public to participate actively at the same time.

The Olympic Games is an opportunity to arouse the Government and the public pay more attention to traffic and walking environment. Since 2000 Beijing has been improving the traffic environment continuously. Beijing is abolishing the vehicle parking on the sidewalk. Nearly 100 thousands trails piles have been hammered in the sidewalk since 2006, and it effectively prevents the vehicle entering walking space. More refuge islands have been settled along the roads and at the intersections; and the signal design became to consider pedestrian demand more. Beijing are changing pedestrian traffic environment gradually. But comparing with the successful pedestrian plan and walking system construction, there still is a big gap between Beijing and other developed cities. It is proposed from the following aspects to continue increasing pedestrian traffic environment in the future

Right of Way

The allocation of road space should consider all traffic participants; take into account the interests of all participants to implement safety first. One group’s benefit should not based on prejudicing to other groups’ benefits, especially vulnerable groups such as the sick and elderly. So it is necessary to plan the road space for pedestrian according to current design standards and guidelines, combined with the actual needs of pedestrians including traffic direction and volume; to design the sidewalks with reasonable width, continuity, separated, and green.

Pedestrian crossing safety facilities

The crossing facility’s type and location should be closely consistent with walking system of the residential areas, commercial areas, railway stations, recreational squares; and become an integrated complete system of city walking system to meet the actual needs of pedestrians. The ground crossing is the best choice for pedestrians, especially for the elder and disabled people. So when the construction is permitted, the priority belongs to the ground crossing facility, next is overpass and finally is underpass. To be notice, the refuge island and enough signal time for pedestrian should be guaranteed for the ground crossing.

Vehicle speed control

Studies show that pedestrians have 90% chance of survival when collisions with motor vehicle speed less than 30km/h; if collision vehicle speeds faster than 45km/h,

pedestrians have only less than 50% chance of survival (World Band, World Health Organization, 2004). Therefore, to lower motor vehicle speed is an important measure to improve pedestrian's safety at intersection.

According to the data of Beijing intersection vehicle speed investigation at night, the average speed and 85% speed respective are 42.3km/h and 58.75km/, they are both generally higher than the safe speed for pedestrian. So it is necessary to use of speed limited signs, hump, road alignment design, traffic management, signal control and other means to reduce the vehicle speed near the sidewalk and pedestrian crossing path.

Pedestrian safety education:

In addition to the engineering-related measures, it is indispensable to strengthen public traffic law's education and increase their safety awareness. There is no mandatory rule for pedestrian traffic safety education, so many pedestrians lack safety awareness, and behave out-of-order, which is one of the main causes of traffic accidents. The effective education and publication will improve road safety for all traffic participants.

Air quality improvement:

On one hand, new motor vehicle is request to apply higher emission standard. And the existing dirty vehicle is being accelerated out of use. On the other hand, the Government adopts the traffic demand management measures to lead reasonable motor vehicle use, effective reducing emissions and energy consumption. Through the rational use of motor vehicles, it is helpful to reduce the impact of exhaust to pedestrians.

6 CONCLUSIONS

Walking system as an important part to construct "Human Traffic, High-tech Traffic and green Traffic", along with the development of public transport and green travel activities, it will become a necessary way of daily trips. Therefore safe and comfortable walking environment become hot needs of citizens. Improve the walking environment includes air quality and traffic facilities. Through the guide use of motor vehicles, increasing pedestrian safety publicity and education, ensuring the right of way for pedestrians and other related human traffic facilities, Beijing will gradually improve the walking environment and build a pleasant city for all traffic participants.

ABSTRACT

The use-level of road network prediction is the key for making a good plan of pavement maintenance. Traditional methods used for the use-level of road network prediction have some limitations. It is difficult for traditional prediction models to set up multi-parameter equations and predict many factors' changes. The precision is low, particularly in dealing with massive data of road networks. A neural network has certain advantages to predict the change of road network service's level. In this paper, a prediction model based on the Back-Propagation Neural Network (BP neural network) was established to predict use-level of a road network. China's road-related standards divide the use-level of road networks into *5* levels, so *5* state vectors were defined in the BP neural network. The status of a large number of roads over the years was turned into a *5*-dimensional time series. The BP neural network was built on the MATLAB software platform. Many methods were used to improve prediction precision, such as Bayesian methods, repeat training, and so on. The prediction method was ameliorated too. Combined with factual data of road conditions in Tianjin, through the comparison of direct prediction and gradually rolling prediction, the results showed that gradually rolling prediction offered a better prediction precision and was more applicable to use in the use-level of road network prediction. Using gradually rolling prediction, this paper predicted and analyzed the changes of the use-level of road network in Tianjin.

INTRODUCTION

The use-level of a road network mainly refers to the proportion that road sections of different states possess. The changes of the use-level of road network are very complicated due to the attenuation of road performance, road network maintenance and many other factors. The traditional model is hard to predict. In this paper, a neural network model was set up to predict ratio-changes of different levels (excellent, good, medium, hypo-medium, bad) of the overall road network status (strength coefficient and roughness). Prediction results could be used to help a road management department master the status and development trends of pavement performance, facilitate decision-making of short-term and long-term road network maintenance and make financial optimization.

Traditional models mainly use Deterministic Model (Empirical Regression,

etc.) and Probabilistic Model (Markov Model, etc.) to study the pavement performance (Yao Zu-kang, 1993), such as Finland Model, Norway Model, AASHTO Model, IDAHO state Model, S-type Model (Cheng Yu-zhu, 2007), and so on. In China, the Empirical Regression model is used in Guangdong, Tianjin and Beijing. The Deterministic Model is used in Jiangxi Province. A General Deterioration Equation for pavement performance was put forward by SUN Li-jun, LIU Xi-ping from Tongji University in 1995 (Sun Li-jun, Liu Xi-ping, 1995), etc. At present, most of these studies are carried out against a road section. It is difficult for the traditional prediction model to set up a multi-parameter equation and predict many factors' change. The precision is low. Therefore, studies about the use-level of road networks are so few that road management departments can not directly assess the entire road network status. BP neural network (BP network for short) can resolve the highly complex problem of nonlinear systems with the ability to dynamically update data, and be able to reverse the propagation of the error to correct model continuously (Ge Zhe-xue, Sun Zhi-qiang, 2007). So, many scholars at home and abroad use the BP network model to study pavement performance. For instance, Bing Wen-shan from Harbin University of C.E. & Architecture (HIT for now) (Bing Wen-shan, 2000), Xie Xu-fei from Harbin Institute of Technology (HIT) (Xie Xu-fei, 2004), Zhou Wen-xian from Tongji University (Zhou Wen-xian, 2006), used BP networks to set up different prediction models; J.D. Lea abroad used a BP network in South African to analyze and forecast road data. Good results had been obtained (J.D.Lea, 1999).

Based on previous studies, this paper makes use of the neural network toolbox in MATLAB for programming. A prediction model based on a BP neural network for predicting the change of the use-level of road network was established. The Prediction method was improved too. Combined with factual data of road conditions in Tianjin, comparing and analyzing prediction results, this paper could provide a reference for road network's maintenance decision-making.

ESTABLISHMENT OF A BP NETWORK MODEL

The structure of a BP network is composed of an input layer, hidden layer and output layer. When a study sample is provided to the network, neuron activation-value transfer input data from the input layer (no transfer-function) to the first hidden layer. The hidden layer deals with the information from the upper layer, and then passes on to the next layer until neurons in the output layer get the network's input-response. BP algorithm is applied to amend connection-weights layer by layer. BP network's structure shape is shown in Figure 1.

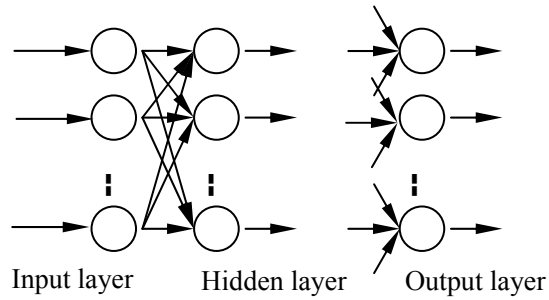

Figure 1. BP network structure.

The decay process of road performance is continuous. Data reflecting road status will form a time sequence (serial relations) (Xie Xu-fei, 2004). It is assumed that there are *q* road sections or routes with the same pavement structure in an area under the same traffic level, historical conditions of *TS* time step of one performance form *q* state sequences separately (Figure 2 (a)). The road sections between each other are not affected, so sequences could be designed as a serial relationship (Figure 2 (b)).

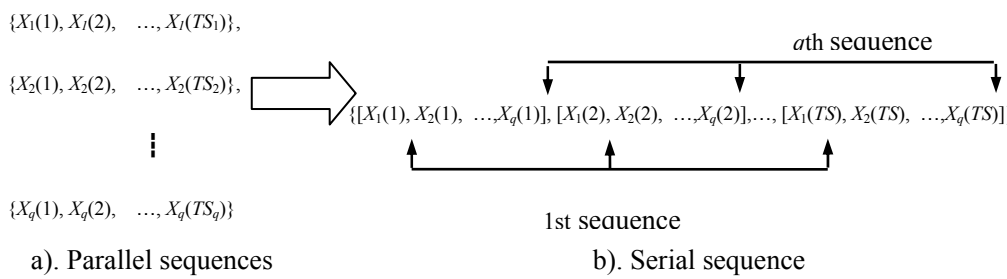

Figure 2. Sequences of data-state.

Performance evaluation levels are generally divided into *5* levels in existing norms of highway industry, which corresponds to *5*-dimensional state space. So in parallel sequence (Figure 2 (a)), state vector of the *t*th step in the *i*th sequence is: *Xi (t) = [xi1 (t), xi2 (t), xi3 (t), xi4 (t), xi5 (t)] T*. The more road condition sequences that are known, the greater the *TS* time step is, and the more comprehensive the information is. This data structure is conducive for the model's continuous updating. Considering a *2*-year recursive-chain network, which means inputs include state of the past and current year, and output includes state of the next year, the sample is: *([X (t-1); X (t)], X (t +1))* . In this paper, MATLAB software was used as a platform to offer neural network toolbox for programming. The flow of data processing in the BP network is shown in Figure 3.

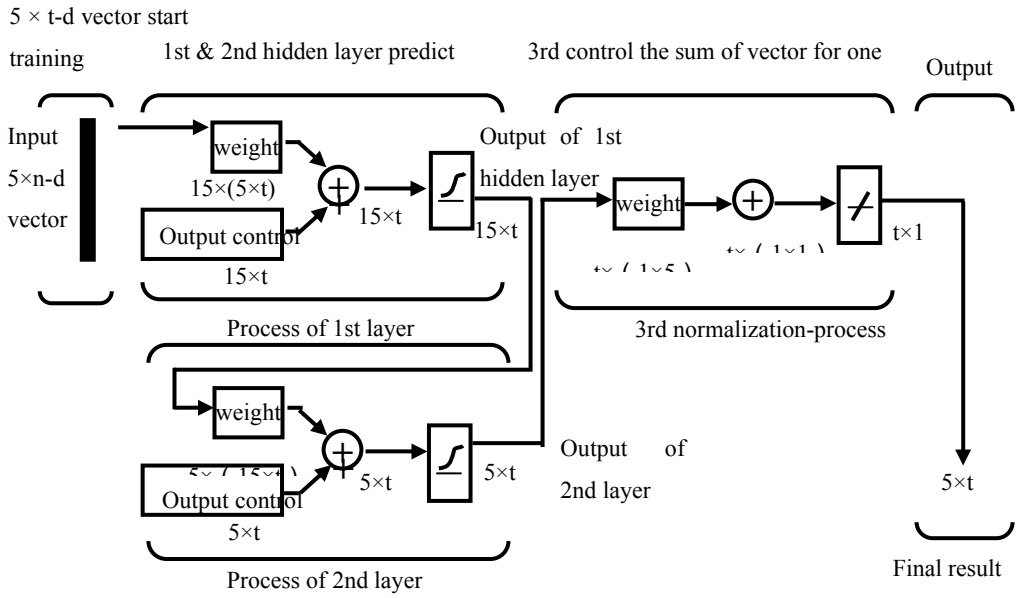

Figure 3. Information of Data-transmission.

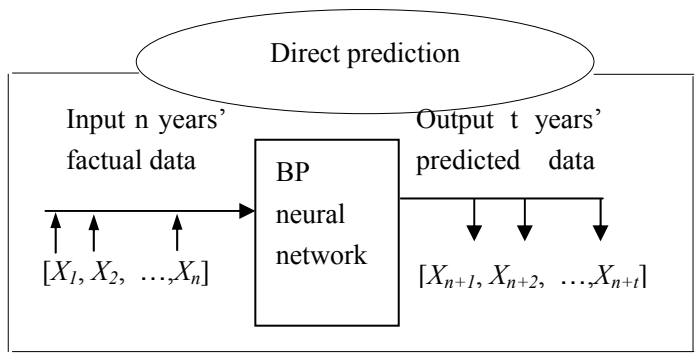
In Figure 3, *5 × t(n)*-d means *5 × t(n)*-dimensional. *n* expresses number of years of known data, *t* expresses prediction cycle.

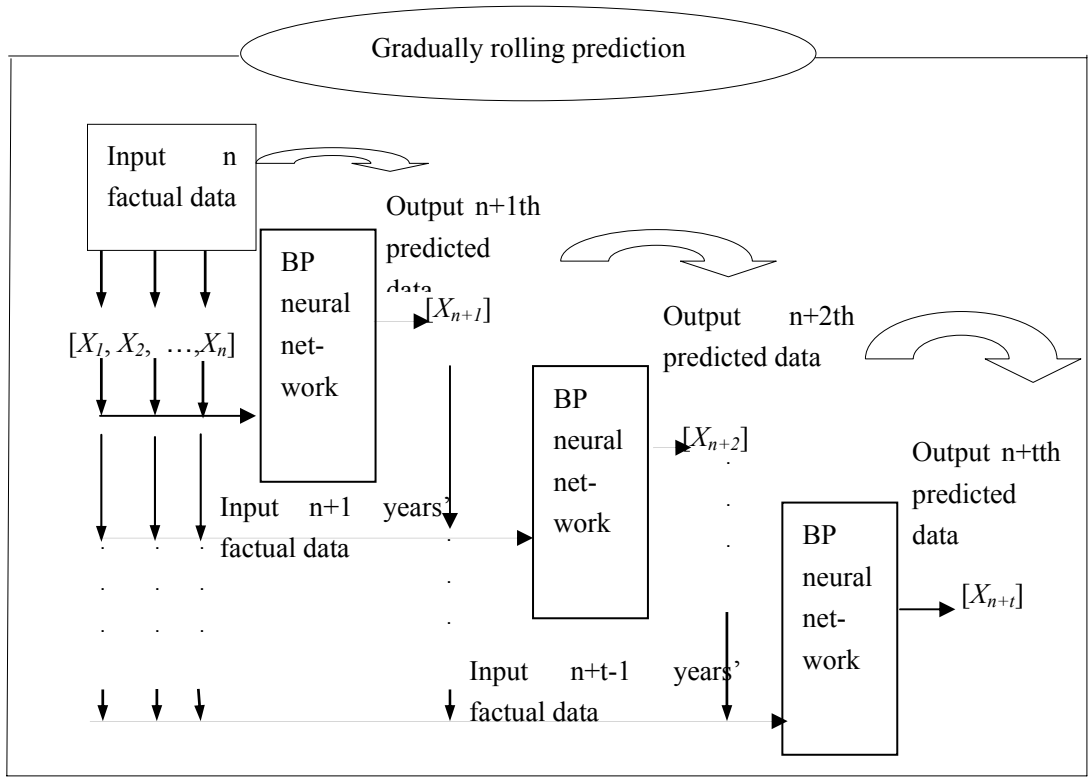
Many methods were used to improve prediction precision. Using Bayesian Methods could determine the best regular parameters to conquer the over-fitting problem. Re-initialization or re-training several times made the greatest degree of local minimum close to the overall minimum. Training stopped (validation stop) when training times increased to a scheduled value.

IMPROVEMENT OF PREDICT METHOD

Previous BP network prediction models support direct prediction. Results of *t*-years forecast are obtained directly. The longer the prediction cycle, the greater the prediction error. Compared to direct prediction, gradually rolling prediction model changed prediction method to improve prediction accuracy, fitting to do further analysis. Comparison of two kinds of prediction methods is shown in Figure 4.



a). Direct prediction flow chart



b). Gradually rolling prediction flow chart

Figure 4. Flow chart of 2 prediction models.

DATA PROCESSING OF ROAD NETWORK

In order to compare the two models, analyses of changes of SSI (structural strength index) are presented combined with the data over the years in Tianjin. At present, "Technical specifications for maintenance of highway Asphalt Pavement" (JTJ073.2-2001) divides SSI of asphalt pavement into *5* levels (Table 1).

Table 1. Evaluation criterion of SSI, (" technical specifications for maintenance of highway Asphalt Pavement "(JTJ073.2-2001)).

Criterion	Highway grade	Excellent	Good	Medium	Hypo-medium	Bad
SSI	Expressway, first class highway	≥1.0	0.83 ~ 1.0	0.66 ~ 0.83	0.5 ~ 0.66	< 0.5

Considering each criterion's requirements, 5-dimensional state space is defined as I = [1 ~, 0.83 ~ 1, 0.66 ~ 0.83, 0.5 ~ 0.66, 0.5 ~ 0]. Historical data of SSI were collected by the road management department. Data with high discreteness were deleted and those that met the requirements were divided into 5 parts (excellent to

bad) through I. The ratio of each part in the total was calculated. Taking year 2001 for example, in the whole road network, SSI of the excellent part takes 40 percent. Treated data compose a network state vector sample set. Using the final BP network model and 2001-2006 year's data, adjusting the time step and prediction cycle, 2007 year's predicted value was obtained. Then on the basis of 2001-2007 year's data (2007's data was a predicted value), 2008 year's predicted value was obtained, followed to 2009. After a normalization-process, the actual data and predicted values are shown in Figure 5.

COMPARISON OF PREDICTION RESULTS

The prediction results of the gradually rolling prediction model established by BP network are shown in Figure 5. Under the present maintenance program, the road network's SSI would continue the change law of previous years. Road sections which belonged to "Excellent" level would be more than 60% of total road network in 2007. With time passing, the sections belonging to the "Excellent" level would drop to about 40% in 2009, "Good" and "Medium" levels remained the same level, while the "hypo-medium" and " bad" level's share dropped in 2007, but increased to 25% and 15% in 2009.

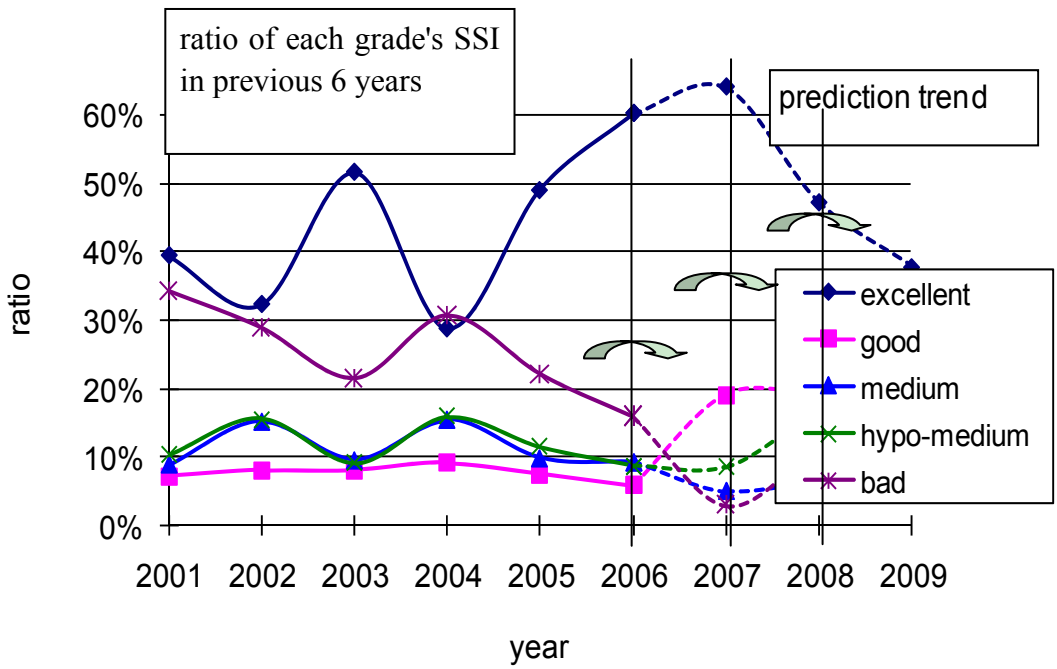


Figure 5. Network SSI gradually rolling prediction.

On the basis of the prediction data, Table 2 compares the errors generated by gradually rolling prediction and direct prediction.

Table 2. Comparison of 2 prediction errors of overall road network SSI.

SSI's grade	Grade range	Prediction value		Direct error relative		Rolling error relative	
		2007	2008	2007	2008	2007	2008
Excellent	1 ~	0.64	0.47	16%	22%	-12%	7%
Good	0.83 ~ 1	0.19	0.19	-12%	-12%	-12%	-9%
Medium	0.66 ~ 0.83	0.05	0.06	2%	0%	6%	5%
Hypo-medium	0.5 ~ 0.66	0.09	0.17	-12%	-14%	1%	-7%
Bad	0 ~ 0.5	0.03	0.10	7%	3%	17%	5%

From Table 2, the error of gradually rolling prediction was smaller than of direct prediction. The error in 2008 had become especially more uniform. No larger error appeared in individual level. This result could help management department not deviate from the original target when making long-term planning for maintenance. A guide was given. No error analysis was presented in 2009 since factual data was absent.

CONCLUSION

A prediction model of the use-level of road network was set up by neural network theory, conquering the limitations of the traditional prediction model. Gradually rolling prediction improved the BP neural network's prediction algorithm. Prediction precision had been improved greatly compared to direct prediction. Using the neural network model, the prediction results of the use-level of road network could help management departments make pavement maintenance decision-making more detailed and comprehensive.

ABSTRACT

Identifying hazardous locations for an in-depth safety analysis and potential safety improvement is one of the key functions of any safety management program. This paper proposes a new method that overcomes the weakness of the current methods. In the proposed method, the integrated highway safety state is analyzed to identify hazardous locations. Three models correlating accident rate, traffic flow characteristics and road facility features are studied and the different risk levels are proposed. Then the integrated highway safety state is defined and two forms are adopted to describe the integrated highway safety state, which are the vector form and the single synthetic form. By analyzing the intrinsic relation among accident data, traffic flow characteristics, road facility features and highway safety, the procedure for identifying hazardous locations using highway safety state has been developed. This method can be used to identify potential hazardous locations and prioritize safety improvement programs which is fundamental to allocate resources under limited budget conditions.

BACKGROUND

Road safety problem worldwide. More than 3,500 people are killed in road crashes and 137,000 more are injured or disabled every day worldwide. In China, more than 600 people are killed and more than 45,000 injured daily, and road traffic fatalities in China are predicted to increase to almost half a million per year by 2020 unless urgent action is taken. Beyond the loss of human life, poor road safety has an enormous economic impact. Annual direct and indirect costs have been estimated at between $12 to 21 billion, approximately 1.5 percent of China's GDP. As part of a systematic approach to road safety, involving safer road user, safer vehicles and safer road, identifying hazardous locations can help address this crisis and save thousands of lives.

Potential for the new way of identifying hazardous locations. Most of the current methods for identifying hazardous locations depend on accident statistics,

thus a significant collision history must exist before hazardous locations are identified and the success of the identification process is governed by the quality of accident data. Unfortunately in many jurisdictions in China, the quantity and quality of collision data is far from enough to reflect the safety level correctly and efficiently due to the lack of a properly detailed and unified methodology to gather data. In addition, the potential hazardous locations can not be identified before the occurrence of accidents so that proactive countermeasures can not be taken to prevent the collision. To help mitigate this problem, the more recent studies try to develop methods that Identify hazardous locations not only based on collision statistics, but the analysis of traffic flow characteristics and road facility features. On the basis of the relevant research works, this paper proposes a new method that overcomes the weakness of the current methods.

DESCRIPTION OF HAZARDOUS LOCATIONS

Characteristics of hazardous locations. Generally, the accident rate in hazardous locations is higher than other safer locations. Most of the previous researches focus on using accident rate to measure risk level. However, accidents may not happen seriously in short period for the sake of careful driving, very low volume or other reasons.

Traffic flow characteristics have much to do with safety. From the macroscopical point of view, stable and free traffic flow contributes to high level of safety, while the turbulence of traffic flow leads to more accidents (Koornstra M. J., 1992). From the microcosmic point of view, if the driver can run at the expected speed and lane, without need to change lane frequently, there is less possibility for them to make mistakes leading to accidents. On the contrary, in the unsafe traffic flow condition, it's difficult for drivers to achieve their expectation so that they have to follow the foregoing car at the unstable speed and even change the lane frequently. Unsafe traffic flow often exists in hazardous locations.

Road facilities, including pavement, signs and markers etc., are the important components of driving environment. Obviously, facilities with good safety performance contribute to high level of safety. Facilities in hazardous locations often have some features unable to satisfy safety request. For example, the alignment is not continuous so that drivers have to accelerate and decelerate suddenly, or some signs provide wrong information to road users so that drivers can't make right decisions in time. All these cases will lead to higher possibility that accidents happen.

Risk estimation index of hazardous locations. By analyzing character of hazardous locations, risk estimation index can be put forward, which consists of three indices defined as accident rate (AR), traffic flow risk (TR) and road facility risk (FR).

Accident Rate, i.e. the accident number occurring on a certain segment per kilometer per year, reflects the risk level quantitatively from post-accident aspect.

Three kinds of driving behaviors can be found in a certain traffic flow

condition: free driving, car-following driving and lane-changing driving. In the low-volume traffic condition, speed tends to be higher, leading to high-speed risk. While in the high-volume traffic condition, drivers have to follow the foregoing cars or change the lane, leading to car-following risk and lane-changing risk. Traffic flow risk is the sum of the three kinds of risks mentioned above. Each kind of risk is modeled based on the speed of each vehicle and the following vehicle and the distance between them (ZHANG Xiao-dong *et al.,* 2006).

Many road facility features impact safety, and facility risk is defined to measure the extent to which facilities offer protection from accidents. According to the research works on safety effect of facility features, the most important factors affecting safety were selected to determine road facility risk, including alignment consistency, sight distance, skid resistance, signs, markings, roadside, etc. (Montella A., 2005).

Obviously, traffic flow risk and road facility risk can be estimated before accidents happen, so they can reflect the risk level from pre-accident aspect.

RISK ESTIMATION MODELS OF HAZARDOUS LOCATIONS

With respect to risk estimation models, previous studies have provided valuable insight regarding the methodologies formulated for road safety analysis, including historical accident data averages, predictions based on statistical models, results from before-and-after studies, and expert judgments made by experienced engineers. Each of these methods, if used alone, has significant weaknesses. On the contrary, there is an advantage to combining elements of each of these methods (Athanasios P. Chassiakos *et al.*, 2005). Due to the difference among three risk estimation indices, the corresponding risk estimation models have been established separately using different mathematical theories.

Risk estimation model based on AR. So far, there has been an established consensus among road traffic safety researchers that a non-linear, non-Gaussian relationship exists between traffic exposure and safety (Kononov J. *et al.,* 2003). This relationship is reflected by the Safety Performance Functions (SPF), which is calibrated for various classes of roads. Safety Performance Function provides a realistic estimate of expected accident frequency per unit of traffic exposure over a unit of time for various types of roads.

Based on substantial empirical evidence derived from observing safety performance of various roads over extended time periods as well as work of other researchers, the following understanding of relationship between safety and exposure has emerged. Accident rates decline when AADT reaches certain threshold endemic to a particular facility in a specific environment. This understanding suggests a choice of underlying function which would reflect this phenomenon. The following model form for SPF is usually employed.

$$E\{y\} = X^{\beta_0}(1 + \beta_1 X + \beta_2 X^2 \cdots) \tag{1}$$

Here, E{y} is the annual number of accidents expected to occur on a segment of road, X is the independent variable (AADT), and β are parameters to be estimated. With the Poisson distribution assumption of accident, the model parameters were estimated by the maximum-likelihood method.

$$\because \mu \in Poisson \therefore E(y) = \mu \ , \ Var(y) = \mu \tag{2}$$

$$P(x = y_i) = \frac{\mu_i^{y_i}}{y_i!} e^{-\mu_i} \tag{3}$$

$$L(\mu_P) = \prod_{i=1}^{n} \left(\frac{\mu_i^{y_i} e^{-\mu_i}}{y_i!}\right) \tag{4}$$

$$Ln(L) = \sum_{i=1}^{n} (y_i \ln \mu_i - \mu_i - \ln y_i!) \tag{5}$$

Where,

μ- Estimated number of accidents on roadway segment over a period of a year

y_i - Observed number of accidents on roadway segment over a period of a year

$L(\mu_P)$- Poisson likelihood function

Take 4-lane freeway for example, on the basis of the accident data in selected 4-lane freeways in China, the Safety Performance Function for 4-lane freeway has been established, shown in figure 1. The accident data and the highway data used in the model were collected from department of public security and highway bureaus. When collecting the accident data, the highways were divided into several segments according to road features, and then the accident rate for each segment was analyzed.

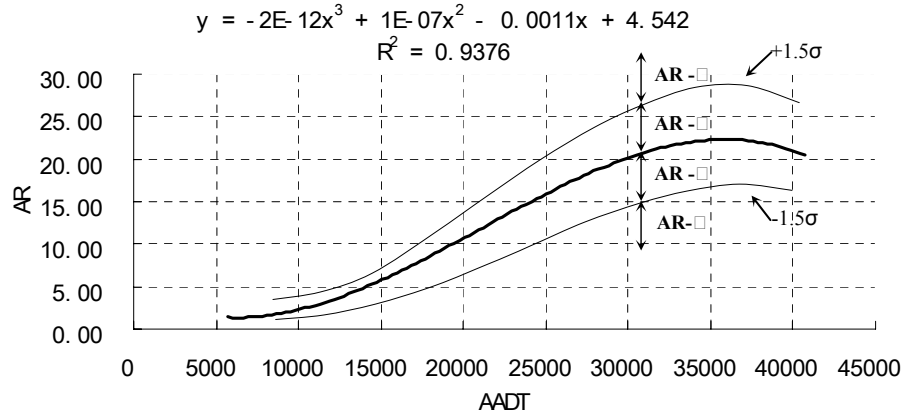

Figure 1. SPF for 4-lane freeway.

The level of safety predicted by the SPF represents normal or expected number of accidents at a specific level of AADT, and then the degree of deviation from the norm can be stratified to represent specific levels of risk. The delineated boundary line is located 1.5 standard deviations from the mean. Four levels of risk (LOR) can be proposed shown in figure 1, and the qualitative description is presented in Table 1.

Table 1. Qualitative Description of LOR based on AR.

Level of risk	Qualitative description
AR - I	Low potential for accident reduction
AR - II	Better than expected safety performance
AR - III	Less than expected safety performance
AR - IV	High potential for accident reduction

Risk estimation model based on TR. Thanks to the development of image identification technology, it's possible to get the speed and position information of vehicles in traffic flow from the visual record in the near future. In this paper, the traffic flow condition was simulated and the parameters for calculating TR were collected automatically by using traffic simulation software VISSIM. The values of TR at different levels of traffic volume were calculated and then the relationship between traffic flow risk and traffic volume has been established by applying regression analysis, shown in Figure 2.

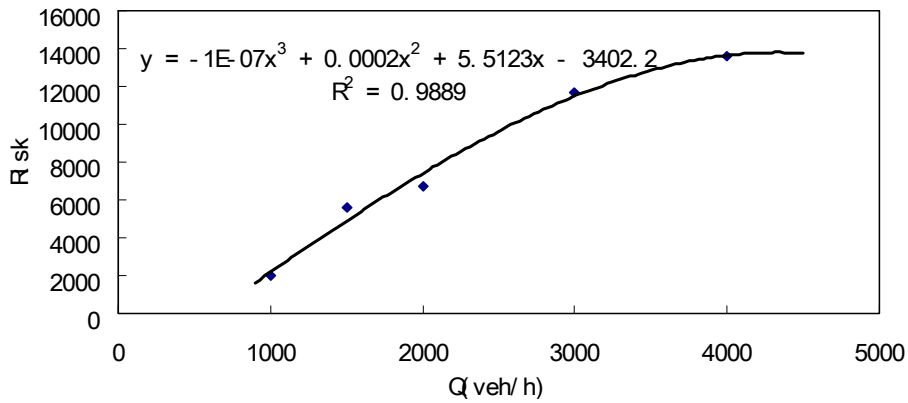

Figure 2. Regression model between traffic flow risk and traffic volume.

Similar to SPF, the value of traffic flow risk predicted by the regression model above can represent normal level of safety at a specific traffic volume, so the degree of deviation from the norm can be stratified to represent specific levels of risk. The delineated boundary line is located 1.5 standard deviations from the mean. Four levels of risk (LOR) can be proposed and the qualitative description is presented in Table 2.

Table 2. Qualitative Description of LOR based on TR.

Level of risk	Qualitative description
TR - I	Very low level of risk in traffic flow
TR - II	Low level of risk in traffic flow
TR - III	High level of risk in traffic flow
TR - IV	Very high level of risk in traffic flow

Risk estimation model based on FR. The risk estimation model based on FR was established by applying the fuzzy set theory. The facility features that affect highway safety have been hierarchically divided, and fuzzy judgment matrix has been

established on the basis of known accident relationships, shown in Table 3 (Lamm R., 1999). Then fuzzy comprehensive judgment is made to assess the risk of facilities features, obtained through weights and memberships of different facility feature. The relative weights were determined by professionals in the field of road safety using the hierarchical analysis method. The scores assigned to each facility feature result from field inspections and estimations by professionals and the trapezoid membership function was selected to determine the membership of each facility feature to different safety level.

Table 3. Fuzzy Judgment Matrix of FR.

Facility feature	Level of Facility Risk			
	FR-I	FR-II	FR-III	FR-IV
alignment consistency(ΔV)	<5km/h	5~10 km/h	10~20 km/h	≥ 20 km/h
sight distance	≥ 2.1SSD	1.6~2.1 SSD	0.75~1.6 SSD	<0.75SSD
skid resistance	≥ 0.50	0.50 ~ 0.40	0.40~0.30	<0.30
sharp curve warning sign	0~3	3~6	6~8	8~10
overtaking line	0~3	3~6	6~8	8~10
roadside	0~3	3~6	6~8	8~10
Excessive density of uncontrolled accesses	0~3/km	3~6/km	6~10/km	>10/km

According to the fuzzy judgment to the risk estimation of facility features, four levels of risk based on FR have been proposed and the qualitative description of each level is shown in Table 4.

Table 4. Qualitative description of LOR based on FR.

Level of Risk	Qualitative description
FR-I	Risk of facility features is very low, no need for improvement
FR-II	Risk of facility features is low, improve when capital is enough
FR-III	Risk of facility features is high, need improvement
FR-IV	Risk of facility features is very high, eager for improvement

HIGHWAY SAFETY STATE (HSS)

HSS Vector. According to risk estimation result, the Highway Safety State (HSS) can be determined by three attributes: accident rate, traffic flow risk, facility risk. Each of them reflects the risk level from different angle. To define the integrated highway safety state, the vector form is recommended. AR, TR and FR were selected as elements of the HSS vector. As discussed before, each element of HSS vector has four grades shown in Table 5, so there are 64(4×4×4) kinds of safety state in all.

Table 5. Grades of elements of HSS vector.

Grade	AR	TR	FR
1	AR-I	TR-I	FR-I
2	AR-II	TR-II	FR-II
3	AR-III	TR-III	FR-III
4	AR-IV	TR-IV	FR-IV

The HSS vector can be represented in the following form.

$$HSS_i = \left(AR_j, TR_k, FR_m\right) \quad (i=1, 64; j, k, m=1, 4) \tag{6}$$

Single synthetic index of HSS. The vector form can present the detailed information of highway safety state, so it helps to diagnose safety problems and select treatments. However, it's easy to compare the risk level of different locations and prioritize the improvement projects using the single synthetic index. Both of them are useful in highway safety management.

Nonlinear dimensionless analysis was adopted to convert original values of AR, TR and FR to standard values. Then the single synthetic index of HSS is defined as follows.

$$HSS_i = a_1 f(AR_i) + a_2 f(TR_i) + a_3 f(FR_i) \tag{7}$$

Where

AR_i, TR_i, FR_i —— the original value of AR, TR and FR in section *i*;

$f(AR_i), f(TR_i), f(FR_i)$—— the standard value of AR, TR and FR determined by dimensionless analysis in section *i*;

a_1, a_2, a_3 ——the weight determined by professionals using hierarchically analytical method.

The nonlinear dimensionless analysis method is described as follows:

$$f(x) = \begin{cases} e^{\frac{x - x_{\min}}{x_{\max} - x_{nin}}} & x > x_{\min} \\ 0 & x \le x_{\min} \end{cases} \tag{8}$$

Where

$x_{\max}$, $x_{\min}$ - the maximum value and the minimum value of index, determined as 3 standard deviations from the mean based on statistical analysis of index values.

It is important to point out that the weight for each index is changeable according to the quality of accident data, traffic flow data and facility data. The higher the quality of data, the more the weight of corresponding index is. What's more, the weight should be different at different locations.

IDENTIFICATION OF HAZARDOUS LOCATIONS USING HSS

Before identifying hazardous locations, highways should be divided into several homogenous sections according to traffic volume and road facility features. Then the integrated safety analysis mentioned above should be implemented on each section, and the risk level of each section will be estimated.

By analyzing the intrinsic relation among accident data, traffic flow characteristics, road facility features and highway safety, comments for highway safety state can be described as follows: the location with all three indices in grade 1,

i.e. *HSS*=(1,1,1), is the best state of highway safety; the location with all three indices in grade 1 or grade 2, such as *HSS*=(2,1,2), can be regarded as safe location; the location with any of the three indices in grade 3 or grade 4, such as *HSS*=(3,1,2), has potential safety problem; the location with all three indices in grade 4, i.e. *HSS*=(4,4,4), is the worst state of highway safety.

More specifically, the location with TR in grade 3 or grade 4, such as *HSS*=(2,4,2), need improvement treatments on traffic flow, such as speed restriction. While the location with FR in grade 3 or grade 4, such as *HSS*=(2,1,4), need improvement treatments on road facility, such as changing alignment, setting warning signs. As for the location with AR in grade 3 or grade 4 but TR and FR in grade 1 or grade 2, such as *HSS*=(4,1,2), the safety problem on this location is probably caused by other factors such as driver error, vehicle broken, instead of traffic flow and road facility problems.

To prioritize the improvement projects, the hazardous locations can be compared using the single synthetic index of HSS, the higher value of HSS means the more dangerous location.

Compared to previous methods, the advantage of the method studied in this paper is that the potential hazardous locations where not many accidents happened but traffic flow risk or facility risk is high can be identified, so the necessary treatment can be implemented to prevent large number of accidents occur in the near future. Furthermore, by considering traffic flow and facility features besides accident data, the method allows more effective and fair identification of hazardous locations, especially in places where accident data collection is disadvantageous.

CONCLUSION

Through analyzing the character of hazardous locations, risk estimation index and risk estimation models for hazardous locations have been studied. Based on the integrated highway safety state analysis, the new method discussed in this paper allows more effective and fair identification of potential hazardous locations compared to the previous methods. It also provides a priority for safety improvement programs which is fundamental to allocate resources under limited budget conditions.

Due to the limitation of the quantity and quality of accident data, traffic flow data and facility data, the risk estimation model discussed in this paper need be revised in the future as the data collection getting more advantageous, but this method provides a new way to do safety analysis which is more valuable than the model itself.

ABSTRACT

Pedestrian security has been becoming increasingly important in urban traffic because of the explosion and intensive activities of urban population. Considering the complexity of crowds' behavior, it is necessary to analyze the characteristics of the crowd and the law of crowds' route choice.

The macro and micro characteristics data were obtained from video observation at the study sites and the researchers' survey, including the flow rate, speed, density of the crowd, etc. Based on the analysis of the relationship between speed and density of the crowd, a crowds' route choice model was derived according to the basic theory of dynamic programming by dividing the route choice process into different stages, selecting the state/decision variables, analyzing the recurrence relation and the expression of the optimal value function. The model was verified by the field data collected in observations and the comparison between the calculation results and field data shows the model proposed can accurately describe the pedestrian route.

The model provides a mathematic method of the crowds' simulation. And the understanding of pedestrian behavior would help to improve the level-of-service of pedestrian traffic facilities in planning and design.

INTRODUCTION

Because of the complex behavior patterns of a crowd and the weakness of the traffic facilities, it is necessary to analyze the characteristics of the crowd, the law of crowd pedestrians' movement and the route choice behavior for developing effective prevention measures and reducing the risk.

The number of models for the crowd pedestrian behavior increases rapidly. A

great deal of research has been devoted to investigate crowd traffic. Besides the analysis of the characteristics of pedestrians, multidisciplinary theories have been widely adopted to develop pedestrian models. The cornerstone models for crowd were rooted in the traditional fluid mechanics models first put forward by L. F. Henderson (1971). In his model, the pedestrians at low density were seen as gas molecules and pedestrians at high density (crowd) were seen as liquid ones. Also in the 1970s Henderson (1974) had compared measurements of pedestrian flows with Navier-Stokes equations with considerable success. The analysis of the crowd was extensively evolved on the basis of Henderson's theory during the next 20 years. His phenomenological fluid-dynamics approach had been improved and mathematically founded by Helbing in the 1990s (1991, 1995) and this model was closely related to some gas-kinetic traffic models (I. Prigogine and R. Herman, 1971; S. L. Paveri-Fontana 1975) and fluid-dynamics (B. S. Kerner and P. Konhäuser 1993, 1994; D. Helbing 1995). Afterward the "microscopic" approaches for the vehicular traffic, series models for the pedestrian motion in microsphere had been proposed including the social force model (D. Helbing,1995) and the CA model in late 1990s (M. Fukui,1999; Blue and Alder 1998,1999). The former was accomplished through the interaction between pedestrians and environment, and described the "forces" as a measure for the internal motivations of the individuals to perform certain actions. The social force model is capable of describing the self-organization phenomena in pedestrian traffic. The latter was proposed based on the Nagel-Schreckenberg (1992) model which was used to model vehicular transportation. The pedestrians in this model were regarded as certain cellular and the movement was along the network of the system. And it modeled the pedestrians' movement and decision making behavior within a built environment. The CA model could offer a simulation of autonomous individuals and the interaction among them. It's also another trend for the development of pedestrian traffic.

Comprehensively, the microscopic models for the crowd pedestrian can be divided into two kinds, discrete models and continuous models. Each kind receives a great deal of interest for its evolution and both of them apply to pedestrian traffic research.

DATA COLLECTION

State boundaries for the pedestrians

The Level-of-Service (LOS) for pedestrian facilities is considered a measurement of validity by which pedestrians can determine the quality of service, including the number of pedestrians per unit area, walking speed which can be reached, the possibility, safety and comfort when pedestrians take some actions like over-taking and crossing, etc. (CHEN, 2003). From the five ranks of LOS, rank C

and below are chosen for the crowd state considering the pedestrian traffic state and the mental feeling. The author's survey aims to the crowd pedestrians in the states in which the unit area is under $2m^2/p$ and the pedestrian walking speed is under 1.0m/s. The hall of the Information Teaching Building in Beijing Institute of Technology was chosen for this study.

Method for data collection

Considering the high freedom of pedestrian movement and the experience with pedestrian traffic observation, a video data collection method with data conversion has been adopted for the field study. According to the video images, the micro/macro pedestrian data can be obtained and analyzed, and a "video-recording—image-processing—data-collecting procedure" is chosen for the data collection. A pedestrian track data collection program, developed by Mr. Sun in Tsinghua University, is used for converting the pedestrian track information into traffic data.

Observing parameters

Walking speed for individual pedestrians

In video observation, pedestrian position is fixed by each frame and a set of successive position points run in a series. Recording the coordinates of a certain pedestrian in the first frame and the coordinates after n ($n \geqslant 2$, even number are better) frames, the average walking speed is the rate of movement per unit time.

During the observation process, because the instantaneous speed in one point can hardly be measured. As a result, assuming n as 2, we consider the average walking speed as the spot speed.

Crowd speed

The concept of crowd speed in this study is defined as the time-mean speed at a certain point and it's the average spot speed of several pedestrians measured at a given point in unit time. It's also used for analyzing the relationship between crowd speed and density.

Crowd density

Crowd density means in the crowd region, the number of pedestrians per unit area (p/ m^2).

DATA ANALYSIS

According to the pedestrian position information obtained by the pedestrian track data collection program, the plane track and the plane coordinates of the pedestrian can also be obtained after coordinate transformation. The traffic parameters are then analyzed as follows:

Pedestrian walking speed

According to the statistical analysis of 545 samples, the average crowd

pedestrian speed is 0.660m/s, and the standard deviation is 0.32. Figure 1 illustrates the distributions of crowd pedestrians' walking speed. The speed distribution histogram indicates that the distributions of walking speed follows normal distribution, the same as the distribution of the pedestrian speed in sidewalks (Xiong Hui,2007) and crossing speed in crosswalks (Jiang Xiaobei, 2008).

Distribution of crowd density

During the process from the sudden increase of pedestrian flow to the evacuation of the crowd, there is a stable distribution of the crowd density in the observation area under a steady pedestrian flow. The statistic histogram of the crowd density is given by Figure 2. Figure 3 shows the high-density area, medium-density area and the low-density area are steadily in certain positions.

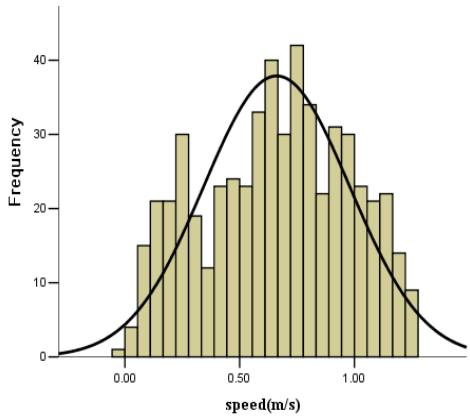

Figure 1. Walking speed distribution density

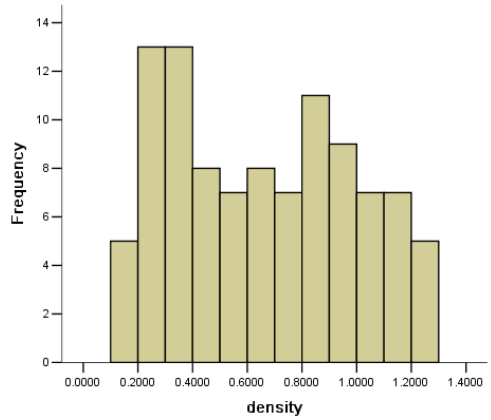

Figure 2. Statistic histogram of crowd

A conclusion from Figure 3 is that the high-density appears near the exits where the moving space for the pedestrian is extremely small, closing to static pedestrian occupancy area; the lower density appears to be decreasing with the larger distance to the exits.

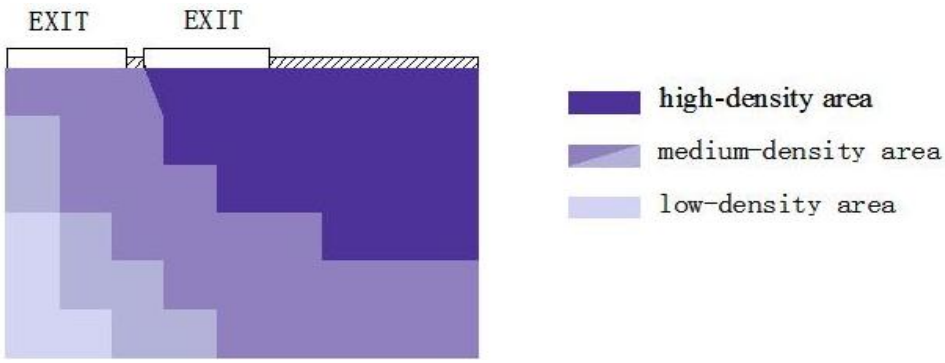

Figure 3. Stable distribution of the density

Relationship between crowd density and walking speed

The relationship between the average spot speed in a certain area in a frame and the density in this area can be expressed in Figure 4. In the classical pedestrian traffic research, the relationship between crowd density and walking speed is always described as linear relationship or exponential relationship. From the observation, an exponential relationship is chosen for fitting the relationship between crowd density and walking speed. The expression of curve in Fig.4 is y = 1.74839e-1.42192x. (R^2=0.807).

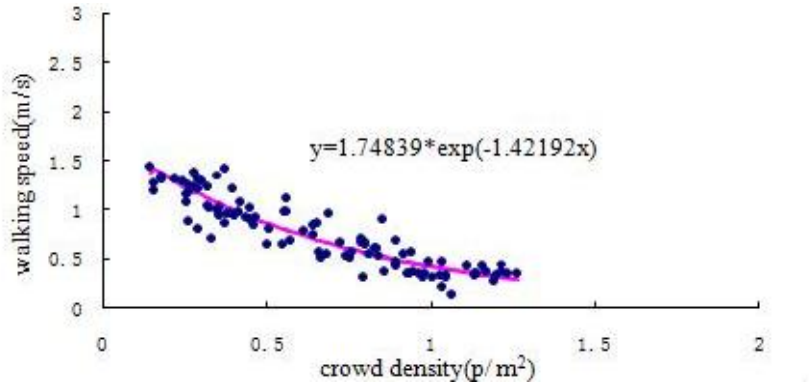

Figure 4. Relationship between crowd density and walking speed

ROUTE CHOICE MODEL BASED ON DYNAMIC PROGRAMMING

A decision making behavior for route choice

According to the node which is the current position of the pedestrian, the impedances of each path will be compared; consider a walking habit to choose one path. Then the pedestrian decides on another node and path. By inference, connecting all the nodes and paths, the final walking route from the origin to destination is formed.

Obviously the pedestrian will make an instantaneous decision when another node will be chosen. Route choice behavior can be judged as decision-making behavior for the position of each node in the whole route, and it is Markov decision processes (Hu Dihe, 1983). The cost is generally measured by the walking distance or time. In field observation, the length of walking time is the main consideration in the pedestrian's route choice.

Model set- up

Simulating for pedestrian walking environment

There are two methods for environment simulating: network system and plane coordinate. Both two are selected for the study. From the observation, the crowd density is between $3p/m^2$~$4p/m^2$, so in this situation occupancy area per pedestrian is about $0.25m^2$ and each grid is designed by 0.5m×0.5m, shown in Figure 5. At the same time, each node is set by a corresponding coordinate for the model calculation. The network is oriented in a plane coordinate system. Assume

each pedestrian will be in one node on the network after a certain state, and the pedestrian takes the link of the node (side/diagonal of the grid) as a certain walking path in a state.

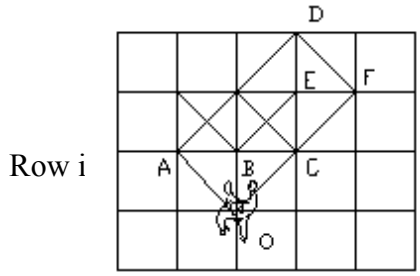

Figure 5. Network of the walking environment

Selecting the state and decision variables

According to the basic theory of dynamic programming, the state and decision variables should be defined for the route choice process. The process state variables with non-aftereffect are chosen to describe the pedestrian traffic state: the coordinate of the node (pedestrian position) (x_{ij}, y_{ij}) and the walking speed (v'_{xij}, v'_{yij}) in this state.

A pedestrian chooses the route with the shortest walking time, as a result, the time of the route is determined as the decision variable. In the network, excluding three nodes behind node $N_{i,j}$ (because in the crowd state, pedestrians can hardly go backward), there are 5 adjacent nodes corresponding with node $N_{i,j}$. If the pedestrian is now at node $N_{i,j}$, the 5 paths in front and the paths at sides will be considered.

Analyzing the recurrence relation and the expression of the model

Regarding the route from origin O to destination D as a state-transfering chart for a finite states system, each node as a certain state, then the arc (the link of every two nodes) is directed from state s_k to state s_{k+1}, corresponding with transfer $s_{k+1} = V_k(s_k, u_k)$. And the length of the arc equals the cost of transfer ($t_k(s_k,u_k)$), that is the walking time of the path.

The definition of objection function is given by

$$T_k = \sum_{m=k}^{n-1} t_m(s_m, u_m)$$

It represents the sum of the state transfer cost for all the following subprocesses, that is, the walking time from the current state to the final state

(pedestrian reaches the destination), and sufficient to satisfy:

1) a quantity function defined for the whole process and the following subprocesses;

2) $T_k(s_k, u_k, s_{k+1}, u_{k+1} \cdots) = \Psi_k[s_k, u_k, T_{k+1}(s_{k+1}, u_{k+1} \cdots)];;$

3) $\Psi_k(s_k, u_k, T_{k+1})$ is monotonic as its variable T_{k+1},

where $t_m(s_m,u_m)$ denotes the objection function of state m, and the recurrence relation is given by $T_k = t_k(s_k, u_k) + T_{k+1}$.

The optimal value function can be deduced by

$$f_k(s_k) = \min T_k = \min[t_k(s_k, u_k) + T_{k+1}] = \min\left(\frac{L_k(u_k)}{V_{i,j}(s_k)} + T_{k+1}\right)$$

where $L_k(u_k)$ denotes the length of the path (side/diagonal of the grid) when taking the decision u_k; $V_{i,j}(s_k)$ denotes the walking speed from state k to state k+1.

The function means that in state s_k the pedestrian makes the decision u_k so as to get a minimum walking time for the following state. Reversing backward from the destination, at any state of the process the walking time from the node to the destination is the shortest. And the calculation of the optimal value function is the whole time for a certain pedestrian to walk through the crowd area.

MODEL VERIFYING AND CONCLUSION

Model Verifying

Based on the equation of the crowd density-speed curve in Figure 4, the average walking speed in each density can be calculated and the paths in the network (side/diagonal of the grid) can also be gained. According to the model, the minimum walking time for the pedestrian is worked out from the optimal value function, and the route can be derived by linking all the nodes of the optimal decisions. Figure 6 describes the routes a_1/a_2, c, d chosen separately by pedestrians from origin A, C and D to destination EXIT.

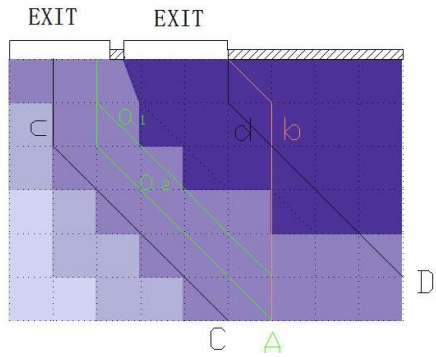

Figure 6. Routes chosen by pedestrians from origin A, C, and D to destination EXIT

The model was verified by the data collected in the field observations. Most tracks of the route from origin A (a bilaterally 0.25m) to the EXIT were between a_1 and a_2. The average walking time among 41 available samples that chose this route is 6.30s, compared with the average walking time derived from the model 6.36s, the error is 0.96%. Another 38 samples were chosen for validating the route d. The average walking time in the observations is 7.50s, compared with the average walking time derived from the model 7.39s, the error is 1.46%. Comparison between field data and calculation results shows that the route choice model proposed in the paper can accurately describe the pedestrian route.

CONCLUSION

The modeling of the crowded pedestrian route choice behavior provides the simulation of the crowd by using a mathematical method. The understanding of pedestrian behavior can help to improve the level-of-service of pedestrian traffic facilities. Due to the restriction of the survey conditions, limited field investigators, etc., the samples in other density zones, especially in the density close to the maximum limit density, were not obtained in this survey. For further studies, it's meaningful to take other density states into account.

ABSTRACT

In order to provide a basis of vehicle velocity calculation and microcosmic analysis of accidents, this paper investigates a vehicle dynamics model in two-dimension collision accidents. Two-dimension collision accidents are classified into two categories: two-dimension centripetal collision and two-dimension non-centripetal collision. The vehicle dynamics models are also set up. By using reconstruction analysis software of road traffic accident, named PC-Crash, simulation experiments have been carried out for the two accident categories. Without considering the instances of double or multiple collisions, the result of experiments indicates that the model calculation results are similar with the simulation results using software, which validates the efficiency of proposed method.

INTRODUCTION

With the rapid development of the world's automobile industry, motor vehicle dynamic performance is getting higher and higher. The results show that vehicle collision accidents occupy more than 2/3 of the gross of road traffic accidents, and the two-dimension collision accident is one of the most familiar accident forms among vehicle collision accidents.

The definition of a two-dimension collision accident is that the accident vehicles only do translation and yaw movement in the same plane before and after impact, without rolling, flying and moving along with the road side slope. In this paper, the vehicle dynamics model for a two-dimension collision accident is set up in accordance with the principle of dynamics. By using this model, the vehicle's pre-impact velocity can be calculated according its post-impact velocity. Moreover, PC-Crash has been applied to validate the vehicle dynamics model.

KINETICS THEORY OF VEHICLE TWO-DIMENSION COLLISIONS

Elastic restitution coefficient of vehicle impact. The coefficient which is used to distinguish elastic or plastic impact is called the elasticity restitution coefficient (Pei Y. L. 2006).

By making the accident's impact point as the origin of coordinates, the coordinates system called $nD\tau$ can be set up. The normal and tangential elasticity restitution coefficients of vehicles can be defined as e_n and e_τ.

$$e_n = \left| \frac{(v_{2n} - v_{1n}) - (\omega_2 x_{2\tau} - \omega_1 x_{1\tau})}{(v_{20n} - v_{10n}) - (\omega_{20} x_{2\tau} - \omega_{10} x_{1\tau})} \right| \tag{1}$$

$$e_\tau = \left| \frac{(v_{2\tau} - v_{1t}) - (\omega_2 x_{2n} - \omega_1 x_{1n})}{(v_{20\tau} - v_{10\tau}) - (\omega_{20} x_{2n} - \omega_{10} x_{1n})} \right| \tag{2}$$

Relationship between plasticity deformation and effective impact speed. International studies have done lots of frontal and rear-end impact experiments for some cars whose engines are proposed. The definition of the effective impact speed and the relationship between it and plasticity deformation of cars has been found in the last reference (Zhang. X. Y. et al. 2007).

HYPOTHESIS OF COLLISION ACCIDENT

For expediently setting up the vehicle collision dynamics model, there are several hypothesis. (1) Because of the short impact time, the position of the vehicle can be considered the same during the course of the vehicles' impact. (2) Because of the vehicles' huge impulsive forces at the moment of impact, the influence of other familiar forces can be neglected.(3) Because of the energy loss, the kinetic energy theorem and energy conservation law are not suitable to academic analysis.

VEHICLE TWO-DIMENSION COLLISION DYNAMICS MODEL

Two-dimension centripetal collision of vehicles. The kind of impact that one impact impulsive force of a vehicle goes through another vehicle's center of mass is called centripetal collision. It can be considered that vehicle A and vehicle B are occurring at centripetal collision point O. The case can be shown in Figure 1.

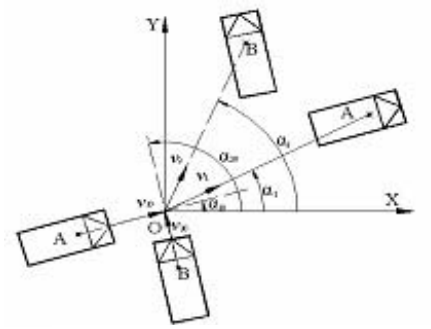

Figure 1. Two-dimension centripetal collision.

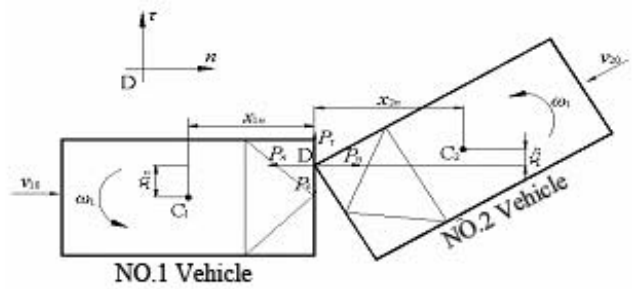

Figure 2. Two-dimension non-centripetal collision.

According to momentum conservation law, formulas (3) and (4) can be shown as flowing. By using the relationship between effective impact speed and plasticity deformation depth, the model can be set up as:

$$m_1 v_{10} \cos\alpha_{10} + m_2 v_{20} \cos\alpha_{20} = m_1 v_1 \cos\alpha_1 + m_2 v_2 \cos\alpha_2 \quad (3)$$

$$m_1 v_{10} \sin\alpha_{10} + m_2 v_{20} \sin\alpha_{20} = m_1 v_1 \sin\alpha_1 + m_2 v_2 \sin\alpha_2 \quad (4)$$

$$29.25 x_1 \cos\alpha_{10} = \frac{m_2}{m_1 + m_2}(v_{10}\cos\alpha_{10} - v_{20}\cos\alpha_{20}) \quad (5)$$

$$29.25 x_1 \sin\alpha_{10} = \frac{m_2}{m_1 + m_2}(v_{10}\sin\alpha_{10} - v_{20}\sin\alpha_{20}) \quad (6)$$

Two-dimension non-centripetal collision of vehicles. The prominent character of the vehicle non-centripetal collision is that the vehicle not only translates but also turns after impact. The movement parameters of vehicles are shown in Figure 2. The model can be constructed by using the definition of normal and tangent elasticity restitution coefficients combined with the momentum theorem and the theorem of moment of momentum. This model can be expressed in matrix form.

$$[A_0][V_0] = [A][V] \quad (7)$$

where $[A_0] = \begin{bmatrix} m_1 & 0 & 0 & m_2 & 0 & 0 \\ 0 & m_1 & 0 & 0 & m_2 & 0 \\ -m_1 x_{1\tau} & m_1 x_{1n} & I_1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -m_2 x_{2\tau} & m_2 x_{2n} & I_2 \\ e_n & 0 & -e_n x_{1\tau} & -e_n & 0 & x_{2\tau} e_n \\ 0 & e_\tau & -e_\tau x_{1n} & 0 & -e_\tau & e_\tau x_{2n} \end{bmatrix}$, $[A] = \begin{bmatrix} m_1 & 0 & 0 & m_2 & 0 & 0 \\ 0 & m_1 & 0 & 0 & m_2 & 0 \\ -m_1 x_{1\tau} & m_1 x_{1n} & I_1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -m_2 x_{2\tau} & m_2 x_{2n} & I_2 \\ -1 & 0 & x_{1\tau} & 1 & 0 & -x_{2\tau} \\ 0 & -1 & x_{1n} & 0 & 1 & -x_{2n} \end{bmatrix}$,

$[V_0] = [v_{10n} \quad v_{10\tau} \quad \omega_{10} \quad v_{20n} \quad v_{20\tau} \quad \omega_{20}]^T$, $[V] = [v_{1n} \quad v_{1\tau} \quad \omega_1 \quad v_{2n} \quad v_{2\tau} \quad \omega_2]^T$

It can be known that the post-impact velocities should be calculated first according to brake mark formulas. Then, the pre-impact velocities can be determined.

VALIDATION OF THE VEHICLE COLLISION DYNAMICS MODEL

This part's content will use road traffic accident simulation reconstruction analysis software PC-Crash to do vehicle impact simulation experiments. Therefore the dynamics model in two-dimension centripetal collisions and two-dimension non-centripetal collisions can be validated.

The validation of dynamics model in centripetal collision. By using the road traffic accident simulation reconstruction analysis software, PC-Crash, six vehicle centripetal collision simulation experiments are carried out. The courses of these experiments are shown in Figure 3.

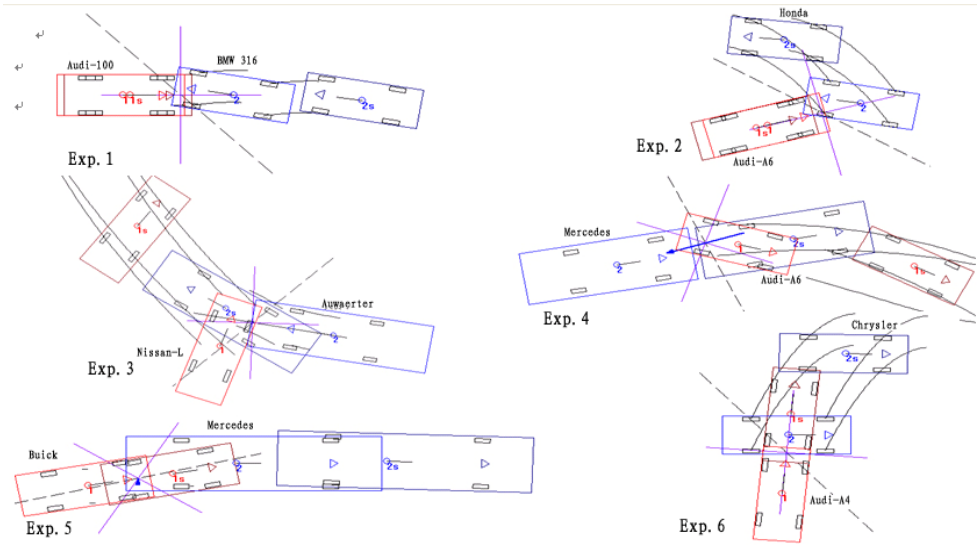

Figure 3. Two-dimension centripetal collision experiments by PC-Crash.

The original data is listed in Table 1. The results of simulation calculation and the model of two-dimension centripetal collision are shown in Table 2.

$v_{i\tau}$(km/h)	-25.88	-24.24	-6.95	-7.82	-10.42	-11.15	34.64	36.23
ω_i(rad/s)	-3.00	-2.31	0.00	0.09	1.00	1.18	-2.00	-1.34

CONCLUSIONS

Without considering the case of more times impacts, the calculation results of the models are similar to PC-Crash. The results of simulation experiments indicate that the maximum relative error between the results of model calculations and software reconstruction is 11.15%. Therefore, it can be believed that the vehicle dynamics model in two-dimension collisions can comparatively accurately calculate the pre-impact velocity of the vehicles according to post-impact velocity of vehicles.

ABSTRACT

This paper provides a basis for vehicle movement trajectory reconstruction in two-dimension collision accidents and accidents disposal. On the basis of studies of predecessors, a different method of impact point named Area Method is put forward. By the statistical analysis of vehicle structure parameters, the moment of inertia calculation formula circling vehicles' center of mass is improved as well as vehicle movement trajectory model. The trajectory error indexes have also been set up. By using the movement trajectory model of the accident vehicle, the trajectories of accident vehicles for some accident cases have been reconstructed. By using the trajectory error indexes, the reconstruction results of the model and the tire marks at the scene have been contrasted and analyzed. The result of analysis indicates that the calculation results of model and the tire marks at the scene are similar, which validates the efficiency of this proposed method.

INTRODUCTION

With the rapid development of the world automobile industry, more and more vehicles have been equipped with ABS. Additionally, the influences of the weather and road makes tire marks of vehicles in collisions more and more illegibile. The vehicle movement trajectory model in two-dimension collision accidents can calculate the movement trajectory of vehicles, according to the final resting position of the accident vehicles. The model has significant guidance meaningful for reconstruction analysis and to judge the liability in collisions.

KINETICS ANALYSIS OF ACCIDENT VEHICLE

Coordinate systems. XOY coordinate system is riveted at earth. *x*O'*y* riveting at the vehicle's center of mass is a relative coordinate system. $\xi_{i,j}O''\eta_{i,j}$ are 4 relative coordinate systems which are riveted at the centers of 4 tires (Figure 1).

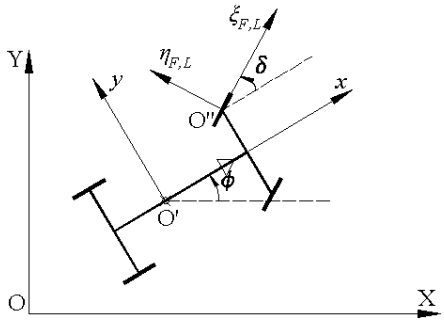

Figure 1. The coordinate systems of kinetics analysis.

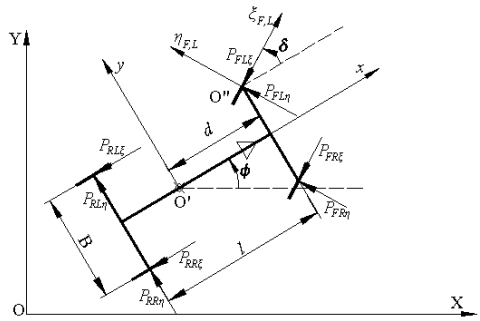

Figure 2. The mechanics analysis of vehicle.

Movement analysis of accident vehicle. The movement of an accident vehicle in a two-dimension plane can be regarded as the translation in *x*O'*y* coordinate system and the revolution about basic point O' of accident vehicle relative to *x*O'*y*.

Forces composition of accident vehicle. The vehicle can be supposed as a vehicle with 4 tires. When the vehicle is under the condition of not only turning but also braking, the forces of the vehicle in the two-dimension plane are shown as in Figure 2. Then, the resultant of forces and moment of the vehicle can be obtained. The calculation formula can be seen in the second reference. However, the longitudinal and transverse force of each tire can be calculated by the GIM Types-Ground model (Wei L. 1992).

HYPOTHESIS OF VEHICLE MOVEMENT TRAJECTORY MODEL

For setting up the vehicle movement trajectory model in a two-dimension collision accident, a hypothesis is demanded.

(1) Only forces and moment from the ground are applied to the vehicle body.

(2) Movements of the vehicle is in the same plane of the road surface.

(3) Movement trajectory of the vehicle at the moment of impact can be ignored.

(4) Its law of mass distribution and geometrical parameters are invariable.

CONSTRUCTION OF VEHICLE MOVEMENT TRAJECTORY MODEL

Form of movement trajectory model. The movement trajectory formula in the plane of the accident vehicle can be set up by using backward difference and middle difference formulas just as formula(1).

$$\begin{cases} v_X(t+\Delta t)-v_X(t)=\Delta t\cdot\dfrac{\sum P_X}{m} \\ v_Y(t+\Delta t)-v_Y(t)=\Delta t\cdot\dfrac{\sum P_Y}{m} \\ \omega(t+\Delta t)-\omega(t)=\Delta t\cdot\dfrac{\sum M}{I_Z} \\ \mathrm{X}(t+\Delta t)-X(t)=\Delta t\cdot\dfrac{v_X(t+\Delta t)+v_X(t)}{2} \\ Y(t+\Delta t)-Y(t)=\Delta t\cdot\dfrac{v_Y(t+\Delta t)+v_Y(t)}{2} \\ \phi(t+\Delta t)-\phi(t)=\Delta t\cdot\dfrac{\omega(t+\Delta t)+\omega(t)}{2} \end{cases} \quad (1)$$

where $v_X(t), v_Y(t), \omega(t)$——re t moment, the velocity component at the direction of OX,OY(m/s) and the yaw angular velocity about center of mass(rad/s);

$\sum P_X, \sum P_Y, \sum M$——component of vehicle's resultant of forces in the direction of OX, OY (N) and the resultant of moments of the vehicle about mass center (N·m);

$X(t), Y(t), \phi(t)$——at t moment, horizontal and longitudinal coordinate of vehicle's centre of mass(m) and the yaw angular displacement of vehicle(rad).

Confirmation method of position of vehicle's center of mass. Hypothesis: (1) The vehicle's centre of mass and gravity are the same point. (2) The vehicle's mass is symmetric about longitudinal axes of the vehicle. Therefore, the position of vehicle's center of mass can be measured by using the gravity method.

Confirmation method of position of impact point. By using two rectangles, that is $A_1A_2A_3A_4$ and $B_1B_2B_3B_4$, the accident vehicles can be described as shown in Figure 3 and Figure 4.

If B_2 is in the rectangle $A_1A_2A_3A_4$, the area summation of triangles $A_1A_2B_2$, $A_2A_3B_2$, $A_3A_4B_2$ and $A_3A_4B_2$ must equal the area of $A_1A_2A_3A_4$. If B_2 is out, the area summation of the 4 triangles must be greater than the area of $A_1A_2A_3A_4$. So, whether and where vehicles are impacting can be distinguished by the area calculation.

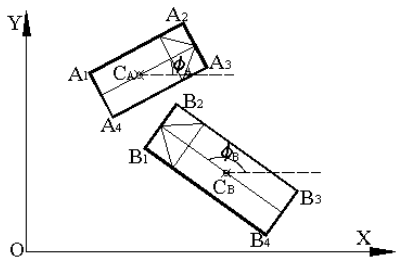

Figure 3. A and B vehicle do not impact

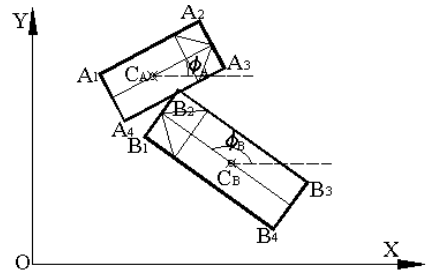

Figure 4. A and B vehicle impact

Vehicle's moment of inertia about the center of mass. Vehicles are classed into three categories which are car, truck and passenger. The data of wheel base, track-axle, mass and moment of inertia of 3 kinds of vehicles have been collected and analyzed. Therefore, the formulas of three kinds of vehicles' moment of inertia can be

expressed as following.

$$I_{Z car} \approx \frac{B \cdot L}{2.595} \cdot m \qquad (3)$$

$$I_{Z\ passenger} \approx \frac{B \cdot L}{1.110} \cdot m \qquad (4)$$

$$I_{Z truck} \approx \frac{B \cdot L}{1.640} \cdot m \qquad (5)$$

VEHICLE'S SPECIAL POINT SELECTED AND COORDINATE SETTING

The vehicle's special points selected in paper include 4 contact points between tires and ground which are E_1, E_2, E_3, E_4 . According to the coordinates of the centroid and the geometric parameters of the vehicle, the coordinates of the special points can be calculated easily (Cao Y. 2007).

ERROR INDEX OF ACCIDENT VEHICLE'S TRAJECTORY

The calculation coordinates of contacting point between the tires and ground can be denoted as (x_i, y_i), i=1,2,3……n. The actual coordinates of the vehicle's tires' braking marks can be denoted as (X_j, Y_j), j=1,2,3……m.

The absolute error of trajectory's length can be defined as ΔL, as follows.

$$\Delta L = \left| \sum_{j=1}^{m-1} \sqrt{(X_{j+1} - X_j)^2 + (Y_{j+1} - Y_j)^2} - \sum_{i=1}^{n-1} \sqrt{(x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2} \right| \qquad (6)$$

The relative error of the trajectory's length can be defined as L_E, as follows.

$$L_E = \left| \frac{\sum_{j=1}^{m-1} \sqrt{(X_{j+1} - X_j)^2 + (Y_{j+1} - Y_j)^2} - \sum_{i=1}^{n-1} \sqrt{(x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2}}{\sum_{j=1}^{m-1} \sqrt{(X_{j+1} - X_j)^2 + (Y_{j+1} - Y_j)^2}} \right| \qquad (7)$$

The maximum of the trajectory deviation can be defined as R_{max}, as follows.

$$R_{\max} = \max_{i=1,2,\ldots n} [\min_{j=1,2,\ldots m} \sqrt{(x_i - X_j)^2 + (y_i - Y_j)^2}] \qquad (8)$$

The relative biased error of trajectory can be defined as R_E, just as following.

$$R_E = \frac{10 \cdot \sum_{i=1}^{n} [\min_{j=1,2,\ldots m} \sqrt{(x_i - X_j)^2 + (y_i - Y_j)^2}]}{n \cdot \sum_{j=1}^{m-1} \sqrt{(X_{j+1} - X_j)^2 + (Y_{j+1} - Y_j)^2}} \qquad (9)$$

The scientific measure method is that by using all 4 error indexes of trajectory, the characters of length and deviation can be analyzed intuitively.

CASE ANALYSIS

General situation of the accident. The front of a specialty truck collided with the right rear of a taxi. The accident scene is shown as Figure 5 and Figure 6.

Figure 5. Accident scene (from south to north in view)

Figure 6. Accident scene (from north to south in view)

Reconstruction result of the trajectory model. The impact point of this accident can be regarded as origin *O*. According to the reconnaissance at the scene, the specialty truck's data is x_1=-1.0537m, y_1=-0.6636m, φ_1=-0.0224rad. The taxi's data is x_2=2.2196m, y_2=-5.8627m, φ_2=-1.3798rad. By using trajectory model, the trajectories can be obtained and shown as Figure 7.

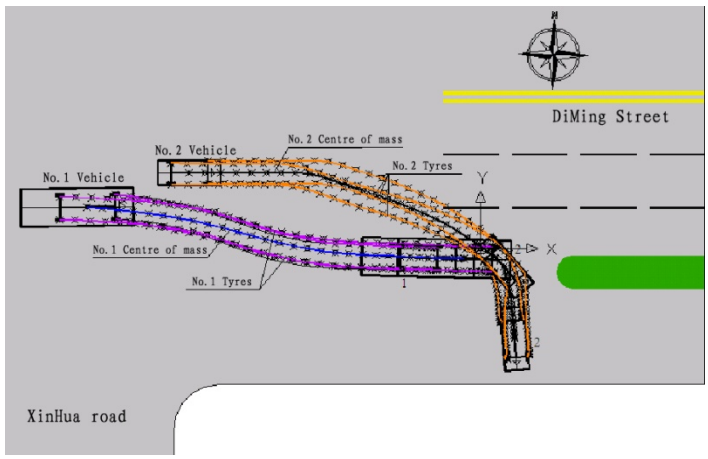

Figure 7. Reconstruction result of trajectory model in collisions case

The error analysis of calculation result of trajectory model. By contrasting the calculation result of the vehicle movement trajectory model with the marks of vehicle's tires left at the accident scene, the calculation errors of model can be discussed. Calculation results of errors are listed in Table 1.

From Table 1. we can see that the L_E of the left-back wheel of the taxi is largest that is 8%. There are 5 other two-dimension accident cases that have been analyzed in this research. The errors are all less than ±10%.

Table 1. Calculation Errors Result of Accident Vehicles

Error analysis	No.1 Vehicle (The specialty truck)		No.2 Vehicle (The taxi)
	Left-front wheel	Right-front wheel	Left-back wheel
ΔL(m)	0.21	0.48	0.28
L_E(%)	0.83	2.00	8.00
R_{max}(m)	0.30	0.27	0.25
R_E(%)	4.60	4.50	3.26

CONCLUSION

Without considering the case of twice impacts or more times impacts, the calculation result of the vehicle movement trajectory model in two-dimension collision accident is similar to the marks of vehicle's tires left at the accident scene. Therefore, it can be believed that the vehicle movement trajectory model in two-dimension collision accidents is valid.

ABSTRACT

At present, runway incursions have the greatest impact on runway safety, and it is also the most frequent cause of flight incidents. In order to prevent incidents of runway incursion, and to find the factors that induce these incidents, a Bayesian Network (BN) model is used to explore the relationship and interaction mechanism among those factors that cause runway incursion. It overcomes deficiencies attributed to the limitation of the sample capacity, and reveals the interaction law among human, aircraft, environment and management factors. It will provide a reliable technique to scientifically improve airport safety management, and further reduce accident rates.

0 Introduction

At present, it is a worldwide recognition that the runway incursion is one of the most unsafe incident types in the world [Gao Yang. 2008]. ICAO (International Civil Aviation Organization) defines runway incursions as: Any occurrence at an aerodrome involving the incorrect presence of an aircraft, vehicle or person on the protected area of a surface designated for the landing and taking off of aircraft [ICAO Annex 14 AERODROMES.1999]. In brief, when an aircraft, vehicle or person accidentally enters the runway being used by other aircraft taking off or landing, the runway incursion will happen.

With the rapid growth of civil aviation industry in our country, runway incursions occurs frequently [Huo Zhiqin. 2006]. A study by the Transportation Department in Canada shows that if the increase of traffic volume in an airport is 20%, then the possibility of runway incursions will increase 140%. While the growth of the traffic volume and the increase of the capacity of the airport are leading to higher stresses in airport safety, runway incursion may be more likely to occur. By 2020, the number of civil aviation airports in China will reach 244, and 97 new airports have been built since 2006[Scott A.Shappell. 2000]. In order to meet the requirements of growing airport capacity, the airport layout will be more complex. In addition to inappropriate design airport, signs and lighting, the airport safety situation will be more complex. Consequently, the occurrences of runway incursion will increase. Furthermore, the potential human errors make the uncertainties develop into a catastrophic accident possible.

The consequence of runway incursion may be catastrophic. Except for 911, the

most severe aviation accident is caused by runway incursion in human aviation history. In 1977, Nally archipelago Turner Reeve in Spain, two B-747 airplanes collided with each other and 583 people died. On April 30th, 2008, two planes fully loaded with fuel conflicted on the runway of Dalian airport (i.e. runway invasion), and the safety of the crew and passengers on the plane were threatened. To this end, how to carry out statistical analysis and study of runway incursion to mitigate running-related risks has become an imminent task in the safety of civil aviation.

There is still no systematic research about runway incursions in our country. In order to understand the trends and conditions of runway incursions which have happened in China, to explore the interaction mechanism of inducing factors, and to further establish effective preventive measures, the author will use a Bayesian network model to analyze the data of runway incursions. Applying the Bayesian network model in the study of runway incursions will not only be able to overcome insufficient data brought by limited sample space, but also can built up a relatively precise mathematical model to obtain a certain accuracy of the statistical properties. Coupled with a strong logical reasoning ability, Bayesian networks can be convenient in practical application and also has a good operability.

1 Review of Research Status

From the author's available research materials, the analysis of runway incursion incidents generally use Severity analysis, Failure analysis, Fault tree and Fault tree analysis etc. These methods can only carry out a brief description and qualitative analysis of the incidents. The typical methods which can identify the failures of equipment and hardware systems are failure mode, effects, and criticality analysis (FMECA) and failure mode and effects analysis (FMEA). But the severity of fault and probability of occurrence are from the experts' experience, limited to a single failure mode, and neglects threats brought by external changes. The Fault tree and Event tree are also common measures. Both are difficult to use the conditional probability calculation, which simply assumes relationships between the nodes are independent, and only can make an approximate description. "Bow" analysis (Bow Tie Analysis) incorporates the two methods together. On the one hand, it is used to identify hazards and determine the measures taken for prevention before the event;on the other hand, it is used to assess the effectiveness of remedial measures to achieve prevention after the event. However disadvantages of these two methods still remain, and ultimately they can not give precise results.

The Bayesian network model inherits the advantages of these methods, but also makes up for their shortcomings. First, the Bayesian network model assumes that the conditions between the nodes are independent, so we only need to consider the limited variables related to the variables. The solution of difficult questions can be simplified, and also a feasible solution of a complex runway incursion question can be obtained. Second, the inference principle of the Bayesian networks is based on the probability theory, and the conditional probability calculation method. The model is in line with reality, the result of the calculation is relatively accurate. Finally, Bayesian networks have the characteristic of the independent conditions, the author is just concerned with the local network diagram that are made up of the nodes, and these nodes are adjacent to each other. In the calculation we can calculate the

probability of occurrence of nodes according to the relevant status of known nodes. The mutual relationship between factors has been fully taken into account, so the calculated result will have a strong persuasion [Zhang Chao.2005].

Early in 1991, the FAA (Federal Aviation Administration) announced the first plan to prevent runway incursions. After that, Canada, Australia and other countries have also started research on runway incursions. In 2001, the ICAO began to conduct a special study of runway incursions.

With the rapid growth of air transport volume, the possibility of runway incursion increases more quickly than the growth in traffic volume. The United States aviation system is the world's most advanced and normative system, the results of its operation can represent the universal trend of civil aviation industry in a certain extent. Over the past 20 years, with traffic growth, the number of runway incursions happening at airports in the United States took an upward trend. It soared by a straight line from 186 times in 1988 to 336 times in 2002. After 2002, the occurrences of runway incursions have been controlled are in a stable trend thanks to the American effective runway safety actions in recent years.

From 2002 to 2006, the numbers of the airport runway incursions incidents in our country are as follows: in 2002 the number of runway incursions was 8, 10 times in 2003, 11 times in 2004, and 18 times in 2005. It can be seen that, in recent years, the number of runway incursions in our country have an overall upward trend. In addition, the low accident rate in the high-risk characteristic of runway incursion suggests that airport safety can not merely consider the issues happening, so analysis of runway incursion in civil airport based on Bayesian network seems particularly important.

2 Establish the model of runway incursion

2.1 Data sources and collating

Based on the analysis and research of 1000 domestic and foreign (domestic 475, overseas 525) runway incursions, 17 kinds of induced factors of runway incursions have been acquired, namely: crossing runway, coordination failures between controllers, obstructive communications, incorrect implement of repeat procedures, the use of non-standard terminology, long or complex controller instruction, controller fatigue, non-standard runway holding position sign or lights, pilot workload, pilot distraction, weather conditions, complicated airport layout, unfamiliarity of the airport, controller workload, inexperience of controller, indiscipline controller, controller distraction.

2.2 Establish the structure chart of Bayesian network

Because the inter-relationships exist among inducing factors of runway incursions, the author can not only classify as person, machines, environment, and management factors. Therefore, the author uses an heuristic search algorithm to set up the optimal structure chart of the Bayesian network. First of all, assume that the node set of the parent node is an empty set, and then add to the node that will turn the results of parent nodes into a biggest probability. This process will go on until the probability of the parent node can no longer be increased, so a possible network structure can be obtained. If this algorithm continues to be repeated, in this condition we can find out a number of possible network structures. By sorting the probability of

the network structure, the optimal Bayesian network structure can be identified, as shown in Figure 1.

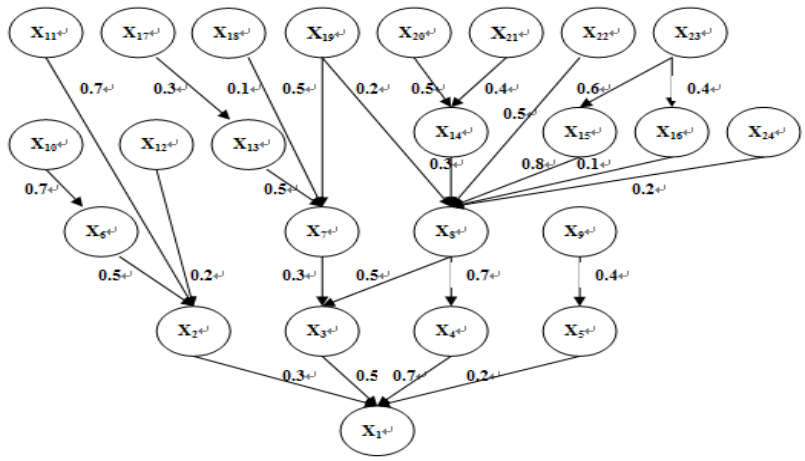

Figure 1. Causal relationship chart of runway incursions

The factor that may lead to runway incursions is known as the surface factor, that is without the arrow point to the figure; vice versa, the factor with the arrow point is the latent factor. Surface and latent factors are shown in Table 1 below.

Table 1. Surface Factors and Latent Factor Classification Table

Latent factors	Surface factors
X_2: Equipment factor	X_1: Runway Incursion
X_3: Human factor	X_9: Bad Weather Conditions
X_4: Management factor	X_{10}: Complicated Airport Layout
X_5: Environmental factor	X_{11}: Obstructive Communications
X_6: Crossing runway	X_{12}: Non-standard Runway Holding Position Sign or
X_7: Pilot Error	X_{17}: Pilot Workload
X_8: Controller Error	X_{18}: Unfamiliarity of airports
X_{13}: Pilot Distraction	X_{19}: Coordination Failures between Controllers
X_{14}: Inexperience of	X_{20}: Long or Complex Controller Instruction
X_{15}: Controller Distraction	X_{21}: Indiscipline Controller
X_{16}: Controller Fatigue	X_{22}: Incorrect Implement of Repeat
	X_{23}: Controller Workload
	X_{24}: The Use of Non-standard Terminology

2.3 Calculation Parameters

The above model can be described as B (D, P), D constitutes of a set of nodes for variable X = (X_1, X_2, ... X_{24}); P is composed of the parameters set of the Mean (u_1, u_2, ... u_{24}), conditional variance (v_1, v_2, ... v_{24}) and degradation coefficients ($b_{ij} \mid j < i$) (given in Figure 1). Obtained from 100 incidents of statistical data, the values of b_{ij} in

Figure 1 are given; $b_{ij} = p_{ij}*u_i/u_j$, p_{ij} are the correlation coefficients of X_i and X_j. Because on the base of $u_i = 0$, the variables have to obey normal distribution; based on the implicit factors of uncertainty, and its conditional variance v_i has a smaller value, when X_i for the implicit factors, so that $v_i = 10^{-5}$; and when X_i factors for the surface, so that $v_i = 1$. To calculate person, machine, environment, and management, four latent factors parameter values, and data curves are shown in Figures 2 and 3.

The mean values changes in the latent factors reflect the degree of change. It can be seen that among the person, machine, environment and management curves, the human factors have the most significant fluctuations which means that runway incursions has the most important impact, and is most vulnerable to accidents, then followed by equipment factors, management factors and environmental factors.

The reduction of the variance factors showed that the transition from a state of uncertainty gradually moves toward a state of certainty of latent factors. Herein, in order to avoid the occurrence of runway incursions the likelihood of improvement should be done first on the equipment factors, followed by management factors, environmental factors and human factors.

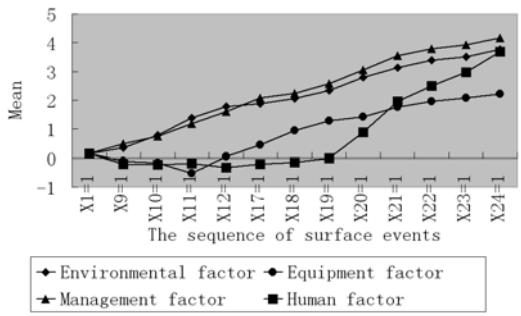

Figure 2. Mean

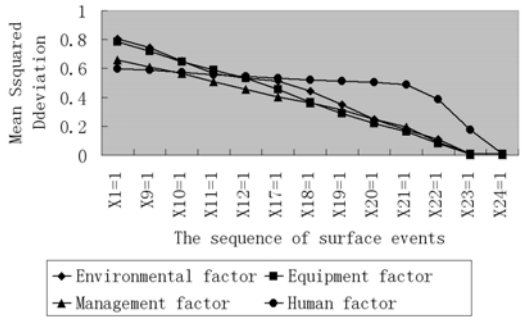

Figure 3. Mean squared deviation

2.4 Result Analysis

The results of parameters showed above manifest the human factor has great impact on the runway incursion. The human factor calculation results are interpreted in Table 2. Similarly, the calculation results of management factors, equipment factors and environmental factors can be drawn, which are not listed here considering the length limitation of this paper.

3. Conclusion

Based on Bayesian network model analysis and research on the influencing factors of runway incursion, the results showed that:

1. The application of the Bayesian network model can analyze runway incursions from the surface factors and latent factors. After that, a relatively precise result can be obtained. The results can provide some references for runway incursion prevention in our countries;

2. The analysis results show that the human factor plays the most important role in runway incursion incidents. The civil aviation system should emphasize the professional skills of personnel while comprehensively considering all the factors involved, and make a rational remedial plan.

Table 2. Calculation Results of Human Factors

Acquired data	Mean	Mean squared deviation	Description
Initial data	0	1.476	
X_1=1 runway incursion	0.159	0.597	Mean increases while mean squared deviation decreases, so human factors may lead to the occurrence of runway incursions
X_9=1	-0.189	0.558	Both mean and mean squared deviation decreases, so the possibility of runway incursions caused by environmental factors decrease
X_{10}, X_{11}, X_{12}=1	-0.324	0.546	Both mean and mean squared deviation decreases, so the possibility of runway incursions caused by Equipment factor decrease
X_{17}, X_{18}, X_{19} =1	-0.002	0.514	Mean increases while mean squared deviation decreases, so the possibility of runway incursions caused by Pilot Error increase
X_{20}, X_{21}, X_{22}, X_{23}, X_{24}=1	3.689	0.01	Mean increases while mean squared deviation decreases, so ATC Controller Error lead to the occurrence of runway incursions

Investigation of the Relationship between Red-Light-Running Frequencies and Intersection Features

Yiyi Cai,[1] Xuesong Wang,[1] and Xiaohong Chen[1]

[1]School of Transportation Engineering, Tongji University, P.O. Box 201804, Shanghai; PH (86) 21-69583946; FAX (86) 21-65982897; email: caiyiyi_2006@yahoo.com.cn

ABSTRACT

Red-light running is a complex problem. There is no simple reason to explain why drivers run red lights. The purpose of this study is to improve understanding of the red-light running and its relationship with the intersection features so that efficient countermeasures can be developed to improve intersection safety. Five large four-legged signalized intersections in Orange County in Central Florida, U.S., were selected. Data collected for these intersections include intersection features and red-light-running violations in 2006 and 2007. Red-light-running violations were modeled at the approach level using Generalized Estimating Equations (GEE) with Negative Binomial as the link function to account for site correlation among the data. The following factors were identified that have significant contributions to red-light-running frequencies: traffic flows to which the conflicting traffic belongs, the number of through lanes on the conflicting approach and speed limit of conflicting approach, and yellow time of a near-side approach.

Keywords: red-light running, intersection features, relationship, Generalized Estimating Equations (GEEs)

INTRODUCTION

Red-light running is one of the primary causes of crash occurrence at signalized intersections. There are three primary crash types (right-angle, left-turn, and rear-end crashes) related to it. According to the estimates given by the Federal Highway Administration (FHWA) in U.S., in 2003 there were nearly 206,000 red-light-running crashes at intersections, resulting in 176,000 injuries and 934 fatalities.

Red-light running is very complex. There is no simple reason to explain why drivers run red lights. This study is going to improve the understanding of red-light running and its relationship with the intersection features, and develop efficient countermeasures.

In China, few researchers focus on this area. Wang et al. (2006) did some research and found that rational signal phases and red-light-running violation camera systems decreased red-light-running behaviors. In the U.S., Bonneson et al. (2001; 2004) systematically analyzed the red-light-running problem. He raised approaches to identify problem locations, and found that red-light-running was related to approach volume, yellow intervals, speed limit etc. using a generalized linear regression technique. Most of the previous studies investigated factors influencing red-light-running violations based on the intersection level. Considering that there are discrepancies in the traffic and geometry features among approaches of an intersection, modeling the total number of red-light-running violations may obscure the real relationship between red-light running and intersection features.

The objective of this study is to investigate the significant factors of intersection features influencing red-light-running frequencies based on the approach level. Since disaggregating intersections into approaches will introduce correlation among observations from the same intersection, GEEs with Negative Binomial as the link function that account for the site correlation were used.

DATA PREPARATION

Five large four-legged signalized intersections in Orange County, Central Florida, U.S., were selected. Geometric designs (i.e., number of lanes, median types, angle of intersecting approaches, etc.) were observed from Google™ Earth (2008). Traffic flows from 2004 to 2007, signal controls, and operational features (i.e., speed limit of each approach, etc.) were collected. Red-light-running data from December 2006 to February 2007 were retrieved from the Traffic Engineering Office in Orange County. Daily average red-light-running frequencies were used in this study.

Both red-light-running frequencies and intersection features were assigned to corresponding approaches. At approach level, each intersection has four observations, defined as entering, near-side, opposing, and far-side approach in the clockwise view

(Wang et al. 2007). For instance, eastbound traffic is at the near-side approach if the observation site is northbound, as shown in Figure 1. The summary statistics are presented in Table 1. Only summary statistics for entering approaches are included in this table.

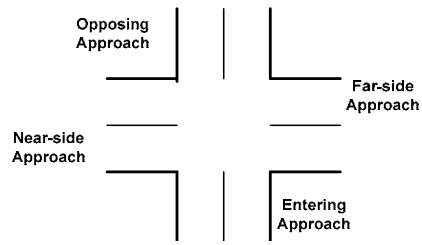

Figure 1. Illustration of entering approach, near-side approach, opposing approach, and far-side approach.

METHODOLOGY

As shown in Table 1, red-light-running frequencies at signalized intersections are non-negative, discrete, over-dispersed count data. There are several methodologies for count data modeling. MLRs and Poisson distribution methods are two approaches used in early studies. MLRs, requiring the variables to be independent, could not overcome the problem of multi-collinearity of the explanatory variables. Poisson distribution is not suitable for modeling over-dispersed data. The Negative Binomial modeling approach, which is an extension of Poisson regression modeling, is a common tool for modeling cross-sectional count data.

However, disaggregating intersections into approaches may introduce site correlation among observations from the same intersection. Using Negative Binomial regression leads to invalid statistical inference, due to incorrect test statistics and standard errors based on the unspecified variance (Wang et al. 2008). Generalized Estimating Equations (GEEs), as an extension of generalized linear models (GLMs), account for the correlation of repeated observations from one intersection (Zeger et al. 1986).

The red-light-running frequency model at approach level was fitted by using the GEEs with the Negative Binomial as the link function. The GENMOD procedure in the SAS software was used to estimate the model. Since all five intersections selected have left-turn protections, red-light-running and left-turn red-light-running were modeled.

MODELING THROUGH RED-LIGHT-RUNNING

There are two conflicting patterns related to through vehicles running a red light. One is the red-light-running vehicle conflicting with vehicles from crossing

approaches (near-side and far-side approaches). The other is rear-end conflict resulting from red-light running related actions, when the front vehicles stop abruptly before a red signal while following vehicles hit the rear of the front ones.

In order to investigate significant intersection factors related to the conflicts, the red-light-running rates of vehicles traveling in the through lanes were modeled in the approach level as shown in Table 2.

It has been found that the logarithm of the product of the conflicting through flows is the most appropriate functional form for the models at approach level. It shows to be significant in the GEEs model. The negative sign of the estimates, different from previous studies (Bonneson et al. 2001), indicates that a large amount of AADT of conflicting through traffic does not necessarily increase the red-light running frequencies.

Table 1. Data summary statistics for the approach level models.

Variable	Mean	Min	Max	Variance	SD
Total number of through lanes on entering approach	2.3	1	3	0.43	0.66
Total number of left-turn lanes on entering approach	1.50	1	2	0.26	0.51
Total number of right-turn lanes on entering approach	0.75	0	1	0.20	0.44
Division on entering approach	4.33	0	14	15.69	3.96
Left-turn protection on entering approach(*1 if "permitted"; 2 if "compound"; 3 if "protected"*)	3	3	3	0	0
Speed limit on entering approach(*mph*)	44.25	35	50	11.25	3.35
Angle of eastbound and southbound(*degrees*)	91.60	81	105	62.57	7.91
All red time on entering approach(*sec*)	1	1	1	0	0
Yellow time on entering approach(*sec*)	4.29	4	4.7	0.02	0.13
Entering approach through AADT(*vehicles*)	13713	2855	34053	76446444	8743
Entering approach left-turning AADT(*vehicles*)	4099	1518	10424	5423394	2329
Entering approach right-turning AADT(*vehicles*)	3570	1077	6735	3354667	1832
Red-light-running frequency of through lanes on entering approach	272	58	709	38110	195
Red-light-running frequency of left-turn lanes on entering approach	209	44	438	18643	137

The number of through lanes on entering and crossing approaches has a negative effect on red-light running. The larger number of through lanes is associated

with larger through volumes and longer crossing distance. From the psychological perspective, drivers are less likely to violate a red indication at wide intersections (Bonneson et al. 2004).

The speed limit on an entering approach and on a far-side approach has been identified to be significant, but they have different effects. The speed limit on the entering approach has a positive effect on the red-light violations, which is reasonable, for drivers at a high speed may underestimate the time it takes to cross the intersection. It is interesting to find speed limit on far-side approach decreases drivers' red-light behaviors. Drivers may take a conservative action when they feel dangerous crossing the intersection.

Yellow time has been found to influence red-light frequencies. The longer yellow time, which means longer clearance time, will reduce the possibility of running a red light.

Table 2. Significant factors of red-light-running model.

Parameter	GEE		
	Coef.	**s.e.**	**p-value**

MODELING LEFT-TURN RED-LIGHT-RUNNING

In a signalized intersection, left-turn traffic may collide with traffic flows from different directions. Wang et al. (2007) classified left-turn crashes into nine patterns based on vehicle maneuvers at the approach level after analyzing 197 four-legged signalized intersections over six years. Among all patterns of left-turn crashes, pattern 1, shown in Figure 2, accounts for the highest proportion (72.5 percent), and pattern 2 in Figure 3 is the second common pattern (14.1 percent).

Figure 2. Conflicting patterns of left-turn red-light-running.

In the future, to understand the relationship between intersection characteristics and left-turn vehicles running a red light, GEE models with Negative Binomial regression as the link function were fitted.

The first three significant factors shown in Table 3 indicate that the logarithm of the product of the conflicting through flows is the most appropriate functional form. The negative sign of the impact of left-turn movements on the entering approach and through movements on the near-side approach on red-light running shows that an increase of AADT of conflicting traffic flows does not necessarily increase the frequency of the red light running. It is consistent with the conclusion above.

The crossing distance of left-turning vehicles is represented by the number of through lanes on the opposing and approach. A higher number of through lanes on the opposing side, which means the crossing distance is larger, is correlated with fewer red-light-running frequencies; while a higher number of left-turn lanes on the entering side and through lanes on the near-side approach is correlated with more red-light-running frequencies. Appearance of left-turn lanes increases the violations.

The speed limit on the near-side approach has been identified to be positively significant in the model. Higher posted speed limits generally produce frequent occurrences of red-light-running vehicles.

Table 3. Significant factors of left-turn red-light-running model.

Parameter	GEE		
	Coef.	s.e.	p-value
Intercept	5.9982	0.6851	<0.0001
Logarithm of the product of the left-turn movements on entering approach and through movements on opposing approach	0.6142	0.1891	0.0012
Logarithm of the product of the left-turn movements on entering approach and through movements on far-side approach	0.9686	0.1732	<0.0001
Logarithm of the product of the left-turn movements on entering approach and through movements on near-side approach	-1.8355	0.2327	<0.0001

45	1.0994	0.356	0.002
35	0	0	-

CONCLUSION

This study explored the safety effects of intersection features on red-light-running frequencies. Generalized Estimating Equations (GEE) with Negative Binomial as the link function have been used to model the relationship between them.

In the models, it is found that: (1) the logarithm of the product of the conflicting through flows is the most appropriate functional form for the models. The frequency of red-light-running is related to the traffic flows to which the conflicting traffic belongs rather than the sum of the traffic flows. In addition, a large amount of AADT of conflicting traffic flows does not necessarily increase the frequency of the red light running. (2) For geometric design features, number of red-light-running entering approach lanes and through lanes on conflicting approach are the significant variables. Long crossing distance decreases the red-light-running frequencies; designing left-turn lanes could probably increase the violations. (3) As for speed limit and signal control, the speed limit of the conflicting approach was found to be

significant in both models; in the through traffic model, speed limit of the entering approach and yellow time on the near-side approach are also significant. Maintaining a longer yellow signal time will decrease red-light-running frequencies.

In conclusion, compared to the intersection level models, dividing red-light-running into two types on the approach level allows us to better understand contributing factors of intersection features. Intersections selected here are common four-legged ones, so the conclusion can be widely used for other signalized intersections. It also provides an analyzing framework for investigating the red-light-running problem in China.

ABSTRACT

The road traffic accidents often occur when one or several links are imbalanced in the dynamic system, which comprises persons, cars, roads and environment. As a special natural phenomenon, sunlight glare makes drivers discomfort. Acting on drivers' eyes, sunlight glare changes drivers' visual condition and affects drivers' judgment on traffic environment. In this paper, the applicability of drivers' psychophysiological indexes under the sunlight glare condition was analyzed. The indexes include heart rate, skin temperature, galvanic skin response and respiration. By use of multi-channel psychophysiological instrument, a lot of practical experiments have been made on roadway. The impact on drivers' psychophysiological indexes generated by sunlight glare was also analyzed. In the end, some quantitative models of drivers' psychophysiological characteristics under the influence of sunlight glare were built with the regression analysis and numerical fitting method.

KEYWORDS: traffic safety, sunlight glare, psychophysiological characteristics

INTRODUCTION

Driving motor vehicle is a very complex Human-Machine interaction procedure, which requires drivers to collect information necessary momentarily, screen all the information rapidly to make correct judgment and response.

From cognition to response, drivers commonly go through three stages: perception, judgment, and response. Perception is the time needed to detect and identify the road information. At this stage, if the objective identified under traffic environment is of low stimulation intensity to sense organs, low contrast to environment, or drivers encounter temporary barriers of sensory function, this will make drivers ignore or misjudge road information, and sometimes cause traffic accidents occur.

Sunlight radiating drivers' eyes affects drivers' vision obviously and produces uncomfortable feelings. Therefore, the ability to perceive driving condition will be affected. Because psychophysiological responses to environmental stimulus are different among different individuals, it is necessary to measure drivers' psychophysiological indexes on roads and analyze the effects of sunlight glare and building the impact models in order to provide theoretical basis for evaluating driving environment and analyzing drivers' behavior characteristics.

PSYCHOPHYSIOLOGICAL INDEXES SELECTION

Indexes commonly used for representing drivers' psychophysiological characteristics are: heart rate (HR), skin temperature, electromyography (EMG), electroencephalogram (EEG), galvanic skin response (GSR), blood pressure (BP), and respiration (RSP). Due to the limitation of the experimental devices and the uncertainties of data sampling, of these indexes, EMG, EEG and BP were not considered in this research.

While driving vehicles, the mutation of light environment may cause the adaptive problem of eyes and the corresponding psychological reactions, such as the decline of the vision and recognition speed. Furthermore, the driver's mood may be affected, for instance, dizziness, upset mood irritability, depression, physical weakness and so on. These impacts will lead drivers being unresponsive. Traffic accidents often occur under these conditions.

TEST AND ANALYSIS

Experimental scheme. NeXus-10 was used for field experiement for this study. It is a ten channel physiological monitoring and biofeedback platform that utilizes Bluetooth 1.1 class 2 wireless communication and flash memory technologies. The advanced technology preamps enjoy independent 24 bit A-D converters per channel with DC coupled amplifiers allowing DC to 800 Hz (-4dB) recording including EEG, ECG, EMG, EOG.

Test is conducted for four days between June 19th and June 24th (5:00am–6:00am, 9.30am-10.30am and 5:00pm–6:00pm), in 2007.

Testing indexes included HR, skin temperature, GSR and RSP. Testing locations include the Zhongshan Road, Changjiang Road and Huashan Road in east-west Harbin city. Meanwhile, video cameras were used to record the road information in the test procedure.

Data Acquisition and analysis. In theory,the impacts of sunlight glare are different under different road conditions. In the test, NeXus-10 were used to record drivers' HR, skin temperature, GSR and RSP to measure the impacts of sunlight glare for different road conditions.

According to the statistical analysis of test data, drivers increased heart rate and psychological stress under sunlight glare environment. Heart rate increased by

about 10 times/min than normal average.The other indexes were changed, too. So sunlight glare is an important factor affecting drivers' behavior. Certainly, heart rate is also connected with other factors such as drivers' attention, mental status, age and sex. This article mainly focuses on the changes of psychophysiological characteristics caused by sunlight glare.

INFLUENCE MODELS

Based on the analysis of experimental data, the corresponding quantitative influence models were developed as follows.

HR model. Based on experiment data, HR fluctuates along a straight line: y=72.5, without sunlight glare. But with sunlight glare, it fluctuates according with cubic curve (see Figure 1). Under sunlight glare condition, the curve fitting model of HR is derived as the following equation:

$$y=71.152-0.05x+0.33x^2-0.11x^3$$

where y represents the value of HR with sunlight glare (*times/min*), x represents the influencing time (*s*).

The fitting degree of curvilinear is 0.992, which illustrates the fitting degree is better for describing the drivers' heart rate changes under the impact of sunlight glare.

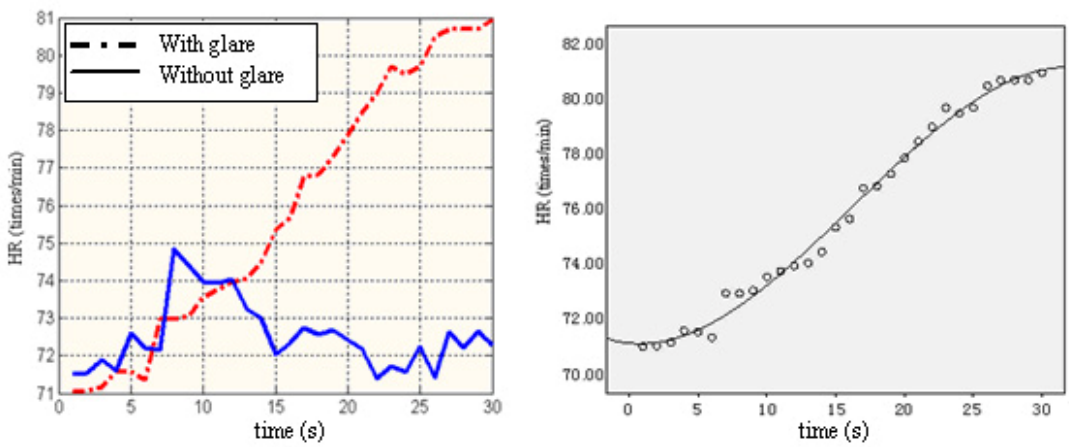

Figure 1. HR and curve fitting

Skin temperature model. There is a noticable impact of sunlight glare upon skin temperature(see Figure 2). Analyzing test data, the skin temperature is between 32.37°C and 32.42°C with average of 32.40°C under non sunlight glare condition and the fluctuation is little; under sunlight glare condition, the skin temperature is between 31.34°C and 32.44°C with average of 31.60°C and skin temperature fluctuation becomes more intense than the fluctuation under non sunlight glare condition.

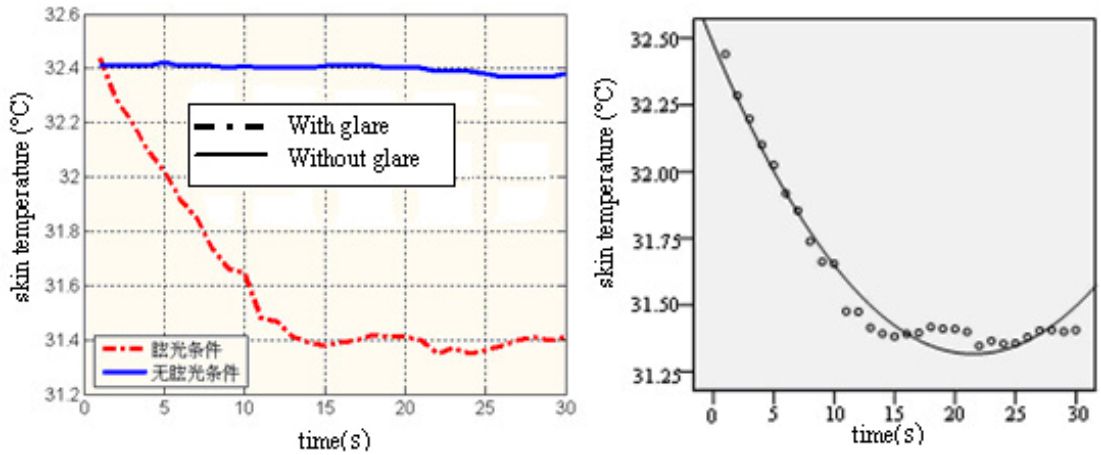

Figure 2. Skin temperature and curve fitting

Based on experiment data, skin temperature fluctuates along a straight line: y=32.4, without sunlight glare. But with sunlight glare, it fluctuates according with the trend of quadratic curve. Under sunlight glare condition, the curve fitting model of skin temperature is derived as the following equation:

$$y=0.003x^2-0.108x+32.479$$

where y represents the value of skin temperature with sunlight glare (°C), x represents the influencing time (s).

The fitting degree of curvilinear is 0.973, which illustrates the fitting degree is better for describing the driver's skin temperature change under the impact of sunlight glare.

GSR model. The impact of sunlight glare upon GSR is significant (see Figure 3). The results of data analysis showed thatthe GSR is between 6.950*mv* and 7.760*mv* with average of 7.181*mv* under non sunlight glare condition and the fluctuation is little; on the contrary, the skin temperature is between 7.450*mv* and 9.770*mv* with an average of 8.939*mv* and GSR fluctuation becomes more intense than the fluctuation under non sunlight glare condition.

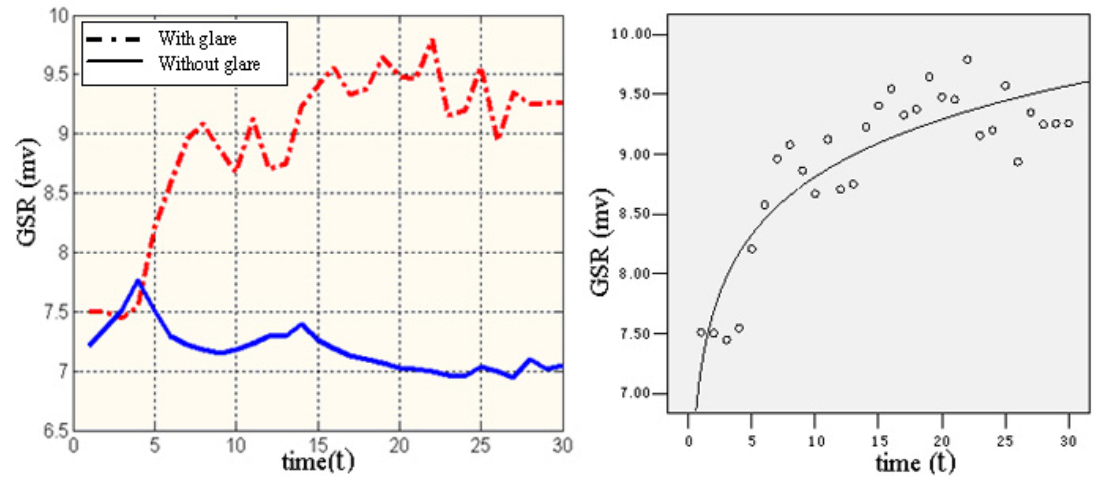

Figure 3. GSR and curve fitting

Based on experiment data, GSR fluctuates along a straight line: y=7.2, without sunlight glare. But with sunlight glare, it fluctuates between 8.5*mv* and 9.5*mv* and accords with logarithm curve. The curve fitting model for GSR under sunlight glare condition is derived as the following equation:

$$y=7.211+0.695ln(x)$$

where y represents the value of GSR with sunlight glare (*mv*), x represents the influencing time (*s*).

The fitting degree of curvilinear is 0.784, which illustrates the fitting degree is better for describing the drivers' GSR change under the impact of sunlight glare.

RSP model. There is a significant impact of sunlight glare upon RSP (see Figure 4). The results of data analysis showed that the RSP is between 1039.15*ml* and 1044.92*ml* with an average of 1041.32*ml* under non sunlight glare condition and the fluctuation is little. On the contrary, the RST is between 1040.27*ml* and 1051.58*ml* with an average of 1048.09*ml* and RSP fluctuation becomes more intense than the fluctuation under non sunlight glare condition.

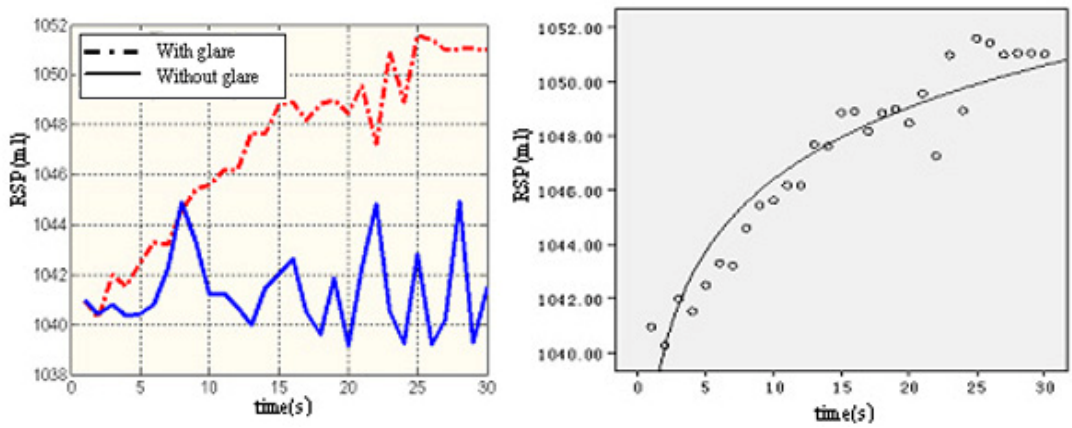

Figure 4. RSP and curve fitting

Based on experiment data, the curve fitting model for RSP under sunlight glare condition is derived as the following equation:

$$y=1037.566+3.831ln(x)$$

where y represents the value of RSP with sunlight glare (ml), x is the same as above.

The fitting degree of curvilinear is 0.890, which illustrates the fitting degree is better for describing the drivers' RSP change under the impact of sunlight glare.

CONCLUSION

In this paper, quantitative models were derived based on the experimental data to measure drivers' psychophysiological indexes including HR, GSR, skin temperature and RSP under sunlight glare condition. The measurement of these psychophysiological indexes can be used for evaluating the safety level under different driving environment.

Since the experimental data were collected from sedan drivers, these

quantitative models cannot be applied for other type of vehicle drivers. In order to find more accurate relationship between driving conditions and drivers' psychophysiological indexes, further study should be done.

ABSTRACT

An improved Fuzzy-AHP method is proposed in this paper for evaluation road traffic safety, based on the traditional AHP method. Several main indexes of road traffic safety were summarized and (0.1~0.9) scale method was used to determine the importance of each evaluation index. The weight of each index was confirmed through adopting a fuzzy consistent matrix, queuing all indexes according to their importance, and adopting a measure of accident prevention according to this. At the same time this verified the effectiveness and rationality of the method.

INTRODUCTION

Road traffic accidents not only directly threaten road users' safety resulting in enormous economic losses, but also seriously affect the normal operation of the road traffic system, reducing the transport efficiency of society greatly and causing a huge waste of social resources. To implement road safety measures, a comprehensive evaluation of the road safety situation including an understanding and grasp of the level of its safety and security posture, and study the distribution laws and the cases of road traffic accidents (Liu Y. T. 2004). To determine the reasonable safety evaluation index system through the AHP method, first draw up the weights of the indexes, then draw up the perfect road traffic safety improvement programs and

accident prevention measures. These are the theoretical basis and practical foundation upon which to reduce the rate and severity of accidents and to improve traffic safety. Therefore, in order to meet the growing requirements of high accuracy, this paper uses an improved Fuzzy-AHP method to evaluate the road traffic safety issue.

SET UP THE IMPROVED FUZZY-AHP MODEL

We used the (0.1 ~ 0.9) scales method in the improved Fuzzy-AHP method; that is to say using five scales (0.1, 0.3, 0.5, 0.7, 0.9) to determine the relative importance between the same level indexes. Model set up steps are as follows：

a) Set up the comparative judgment matrix $F = (f_{ij})_{n\times n}$, according to general AHP regulation. (0.2, 0.4, 0.6, 0.8) can be considered the medium value of the above-mentioned adjacent judgments.

The measurement results are complementary by such scales, and the elements of matrix $F(f_{ij}$ and $f_{ji})$ have the following properties: $0<f_{ij}<1$、$f_{ij}+f_{ji}=1$、$f_{ii}=0.5$.

b) Transform the complementary judgment matrix into the fuzzy consistent matrix: $P = (p_{ij})_{n\times n}$.

So that p_i, p_j, respectively, are the of sum rows, columns of the comparative judgment matrix F, that is: $p_i = \sum_{j=1}^{n} f_{ij}$, $p_j = \sum_{i=1}^{n} f_{ij}$ $i,j=1,2,\ldots,n$ (1)

Where $p_{ij} = p_i - p_j / 2(n-1) + 0.5$ $i,j=1,2,\ldots,n$ (2)

P matrix meets the consistency condition, so it isn't needed to carry out the consistency test, and the complementary judgment matrix P transformed into the reciprocal matrix: $A = (a_{ij})_{n\times n}$, $a_{ij} = p_{ij} / (1 - p_{ij})$ or $a_{ij} = p_{ij} / p_{ji}$. (3)

And a_{ij} meet $a_{ij}>0$, $a_{ji}=1/a_{ij}$, $a_{ii}=1$, $i,j=1,2,\ldots,n$

c) Use normalizing aggregation method for priorities to obtain weight vector of judgment matrix: $Q = \{q_1, q_2, ..., q_n\}^T$ and $q_i > 0, \sum_{i=1}^{n} q_i = 1$.

Because of reciprocal comparison matrix A satisfies the conditions of complete consistency, $a_{ij}=a_{ik}a_{kj}$. , we can obtain: $a_{ij} = \frac{1}{n}\sum_{k=1}^{n} a_{ik}a_{kj}$ $i,j,k=1,2,\ldots,n$ (4)

The a_{ij} has the following characteristics according to the properties of the coincidence reciprocal comparison matrix: $a_{ij} = q_i / q_j$ $i,j=1,2,\ldots,n$ (5)

Separately on both sides of equation (4) for i, j sum was:

$$\sum_{i=1}^{n} a_{ij} = 1/q_j \qquad i,j=1,2,\ldots,n \text{ and } \sum_{j=1}^{n} a_{ij} = q_i \sum_{j=1}^{n} 1/q_j \qquad i,j=1,2,\ldots,n \tag{6}$$

We can obtain: $$\sum_{j=1}^{n} a_{ij} = q_i \sum_{j=1}^{n} \sum_{i=1}^{n} a_{ij} \qquad i,j=1,2,\ldots,n \tag{7}$$

After finishing get: $$q_i = \sum_{j=1}^{n} a_{ij} \Big/ \sum_{j=1}^{n} \sum_{i=1}^{n} a_{ij} \qquad i,j=1,2,\ldots,n \tag{8}$$

Then we obtain the weight vector matrix Q of the matrix A.

APPLICATION IN THE ROAD TRAFFIC SAFETY EVALUATION

The principle of indexes' selection. It is very important to select reasonable evaluation indexes to the correct or not of evaluation model. So in the process of the indexes' selection, such principles should be followed: scientific, reliable, comparable, measurable, qualitative with quantitative analysis, etc.

Set up the evaluation index system. For evaluation indexes system of road traffic safety, four criteria layers are set ranging from road's basic conditions C_1, road environment, road management C_3 to road accident C_4, which has geometric alignment S_1, road Conditions S_2, intersection facility S_3, lane Width S_4, sight distance S_5 and security protection facility S_6, traffic signs and marking S_7, drainage facility S_8, lighting facility S_9, Others S_{10}, and road maintenance S_{11}, management system S_{12}, management tools S_{13} and accident quantity S_{14}, death toll S_{15}, injury number S_{16}, for each criteria layer (Shen F. M.et al. 2007) (Pei Y. L.,et al. 2004).

Set up the comparative judgment matrix. According to the (0.1 ~ 0.9) scales of the improved Fuzzy-AHP model, we have analyzed the expert evaluation results with the fuzzy mathematics theory, found the relative importance of indexes, then assessed the relative importance of indexes in the matrix.

a) The comparative judgment matrix: In this paper, we produced the indexes, the evaluation matrix, and distributed the domestic industry 9 experts to score. Experts compared and determined the essentiality of the T-C layer indexes and C-S layer 16 indexes based on the score criteria and their practical experiences, and got the T-C comparative judgment matrix (Table 1) and C-S comparative judgment matrix (Table 2) through collating the score values of all the experts.

b) Transformation the complementary judgment matrix into the fuzzy consistent matrix: The matrix 2 and 3 (Table 1 and 2) are converted to the fuzzy consistent matrix according to the equation (1) and (2), as shown in Table 3 and 4. $C_{ij}(1) + C_{ji}(1)=1$ (i, j=1, 2, 3, 4) is got by above matrix vector obviously.

c) Transform the complementary judgment matrix into the reciprocal matrix: Although the matrixes 3 and 4 (Table 3 and 4) meet the consistency requirement, they are complementary. So, in order to guarantee the independence of data, to avoid

mutual influence and get the veracious weight vector of indexes, we must convert matrixes 4 and 5 into the reciprocal matrix, as shown in Table 5 and 6.

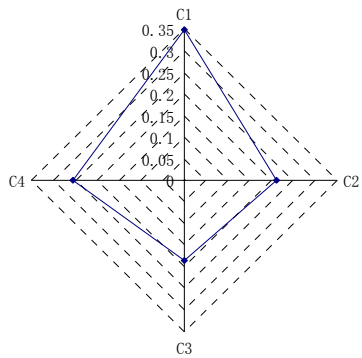
d) Weight vector matrix: Through calculation of equation (4) ~ (8), we can get the weight vector matrix (Table 7) of all layers indexes.

Table 7. Indexes weight matrix

Criteria layer		Scheme layer							
Index	Weight	Index	Weight	Index	Weight	Index	Weight	Index	Weight
C_1	0.347	S_1	0.208	S_6	0.255	S_{11}	0.306	S_{14}	0.279
C_2	0.212	S_2	0.157	S_7	0.284	S_{12}	0.306	S_{15}	0.418
C_3	0.185	S_3	0.221	S_8	0.118	S_{13}	0.389	S_{16}	0.303
C_4	0.256	S_4	0.230	S_9	0.182	—	—	—	—
—	—	S_5	0.184	S_{10}	0.161	—	—	—	—

We can get the relative importance of the indexes from the weight vector matrix 8 (as in Table 7), then we realign the indexes of the criteria layer (as in C layer) and the scheme layer (as in S layer) of the comprehensive evaluation of road traffic safety. So the new matrixes are as follows: C= {C_3, C_2, C_4, C_1}, S= {S_8, S_2, S_{10}, S_9, S_5, S_1, S_3, S_4, S_6, S_{14}, S_7, S_{16}, S_{11}, S_{12}, S_{13}, S_{15}}, Figure 1 and Figure 2 show the weight dispersion of C layer and S layer respectively.



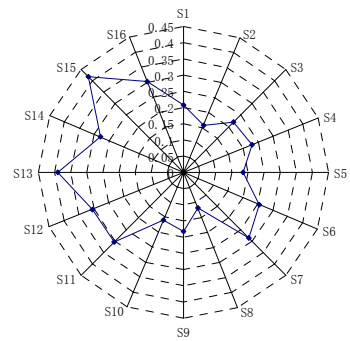


Figure 1. C layer weight dispersion **Figure 2. S layer weight dispersion Result**

From the sequencing results, we can find that the sequence of the sequencing of the sixteen indexes (As S layer or called micro evaluation layer) is inconsistent when compared with the sequencing of the macro evaluation indexes (as in C layer), but the general trend can be able to find the law. For instance, the weight of the road accident is very big in C layer, and the death toll is biggest in S layer, so we can say that the happenstance of accident is the absolute evaluation standard to test the road traffic safety level regardless of the macro evaluation or micro evaluation.

CONCLUSION

Through the study of a comprehensive evaluation of road traffic safety based on an improved Fuzzy-AHP method, we set up the road traffic safety comprehensive evaluation model. This improved model offers a simple and effective tool for solving the road traffic safety evaluation problem of many indexes.

ABSTRACT

Road traffic safety evaluation plays an important role in the traffic safety research. The traditional safety evaluation methods are mostly based on historical accident data, which belong to the macroscopical level and have obvious defects in traffic safety management. To realize the road traffic safety micro-evaluation, the paper established accident Probability Density Function (PDF) by using Kernel Density Estimation (KDE), proposed Accident Probability Prediction (APP) model based on Empirical Bayes (EB) method for considering the impact of accident location characteristics and historical data. The paper also established the method for road traffic safety micro-evaluation by adopting Traffic Accident Probabilities of Equivalent ten thousand Cars (TAPEC) indicator, and a comparative evaluation was conducted by the proposed method against cumulative frequency curve method. Through analyzing accident data collected from the G301, the results show that the proposed method is more reliable and can access to the transformation priorities of potentially dangerous road sections. So it can provide theoretical basis for checking the dangerous sections and improving accident prevention and response.

INTRODUCTION

Traditional safety evaluation models are mostly based on a large number of historical accident data that have limitations. The estimated values obtained by these models may not fit a specific condition. Therefore, the safety evaluations based on the traditional models sometimes cannot be applied for a single point. They are good for a set of points. And the evaluation results are mostly after the accidents happened.

In contrast, the probability evaluation model based on Bayes can identify the vulnerability of the traffic system and determine the accident probability of the road sections. Consequently it can rank the hazardous location by calculating the accident probability. Miaou S. P. (2003) studied the differences between the Bayes and the EB

method, and calibrated the parameters of these models; Persaud B.(1999) compared EB function with other conventional functions, and verified the efficiency of EB function for predicting the accident. Zheng H. (2008) constructed the indexes to estimate the road-side safety and the approaches based on Bayes theory to assess the road-side safety; Sun G. (2005) argued that multivariate regression EB-based approach could be used to estimate the safety levels of road sections.

Based on the above analysis, the paper proposes the Bayes-based APP model as the road traffic safety evaluation method by using TAPEC as indicator, to assess the road safety in a microscopic perspective and developed guidelines for transportation agencies to identify the potential hazardous road segments.

ACCIDENT PROBABILITY PREDICTION BASED ON BAYES THEORY

The EB method that combines the theoretical values with and the historical data is applied in the paper to add the influences of accident location characteristics and the dynamic traffic flow. The APP model is established as the following three steps:

1. Summarize the historical accident data and build up the distribution of the PDF to fit the probability distribution of the accident.
2. Set up a posteriori probability model of the accident prediction based on the accident probability density distribution function, to predict the probability of the traffic accidents in a particular traffic state.
3. Use the accident data of the study road sections, considering the impacts of the historical accident data, transform the prior prediction into posterior prediction of the probability distribution based the EB method.

Due to the incertitude of the accident, it is hard to obtain the PDF of the traffic accident. KDE can be infinitely close to the true sequence of a sample density function, which could be seen as a good approximation of the sequence. So KDE is applied in the paper to establish the accident PDF, which can be expressed as:

$$\hat{f}_h(x) = \frac{1}{Nh}\sum_{i=1}^{N} K(\frac{x - X_i}{h}) \tag{1}$$

Where $\hat{f}_h(x)$ is the PDF based on KDE, $K(\cdot)$ is the kernel function and the paper adopts Epanechnikov kernel function which can be expressed as formula (2), h is the window breadth parameter of the KDE model which can be expressed as formula (3), N is the number of the sample.

$$K(u) = \begin{cases} \frac{3}{4}(1-u^2) & if\,|u| \le 1 \\ 0 & otherwise \end{cases} \tag{2}$$

The h is so important for the KDE function that it will affect the resolution of results. If it is too large, the results will be too smooth to cover up the data's trend,

otherwise the model will produce excessive noise. So the optimal selection method which was proposed by Silverman in 1986 is applied in the paper as following:

$$h = 0.9n^{-1/5} \min(s, R/1.34) \tag{3}$$

Where n is the number of observation data, S and R is the standard deviation and quartile of X respectively.

There is a special approach to get x in the KDE model, dividing X into N due to the difference of the maximum and minimum of it, which can be expressed as:

$$x_i = X_{\min} + (X_{\max} - X_{\min})i/N \ , \ i = 1 \cdots N \tag{4}$$

The accident probability density distribution model can be obtained by putting (2) into (1), which can be expressed as follows:

$$\hat{f}_h(x) = \frac{3}{4Nh}\sum_{i=1}^{N}[1-(\frac{u_i}{h})^2] \ , \quad \left|\frac{u_i}{h}\right| \le 1 \tag{5}$$

Where u_i is the sample spacing that is $u_i = x_i - X_i$.

We use E_p denotes the APP result, and the PDF for predicting traffic accident based on EB method is as follows:

$$E_p = w \times \hat{f}_h(x) + (1-w) \times P(A) \tag{6}$$

Where w is the weight, $w = 1/[1 + Var(x)/E(x)]$, $E(x)$ is the sample mean of the accident probability at a certain period time of the similar road sections, $Var(x)$ is the sample variance of the accident probability at a certain period time, $P(A)$ is the accident probability by statistical analysis of historical observed data.

ROAD TRAFFIC SAFETY MICRO-EVALUATION BASED ON ACCIDENT PROBABILITY

Obtaining the probability of traffic accidents is important for predicting the state of road safety in advance. By sorting accident probability and setting the identification threshold of dangerous road sections, we can identify potentially dangerous road sections, and we can also access the transformation priorities of potentially dangerous road sections, ensure the full use of limited fund for potential safety risks.

For validating the evaluation results and comparing with the Cumulative Frequency Curve Method (CFCM), the paper adds the impact of the traffic accident severity, and adopts the Equivalent Traffic Accidents Number (ETAN) indicator.

$$ETAN = TAN + 9.5F + 3.5J \tag{7}$$

Where, TAN is the number of accidents-happened road sections, F is the number of accident deaths, J is the number of accident injuries.

Accident Probability Evaluation Method (APEM) adopts the TAPEC as evaluation indicator, the formula is as follows:

$$TAPEC = \frac{E_p}{Q} \times 10^4 \tag{8}$$

Where E_p is the prediction probability of accidents, Q is the two-way traffic volume of road sections.

By calculating the above two evaluation indicators, the paper proposed the identification threshold of accident-prone and potentially dangerous road sections: CFCM uses the inflection point of cumulative curve as identification threshold, where APEM applies the accident probability value to identify dangerous road sections, so as to implement the micro-evaluation of road safety.

CASE STUDIES

G301 is an important trunk road of National Trunk Highway Network, by collecting 1999~2003 traffic accident data of Heilongjiang Province K621~K747 sections, selects 194 effective pieces from 233 collected accident data, and the by-stake accident distribution of ETAN is shown in Figure 1.

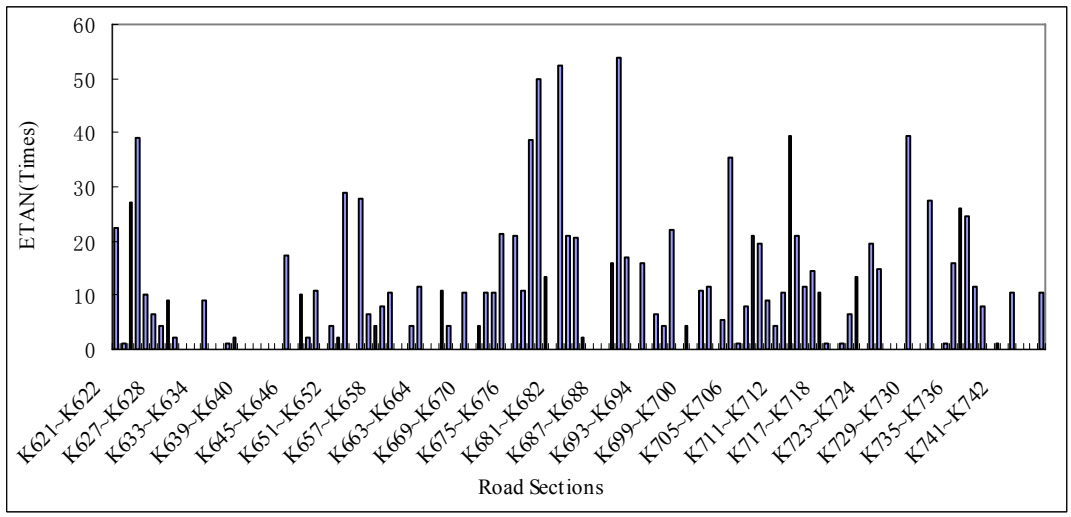

Figure 1. Statistical ETAN distribution of G301 K621 ~ K747 sections

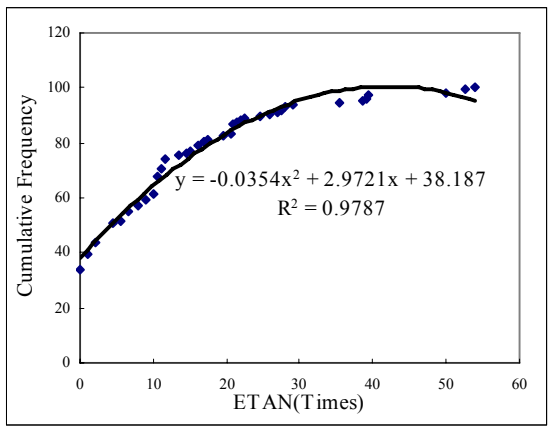
The mathematical model of CFCM is shown in Figure 2, the relationship between ETAN and cumulative frequency curve fit parabola, through its derivation, and the ETAN inflection point reached 41.9. As 0.95 level of cumulative frequency was adopted in the paper, and the identification threshold of ETAN is 35.5.

As 1999~2002 is the base year and 2003 is the predicted year based on Bayes theory. Eviews 5.0 statistical analysis software is applied to plot the KDE-based probability distribution for predicting accident (see Figure 3), the relationship between number of accidents and accident probability is a single peak curve, and the APP results based on EB method are shown in Figure 4. Considering related factors, the probability criterion threshold of potentially dangerous sections is set to 0.05.

The comparative results of CFCM and APEM are shown in Table 1. The gray shaded areas are the same identified sections. It is show that both methods have good consistency, but the identified results of APEM slightly better than CFCM because

traffic flow and location characteristics are considered, and a relatively conservative threshold is adopted in the former. In addition, according to the size of the accident probability of dangerous road sections, the paper sorting road sections in accordance with the severity and give the several top sections of the potential danger.



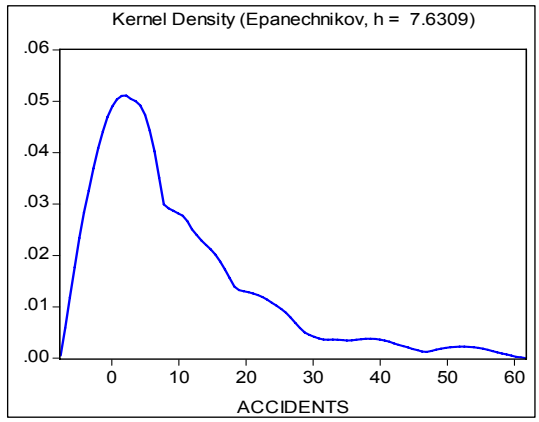


Figure 2. Cumulative curve of ETAN **Figure 3. Accident probability prediction**

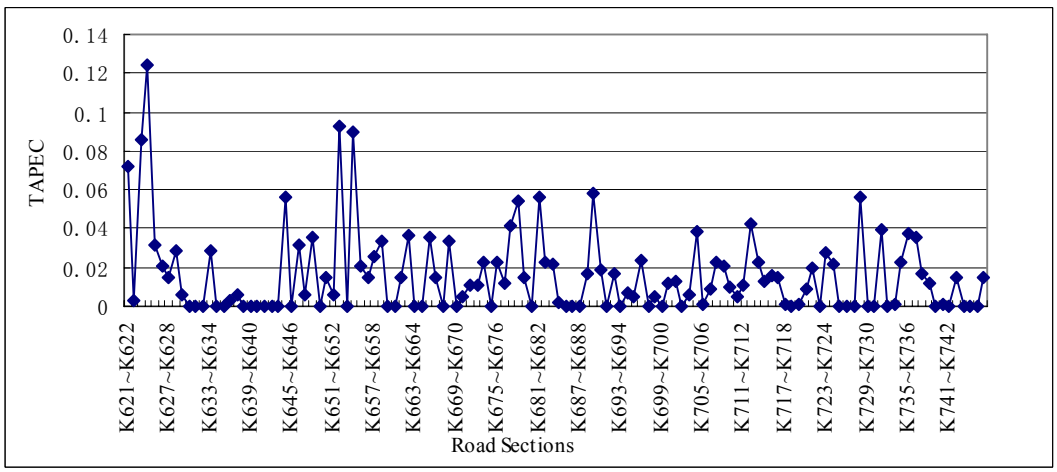

Figure 4. Results of accident probability evaluation

Table 1. The Comparative Results of CFCM and APEM

Sections order	CFCM accident-prone	CFCM ETAN	APEM potential danger	APEM TAPEC
1	K689~K690	54	K624~K625	0.124275
2	K681~K682	52.5	K652~K653	0.092414
3	K678~K679	50	K654~K655	0.089236
4	K712~K713	39.5	K623~K624	0.086054
5	K728~K729	39.5	K689~K690	0.058091
6	K624~K625	39	K728~K729	0.056533
7	K677~K678	38.5	K681~K682	0.056478
8	K704~K705	35.5	K644~K645	0.055808
9			K678~K679	0.053788

The statistical results show that accident-prone sections identified by CFCM accounted for 6.3 percent of the total mileage, and cumulative ETAN of them accounted for 29.3 percent of the total number, the ETAN on average is 46.3 times per kilometer (overall average is 9.5 times per kilometer). The potential danger sections identified by APEM accounted for 7.1 percent of the total mileage, and the TAPEC on average is 0.075 per kilometer (overall average is 0.016 per kilometer).

CONCLUSIONS

In the paper, accident probability density distribution is set up through the use of KDE function, while considering the impacts of accident location characteristics and historical statistics. The probability of accident prediction model is also set up based on EB method through the use of TAPEC indicator, and finally the road traffic safety micro-evaluation method is constructed by using APEM. Case study results show that APEM has a high reliability compared with CFCM, which identify potential hazards of the road sections, meanwhile it can access the transformation priorities of potentially dangerous road sections, so as to provide theoretical basis for accident prevention and response.

ABSTRACT: This paper studies the restriction of countdown devices to the location of detectors and the response interval of red truncation by simulating different countdown situations using VISVAP programming software on VISSIM platform on the basis of theoretical analysis. It pointed out that, by shortening the countdown time of the transit stage and bringing the detector forward, the state of transit is more stable in the lower reaches of the detector which assures the validity of green extension; by shortening the countdown time of the non-transit stage the response interval is extended which improves the effect of red truncation; the travel time is 23% and 37% shorter under 5s countdown and non-countdown than at 15s countdown. So the countdown device should be used as little as possible or not at all; it is suggested to set at 5s when it is obligatory.

Keywords：countdown device; transit priority; signal control

1 INTRODUCTION

A bus has the characteristics of carrying more people than cars, using less space, having high efficiency, saving energy and being environmentally friendly; it will reflect the idea of sustainable development better and be the only way to solve traffic problems of the city.

Bus priority is being carried out in all of the country. The bus priority signal control contains different varieties; there are passive, active and real-time priorities. But in recent years, the traffic countdown devices have been widely used in many cities of our country. The existing literature (Wang Yan 2006, Yu Xuan, 2008) have discussed traffic safety and efficiency problems which come along with countdown devices. This paper has no comments about that. In order to implement the bus priority development

strategy, improve speed and service level of public transport, the writer will mainly analyze the impact analysis of the countdown device on active transit priority signal control and gives reasonable control recommendations in the section which will implement the bus priority strategy to set the countdown device.

2 ACTIVE BUS PRIORITY

Signal active priority strategy provides priority service for special buses based on detection information of the bus or priority claim that the vehicle/system has issued. It detects buses in the traffic flow and modifies signals for them directly. The active priority contains strategies as shown below: green extension, red truncation and compressing non-bus stage to bus stage and so on. Buses are orientated by selected detectors in the system, which is the basis for modifying green extension and red truncation. When the detected bus arrives during the red stage, the green stage of the other directions will be ended ahead of schedule to start up the green stage for the bus early by using early green strategy, as shown in Figure 1 (Chen-Fu Liao, Gary A. Davis(2006)). When the detected bus arrives between the green stage, the green display time of this direction will be extended using green extension strategy, as shown in Figure 2.

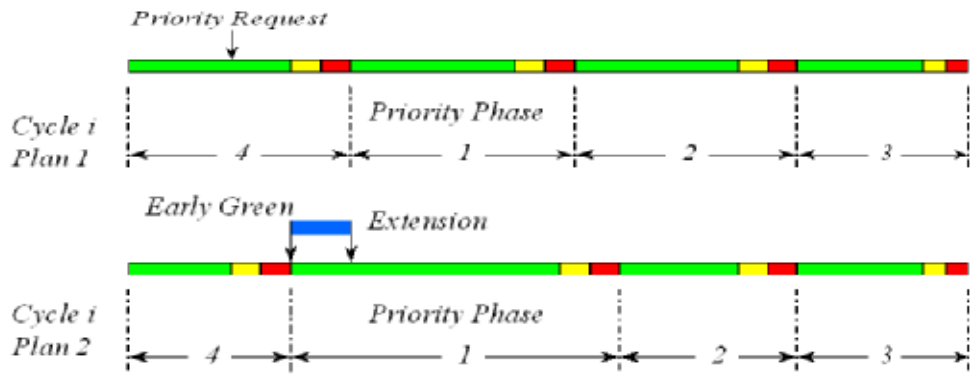

Figure 1. Signal Priority Control – Early Green/Red Truncation.

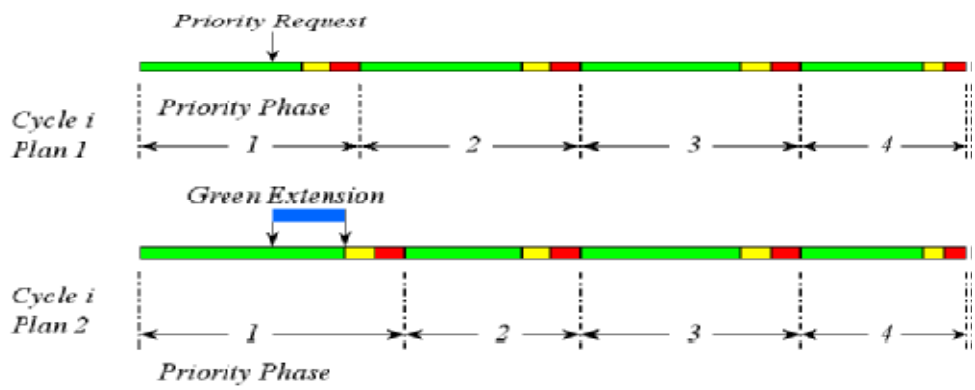

Figure 2. Signal Priority Control – Green Extension at Priority Phase.

3 IMPACT ANALYSIS OF COUNTDOWN DEVICES ON EARLY GREEN AND GREEN EXTENSION

3.1 Green extension

(1)Definition

Suppose a bus is arriving at the intersection, and will go through at the end of the current signal phase, while it cannot pass with its normal speed in the remaining green time. In that case, we can appropriately extend the green time to ensure that the bus can pass through the intersection in this signal phase. This kind of bus signal priority strategy is called “Green extension”.

(2)Location of detectors

1) Fundamental principles analysis

Because of the operating characteristic of signal controllers, once the stage closing signal of this phase is given (i.e. the vehicle countdown begins, or the pedestrian green flash begins), the end time of the current signal phase is completely determined, thus signal controllers cannot respond to a green extension claim. Consequently, detectors should be located at a far enough distance from the stop line.

Figure 3 reveals the relationship between the corresponding claim section of green extension/early green strategy and the stage closing signal, under the condition that the detection point is L distant from the stop line.

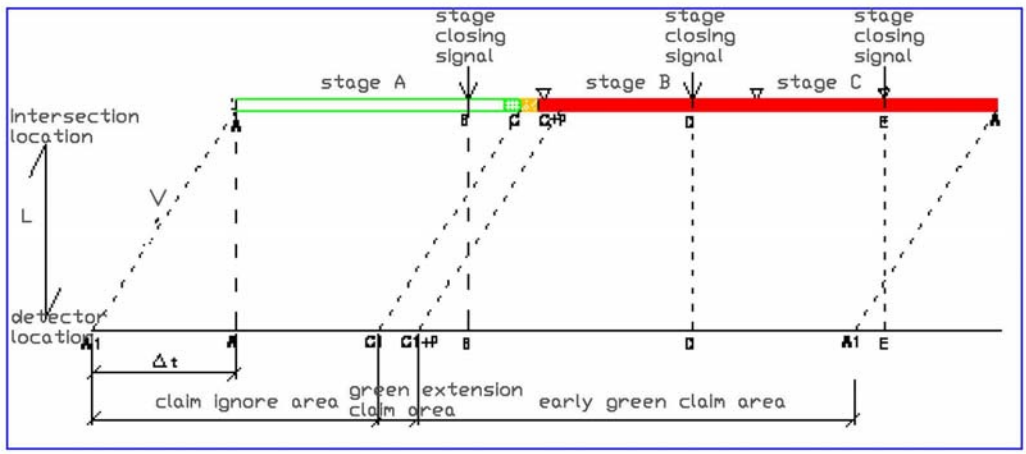

Figure 3. Bus signal priority claim section.

In the green extension/early green strategy showed in Figure 3, three claim sections are mentioned:

Claim ignore section - Buses detected in this section will not be given priority; they can across the intersection in the normal signal phase without stopping.

Green extension claim section - Buses detected in this section cannot across the intersection in the normal signal phase without stopping, but they can pass through when extended green time is given.

Early green claim section - Buses detected in this section cannot pass through the

intersection in the normal signal phase without stopping; they need to wait for the next green time for passage. But we can advance the green time to reduce the buses' waiting time.

As illustrated in Figure 4, if the detectors are located overly close to the stop line, or the stage closing signal is given too early, the green extension claim section will disappear.

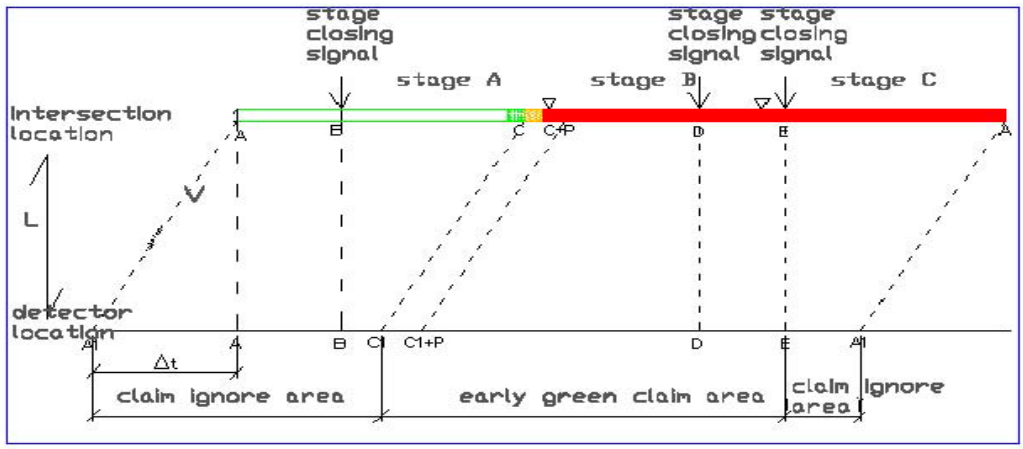

Figure 4. Impact of countdown device on claim section.

If the phase closing section is too long, the original "green extension claim section" C1-C1+P will lag behind B, then the "green extension claim section" will disappear; we cannot extend the green time. In such a case, we may increase the value of L, i.e. transfer the detect points to the upstream; or we may shorten the stage closing section, making sure that C1+P is before B, to keep the "green extension claim section".

2) Conclusion

Assume the distance between transit priority claim detector and the intersection is L, the vehicle speed is V and the closing period of priority claim of stage A is TA. From these analyses, we can see that the requirement to implement the green extension strategies of stage A are as follows: L/V>TA.

Or described in words as: The minimum distance between the transit priority claim detector and the stop line should be the travel distance with speed V during the closing period.

Also in order to ensure there is a certain period of "green extension claim section", the best distance between transit vehicle detector and the stop line is L=(TA+P)*V.

Or described in words as: The travel distance with speed V during the stage closed period and the additional P seconds, shown in Figure 5.

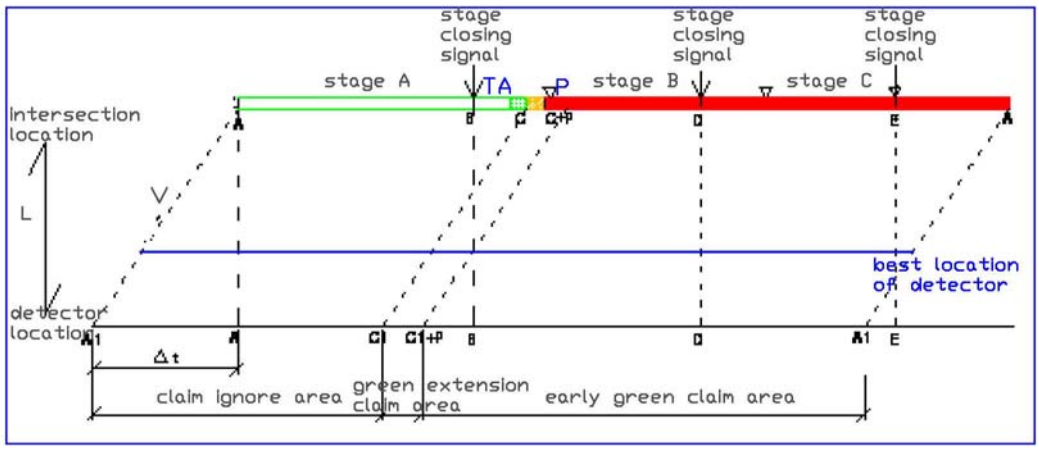

Figure 5. The best location of the detector.

These are the following conclusions:

1) Increasing the distance between the detectors and the stop line, which is L, can avoid the situation that "green extension" strategy can not be used happening. But if the value of L is too large to estimate the travel time, vehicles may not be able to enjoy the signal priority. Therefore, under the condition of meeting these requirements above, the value L should be as small as possible, which is L= (TA+P)*V.

2) If the detector is fixed, and the stage closing period is long, then "green extension" strategy may not be validated. Then shortening the countdown time can avoid it. Especially because the distance between intersections in Shanghai is generally short, it is suggested to shorten the countdown time if conditions allow.

3.2 Early green

(1)Definition

There are buses arriving at the end of the current stage and they are going to get across the section in this stage, but even if we have extended the green time of this stage, the buses are not certified to across the intersection according to their normal speed during the extra green time, or the buses arrive during red stage, then the green signal of claimed stage will be started in advance to get the buses across the intersection early.

(2)Location of detector

If green extension and early green are used together, then their detectors can be the same to save budget.

If early green is used separately, then the detectors are appropriate to set at the stop line, because buses can spring the detectors when they queue at the stop line. The analysis of impact of early green to detectors can also be seen in "3.1 green extension".

(3) Early green responding section

Accordingly, early green claim section is contained in the three claim sections,

which can be divided into responding section and non-responding section. Because of the characteristics of the signal controlling device, once the green countdown starts, the signal plan cannot be modified to start the green signal for bus stage early even the buses are detected during this time. So the early green responding section is shortened which results in the implement effect being discounted. The early green responding section is displayed as below.

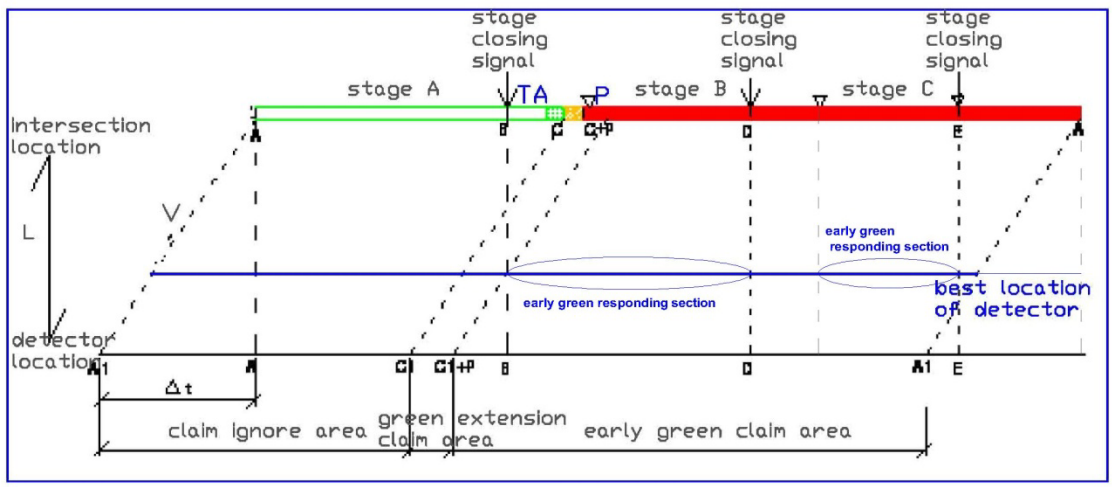

Figure 6. Early green responding sections

4 INSTANCE ANALYSIS

The theory mentioned above is validated on the VISSIM platform of PTV Corporation.

Section of North Cheng Du road and West Nan Jing road (Figure 7) under the south-north expressway of Shanghai was selected to be analyzed. Different countdown options were simulated using VISVAP software of VISSIM to analyze the impact to travel time of buses, shown in Table 2 and Figure 8.

There are three options (15s countdown, 5s countdown and non-countdown) being simulated at this section, under the condition that maximal green extension is 15s (P=15s), speed of the bus is measured at 18 KM/H, location of the detectors must be 150m, 100m, and 75m upstream of the stop line. Locations of the detector under different countdown times are shown in Table 1.

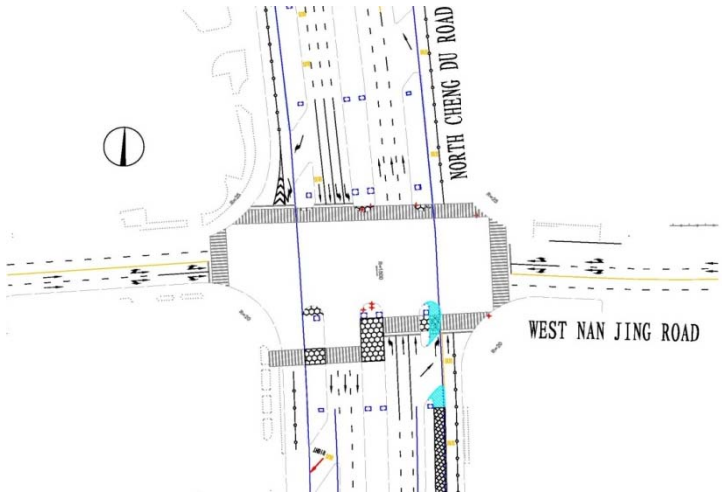

Figure 7. layout of Section of North Cheng Du road and West Nan Jing road .

Table 1. Locations of the detector under different countdown times.

countdown time (s)	15	5	non-countdown
location of detector (m)	150	100	75

Table 2. Travel time of buses under different countdown times.

	15s countdown	5s countdown (just main road)	5s countdown	non-countdown
travel time of buses (s)	58.7	56.5	45.1	37.2

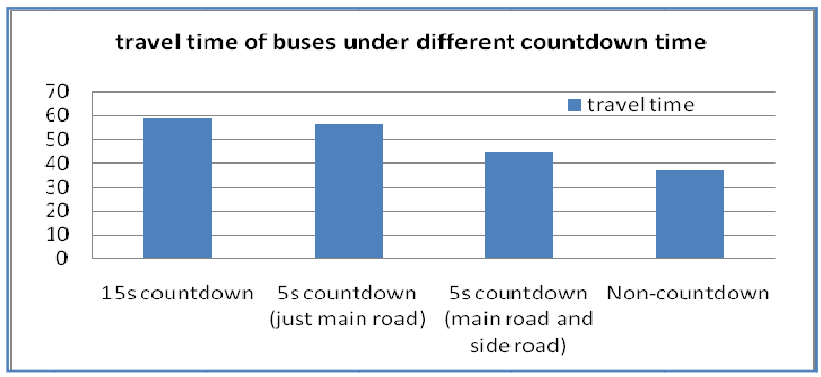

Figure 8. travel time of buses under different countdown time

The travel time is 23% and 37% shorter under 5s countdown and non-countdown, respectively, than 15s countdown. There are conclusions as below:

- The travel time of buses from detectors to stop line is difficult to forecast

when the distance between the detector and stop line is too long, in some cases green extension strategy will be invalidated. If the countdown time is shortened, then the location of the detectors can be moved forward where the state of the buses will be more stable.

- Green countdown of non-bus stage restricts the early green strategy. Because of the characteristics of the signal controlling device, once the green countdown starts, the signal plan can not be modified to start the green signal for the bus stage early even if the buses are detected during this time. So the early green responding section is shortened which results in the intended effect being discounted.
- Travel time of buses is reduced with the reduction of countdown time.

5 CONCLUSIONS AND RECOMMENDATIONS

1) Shortening the countdown time of the bus stage and advancing the location of detectors confirms the validity of green extension strategy because the state of buses is more stable downstream of the detector.

2) Shortening the countdown time of the non-bus stage enhances the intended effect of early green strategy because the early green responding section is increased.

3) From the analysis above we can see that the countdown device has a great restriction to bus priority strategy. So it should not be or less used at the section which will apply active bus priority strategy. It is suggested to set at 5s when it is obligatory.

4) This paper just simulates sections with bus lanes; actually, it will be more complicated when the non-bus lane, bicycles and pedestrians are considered. They are pending further study in the future.

ABSTRACT

The climbing lane is a benefit to traffic safety through changing the traffic flow characteristics of the highway and avoiding overtaking maneuvers. This study was conducted by means of a driving simulator experiment to examine the effects of a climbing lane on an upgrade of an existing two-lane rural highway in Yunnan province. To construct and improve the fidelity of traffic flow scenarios on the driving simulator, simulated traffic flows under two special traffic volumes with and without the climbing lane were obtained from VISSIM. Thirty-two subjects were selected to drive on the test road in the driving simulator. On the basis of the simulation results, comparison evaluations of speed and track lateral position of the test vehicle along the section with and without climbing lane were conducted. In addition some simulation experiments from VISSIM were done to find the threshold of traffic volume for the setting of climbing lane. The result shows that there is a higher and steady speed after setting a climbing lane under different given traffic volumes. Moreover, it reduces conflicts with cars from the opposite direction. But this benefit will be reversed with the increase of traffic volumes.

INTRODUCTION

The climbing lane is a lane added on an uphill grade for use by trucks, long vehicles and heavy vehicles with speeds significantly reduced by grade. Current "Highway Engineering Technical Standards" in China provides that the freeway and highway should be set up with a climbing lane along the uphill when the slope is more than 4 percent. The climbing lane can make cars pass the truck and other slowly moving vehicles quickly. This will not only reduce the travel time, improve the mean speed and level of service of this section, but also avoid overtaking maneuvers. This can benefit traffic safety. The study results of Abishai Polus and Israel Reshetnik

(1987) showed that the climbing lane on upgrades could provide substantial flow benefits - reduction in delay and in passenger-car platooning- with implications for better safety.

Generally, the principal methods to study climbing lanes are ground test or pure software simulation. Werner Briton and Andrea Bressler (2004) focused on the derivation of capacities and traffic flow characteristics for freeway upgrades by methods employing empirical investigations based both on microscopic measurements and continuous traffic monitoring as well as on microscopic simulation. Sun Jiafeng and Zhou Ronggui (2006) simulated the average speed and delay on the climbing lane on a long upgrade under different traffic flows by simulation software. In this paper, driving simulator experiments had been done in order to study the effects of traffic characteristics with and without the climbing lane. The climbing lane for the experiment comes from a specific upgrade section of a real two-lane rural highway in Yunnan province.

EVALUATION INDEX

Indexes to evaluate the effect with and without the climbing lane may generally be categorized into two types. One is an objective index such as the traffic characteristics data, and the other is a subjective index such as the driver's assessment of his own condition. The objective index included speed, acceleration, road capacity, level of service, track lateral position and braking operation, etc. In this study, we selected the speed and track lateral position as indexes. The track lateral position is the displacement of the vehicle's track from the road center line (RCL: the middle line of the two-lane without the climbing lane).

EXPERIMENTAL PROGRAM

Driving simulation experiments were arranged to evaluate the effect of the climbing lane. The experiments were accomplished by subjects at four driving simulation scenarios with and without the climbing lane setting. All the data were collected directly from the driving simulator, and based on the data the comparison evaluations of the test track were investigated.

Equipment. The main equipment in the experiment is a full-size advanced driving simulator (KMRTDS) set up in the simulation laboratory at Faculty of Transportation, Kunming University of Science and Technology, which is comprised of six subsystems including driving cab system, control system, vehicle dynamic model system, visualized system, traffic simulation system and sound system. KMRTDS provides researchers a scientific tool to study road traffic and transportation under controlled experimental conditions. It allows researchers to create any visual data and scenario to study traffic problems in the surrounding design, special experiment and real world situations. By controlling the performances of driving vehicles, traffic flow, pedestrians' behavior and other environmental factors,

simulation experiments can be implemented and test data can be collected. With the optimized image processing speed of above 30 frame/s, and the calibration for the speed and visual, KMRTDS can ensure the real-time operation of the system and the fidelity of the experimental scene.

Another study tool is VISSIM, a microscopic simulation tool for traffic flow which describes vehicle performance and driver behavior in a very detailed manner. It provides the driving simulator traffic flow for the experiments

Test track and virtual scene. Figure 1 shows the structure design of the test track. The test site was a double two-lane rural highway at Xiaomo highway in Yunnan province. The length of the climbing lane was 650 meters, and the slope was 5 percent. The main lane width was 3.75 meters with a 3.5-meter-wide climbing lane on the right. The test track is divided into five sections including the entrance forward section (EFS), Climbing entrance section (CENS), Climbing parallel section (CPS), Climbing exit section (CEXS) and exit backward section (EBS). The layout of these five sections can be seen in Figure 2.

The traffic flow in the virtual scene was generated by VISSIM after some calibration work, and then was introduced to the test track by the interface software of VISSIM and KMRTDS. The traffic composition included cars, heavy vehicles and motorcycles with the proportion of 44%：44%：12%. The traffic volumes of 500pcu/h and 600pcu/h were selected as the simulation flow to the two main lanes, and the heavy vehicles were only allowed to enter the climbing lane.

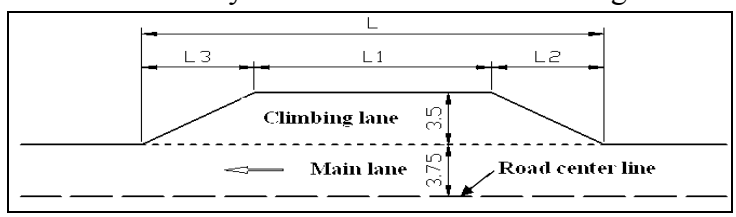

Figure 1. Structure design of climbing lane.

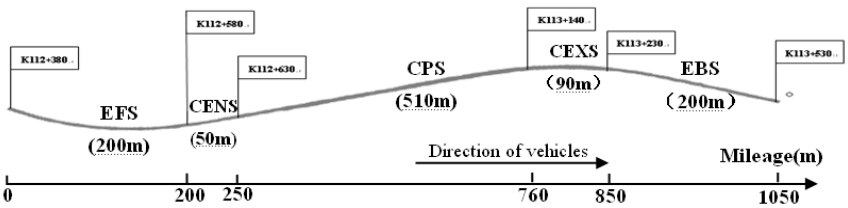

Figure 2. Layout of five sections of the test track.

Subjects. The subjects (test drivers) composition included 27 men and 5 women drawn from corporations in Kunming city with age ranging from 28 to 58 years. They were experienced drivers with at least two years of driving experience. No speed limit was set on the test road section, but subjects were asked to drive at the speeds they normally expected to.

Procedure. Figure 3 shows the view of the virtual scene in the experiment. To

carry out the experiment on KMRTDS, the steps followed were:

- Create two virtual test tracks exactly based on sample road section with and without the climbing lane.
- Build the simulation scenarios with traffic flows of 500 and 600pcu/h.
- Train the subjects to fit to the simulator. Before starting, preliminary test and calibration were required to make the parameters match with the real world.
- Carry out the experiments and collect the data.
- Require subjects to finish the questionnaire.
- For further analysis and evaluation all data acquired from the KMRTDS had to be treated with respect to the exact position along the test course.

Figure 3. View of the virtual scene of the test track outside and inside KMRTDS.

DATA ANALYSIS AND RESULTS

Based on 32 subjects' data in the test track from KMRTDS, we analyzed the indexes of speed and track lateral position. In the following description, we defined F1 and NF1 as the test scenarios with and without the climbing lane when traffic volume was 500pcu/h, and F2 and NF2 corresponding with traffic volume of 600pcu/h.

Profiles of indexes. The profiles of mean speed and track lateral position in four scenarios (F1, NF1, F2, and NF2) are shown in Figure 4 and Figure 5. Here we can see a comparison of mean speeds which are shown in Figure 4. It is obvious that the mean speed for cases F1 and F2 with the climbing lane is faster than the speeds at cases NF1 and NF2 without the climbing lane. It means that the speed can be improved after the setting of the climbing lane.

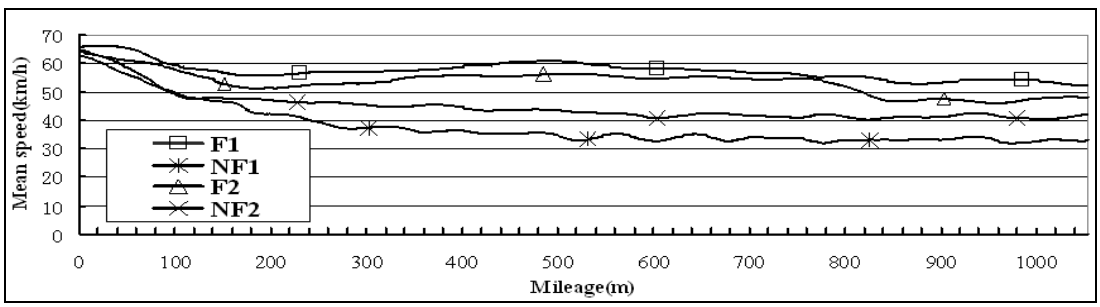

Figure 4. Profiles of mean speed of test track in four scenarios.

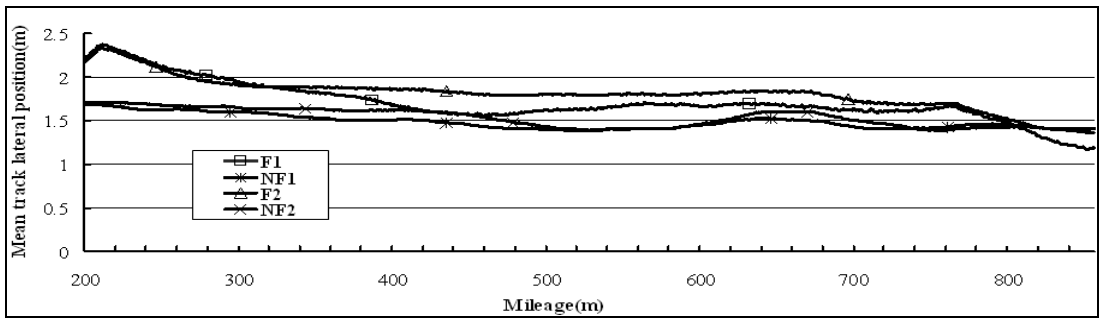

Figure 5. Profiles of mean track lateral position of test track in four scenarios.

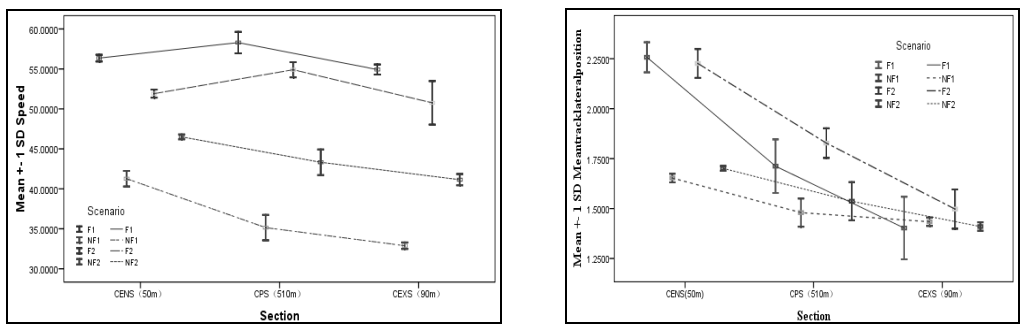
In Figure 5, we draw the profile of track lateral position in three middle sections (CENS, CPS and CEXS sections, which length is from 200m to 850m,). We can know that the track lateral position (F1, F2) with climbing lane is further from RCL than that (NF1, NF2) without the climbing lane. These show that the setting of the climbing lane can improve the traffic characteristics and safety under these traffic volume conditions.

Analysis for middle sections. For further analysis, the mean and standard deviation of indexes were calculated at three middle sections (CENS, CPS and CEXS). Figure 6(a) shows the mean speeds with the climbing lane at these sections are faster than those without the climbing lane. The speed at F1 and F2 accelerated at CPS section, while at NF1 and NF2 decelerated all along. The standard deviations of mean speed at CENS and CPS are nearly same, while that at F2 at CEXS are greater than others. The reason is the more heavy vehicles will enter the main lane at CEXS with the traffic volume increased, which would influence the car in the main lane, thus made a greater wave of speed.



a) speed b) track lateral position

Figure 6. Chart of clustered error bar of speed and track lateral position of three special sections in four scenarios.

Similarly, the mean track lateral position with the climbing lane at CENS and CPS sections are larger than those without the climbing lane, while those are nearly equal at CEXS (see Figure 6(b)). This means the setting of the climbing lane would make the vehicles deviate further from RCL. Figure 6(b) also displays the standard

deviation of track lateral position with the climbing lane were bigger than those without the climbing lane. This means the setting of the climbing lane would improve the variation of the car in the lane. Although Homburger Wolfgang S. (1987) had concluded the merging area at the terminals of climbing lanes on two-lane roads do not present a hazard of major proportions, we concluded that the CEXS with the climbing lane was a hazard area under the two traffic volumes because of their larger standard deviation of track lateral position and higher speed.

Statistic analyses of indexes for whole test track. Mean, standard deviation and Std. error mean of speed and track lateral position in the whole test track (distance is from 0m to 1050m) for each scenario were calculated. The group statistics results are presented in Table1 and Table 2. The results from Table 1 show the mean speed of the whole test track with the climbing lane is higher than that without the climbing lane, while the standard deviation is smaller. This displays the speed is faster and speed consistency is better after the setting of the climbing lane under 500pcu/h and 600pcu/h.

Table 1. Group Statistics of speed.

Scenario	Mean（km/h）	Std. Deviation（km/h）	Std. Error Mean
F1	54.8938	7.95911	.19004
NF1	42.5553	10.61505	.25346
F2	52.0310	7.45993	.17812
NF2	47.9049	8.53911	.20389

Table 2. Group Statistics of track lateral position.

Scenario	Mean（m）	Std. Deviation（m）	Std. Error Mean
F1	1.710700	.2338593	.0091237
NF1	1.486700	.0809144	.0031568
F2	1.811975	.1834159	.0071557
NF2	1.531465	.1073676	.0041888

In Table 2, the standard deviation of mean track lateral position in the whole test track with climbing lane are greater than those without the climbing lane, which means the further from RCL and the less hazard from the opposite main lane.

Analysis with VISSIM. In order to find out the threshold of the traffic volume for setting climbing lane, VISSIM simulation experiments have been implemented. In the same test tracks as the driving simulation experiment, the mean travel times, mean speed and average delay per vehicle had been measured in the VISSIM simulation experiments under four kinds of traffic flow. The traffic volumes are set as 600, 1000, 1300 and 1600 pcu/h separately. Measured results are shown in Table 3. In table 3 and table 4, the scenarios CL and NCL means with and without the climbing lane.

Table 3. VISSIM simulation results with and without climbing lane

Traffic volume	600 pcu/h		1000 pcu/h		1300 pcu/h		1600 pcu/h	
Scenario	NCL	CL	NCL	CL	NCL	CL	NCL	CL
Mean travel time (s)	51.6	51.7	53.2	54.8	54.7	73.0	56.1	179.1
Mean speed (km/h)	46.6	46.4	45.1	43.8	43.9	32.8	42.7	13.4
Average delay per vehicle (s)	2.7	2.8	4.3	5.9	5.8	24.2	7.2	130.4

It can be seen from Table 3 that the mean travel time and delay of test track with the climbing lane of 1000 pcu/h is a little greater than those without the climbing lane. So the setting of the climbing lane has no influence on the road traffic characteristics. While the mean travel time and delay increased remarkably with 1600 pcu/h, the mean speed decreased rapidly. In this case, the traffic flow characteristics deteriorated rapidly. A further VISSIM simulation with climbing lane under traffic volume of 1200, 1300, 1400 and 1500 pcu/h separately had been done to find out the threshold of traffic volume. The simulation results are shown in Table 4. It can be seen from Table 4 that when the traffic volume exceeds 1300pcu/h, the mean travel time and delay increase all along with the mean speed decreases rapidly. In this case the volume of 1300pcu/h has approach to the saturated one.

Table 4. VISSIM simulation results for the test track with climbing lane.

Traffic volume （pcu/h）	1200	1300	1400	1500	1600
Scenario	CL	CL	CL	CL	CL
Mean travel time (s)	58.3	73.0	93.8	174.8	179.1
Mean speed (km/h)	40.6	32.9	25.5	13.8	13.4
Average delay per vehicle (s)	9.6	24.2	45.1	125.4	130.4

CONCLUSIONS

- When setting a climbing lane, the mean speed of vehicles increased and speed standard deviation decreased in the whole test track under the given traffic volumes.
- The traffic flow characteristics will be improved efficiently under lower traffic volumes after setting the climbing lane. But it will become the reverse case when traffic volume approaches saturation.
- In the exit of the climbing lane, the heavy vehicles will impact the cars in the main lane, and it will become serious with increased traffic flow.

A Safety Protection Technology System on Highway Roadside in China

LI Yang[1] MA Rongguo[1] NIU Yuxin[1] WANG Longfei [1]

1 Department of Traffic Engineering, School of Highway, Chang'an University, 710064, Xi'an, China, PH (86)29-82334856; email:dorothy06@gmail.com (LI Yang); mrg@chd.edu.cn (MA Rongguo); xinxin8286@qq.com (NIU Yuxin); choseoner002@gmail.com (WANG Longfei).

Abstract: In order to reduce the rate of roadside accident and help engineers make an informed decision or take the most effective measures in highway roadside safety improvement program, the authors put forward the roadside safety protection technology system (RSPTS) that suited to the actual situation to deal with the typical roadside safety problems appearing in China. RSPTS is built in accordance with a priority of active guidance, appropriate protection and timely security, including the technologies to prevent vehicles from leaving the road out of the lane (active guidance technology), to reduce the collision and rollover accident rate, and to alleviate the severity of roadside accidents. The potential benefit of this study is to reduce the roadside accident rate, in particular to alleviate the severity of the serious traffic accidents which can result in many injuries and deaths.

Key words: *Roadside traffic accidents; Safety tolerant design; Roadside safety protection technology system*

1 Introduction

With the rapid economic and social development, highway traffic safety has become a worldwide problem to be solved. According to the statistics, China is the largest traffic accidents country in the world by the end of 2008. The indicators of traffic accidents from 2001 to 2008 in China are shown in table1. Based on statistic data which were provided by the Administration Ministry of Public Security White Paper, about 12% deaths were caused by the roadside accident from 2001 to 2007, which is only account for 8% of the total highway accidents. About 70% traffic accident occurred in the secondary highway or lower grade highway and about 30% of total crashes are roadside crashes.

According to statistics, roadside safety problems in low grade are prominent. Lack of protective facilities, insufficient of crash protection, the configuration of protective facilities and hidden danger of slope and ditch evoked large amount of serious accidents. Thus, in allusion to the typical roadside safety problems appearing in China, the roadside safety protection technology system (RSPTS) is proposed in this paper. RSPTS is aimed to reduce the roadside accident rate, as well to alleviate the severity of traffic accidents.

Table 1. The indicators of traffic accidents from 2001 to 2008 in China.

year	Traffic accidents (ten thousand)	Death (ten thousand victims)	Injury (ten thousand people)	Property loss (billion rmb)
2001	75.5	10.6367	57.10	30.9
2002	77.3	10.90	56.20	33.2
2003	66.7507	10.4372	49.4174	33.7
2004	56.7753	9.9217	45.1810	27.7
2005	45.0254	9.8738	46.9911	18.8
2006	37.8781	8.9455	43.1139	14.9
2007	32.7209	8.1649	38.0442	12.1
2008	26.5204	7.3484	30.4919	10.1

2 Analysis of the roadside safety situation and problems in China

Roadside Safety problem of China is becoming increasingly serious, in particular in the mountainous area. The problems are mainly existed in the 100,000 kilometers low grade highway (Kan Weisheng 2007). The general problems are summarized as follows:

(1)The level and type of safety facilities can not match the roadside characteristics. The protective performance and reliability of facilities can not meet the actual requirement. A road section without security protection facilities or lack of protection is shown in figure1.

(2)Due to the large population and the shortage of land resources, there is no guarantee for the clear zone in China (see figure2).

(3)By using the high embankment, the design of the ditch and slope is not standardized, which makes the driver suffered a potential safety risks (see figure3).

(4)The column of traffic signs and the light poles are set inside clear zone, and the breakaway supports were hardly set and used (see figure4).

(5)There a lack of special guardrail terminal and transition treatment.

(6) No a clear specification for the work zones protection.

Figure 1. Lack of guardrail protection.

Figure 2. Dangerous road shoulder.

Figure 3. Dangerous wide ditch.

Figure 4. Untreated Rigid bridge Pier.

3 The leitmotiv and the framework of RSPTS

3.1 The leitmotiv description of RSPTS

Because traffic accidents are caused by the interaction among drivers, vehicles, highways, and environment, it is impossible to totally avoid the accidents. RSPTS is proposed in accordance with principles of active guidance for minimizing the injury extent and appropriate protection. Tolerance design concept is integrated into RSPTS, at the same time environmental protection and harmonious disposal should be taken into consideration (Li Yang 2008). Three leitmotivs of RSPTS are as follows:

(1) To prevent the vehicles run off the road and intrusion into the roadside region.

(2)To decrease the occurrence probability of collisions in circumstances of vehicle shave run off the road.

(3) RSPTS is devoted to alleviate the severity of roadside accidents.

3.2 The framework structure of RSPTS

It is necessary to stick to the three leitmotivs above to pay attention to the protection of clear zone and the reasonable installation of guardrail and the proper treatment to road shoulder, slope and ditch. The specific RSPTS system structure is shown in figure 5.

4 Active roadside safety guidance technologies

Active guidance refers to a benign interaction between driver and highway which was realized by installation of traffic safety facilities and improvement of the highway traffic environment. During the information interactive process, traffic environment has played an “active” role of guide to prevent vehicles from running out of the road, so as to lower the decrease the accident occurrence probability (David, J2005).From a technical point of view, the elimination of potential safety risk depend on the correct installation of deceleration vibration marking, contour marking and chevron alignment sign and so on to warn the driver keep driving inside the road (Avinoam Borowsky 2009). The specific roadside safety active guidance technology is shown in table2:

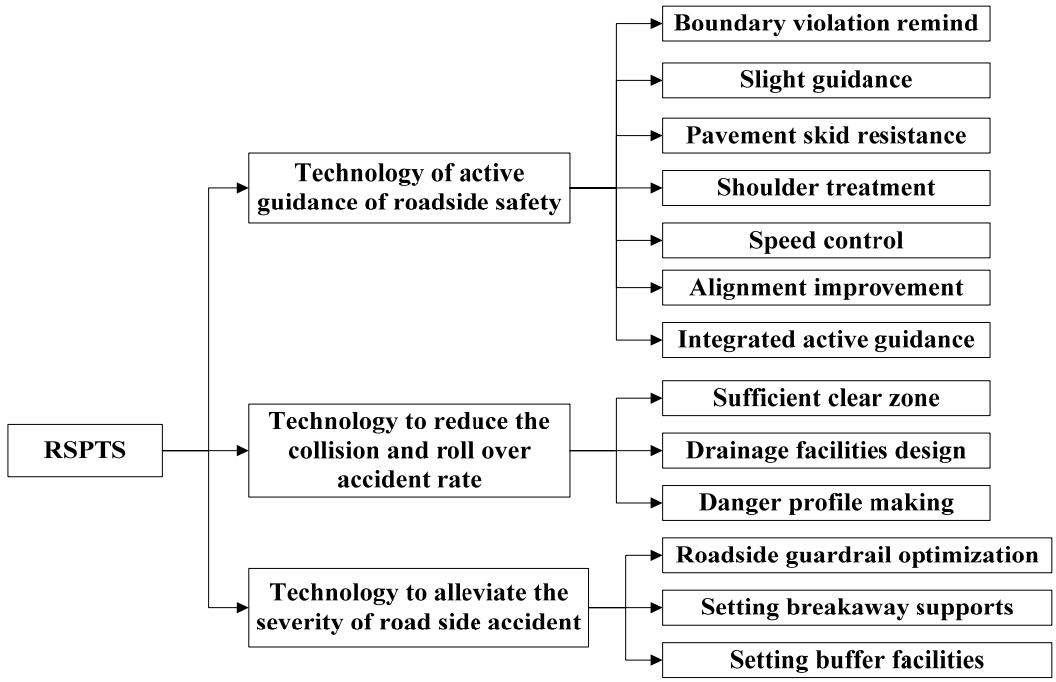

Figure 5. The specific RSPTS system structure

Table 2. Roadside safety active guidance technology

Technical measures	Instructions
Sight guidance	Setting the contour marking rationally
	Setting the chevron alignment sign rationally
	Setting the warning pier
Boundary violation remind	Setting the vibration marking
Pavement skid resistance	Using anti-sideslip wheel belt
	Increase pavement structural depth
	Laying special pavement
Shoulder treatment	Widening and hardening the shoulder
	Set the shoulder vibration zone
	Ensuring maintenance of shoulder
Speed control (Fred annering2009)	Setting deceleration facilities
	Setting the speed limit sign and marking
	Speed feedback sign
	Visual and mental deceleration facilities
Alignment improvement	Applied operating speed theory and alignment improvement for black pot and the sections of negative linear combination
Integrated active guidance	Applied comprehensive prevention for the roadside dangerous segment

5 Collision and rollover rate reduction technologies

The technology to reduce the collision and rollover rate is shown in table3:

Table 3. Roadside safety active guidance technology

Technical measures	Instructions
Sufficient clear zone	Embankment slop design
	Cutting Slope design
	Treatment of dangerous object
Drainage facilities design	Tolerance side slop design
	Traversal culvert design
Danger profile marking	Setting warning sign on the front of dangerous object
	Brushing the reflecting paint or film

6 Accident severity mitigation technologies

6.1 Optimal design of the roadside guardrail

(1) Guardrail end treatment

The tremendous acceleration which caused by a sudden brake will be a great risk and harm to the passengers, at the same time, the guardrail terminal is likely to cut into the vehicle body or make the vehicle roll-over. Hence, it is necessary to deal with the guardrail end so as to decelerate the vehicle speed and alleviate the severity of the serious traffic accidents (see figure6).

Figure 6. Abduction guardrail end and breakaway and buffer guardrail end.

(2) Guardrail transition treatment

The transition treatment should be taken on the different stiffness and type guardrails to maintain the continuity of intensity guardrail and also to prevent the occurrence of accidents in the discontinuous guardrails pot. The stiffness transition is ensured and the large Stiffness guardrails are avoided to become the roadside obstacle object, two examples are shown in figure7.

Figure 7. Guardrail transition treatment.

6. Installation of buffer facilities

Because vehicles need to shut on the expressway passageway and intersection also the entrances of separate type subgrade section, the accidental probability is higher than general road section. Except for dealing with the guardrail end in the dangerous trigone zone, it is necessary to set the buffer facilities such as anti-collision barrels in front of the trigone zone (see figure8).Many actual cases proved that the severity of accidents will evidently alleviated by setting buffer facilities (Fred Mannering, 2009).

6.3 Installation of breakaway support

Application of the breakaway support is very sparse in China, so it is effective to set the breakaway support to improve the roadside problem. With the development of economy and more and more regard to life, it is believed that the breakaway support will be extensively applied to play a role in life protection.

Figure 8. Setting the anti-collision barrels in front of the trogon zone

7 Conclusion

(1) RSPTS is established aiming at the leitmotiv of active guidance and minimize the injury extent and appropriate protection, which is suitable for the state situation and conform to the actual roadside safety problem in China.

(2) The suitable proposal of the types of safety facilities according to the actual situation is provided by RSPTS. This systemic technology can help engineers to make an informed decision or take the most effective measures in highway roadside safety

improvement program.

(3) Due to the incomplete data collection and other aspects, many factors which are involved in the roadside safety have not expounded in RSPTS. The relation between roadside safety and the geometric alignment, the composition of traffic volume should be discussed further in the systematical construction of RSPTS.

College of Transportation Engineering, Ludong university, P.O. Box 264025, Yantai Shandong Province, China; PH (+86) 13645359106; email: gujiuchun@163.com

Abstract : Crosswalk safety around many universities in China is increasingly getting worse. In order to come up strategies and measures for pedestrian safety around campuses, as a case study this paper investigated the road traffic and pedestrian's crossing characteristics in crosswalk around Ludong University. In addition, illegal crossing road behavior of pedestrians was surveyed and analyzed in details. As the conclusion, the paper summarized the strategies grouped into demand management, supply management, education and enforcement for improving the pedestrian safety at crosswalk, which might be useful to improve pedestrian's safety in crosswalk around campus in China.

Key words: *Pedestrian Traffic; Campus; Pedestrian safety; Countermeasures*

1 INTRODUCTION

With the rapid growth of higher education of China, the high student enrollment and large sizes of many college campuses have made walking a common and convenient mode of transportation. Almost all of students walk for most or all of their trips around campus. However, the interaction with vehicle traffic presents potential conflicts and hazards to pedestrians around campus. In most universities, the growing out-of-campus activities of students createa clash with autos, whether they live in the main campus or in secondary campuses. Therefore, pedestrian safety has become a concern for the universities in China.

In order to provide a safe pedestrian environment, we draw our cases from three crosswalks in front of gates of Ludong University (Figure 1). These cases are relevant because of their potential to foreshadow development in other universities in China. As an example this paper investigated the road traffic characteristics and pedestrian's crossing characteristics in crosswalk, and illegal crossing road behavior of pedestrians was surveyed and analyzed in details. At last, this paper discusses three safety countermeasures that can be applied to provide a safe environment around campus.

2 OVERVIEW OF TRAFFIC ENVIRONMENT

The environment around Ludong university campus comprises a mix of pedestrian environments. The west gate and south gate face Hongqi arterial and 500 meters apart from each other. The arterial, which is a two-way six-lane, 40 meters width and 60km/h speed limit major road on the south side of Yantai, also separates the campus into north part and south part and there is an overpass between two parts.

The east gate faces Qingnian arterial that is the same characteristics of Hongqi road (Figure 1). The university registers more than 20,000 students who need to cross road to get to and from bus stop or other out-campus areas, so the crosswalks in three gates are problematic because these roads have characteristics that make them hostile to pedestrians. Risks in the pedestrian environment are so serious that they made the news in Yantai. For instance, a February 2008 article in webpage (http://www.jiaodong.net), described that five students were clashed by car within three-day period at front of three gates crosswalks.

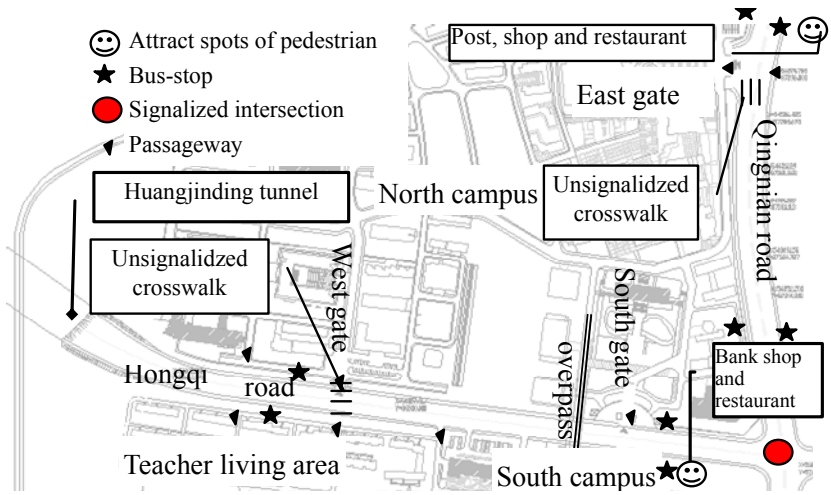

Figure 1. The illustration of traffic survey around Ludong University

3 VEHICLE DATA SURVEY AND ANALYSIS

In order to show the impact of volume and speed on pedestrian's safety, we employed the traffic stream characteristics analysis around three gates of Ludong University. Data was all collected on May 27, 2008 during the peaking hour.

The survey indicates the morning PHV of Hongqi road was 3678pcu/h, Qingnian road was 3820pcu/h and the evening peak hour volume approximately was equal. We can say that pedestrians would have to wait long time for an available gap to cross.

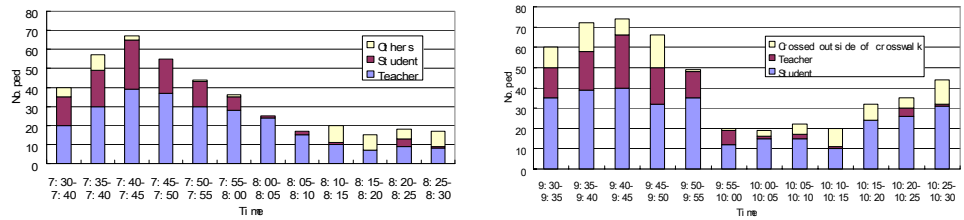
Spot speed data was collected using a laser speed gun at two locations in 20 meters apart from west gate and east gate crosswalk during the morning peak-hour period. The survey shows that approximate 4-15% drivers didn't obey the speed limit (60km/h), and approximate 6 percent vehicles traveled at speeds over 70 km/h which was 10 km/h over the posted speed limit. So it is necessary to provide a supervise device to increase speed limit compliance.

4 PEDESTRIAN TRAFFIC CHARACTERISTICS AT CROSSWALK

4.1Pedestrian traffic volume survey

The two crosswalks in survey are unsignalized crosswalks whose upstream vehicles arrival is discrete. Opposite the west gate around crosswalk, it is the teacher living area, and opposite the east gate around crosswalk, there is public community,

including post office, bus stops and shops (Figure 1). Most of students there walked across the road for daily living trip purposes in the observation period. The survey includes one-hour period in AM peak hours and normal hours. Figure 2 shows that the demands for pedestrians crossing were very concentrated. In figure 2(b), the violation of crossing outside of crosswalks is obvious.



(a) (b)

Figure2.Pedestrian volume histograms at west gate(a)and east gatecrosswalks(b)

4.2 Pedestrian speed and waiting time

4.2.1Pedestrian speed in two crosswalks

The on-site survey shows that pedestrian speed on the west gate is 1.52 m/s, and 1.40m/s for the east gate respectively. For the different survey periods, it is time for working and studying at the west gate crosswalk, most of pedestrian trip purposes are about attending class in haste at a higher speed, comparing to go out of campus for traveling and shopping at a lower speed at the east gate crosswalk. Moreover, a proportion of pedestrians make acceleration in midway, mostly after midline, so there needs a calming environment. For the east gate crosswalk, the pedestrians usually cross the road with linked arms and walk together in groups and they walk in a lower speed than other categories. The reason results from most pedestrians of this type walking and chatting, and writing short message, with less caution on purpose, sometimes calling and having earphones, as previous study presented (SHI Jiangang,2007; XI Jianfeng,2006). In addition, students are easily aroused the attention by surroundings that make students easy targets for clash while crossing.

4.2.2 Waiting time

Table 1 shows the statistic of waiting time when pedestrians are on roadside and midline. In observation, few pedestrians took adventure and most pedestrians yielded to vehicle, the condition that vehicle yielding to pedestrian did not appear, when the waiting time is more than 40s, the percent of running across in risk is higher. In east gate crosswalk, the rate of risk type and impatient pedestrians are rather high and these walkers take shorter gap to carry out walk course, which can interpret as vehicle restrict pedestrian personal characters in walking. So related countermeasures should be used to reduce waiting time and give the vulnerable road user priority.

Table 1. Statistics of pedestrian waiting time

Index	West gate crosswalk	East gate crosswalk
Maximum roadside waiting time (sec)	43.31	50.47
Maximum midline waiting time (sec)	34.87	46.32
Mean of roadside waiting time(sec)	9.65	11.33
Mean of midline waiting time(sec)	6.56	7.48

4.3 Students safety perceptions analysis

Because of the old crosswalk in front of south gate being replaced by overpass 15 meters apart, in order to understand the causes of students illegal crossing better, the campus-wide opinion surveys for students were conducted to collect and analyze users' safety perceptions after traffic environmental changing. Survey questionnaires were distributed to some affiliated people (rough 500 students, 382 participants who returned valid surveys (male: 40%, female: 60%)). Coincidentally over 80% of respondents in this survey are those who indicated "time saving and convenient" or "unaware of erased crosswalk marking" or "accustomed to crossing behavior" (Figure 3(a)). In addition to questionnaire surveys, field pedestrian behavior data was collected by south gate on-site observation and individual interviews (male: 20, female: 20). Some of the causes of still crossing including having an urgent matter, time saving and convenient, custom formerly crossing, lack of management and lucky-me attitude and so on. The results presented in Figure 3(b) indicate about 30% of the pedestrians crossing using the old crosswalk. The interview violation causes result is in good agreement to the questionnaire.

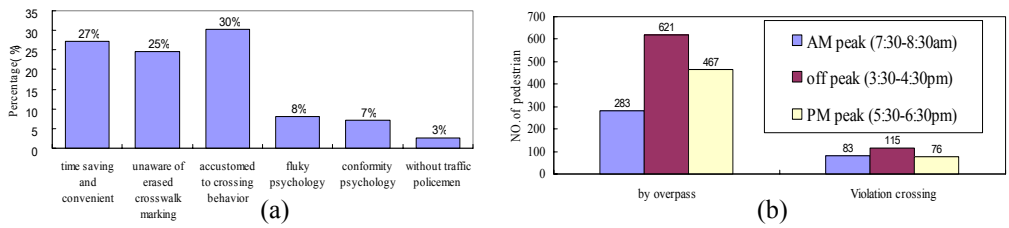


Figure 3. Reasons for pedestrian violation by questionnaire (a) and number of crossing statistics (b) at south gate

5 DESIGN STRATEGIES FOR IMPROVED SAFETY

From the analysis of upper materials, the field studies reveals several risk factors. The travel habit doesn't change with road environment variation, which causes higher accident rate at the beginning of traffic through. The peak traffic flows are heavy and few gaps for pedestrians crossing, and the vehicle can be fast, which makes crossing dangerous for pedestrians. There are additional hazards for pedestrians who were illegal to cross the road anywhere. Barriers to prevent pedestrians' crossing may be fully successful. The bridge doesn't design to integrate with bus stop. The environment of current designs for pedestrian travel on roads around Ludong University does not fully address students' crossing necessities.

These failures to accommodate pedestrians do not deter their presence but do put them at risk.

5.1 Pedestrian traffic demand management

Traffic demand management plans can be grouped into three categories: elimination, separation, and crosswalk coordination with bus stops (Jarice D. Rodriguez-Seda, 2008). The elimination of conflicts between pedestrians and vehicles is achieved by (1) separation of pedestrians and motorists with iron barriers along Hongqi road on central-line, which helps to channel pedestrians to crosswalks, overpass and discourage jaywalking. (2) Providing overpass for pedestrian crossings between two campuses.

The best practice is to install push button actuated pedestrian lights at west gate and east gate crosswalks and signalized crosswalk provides significantly lower pedestrian crash rates compared with before unsignalized crosswalk. Figure 4 shows the before photograph (a) and after photograph (b) of the studied crosswalks.

(a) unsignalized

(a)closed gate due to risk

(a) without barrier

(b) push button signal

(b)guide pedestrian to overpass

(b)metal fence along road

Figure 4. Illustration of studied spot photograph before and after

Crosswalk locations need to be coordinated with bus stops to guide pedestrians toward the crosswalk (C.McAndrews, 2008; Jarice D. Rodriguez-Seda, 2008). Such as a limited-access transit stop that is integrated with overpass for student riders who cross the street at south gate and we also adjusted bus stops at other gates of campus.

5.2 Supply management

The supply management strategies implemented around campuses consisted of the following: right of way markings and treatments; signages to guide pedestrians to crosswalks; using of speed-calming markings and contrasting marking color and texture. The supply management makes drivers more aware of the presence of crosswalk and slow vehicle speed. (Huang, H.F, 2000; Jarice D. Rodriguez-Seda, 2008; Karkee G.J, 2006) Furthermore, an appropriate coordination between pedestrian crossing locations and campus entrances would guide pedestrians to crosswalks and would prevent putting them at a place that does not have a crosswalk.

5.3 Education and enforcement

At first, we ignored students' traffic safety education at the beginning of traffic through on Hongqi and Qingnian road, which caused some pedestrians' accidents, so we take some traffic safety education strategies. We use freshman week to promote traffic safety during new employee orientation sessions (as presented by Jarice D. Rodriguez-Seda, 2008), such as visiting the traffic environment around campus , distributing pedestrian traffic safety brochures and providing freshman traffic safety class. We also established a safety student union to carry some programs focusing on improving traffic awareness. Furthermore, the student union concentrates efforts at the beginning of each semester to discourage jaywalking by writing "name-banner". Law enforcement measures are needed to complement education and all universities crosswalks should reinforce jaywalking enforcement on a regular basis and provide supervise devices to increase speed limit compliance and reduce red-signal violation rate at crosswalk.

6. CONCLUSIONS AND RECOMMENDATION

This paper summarizes some of strategies and measures to improve pedestrian safety at crosswalks around campus. The purpose of the paper is to provide examples of the techniques being implemented around Ludong university campuses that could be used by other campuses in China. As the conclusion, the strategies are grouped into demand management, supply management, education and enforcement. According to the results, there are some specific recommendations about crosswalk around campus: (1) Providing the convenient, comfortable pedestrian bridges and underpass around university, most importantly the co-location of pedestrian overpass and bus stops may improve its usage; (2) installing pedestrian push-button signal, (3) installing supervise devices to discourage the violation of traffic law, (4) providing traffic violation calming facilities, and (5) carrying out a freshman education campaign to promote traffic safety.

This paper presents some of strategies implemented around Ludong Universities, but road situation of each campus is different; it is recommended to seek techniques that are proven to work in a similar setting.

ACKNOWLEDGEMENTS

The authors wish to acknowledge the financial support to this research by the planning of traffic management system of Yantai project (grant number 2008L283).

ABSTRACT

To strengthen airport wireless services and security, optimal-degree spider-web networks are prototyped in both cellular communication and supervisory control and data acquisition (SCADA) networks. This paper provides details about a study of network information transmission to establish dual surveillance and mutually-independent-hamiltonian-path (MIHP) performance to benefit coping with detection-unavailability, radio interference, and multipath effects. Using sequential order, integrative connectivity, and reliability, SCADA networks can also improve maintenance, environmental control, and service-oriented images because the networks allow real-time parallel sensing, systematic fault-tolerance, and integrative management in area perspectives. Such configurations can offer integrated response capabilities even if the SCADA networks of two paths are destroyed.

INTRODUCTION

The examination of casino surveillance systems, where more than eight cameras may be required to monitor a game table, helps us to recognize that the line-of-sight environment can be dynamic, and unexpected faults can exist. However, the traditional approach to traffic surveillance employs the use of only one or two cameras that are installed in the middle of a section of road; such an approach cannot provide left- or right-side views of vehicles in the left- or right-hand traffic system. Thus, accidents may happen because the sightline is unavailable (Hsu, 2008a, b).

Contemporary terrorists' activities often relate to airports and may happen at any time, from any position, and even concurrently. For the landside of airports, monitored vehicles can be hidden by other vehicles. For the airside, landing/departing planes also can be involved in accidents related to failures of communication or surveillance, which can be improved by supporting a parallel mechanism. Such

mechanisms already exist in airsides, for example, the cooperative unit of two practical fault-tolerant radars or radar with multiple affiliated sensors (e.g., the advanced airport-surface-detection-equipment radar, ASDE-X) is applied to counter issues like blind spots, false images, or repair requirements. However, airports' network performance can be further improved.

For invisible applications such as radio frequency identification (RFID), dual surveillance can help counter material interference (information transmission covered by materials like metal or water) using a method similar to that used to counter sightline unavailability, and it can help deal with frequency interference or multipath effects by analyzing acquired data related to different positions and time sequence using mutually independent hamiltonian paths (see MIHP in next section). Analogically, the cooperative function of parallel surveillance is similar to that of the cooperation between the two eyes or two ears of a human being that compare images derived from (slightly) different positions or times. Moreover, a series of such dual-surveillance could be located along the path at blind-spot concerned positions to get parallel and thorough recordings as the diagnostic tool. Such parallelism is recommended in a critical/dynamic environment. Specifically, it is placed along the path, probable at exterior or interior positions, which can be integrated as an area-based resilient supervisory control and data acquisition (SCADA) network system (Hsu, 2008b). In addition, cellular communications, global positioning systems (GPS), and geographic information systems (GIS) can be integrated naturally to further strengthen responding capability.

A mathematical, optimal-degree, dual-surveillance-based spider-web network prototype, SW(m,n) (see next section) is proposed for airports and their neighboring areas for both wireless/heterogeneous SCADA networks on paths (Figure 1(a)) and interference-free oriented cellular communication (Figure 1(b)) (Hsu, 2008a, b). For both the airside and the landside, such a SCADA network that has fault tolerance and an order (properties of 1-edge hamiltonian and 1p-hamiltonian, see next section) for promoting maintenance efficiency/effectiveness is addressed. Such networks can be adapted to accommodate surveillance modes such as surveillance of both forward and backward directions and for accommodating the SCADA operation when one lane of a path is under maintenance. Moreover, such networks are scalable; i.e., they have the flexibility to extend a path or survey area to meet future requirements.

MATHEMATICAL PRELIMINARIES

Communication networks are usually illustrated by graphs in which nodes represent processors and edges represent links between processors. Let G=(V,E) be a

graph if V is a finite set and E is a subset of {(a,b) |(a,b) is an unordered pair of V}. A path is delimited by $(x_0,x_1,x_2,\ldots x_{n-1})$. A path is called a hamiltonian path if its nodes are distinct and span V. A cycle is a path of at least three nodes such that the first node is the same as the last node. A cycle is called hamiltonian cycle or hamiltonian if its nodes are distinct except for the first node and the last node, and if they span V. A bipartite graph G = (V,E) is a graph such that $V=A\cup B$ and E is a subset of {(a,b)| $a\in A$ and $b\in B$}; if G-F remains hamiltonian for any F={a,b} with $a\in A$ and $b\in B$, then G is 1_p-hamiltonian. A graph G is 1-edge hamiltonian if G-e is hamiltonian for any $e\in E$; moreover, if there is a hamiltonian path between any pair of nodes {c,d} with $c\in A$ and $d\in B$, then the bipartite graph G is hamiltonian laceable.

The spider web network, SW(m,n), is the graph with the node set {(i,j)| $0\leq i<m$, $0\leq j<n$}, where m and n are positive integers with m, n being even, such that (i,j) and (k,l) are adjacent if they satisfy one of the following conditions: (1) i=k and $j=l\pm1$; (2) j=l and k=i+1(**mod** m) if i+j is odd or j=n-1; (3) j=l, k=i-1(**mod** m) if i+j is even or j=0. The configuration of SW(m,n) is shown in Figure 1. SW(m,n) is proved 1-edge hamiltonian if $n\geq4$; 1_p-hamiltonian if $n\geq4$ (Hsu & Kao, 2007; Kao & Hsu, 2005a). Thus, the fault-tolerance engaged in is systematically based. Moreover, SW(m,n) are hamiltonian laceable if $n\geq4$ (Kao & Hsu, 2005b), see Figure 1(a).

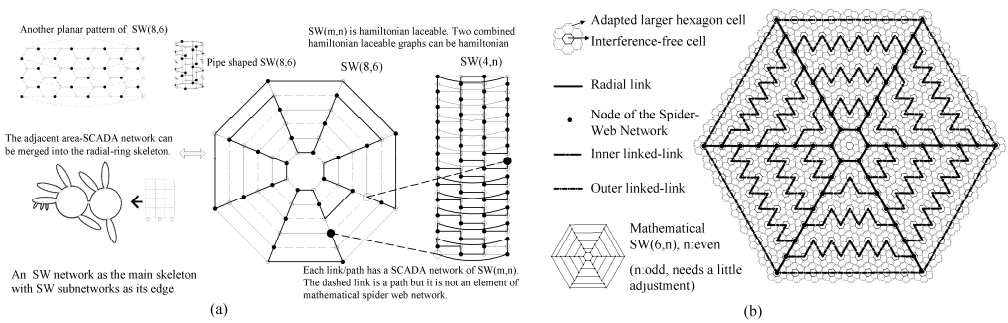

Figure 1. Spider-web network applications. (a). area based SCADA networks, (b). interference-free oriented cellular communication networks – SW(6,n).

The number of links connecting a node is called the degree; a network regularly having smaller degree is generally economical (Stojmenovic, 1997). Two hamiltonian paths, $P_1=(u_1, u_2,\ldots,u_{n(G)})$ and $P_2=(v_1,v_2,\ldots,v_{n(G)})$ of G from u to v, are independent if $u=u_1=v_1$, $v=u_{n(G)}= v_{n(G)}$, and $u_i\neq v_i$ for every $1<i<n(G)$. A set of hamiltonian paths, $\{P_1,P_2,\ldots,P_k\}$, of G from u to v, are mutually independent if any two distinct paths in the set are independent from u to v (Teng et al., 2006). Researches discovered that SW(m,n) has the performance of MIHP between any pair of bipartite nodes, and such a performance can be extended from SW(4,n), $n\geq4$; two pairs of MIHPs have been studied for SW(6,n) (Figures 2, 3) (Hsu, 2008a, b). There

are three horizontal extensive shapes (Figures 3(a)). Similar attributes can often be found between the cases with corresponding MIHP performance (Figure 3(b)).

(a)

(b)

Figure 3. Horizontal extensive MIHP in SW(m,n). (a). three basic horizontal extensive shapes and their examples, (b). a typical MIHP pattern in SW(m,n).

SIGNIFICANCE

Reliable parallelism supports network performance. False detections may happen for many reasons such as multipath effects, node or link (transmission) faults, and a combination of the two. After configuring adaptable dual-surveillance as a basic detection-availability platform, systematic fault-tolerance, connectivity, and management efficiency enhances detection-availability. Furthermore, a diagnostic

performance MIHP can be established to analyze time-series related adversary conditions using independent, alternative, time-series recordings for data mining or diagnosing problems. This is similar to physicians employing independent alternatives and time-series records to diagnose a disease. In addition, the MIHP parallelism can offer inherent dynamic authorization/authentication during routine operations when alternative sequences offer corresponding meanings (Hsu, 2008a).

Benefit both passenger and freight transportation. Mobile commerce (m-commerce) can be improved through the use of the proposed wireless communication networks with data integrity and reliability; moreover, aiding the disabled or the elderly can be improved (Hsu & Cho, 2006). The detection-availability for applying RFID, which has emerged especially in logistic processing, can be more assured. The execution of MIHP-related authentication/authorization can also be initiated via RFID, and active RFID can be better reauthorized to deal with privacy issues.

Resilient area-based management system. The hamiltonian laceability can help flexibly integrate individual SCADA networks along paths, including interior paths, to area-based SCADA networks. If such networks can be adapted to an inherent "spider-web" skeleton (Figure 4), then they can have the performance of spider-web; i.e., offering responding capabilities even after two paths of a SCADA network have been seriously compromised.

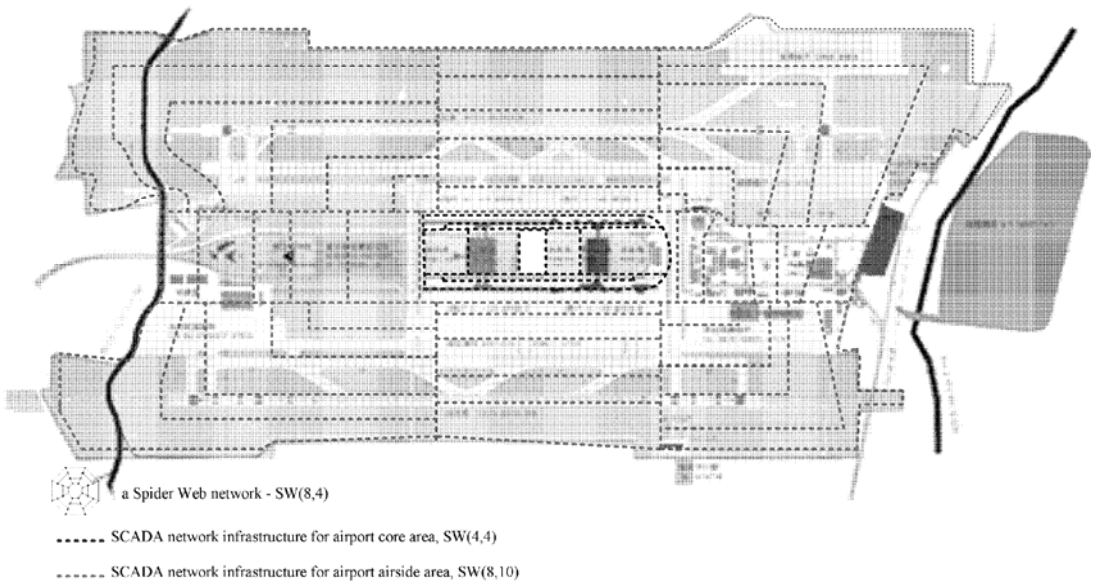

Figure 4. A SCADA network proposal for Taoyuan airport, Taiwan.

CONCLUSION

Communication is essential for airport. To improve airport services and security, network prototypes such as SW(m,n), which can provide detection availability, maintenance efficiency, and optimal degree, offer robustness and data integrity for both cellular communication and wireless/heterogeneous SCADA networks. Radial-ring spider-web configurations are prototyped for interference-free cellular telecommunication and are adaptively applied to develop area SCADA networks composed of dual-surveillance based subnetworks along paths with its advantages, including fault-tolerance, parallel processing, dynamic authentication/authorization, detection-availability, and/or countering the multipath effects of radio. Moreover, such configurations can offer integrated response capabilities even after the SCADA networks of two paths have been destroyed.

Dynamic Responses of a Magnetically Levitated Vehicle in a Crosswind

Jian-Jun Wu[1] and Xiao-Hong Shi[1]

Key Laboratory of Mechanics on Disaster and Environment in Western China (Lanzhou University), Ministry of Education, Lanzhou, Gansu 730000, China; PH (86) 931-8914240; FAX (86) 931-8912229; email: wujjun@lzu.edu.cn

ABSTRACT

The dynamic responses of a magnetically levitated vehicle (maglev) in a crosswind are studied because the action of the wind field is one of the main factors affecting the stability and safety of the maglev at high speeds. First, a model of the maglev system is established to represent four vehicle motions: heave, sway, pitch and roll. Then based on the steady and incompressible Navier-Stokes equation and $K-\varepsilon$ turbulent model, the aerodynamic characteristics of the maglev are numerically simulated by the finite element method to validate the model and algorithm suggested in this paper. Finally, numerical analyses are performed on the dynamic behavior of the vehicle in both steady and fluctuating crosswinds. It is shown that the stability of the maglev is greatly influenced by the wind velocity and its fluctuating component. Additionally, the variation of the maglev's dynamic response to wind velocity and its fluctuating component are described.

INTRODUCTION

The maglev is a new tool in high speed ground transportation. Due to its higher speed, lower friction, reduced noise, improved energy consumption and comfortable ride, the maglev system is becoming the focus of transportation worldwide (Cai et al., 1994; Zheng et al., 2000; Zhao et al., 2001; Wu et al., 2004). It is a nonlinear and multidimensional system, in which the dynamic stability of the vehicle at high speeds is highly sensitive to external disturbances. Therefore much attention has been directed to potential safety problems in recent years. Previous research focused only on the effects of guideway deformation and irregularity on the maglev, neglecting the influence of the wind field. In fact the wind field, especially the crosswind component, is one of the main factors affecting the stability and safety of the maglev. Thus it is necessary to study the aerodynamic characteristics and dynamic behavior of the maglev high speeds.

Cherchas (1979) suggested that the aerodynamic effects include longitudinal resistance and lateral force induced by crosswinds, which should be taken into consideration of the dynamic disturbances suffered by the maglev system. Garg and Barrows (1981) established a two-degree-of-freedom model of a maglev subjected to crosswind gusts in which vehicle motion was limited to sway and yaw. Their numerical simulations showed that aerodynamic drag and side tumbling moment

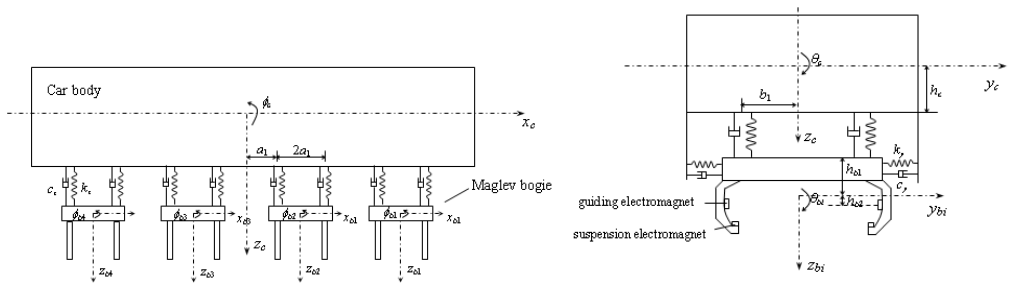
increased with vehicle speed. The aerodynamic drag, lift and pitching moment of a maglev subjected to longitudinal wind at different traveling speeds were numerically analyzed by Li et al. (2004) using the finite volume method. The influences of the suspension air gap on these aerodynamic forces were calculated, showing that suspension air gap had little effect on aerodynamic drag, but had much more significant effect on the lift force of the maglev.

Based on the above studies, a model of the maglev system is developed to represent four vehicle motions: heave, sway, pitch and roll. Then to validate the model and algorithm, the numerical simulations of the aerodynamic characteristics in a crosswind are compared with experimental results. Finally, the dynamic behavior of the vehicle in both steady and fluctuating crosswinds is discussed.

DYNAMIC MODEL OF A MAGLEV IN A CROSSWIND

Dynamic equations of the maglev system

As shown in Figure 1, the maglev system is composed of a car body and four maglev bogies. The maglev bogies are linked to the car body by vertical and transversal springs and dampers. Taking the car body's center of mass as the origin, a coordinate system is established with x, y, z axes as shown in Figure 1. The corresponding elastic coefficients and damping coefficients are denoted by k_z and c_z of the vertical springs, and k_y and c_y of the transversal springs, respectively. The car body and four maglev bogies all move with four degrees-of-freedom, which are denoted by z_c, y_c, ϕ_c and θ_c for the car body, and z_{bi}, y_{bi}, ϕ_{bi} and θ_{bi} for the i^{th} maglev bogie, where the subscript i is the index of the maglev bogie. The other notations of the maglev system in Figure 1 are listed in Table 1.



(a) Side view (b) Rear view

Figure 1. Schematic diagram of the maglev system.

Table 1. Notations of the maglev system.

Notation	Physical meaning	Value
m_c	Mass of car body (kg)	3.90×10^4
m_b	Mass of maglev bogie (kg)	6.60×10^2

Notation	Physical meaning	Value
I_{cy}	Car body's moment of inertia in pitch (kgm^2)	1.75×10^6
I_{cx}	Car body's moment of inertia in roll (kgm^2)	6.46×10^4
I_{by}	Maglev bogie's moment of inertia in pitch (kgm^2)	5.50×10^2
I_{bx}	Maglev bogie's moment of inertia in roll (kgm^2)	5.80×10^2
h_c	Distance between car body's center of mass and its bottom (m)	1.5
h_{b1}	Distance between maglev bogie's center of mass and its top (m)	0.4
h_{b2}	Longitudinal distance between maglev bogie's center of mass and that of guiding electromagnet (m)	0.1
a	Length of suspension electromagnet (m)	0.4
b	Width of suspension electromagnet (m)	0.1
c	Length of guiding electromagnet (m)	0.2
d	Width of guiding electromagnet (m)	0.05

The electromagnet and reaction plate of the guideway comprise a closed magnetic circuit through a control system. The electromagnetic force F is given by

$$F = \frac{\mu_0 N^2 A}{4}\left(\frac{i_0 + i}{\delta_0 + \delta}\right)^2 \tag{1}$$

in which i_0 is the current related to the control goal δ_0, i is the bias of the control current, δ_0 is the control goal of the air gap, and δ is the bias of the suspension air gap to δ_0. μ_0, A and N are respectively magnetic permeability in vacuum, pole area of the electromagnet, and number of turns in the coil.

In the maglev system, the controlling law of the guide control system is the same as that of the suspension control system, which is given by

$$i_z = G_{1z}\delta_z + G_{2z}\dot{\delta}_z, \quad i_y = G_{1y}\delta_y + G_{2y}\dot{\delta}_y \tag{2}$$

where G_{1z} and G_{2z} are displacement and velocity feedback control gains of the suspension electromagnet, and G_{1y} and G_{2y} are displacement and velocity feedback control gains of the guiding electromagnet.

According to Newton's second law and angular momentum theorem, the following dynamic equations describing the maglev system's four-degree-of-freedom motion are obtained:

Heave: $$m_c\ddot{z}_c + \sum_{i=1}^{4}\sum_{j=1}^{2}\sum_{k=1}^{2} F_{2z}(i,j,k) + F_L = 0 \tag{3}$$

Sway: $$m_c\ddot{y}_c + \sum_{i=1}^{4}\sum_{j=1}^{2}\sum_{k=1}^{2} F_{2y}(i,j,k) - F_D = 0 \tag{4}$$

Pitch: $$I_{cy}\ddot{\phi}_c - \sum_{i=1}^{4}\sum_{j=1}^{2}\sum_{k=1}^{2} L(i,j)F_{2z}(i,j,k) = 0 \quad (5)$$

Roll: $$I_{cx}\ddot{\theta}_c + b_1\sum_{i=1}^{4}\sum_{j=1}^{2}(F_{2z}(i,j,2) - F_{2z}(i,j,1)) - h_c\sum_{i=1}^{4}\sum_{j=1}^{2}\sum_{k=1}^{2} F_{2y}(i,j,k) - M_m = 0 \quad (6)$$

Here F_L, F_D and M_m represent the lift force, the side force and the rolling moment, respectively, of the car body subjected to a wind field. $F_{2z}(i, j, k)$ and $F_{2y}(i, j, k)$ represent vertical and horizontal components of the second suspension force, respectively, in which i is the index of the maglev bogie, numbered 1 through 4 from right to left. j =1(2) represents the front (back) end of the maglev bogie, and k =1(2) represents the left (right) side of the maglev bogie. They are respectively given by

$$\begin{aligned} F_{2z}(i,j,k) = k_z[z_c - L(i,j)\phi_c + Ls(j)\phi_{bi} + (-1)^k(b_1\theta_c - b_1\theta_{bi})] \\ + c_z[\dot{z}_c - L(i,j)\dot{\phi}_c + Ls(j)\dot{\phi}_{bi} + (-1)^k(b_1\dot{\theta}_c - b_1\dot{\theta}_{bi})] \end{aligned}$$

$$F_{2y}(i,j,k) = k_y(z_c - z_{bi} - h_c\theta_c - h_{b1}\theta_{bi}) + c_y(\dot{z}_c - \dot{z}_{bi} - h_c\dot{\theta}_c - h_{b1}\dot{\theta}_{bi})$$

Additionally, $Ls(k)$=(13-4i-2j) a_1 represents the force arm of the j^{th} second suspension force of the i^{th} maglev bogie on the car body's pitch. For i =(1, 2, 3, 4) and j =(1, 2), $Ls(k)=(-1)^{k+1}a_1$.

For the bogie, dynamic equations can be written as follows:

Heave: $$m_b\ddot{z}_b(i) - \sum_{j=1}^{2}\sum_{k=1}^{2} F_{2z}(i,j,k) + \sum_{j=1}^{2}\sum_{k=1}^{2} F_{1z_add}(i,j,k) = 0 \quad (7)$$

Sway: $$m_b\ddot{y}_b(i) - \sum_{j=1}^{2}\sum_{k=1}^{2} F_{2y}(i,j,k) + \sum_{j=1}^{2}[F_{1y}(i,j,2) - F_{1y}(i,j,1)] = 0 \quad (8)$$

Pitch: $$I_{by}\ddot{\phi}_b(i) + Ls(k)\sum_{j=1}^{2}\sum_{k=1}^{2} F_{2z}(i,j,k) - Ls(k)\sum_{j=1}^{2}\sum_{k=1}^{2} F_{1z_add}(i,j,k) = 0 \quad (9)$$

Roll: $$I_{bx}\ddot{\theta}_b(i) + b_1\sum_{j=1}^{2}[F_{2z}(i,j,2) - F_{2z}(i,j,1)] + b_1\sum_{j=1}^{2}[F_{1z_add}(i,j,2) - F_{1z_add}(i,j,1)] = 0 \quad (10)$$

Here $F_{1z_add}(i, j, k)$ represents the change of electromagnetic force in heave, expressed by

$$F_{1z_add}(i,j,k) = \frac{\mu_0 N^2}{4}a(b - |\delta_y(i,j,k)|)\left(\frac{I_{0z} + i_z(i,j,k)}{\delta_0 + \delta_z(i,j,k)}\right)^2 - \frac{\mu_0 N^2}{4}ab\left(\frac{I_{0z}}{\delta_0}\right)^2$$

in which $\delta_z(i,j,k) = z_{bi} - Ls(k)\phi_{bi} + (-1)^k b_2\theta_{bi}$, $i_z(i,j,k) = G_{1z}\delta_z(i,j,k) + G_{2z}\dot{\delta}_z(i,j,k)$.

$F_{1y}(i, j, k)$ represents the change of electromagnetic force in sway, expressed by

$$F_{1y}(i,j,k) = \frac{\mu_0 N^2}{4}c(d - |\delta_z(i,j,k)|)\left(\frac{I_{0y} + (-1)^k i_y(i,j)}{\delta_0 + (-1)^k \delta_y(i,j)}\right)^2$$

in which $\delta_y(i,j) = y_{bi} - h_{b2}\theta_{bi}$, $i_y(i,j) = G_{1y}\delta_y(i,j) + G_{2y}\dot{\delta}_y(i,j)$.

Equations (3)-(10) above constitute the dynamic equations of the maglev system.

Wind field equation

The wind field is described by the following equations of turbulent kinetic energy k, turbulent kinetic energy dissipation rate ε, wind speed u and relative pressure p.

Continuity:
$$\frac{\partial u_i}{\partial x_i} = 0 \tag{11}$$

Momentum:
$$\frac{\partial}{\partial x_i}\left(u_i u_j\right) = -\frac{1}{\rho}\frac{\partial p}{\partial x_i} + \left(\mu + \mu_t\right)\frac{\partial^2 u_i}{\partial x_j \partial x_j} \tag{12}$$

Turbulent kinetic energy:
$$\rho u_j \frac{\partial k}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right] + \mu_t \frac{\partial u_i}{\partial x_j}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - \rho\varepsilon \tag{13}$$

Turbulent kinetic energy dissipation rate:
$$\rho u_j \frac{\partial \varepsilon}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_j}\right] + C_1 \frac{\varepsilon}{k}\mu_t \frac{\partial u_i}{\partial x_j}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - C_2 \frac{\rho\varepsilon^2}{k} \tag{14}$$

where u_i (i=1, 2, 3) is the speed component, μ_t is the turbulent viscosity coefficient given by $\mu_t = \rho C_\mu k^2/\varepsilon$, C_μ is an empirical constant, and σ_k and σ_ε are Prandtl numbers corresponding to turbulent kinetic energy and the turbulent kinetic energy dissipation rate. C_1 and C_2 are empirical constants, ρ =1.225 kg/m^3 is fluid density, and μ =1.7894$\times 10^{-5}$ N/m^{2}s is kinetic viscosity. Launder and Spalding (1974) suggested that C_μ=0.09, σ_k=1.0, σ_ε=1.3, C_1=1.44, and C_2=1.92.

Boundary conditions

The maglev car body is subjected to a steady wind field, which is assumed to be a large volume with length, width and height, respectively, taken as 130, 100 and 50 times the width of the car. The modeled wind field dimensions and position of the vehicle within are displayed in Figure 2. Taking the car body's center of mass as the origin, the coordinate system shown in Figure 2 is established, in which the x axis is parallel to the wind, the y axis is vertical, and the z axis is parallel to the length of the car body. Length, width and height of the car are a_c, b_c and h_c; average wind velocity is U; vehicle velocity is V; and p is relative pressure.

Boundary conditions of the modeled wind field volume are given by

$$\begin{cases} x = -30b_c : u_x = U, u_y = u_z = 0 \\ x = 100b_c : p = 0 \end{cases} \qquad \begin{cases} y = -\left(h_c/2 + r\right): \quad u_x = u_y = u_z = 0 \\ y = 50b_c - \left(h_c/2 + r\right): u_x = u_y = u_z = 0 \end{cases}$$

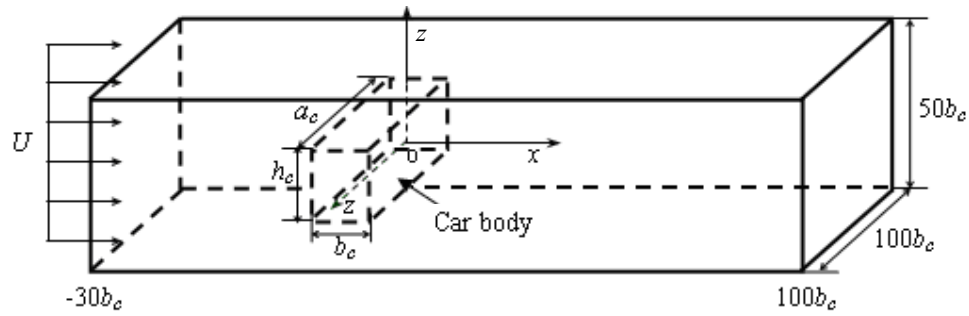


Figure 2. Modeled wind field dimensions and maglev position within.

Boundary conditions of the surface of the maglev are given by

$$\begin{aligned} &-b_c/2 \le x \le b_c/2,\ y = -h_c/2; \quad -b_c/2 \le x \le b_c/2,\ y = h_c/2; \\ &x = -b_c/2,\ -h_c/2 \le y \le h_c/2; \quad x = b_c/2,\ -h_c/2 \le y \le h_c/2: \end{aligned} \quad u_x = u_y = 0,\ u_z = V$$

Based on the above fundamental wind field equations combined with the boundary conditions, the side force, lift force and side overturning moment are obtained by the finite element method.

To verify the effectiveness of the wind field algorithm, vehicle parameters taken from Li (2003) are used to simulate the side force F_D of the vehicle in a crosswind by the finite element method. Then the coefficient of side force C_D is obtained from F_D through the following equation:

$$C_D = \frac{F_D}{(1/2)\rho_a a_c h_c U^2} \tag{15}$$

where ρ_a is air density. The results calculated from Equation (15) are listed in Table 2 with the experimental results given by Li (2003), in which the volume of the car body is 2.1m×0.472m×0.353m.

Table 2. Comparison of the coefficients of side force.

Wind velocity	10 m/s	20 m/s	30 m/s
Experimental results given by Li (2003)	0.45	0.42	0.38
Numerical results in this paper	0.42	0.38	0.36

It can be seen that the numerical results in this paper coincide with the experimental results given by Li (2003) very well, further justifying the method of modeling the wind field suggested by this paper.

Description of fluctuating wind

The fluctuating wind is simplified into White noise, described by

$$U(t) = \sum_{k=1}^{N(T)} Y_k \delta(t - \tau_k) \tag{16}$$

where Y_k are independent random numbers with uniform distribution. $N(T)$ is a random

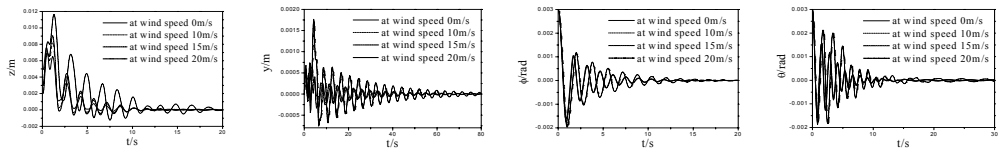
Poisson distribution with uniform increments of λ_0.

NUMERICAL SIMULATION AND RESULTS DISCUSSION

The side force, lift force and side overturning moment of the maglev are calculated in varying crosswind speeds by the model and algorithm given in the last section. Then the dynamic behavior of the maglev in the crosswind is analyzed by the Runge-Kutta-Merson method.

Dynamic response of the maglev in a steady crosswind

With constant control gains, that is G_{1z}=1.42×10^3, G_{2z}=1.0, G_{1y}=1.0×10^3, and G_{2y}=14.2, the vehicle moving at 50m/s is subjected to steady crosswind speeds of 0m/s, 10m/s, 15m/s and 20m/s. The dynamic response of the maglev is shown in Figure 3.



(a) heave (b) sway (c) pitch (d) roll

Figure 3. Maglev dynamic response in a steady crosswind of varying speeds.

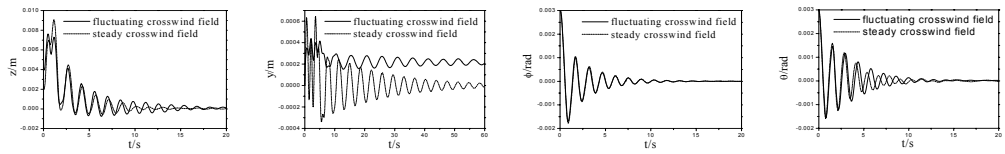
It can be seen that the amplitude of all motions increases with increasing wind velocity. In other words, the stability of vehicle becomes worse, and the time needed to regain stability becomes longer. When wind velocity is less than 15m/s, the influence of the crosswind on every motion of the vehicle is relatively small, which can be neglected. When wind velocity reaches 20m/s, the influence of the crosswind on every motion of the vehicle is greater, requiring specific attention in practical engineering.

Dynamic response of the maglev in a fluctuating crosswind

When the vehicle moving at 50m/s is subjected to a steady and/or fluctuating crosswind of 15m/s, the dynamic responses of the maglev are as shown in Figure 4. It is shown that the influence of a fluctuating crosswind on heave, pitch and roll motion is quite feeble. However, the dynamic response in sway motion of a maglev subjected to a fluctuating crosswind is more pronounced than that of a vehicle subjected to a steady crosswind. Therefore, the influence of a fluctuating crosswind field on the maglev's dynamic stability is relatively significant for sway motion.

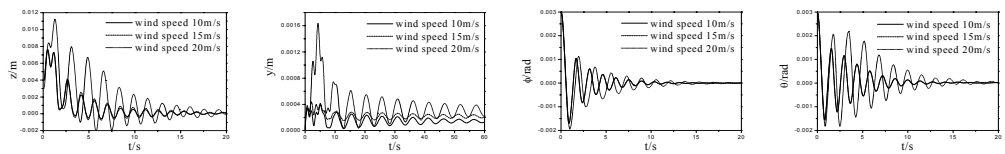
When the vehicle moving at 50m/s is subjected to a fluctuating crosswind with speeds of 10m/s, 15m/s or 20m/s, the dynamic response of the maglev is as shown in Figure 5. At windspeeds below 20m/s, it is obvious that the influence of a fluctuating crosswind on every motion of the maglev is quite feeble, which can be ignored. However, when the speed of the fluctuating crosswind reaches 20m/s, the

influence on dynamic stability is relatively significant for all four motions.



(a) heave (b) sway (c) pitch (d) roll

Figure 4. Comparison of maglev dynamic response to a steady and/or fluctuating crosswinds of 15m/s.



(a) heave (b) sway (c) pitch (d) roll

Figure 5. Comparison of maglev dynamic response to a fluctuating crosswind of varying speeds.

CONCLUSIONS

Based on a four-degree-of freedom model of a maglev system subjected to a crosswind of varying speeds with and without a fluctuating component, numerical analyses are conducted on the vehicle's dynamic response to understand the dynamic stability of a high-speed maglev. The main results are as follows:

(1) For a vehicle traveling at constant speed, the influence of a steady crosswind on all four vehicle motions is quite small when the wind speed is less than 15m/s. This is also true for the influence of a fluctuating crosswind. However, when the speed of a fluctuating crosswind reaches 20m/s, the influence of the crosswind on the dynamic stability of each vehicle motion is relatively significant.

(2) The influence of a fluctuating crosswind on maglev dynamic stability is significantly stronger than that of a steady crosswind.

(3) Whether the maglev is subjected to a steady crosswind or fluctuating crosswind, the sway component of motion will exhibit the most influence by the crosswind action.

ACKNOWLEDGEMENTS

The authors would like to express their sincere appreciation to the funding from the Program for New Century Excellent Talents in University (NCET-04-0979).

ABSTRACT

The inner horizontal surface is mainly used to protect the space for a visual circling approach. The radius and height of the inner horizontal surface is described in The Convention on International Civil Aviation Annex 14-Aerodromes and Airport Services Manual Part 6: Control of Obstacles. However, they could not guarantee the space specified by another criterion, Procedures for air Navigation Services: Aircraft Operations. Vol. II, Construction of Visual and Instrument Flight Procedures (ICAO Doc. 8168-OPS/611). Urban construction was also restricted. This paper focuses on this problem and a method is given to consummate the obstacle limitation requirements of the airport.

1 Introduction

The obstacle limitation surfaces of the airport are vital to the limitation of obstacles around the airport and aircraft safety while taking off, climbing, approaching and landing so that aircraft can carry out their flight procedures. The requirements for obstacle limitation surfaces are based on the purpose of the runway, such as take-off or landing, and types of approach. But for all kinds of the runways, inner horizontal surface, conical surface, approach surface and transition surfaces shall be established. The inner horizontal surface is mainly used to protect the space for visual circling approaches(GAO Jin-hua,2000).

The notice about airport clearance protection issued by General Administration of Civil Aviation of China in 1995 had definitely pointed out that any units or individuals who construct building or facilities in the airport clearance region must be approved by the airport authorities, and then report to the departments of local urban construction planning for approval(CAAC,1995). Due to the influences from flight procedure design, aircraft performance, meteorological conditions and navigation equipment, in practice, the limitation of the obstacle height should be consulted by the airport authorities and navigational fairs management department. It needs to be further studied how to design the obstacle limitation surfaces to comply with the airport obstacle limitation criterion and maximally satisfy the needs of construction around the airport while not affecting the flight procedures. According to

the calculation of visual circling radius and obstacle clearance height (OCH), the paper makes an analysis and research on the inner horizontal surface design.

2 Standards related to airport inner horizontal surface design

There are many references involved in the airport clearance. The main bases in the design of the inner horizontal surface are International Civil Aviation Annex 14-Aerodromes (Annex 14) and Procedures for air Navigation Services: Aircraft Operations. Vol. II, Construction of Visual and Instrument Flight Procedures (ICAO Doc. 8168-OPS/611). There is some illustration in Airport Services Manual Part 6: Control of Obstacles. In China, the design requirements for inner horizontal surface in Civil Airport Airfield Technical Standards (MH5001-2006) strictly observe the related norms of Annex 14. In other countries, the designs of inner horizontal surface are also based on Annex 14, and slightly modified according to the actual conditions. For instance, an inner horizontal surface radius divide in UK CAP168 was defers to the main runway and subsidiary runway and the pattern of the surface is circular or just like a racetrack lies on the length of the runway whether more than 1800m(CAA,2001).

2.1 The main parameters standards of inner horizontal surface

The main parameters in inner horizontal surface design are radius and height, which are precisely defined in Annex 14 and Airport Services Manual Part 6 (see Table 1)(ICAO,2004;ICAO,1983). The inner horizontal plane is about 45m higher than the established airport elevation. From the average elevation of the centers on the strip ends of the runway, two circular arcs centered at the middle points of the two ends of runway are obtained with given radii. Then an approximate ellipse is formed by the tangency of the two straight lines parallel to the midline of the runway and the two circular arcs. (see Figure 1). The inner horizontal surface also can be simplified as a single circular when it as being to protect airspace for visual circling prior to landing at shorter runway with a lower velocity. For multi-runway airports, the constructed method was the same (see Figure 2).

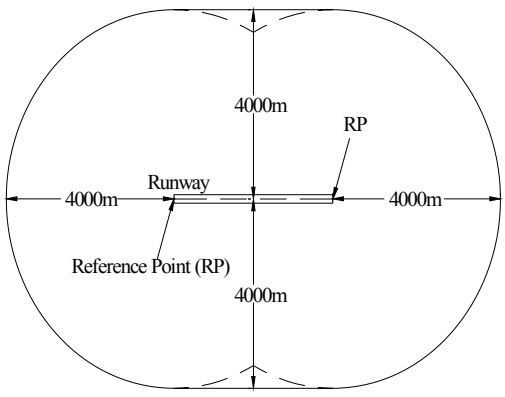

Figure 1. Inner horizontal for code number 4.

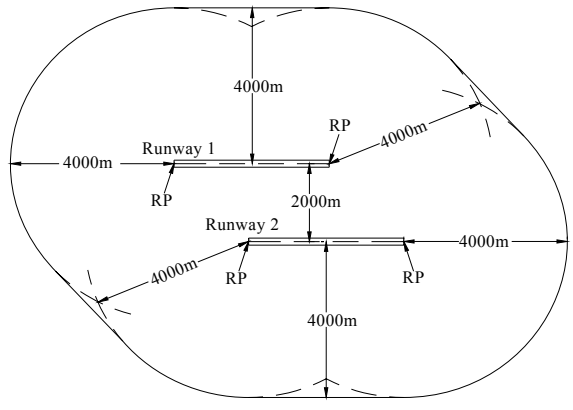

Figure 2. Composite inner horizontal for two parallel code number 4.

Table 1. Dimensions and slopes of inner horizontal surface.

Surface and dimension		Runway classification									
		Non-instrument				Non-precision approach			Precision approach category		
		Code number				Code number			I		II or III
									Code number		Code number
		1	2	3	4	1,2	3	4	1,2	3,4	3,4
Inner Horizontal	Height	45	45	45	45	45	45	45	45	45	45
	Radius	2000	2500	4000	4000	3500	4000	4000	3500	4000	4000

2.2 The visual circling area scope definition

The purpose of setting inner horizontal surface is to protect airspace for visual circling prior to landing. The visual circling area is the area in which obstacle clearance shall be considered for aircraft circling and the size varies with the category of the aircraft(ICAO,2006) To define the scope of the area, draw an arc from the centre of the threshold of each available runway with a radius $\overline{R}$ appropriate to the aircraft category, and then from the extremities of the adjacent arcs draw lines tangent to the arcs and connect the tangent lines at the last. For a multi-runway airport, the runways which are not available to Category E aircraft can be ignored if the calculation is about the area of Category E aircraft. The radius $\overline{R}$ can be calculated as follows:

$$\overline{R} = 2r + d$$

In this formula, r is the turning radius. The wind speed should be considered when calculated. d is the flying distance of aircraft in 10 second when there is no wind. OCH for visual circling area varies with the category of the aircraft either (see Table 2). The OCH is the sum of the altitude of the highest obstacle in the area and minimum obstacle clearance (MOC). Maximizing OCH for a visual circling approach, final approach and missed approach is the one for a visual circling approach.

Table 2. MOC and OCA/H for visual circling approach.

Aircraft category	A	B	C	D	E
Minimum obstacle Clearance (m)	90	90	120	120	150
Lower limit for OCH above aerodrome elevation (m)	120	150	180	210	240

3 Defects in airport inner horizontal surface design

According to Airport Planning and Environmental Protection (authors are QIAN Bing-hua and ZHANG Yu-fen), the initial design of the inner horizontal surface is based on the requirement identified by visual circling approach procedures. For instance, the inner horizontal surface for code number 4, whose radius is 4000m and height 45m, is to ensure that both sides of a light aircraft on the runway to fly over 150m high visual approach procedures and the MOC is 105m(QIAN Bing-hua,2000).

3.1 Research on the height of inner horizontal surface

Airport Planning and Environmental Protection does not illuminate the exact category of the light aircraft, in line with the OCH during final approach and missed approach, for Category A aircraft, the procedure needs MOC 90m when flying height is 120m, which means obstacles in this area are necessary to control the heights below 30m and the height of the inner horizontal should be designed as 30m. If there is an obstacle, whose altitude is between 30m and 45m, existing in this area the procedure of the visual circling approach will debug and the OCH is the sum of the obstacle height and the MOC 90m. Similarly, Category B, C, D and E aircraft can be calculated based on Table 2 and the conclusion is no influence to the procedure for Category B aircraft and higher when the height of the inner horizontal is 60m.

For the design of inner horizontal height there are some details worthy of our attention. The following case in an article in which the author engaged in related work shows the problem to a certain extent and the following brief analysis will be carried out.

The elevation at the threshold of runway 14 in Yichang Three Gorges Airport is 205m and runway 32 is 190m, height difference is 15m. In the inner horizontal surface near the transitional surface, two chimneys, whose heights are 249m, 44m higher than the elevation of runway 14, 59m over runway 32, penetrate through the inner horizontal seriously(SONG De-kuan,2000).

If the height of the inner horizontal surface is 60m, the problem in this case would not emerge, but because the obstacles are chimneys, the influence to the airport clearance is not only limited to the height, but also dust emission, which must be strictly controlled. There is an obvious problem in this case that the height difference of the runway 14/32 two thresholds is a little larger. According to the description in Civil Airport Airfield Technical Standards (MH5001-2006), the elevation of the inner horizontal shall be equal to the average elevation of the mid-point of the two thresholds(MH5001,2006). It is unreasonable using the average here because the evaluation can not identify the obstacle which penetrates through the inner horizontal surface established for runway 32 since its elevation is 240m in this case.

The calculation of the inner horizontal radius is not only impacted by the category of the aircraft, but also takes into account the elevation of the airport. For Category A aircraft, the required visual circling area is no more than a radius of

4000m except Tibet Qamdo Bangda Airport which elevation reaches to 4334m, and plain airports do not exceed 3000m. It is large enough to protect the light aircraft visual circling approaching with 4000m radius, but not for Category B aircraft and much heavier aircraft.

With regard to the calculation of the radius, the interpolation can be used to obtain the conversion factor k for the conversion of indicated airspeed (IAS) to true airspeed (TAS) based on airport elevation.

$$k = k_0 + \frac{(k_1 - k_0)}{500} \times (H - H_0)$$

In this formula, H is the airport elevation; assume a temperature of ISA+15°C and check the table to find out the value of k_0 and k_1 so as to get the value of k and calculate the TAS with the following formula. The calculation of the radius $\overline{R}$ refers the previous paper.

$$TAS = k \times IAS$$

Considering the calculation accuracy, this paper uses Excel to calculate the radii of visual circling area in Yichang Three Gorges Airport, Beijing Capital International Airport, Kunming Wujiaba Airport and Tibet Qamdo Bangda Airport. The computed result is shown in Figure 3. The calculation results reveal that plateau airports need much larger radii for protection than plain airports and the standards of radius without distinguishing by elevation become the potential hazard. Only for plain airports, such as Beijing Capital International Airport, the radius can not ensure the safety for aircraft flying frequently like B737 and A320 which are Category C.

Figure 3. Calculation of radius for visual circling with Excel

4 Recommendations for inner horizontal surface design

These recommendations are based upon the calculations and analysis above.

(1) The height of the inner horizontal surface should be increased to 60m. This figure is designed for B737 and A320 which are Category C used for short-haul and medium-haul flights. These two models are most frequently used in China. The visual circling procedure of Category B aircraft and aircraft which are heavier will not be affected if the obstacles are lower than 60m. Aircraft of Category A which are usually used for general aviation are not considered for their low usage frequency, so that city construction will not be affected.

(2) The radius of the inner horizontal surface should be increased to 5000m. Though the additional 1000m will not make any difference in protection level, another 2000m gained in the expansion of the conical surface at 5% grades can give basic protection to the visual circling procedure of Category C aircrafts. The calculation of radius should be based on the data of the particular airport. This result is just a reference.

(3) The altitude of one threshold is much different from another in some runways. In this case, the calculation should make use of the data of both thresholds. The obstacles should not be higher than the lower surface in the overlap region.

5 Conclusions

This paper focuses on the design of inner horizontal surface. Recommendations are given to adjust the design parameters through the calculation and analysis, so that the requirements of the airport clearance, flight procedure and the development of the urban construction can be maximally satisfied.

ABSTRACT：

Road traffic accidents are caused by many factors, which could be considered as the grey system with the characteristics of complexity, imperfect information, and non-definition. To quickly analyze the main factors contributing to traffic accidents, the grey relational analysis method is presented. In that, the grey relational degree and the grey relational order of each traffic accident factor are calculated, while the relative significance of each influence factor for traffic accidents is determined. So, the main reasons for traffic accident are specifically identified. According to a study of 2000 traffic accidents in one city in Northeast China between 2005 and 2007, the relational degree of weather is analyzed by using the grey relational analysis method when the amount of traffic accidents are looked upon as the decision attribute. The first three factors, and corresponding relational degree, are snowy (0.8587), cloudy (0.8491), and rainy (0.7877), respectively.

KEY WORDS: grey relational analysis, traffic accident, accident reason

INTRODUCTIONS

Based on a large amount of road traffic accident data used to deeply analyze the rules of the regional road traffic accidents, the influencing factors and reasons, we are able to extract useful information from a large amount of data to provide a basis for prevention countermeasures of road traffic accidents. So, some scholars have applied data mining methods such as rough set theory, association rules, and neural networks to analyze the main factors of traffic accidents and their significance (Li 2006; Yao 2005; Wu 2005).

In this paper, road traffic accidents are regarded as a complex, incompletely informational, inaccurate grey system. The grey relational analysis method is applied to analyze the influencing factors and degree of the road traffic accidents.

THE BASIC PRINCIPLES OF THE GREY RELATIONAL ANALYSIS

The grey system theory focuses on the "small sample", "poor information" uncertainty questions which can not be solved by probability and statistics and fuzzy math. The basic idea of the grey relational analysis is based on the geometry form similarity of the sequence curve to determine whether their relation is close or not. If the curve is close, the relational degree between the corresponding sequences is greater and vice versa (Deng 2002). Figure 1 shows the accident frequency of three kinds of vehicles in a place from 1993 to 1998, which can simply explain the important relationship between the grey relational degree and the degree of attribute values.

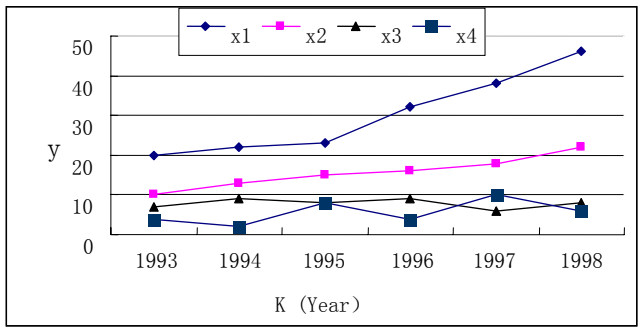

Figure 1. The accidents frequency of three kinds of vehicles.

In Figure 1, X1 is the curve of the decision-making attribute, which represents the total number of traffic accidents in the location of the study each year. X2, X3, X4, respectively, represent the number of accidents under the conditions of the three kinds of vehicle each year. From Figure 1, X2 and X1 have the most similar shape of the decision-making attribute curve, so the relational degree between X2 and X1 is the largest, while the impact of X2 is the largest too. In other words, in three transport modes X2 is the main influencing factor of the traffic accidents in the area.

PUTTING FORWARD THE METHOD

In this paper, we make use of the grey relational analysis to analyze which one of a number of the attribute values relating the road traffic accidents is most likely to affect the result of traffic accidents. The process of the method is shown in Figure 2.

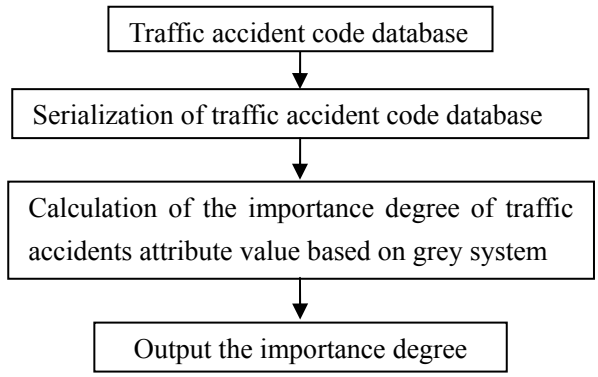

Figure 2. The process of grey relational analysis method of the causes of road traffic accidents.

THE SERIALIZATION OF TRAFFIC ACCIDENT DATA

In traffic accident data, the number of deaths can express the accident severities, the frequency can express how often the accidents happen, so this data can be directly used for relational analysis. In order to achieve this goal, this study uses the number of deaths of the traffic accidents as the sequence number, and the number of accidents or loss of property as a sequence of grey numbers. For example, assume that the number of accidents is 5876, 298, 187, 123, 45, 16, 7, when the corresponding deaths is 0,1,2,3,4,5,6, respectively. Then the sequence is:

$$X_1(k) = \{5876,\ 298,\ 187,\ 123,\ 45,\ 16,\ 7\} \quad (1)$$

Because the computer can not deal with the array variable in which the sequence number is zero, so here 1 is the beginning of the serial number. We put $X_1(k)$ as the decision-making attribute sequence. When we intend to study the relationship between the weather and the accident death number, we use the number of traffic accidents corresponding to the death number under different weather conditions as the behavior sequences. For example, the number of accidents is 876, 49, 27, 13, 7, 3, 0, which corresponds to the death number of 0, 1, 2, 3, 4, 5, 6, respectively. Then the sequence is:

$$X_2(k) = \{876,\ 49,\ 27,\ 13,\ 7,\ 3,\ 0\} \quad (2)$$

We put the sequence of $X_2(k)$ as one of the attribute values of the weather condition (sunshine). Similarly, we can get the other attribute values sequence of $X_3(k)$ (cloudy), (rain), $X_5(k)$ (snow), $X_6(k)$ (fog) and $X_7(k)$ (others). So, we can establish a sequence database when look at the means of the behavior sequences above as the grey number matrix.

CALCULATING THE IMPORTANCE DEGREE OF THE TRAFFIC ACCIDENT ATTRIBUTE VALUES

Traffic accident generalized grey relational analysis includes absolute grey relational degree, relative grey relational degree and general relational degree (Li 2006; Liu 1997).

(1) Calculate the traffic accident absolute grey relational degree ε_{0i}:

1. starting point of zero image;
2. calculate ｜s0｜, ｜si｜, ｜si-s0｜;

$$\begin{aligned} |s_0| &= \left|\sum_{k-2}^{n-1} x_0^0(k) + \frac{1}{2}x_0^0(n)\right| \\ |s_i| &= \left|\sum_{k-2}^{n-1} x_i^0(k) + \frac{1}{2}x_i^0(n)\right| \end{aligned} \tag{3}$$

$$|s_i - s_0| = \left|\sum_{k-2}^{n-1}(x_i^0(k) - x_0^0(k)) + \frac{1}{2}(x_i^0(n) - x_0^0(n))\right| \tag{4}$$

3. solve the value of the absolute grey relational degree

$$\varepsilon_{0i} = \frac{1 + |s_0| + |s_i|}{1 + |s_0| + |s_i| + |s_i - s_0|} \tag{5}$$

(2) Calculate the relative grey relational degree γ_{0i}

Grey relative degree is the quantitative characterization of the variation rate relative to the starting point of the sequences of X_0 and X_t. If the variation rate of X_0 and X_t is closer, γ_{0i} is bigger and vice versa. Calculation steps are below:

1.Initial image;
2.starting point of zero image;
3.calculate ｜s0｜, ｜si｜, ｜si-s0｜;

$$\begin{aligned} |s_0| &= \left|\sum_{k-2}^{n-1} x_0^0(k) + \frac{1}{2}x_0^0(n)\right| \\ |s_i| &= \left|\sum_{k-2}^{n-1} x_i^0(k) + \frac{1}{2}x_i^0(n)\right| \end{aligned} \tag{6}$$

$$|s_i - s_0| = \left| \sum_{k-2}^{n-1} (x_i^0(k) - x_0^0(k)) + \frac{1}{2}(x_i^0(n) - x_0^0(n)) \right| \quad (7)$$

4. calculate the value of the relative grey relational degree

$$\varepsilon_{0i} = \frac{1 + |s_0| + |s_i|}{1 + |s_0| + |s_i| + |s_i - s_0|} \quad (8)$$

(3) Calculate the value of the traffic accident grey general relational degree

$$\rho_{0i} = \theta\varepsilon_{0i} + (1-\theta)\gamma_{0i} \quad (9)$$

So, the process of the calculation of the grey general relational degree is shown as Figure3.

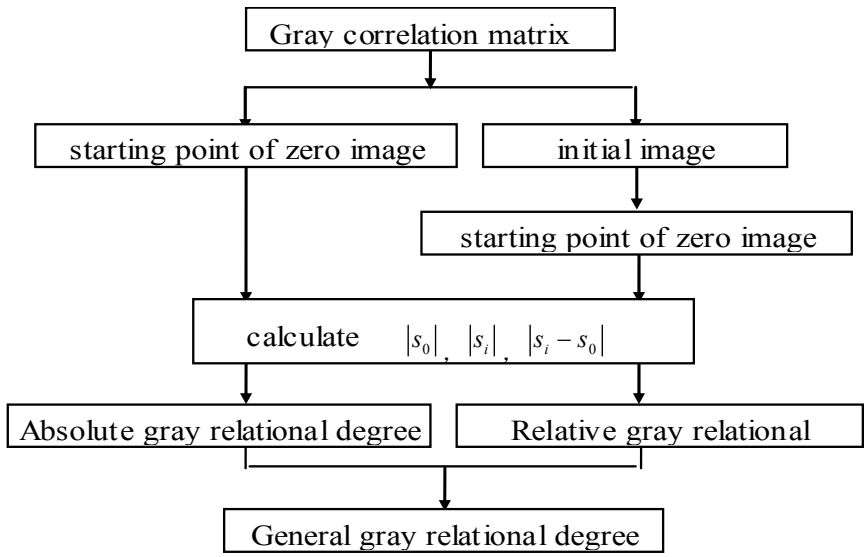

Figure 3. The process of the calculation of the general grey relational degree

5 THE CASE STUDY

Choosing data for 2000 traffic accidents in one region of Northeast China as the analysis object and mapping the traffic accident code database for serializing database, we can do the grey relational analysis case using Matlab software.

Taking the number of deaths as the decision-making attribute, the value of the death number 1, 2, 3, 4, 5, 6 is the behavior sequence. The corresponding total number of accidents of the death number is called $Y(i)$ （$i = 1,2,3,4,5,6$）, in which the corresponding total number of accidents of each attribute j is called $X_j(i)$ （$i = 1,2,3,4,5,6$）. Then we can get the correlation matrix.

(1) After analyzing the relational degree of transport modes, the results are

found as shown in Table 1:

Table 1. The order of relational degree of transport modes.

attribute	motor vehicle	non-motor vehicle	transit trip	walking	others
general relational degree	0.8598	0.7750	0.9011	0.9580	0.7508
importance	3	4	2	1	5

(2) After analyzing the relational degree of improper behavior, the results as Table 2.

Table 2. The order of relational degree of improper behavior.

attribute	illegal behavior	serious improper behavior	improper behavior	pedestrian improper behavior
general relational degree	0.8637	0.7813	0.8878	0.7703
importance	2	3	1	4

(3) After analyzing the relational degree of weather, the results as shown in Table 3.

Table 3. The order of relational degree of weather.

attribute	sunny	cloudy	rainy	snow	others
general relational degree	0.7295	0.8491	0.7877	0.8587	0.6480
Importance	4	2	3	1	5

From Table 1 to Table 3, pedestrian, improper behavior and snow are the primary factors for traffic accidents. So pedestrian is not only the accident reason, but is also the victim in the severity traffic accident. Many accidents which can be effectively avoided are caused by illegal behavior. Snow is also a quite important influencing factor for accidents. In a word, the analysis results are corresponding to the mixed traffic, the weakness of safety consciousness and concepts of drivers' obeying the law, and the long winter period in Northeast China.

6 CONCLUSION

We can accurately get the primary causes of traffic accidents from the massive traffic accident data available by using the relational analysis method based on grey system theory. For Northeast China, especially in winter, the education of vehicle drivers and pedestrian, and the surveillance of the illegal activities are key effective actions for preventing traffic accidents. But the value of general relational degree in the case is quite close (such as snow (0.8587), cloudy (0.8491)). Whether

their influence to traffic accident have obvious difference should be further investigated.

ABSTRACT

The bicycle safety problems at urban grade intersection should be regarded in China. Firstly, according to the amount of conflicts and the degree of danger, the vehicle-bicycle conflicts at a four-leg intersection are classified into 3 groups using the fuzzy clustering theory, and the interference between the through bicycles and the right-turn vehicles in the adjacent lane is used as the case study. The failure tree model of bicycle traffic safety is built and the main reasons for vehicle-bicycle conflict are explained from two aspects: the minimal cut set and the structural importance. Secondly, based on the failure tree analysis results, the fuzzy neural network model of vehicle-bicycle conflicts at grade intersections is built, the analysis results show that the reasons causing bicycle traffic conflict at grade intersections can be well analyzed and evaluated using the fuzzy neural network model.

Keywords： intersection; bicycle; traffic conflict; failure tree; fuzzy neural network

1 INTRODUCTION

Vehicle-bicycle conflicts are one of the most important features at urban grade intersections in China. It is essential to give an embedded study on the severity and the influence of traffic safety at grade intersection. Qian Dalin (2006) established the decision-making model of right-turn vehicles passing through the through bicycles; Liu Xiaoming (1997) established the traffic conflict probability distribution model and the safety evaluation standard at grade intersections; Jing Chunguang (2004) analyzed the vehicle-bicycle conflict situation in the mixed-traffic environment, and set up the critical value of left-turn bicycle flow for the phase setting. But the researchers paid less attention to the relation between the vehicle-bicycle conflict reasons and the conflict types. So in this paper, the fuzzy cluster method is used to analyze the vehicle-bicycle conflict seriousness. Then the failure tree of through bicycles and right-turn motor vehicle conflicts is set. Finally, using the minimal cut set of the failure tree as the input stylebook, and the vehicle-bicycle conflict fuzzy neural network prediction model is established, the analysis results show that the prediction model may well forecast vehicle-bicycle conflicts.

2 FUZZY CLUSTER ANALYSIS OF VEHICLE-BICYCLE CONFLICTS

The vehicle-bicycle conflicts at intersections may be divided into 5 types (see Figure 1) and look the conflict types which have the most account and the most dangerous as the object to study Based on the statistical vehicle-bicycle conflict quantities TC and the equivalent weight traffic amount of vehicle and bicycle MPCU at Ganjiakou intersection (see Table 1), the vehicle-bicycle conflict ratio TC/MPCU is regarded as the evaluated index. Ten conflict points are regarded as the evaluation set $X=(X_1, X_2, X_3 \ldots X_{10})$, the conflict danger degree X_K is divided into three kinds of type: lower danger, danger, higher danger.

Table 1. TC / MPCU at 10 conflict points.

	7:30-7:50	7:50-8:10	8:10-8:30
1 north A	0.0155	0.0185	0.0312
2 north B	0.0127	0.0157	0.0097
3 north C	0.3323	0.3072	0.2315
4 north D	0.1753	0.2389	0.1913
5 north E	0.2471	0.2253	0.2321
6 west A	0.0102	0.0105	0.0061
7 west B	0.0135	0.0150	0.0103
8 west C	0.2461	0.3890	0.2042
9 west D	0.0911	0.0795	0.0673
10 west E	0.0795	0.0673	0.0541

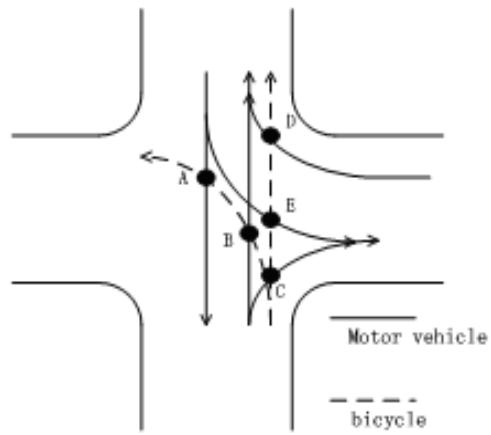

Figure 1.Vehicle-bicycle conflict types.

The fuzzy cluster analysis result (see Table 2) indicates that the interferences between the through bicycles and the right-turn vehicles are the most representative and the most dangerous. So the conflicts between the through bicycles and the right-turn vehicles are regarded as the research object in this paper.

Table 2. The fuzzy cluster analysis result of the vehicle-bicycle conflicts.

The grading of danger	the low danger	danger	the high danger
The number of conflict	1、2、6、7	9、10	3、4、5、8

3 FAILURE TREE ANALYSES

Three two-phase signaled intersections are taken as the example studies, according to the data from the video, the main reasons for the conflict between through bicycles and right-turn vehicles are shown in Figure 2. Based on the reason analyses, the failure tree is described in Figure 3. In the failure tree, the meaning of the letters is as follows:

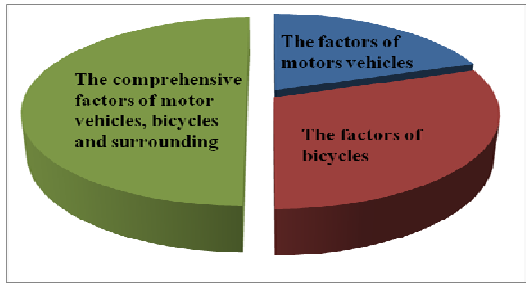

Figure 2. Vehicle-Bicycle Conflict factors.

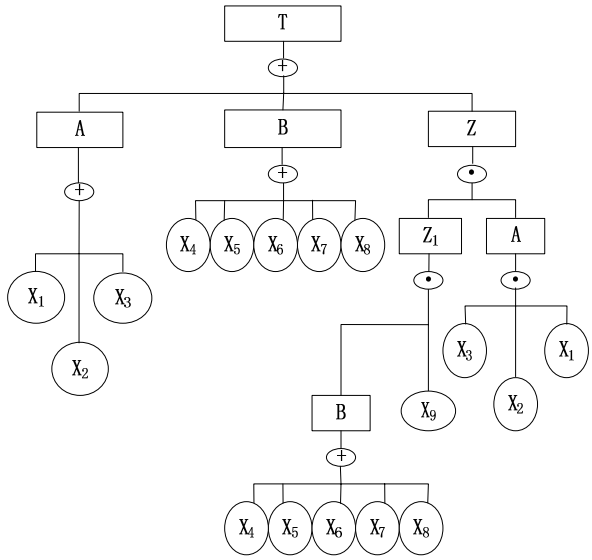

Figure3. The vehicle-bicycle conflicts failure tree.

T: through bicycles and right-turn vehicle conflict;

A: motor vehicle factors; B: bicycle vehicle factors; Z: the comprehensive factors of circumstance, motor vehicles and bicycles; Z_1: the condition of bicycle flow is not perfect;

X_1: right-turn motor vehicles occupy the bicycle lane; X_2: right-turn motor vehicle speed is excessively fast; X_3: right-turn motor vehicles don't avoid the through bicycles; X_4: bicycle speed is excessively fast when passing through the intersection; X_5: bicycles stop over parking line; X_6: bicycles go through intersection at random; X_7: bicycles pass through at a red light; X_8: bicycles run conversely; X_9: bicycle volume is excessively heavy when there is a green light.

By analyzing the minimal cut set of the failure tree, 13 minimal cut sets of the conflicts between through bicycles and right-turn motor vehicles in the adjacent lane are found. Based on the failure tree theory, the number of conflict patterns is 13.

$K_1=\{X_1\}$; $K_2=\{X_2\}$; $K_3=\{X_3\}$; $K_4=\{X_4\}$; $K_5=\{X_5\}$; $K_6=\{X_6\}$; $K_7=\{X_7\}$; $K_8=\{X_8\}$; $K_9=\{X_1X_2X_3X_4X_9\}$; $K_{10}=\{X_1X_2X_3X_5X_9\}$; $K_{11}=\{X_1X_2X_3X_6X_9\}$; $K_{12}=\{X_1X_2X_3X_7X_9\}$; $K_{13}=\{X_1X_2X_3X_8X_9\}$.

4 VEHICLE-BICYCLES CONFLICT FUZZY NEURAL NETWORK MODEL

In this paper, the relations between all kinds of factors and the traffic conflicts occurring at the intersection in Beijing are analyzed and forecasted, and the traffic conflict forecast model, based on fuzzy discursion of the neural network, is put forward. According to the video collection, the stylebooks may be determined.

Training stylebook 1: the through bicycles from north and the right-turning motor

vehicles on adjacent-lane motor vehicles at Ganjiakou intersection;
Training stylebook 2: the through bicycles from south and the right-turning motor vehicles on adjacent-lane vehicles at Ganjiakou intersection;
Training stylebook 3: the through bicycles from east and the right-turning motor vehicles on adjacent-lane vehicles at Ganjiakou intersection;
Training stylebook 4: the through bicycles from east and the right-turning motor vehicles on adjacent-lane vehicles at Fuchengmen intersection;
Training stylebook 5: the through bicycles from south and the right-turning motor vehicles on adjacent-lane vehicles at Fuchengmen intersection;
Training stylebook 6: the through bicycles from north and the right-turning motor vehicles on adjacent-lane vehicles at Fuchengmen intersection;
Testing stylebook 1: the through bicycles from west and the right-turning motor vehicles on adjacent-lane vehicles at Zhanlan road intersection;
Testing stylebook 2: the through bicycles from east and the right-turning motor vehicles on adjacent-lane vehicle at Zhanlan road intersection
Testing stylebook 3: the through bicycles from south and the right-turning motor on adjacent-lane vehicle at Zhanlan road intersection

The vehicle-bicycle conflict model at grade intersections is the system of neural network-driven fuzzy reasoning of the vehicle-bicycle conflicts. The structure of the fuzzy neural model is shown Figure 4, where: X is the input variable, Y is the output variable, g_j is the output variable of network NN_j, μj is the fitness of each network, R=3.

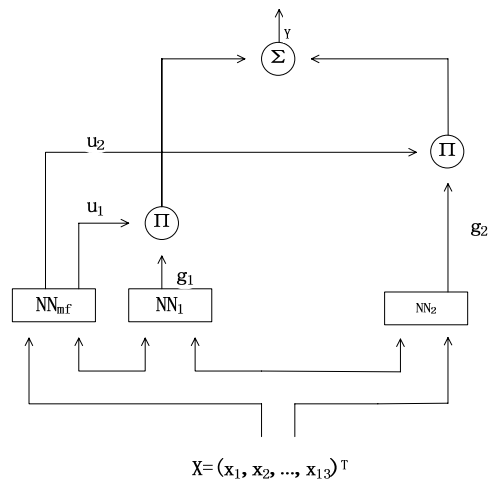

Figure4. The conflict fuzzy NN model

There are 3 neural networks in the vehicle-bicycle conflict fuzzy neural network model: the network NN_1, NN_2, the output numbers of conflict "y" which has two fuzzy rules in conclusion part. While the network NN_{mf} has given the fitness "μ_j" which include the two fuzzy rules corresponding to the input variable "p". The output variable "y" is decided by the formula (1)

$$y = \sum_{j=1}^{R} \mu_j \bullet g_j \qquad (1)$$

The vehicle-bicycle conflict fuzzy NN model adopts the BP model, the transfer function is sigmoid, and the output layer of network NN_j adopts the linear function. The concrete step as follows:
Step 1: To divide the input variable and the output variable into two parts properly. One part is training network whose training stylebooks are 1.2.3.4.5.6; another is the

testing network whose testing stylebooks are 7.8.9.

Step 2: Using clustering method cluster the input stylebooks. The first group contains 1.3.6; the second group contains 2.4.5, each cluster has a fuzzy rule, so this model has two fuzzy rules.

Step 3: The network NN_{mf} is made up of four input variables and two output variables. The learning stylebook is defined as follows: if the input pi of the training stylebook is clustered as the S group, then the S group training rule is followed. （S=one or two）

Step 4: The network NN_s corresponds to the article S rule corresponding to the S group divided in the second step, so the input stylebook in the S group is the learning stylebook of network NN_s. Avoiding excessive network learning, we can introduce the rule function as follows:

$$I_s = \frac{n_c}{n_i^s + n_c} \sum_{i=1}^{n_i^s} \{y_i - g_s(x_i)\}^2 + \frac{n_i^s}{n_i^s + n_c} \sum_{i=1}^{n_s} \{y_i^s - \mu_s(x_j) \bullet g_s(x_i)\}^2 \qquad (2)$$

Where: n_c is the account of testing stylebook, n_i^s is the account of stylebook in the S group, y_j^s is the output stylebook in the S group corresponding to the input variable p_j . When Is takes the minimum in the network NN_s , it can stop.

Regarding the reason sets, p_1 p_2 p_3 p_4 p_5 p_6 p_7 p_8 p_9 p_{10} p_{11} p_{12} p_{13}, which are contained in the minimal cut set of the failure tree as the input variables, y is the network conflict account output. The vehicle-bicycle conflict fuzzy neural network reasoning system established is shown in Figure 5.
