In real-time video surveillance and motion analysis applications, the primary task is to detect moving objects from video sequences efficiently. Frame difference including background subtraction and inter-frame difference is the common method utilized for this task. The need to construct efficient background models in real-time that adapt to the environment's changes can lead to an empty or tailing appearance in the image of inter-frame differences . This is because the camera's shooting speed usually does not match the foreground objects' speed. These two points limit the frame difference method in target detection. Recently, several other detecting methods suitable for a complex environment have been proposed (such as a method based on pixel filtering and an adaptive background modeling method). Among them, the adaptive mixture Gaussian model (MOG) is one of the most successful methods for its simple structure and low computational cost. But by only depending on the learning rate to adapt to background changes, the MOG faces trade-off problems. With its slow learning rates and convergence, it produces a wide model that has difficulty detecting a sudden change in the background. If the model adapts too quickly, slowly moving foreground pixels will be absorbed into the background model, resulting in a high false negative rate. Recently, some researchers have presented more improved mixture Gaussian models [Lee, D-S. (2004), Arandjelov, C. R. (2005), Chen, Z., Chen, X., Hong, H. (2007), Ma, Y., Zhu, W., etc. (2007), Chen, Z., Zhou, R., etc. (2007)], but the results still have not been satisfactory. In order to improve the robustness of the surveillance system, this paper proposes a novel method to extract foreground objects from a real-time complex video under the Bayesian decision framework. The proposed method can deal with the problems

both of gradual and sudden background changes in the detection of foreground objects and has detected vehicles effectively amid complex environments in our experiments.

THE METHOD OF MOVING FOREGROUND OBJECTS DETECTION BASED ON THE BAYESIAN DECISION RULE

The method of vehicle detection based on the Bayesian decision rule is composed of the following parts. During initial classification, pixels are classified simply by frame difference at first. In principal feature selection, different feature vectors are constructed to represent the statistical properties of the pixels according to their spectral, spatial, and temporal features. Employing classification under the Bayesian framework, from the statistical distribution of feature vectors we get background and foreground classification. In updating parameters, we update the background model and the feature vectors of the pixels.

Initial classification and feature vector selection

First of all, each pixel of the current frame is classified through the background subtraction initially. In this way, the pixel is classified as the background point if the pixel gray value is less than the threshold, otherwise it is classified as a changing point. Secondly, if the changing point pixel changes between frames then it is marked as a dynamic point, otherwise it is marked as static point. Considering that background variation at neighboring pixels has strong spatial and temporal correlations, the changed points are divided into two types of static or dynamic pixels so that they can be described by their appropriate principle features respectively. The principle features of the background at each pixel may provide enough information for foreground and background classification. For a static pixel, the stable and most significant features are its color, so the feature vector is represented by $v_t = [r_t, g_t, b_t]^T$. For dynamic pixels associated with non-stationary objects, color change occurrences $v_t = [r_t, g_t, b_t, \Delta r_t, \Delta g_t, \Delta b_t]^T$ are used as their dynamic features, where $\Delta r_t = r_t - r_{t-1}, \Delta g_t = g_t - g_{t-1}, \Delta b_t = b_t - b_{t-1}$.

But the adaptive mixture Gaussian model mentioned in section 1 only uses a color vector to represent the background features; it doesn't take into account the background variation's strong correlation in neighboring pixels. In addition, backgrounds having fast variations are not easily or accurately modeled with just a few Gaussians, so that model may fail to provide effective detection.

Baytesian models

This paper proposes a Bayesian framework **(**Liyuan Li, Weimin Huang, Irene Yu-Hua Gu, Qi Tian (2004)**),** which incorporates different types of features for modeling complex backgrounds. For a stable real-time outdoor surveillance system, background pixels are subject to Gaussian distribution, while the background models can be represented by significant vectors from a principal features analysis. According to the probability distribution of eigenvector, the pixels will be classified as foreground or background under the Bayesian framework. This method is described as follows.

Let $s = (x, y)$ be the position of an image pixel, $I = (s, t)$ be the input image

at time t, and v_t be a feature vector extracted from an image sequence at the point s and time t. Using the Bayesian decision rule, a posterior probability of v_t from the background b or foreground f is

$$P(B|v_t,s)=\frac{P(v_t|B,s)P(B|s)}{P(v_t|s)}, \qquad B=b \text{ or } f \qquad (1)$$

Using the Bayesian decision rule, a pixel is classified as background according to its feature vector observed at time t.

$$P(b|v_t,s)>P(f|v_t,s) \qquad (2)$$

Otherwise, it is classified as foreground.

Note that the feature vectors at the pixel s comes either from background or foreground objects, it follows

$$P(v_t|s)=P(v_t|b,s)P(b|s)+P(v_t|f,s)P(f|s) \qquad (3)$$

Substituting (1) and (3) into (2), then the Bayesian decision rule becomes

$$2P(v_t|b,s)P(b|s)>P(v_t|s) \qquad (4)$$

Therefore, if the prior probability and conditional probability $P(v_t|b,s)$, $P(b|s)$and $P(v_t|s)$ at pixel s are known in advance, the pixel can be classified as background or foreground according to the Bayesian decision rule.

The statistic characteristics of the feature vector

Generally, the prior probability and conditional probability $P(v_t|b,s)$, $P(b|s)$and $P(v_t|s)$ are unknown. A type of non-parameter kernel density function is used in this paper to estimate them.

According to the principle that background pixels are subject to Gaussian distribution and mainly located in the neighborhood of the mean, from a histogram distribution of the background, the feature vectors should be highly concentrated in a small region. But when moving objects cross the space, feature vectors can spread widely in the feature space. So some small significant feature vectors can be selected to represent the background effectively.

Let V_i be the quantized feature vectors (Liyuan Li, Weimin Huang, Irene Yu-Hua Gu, Qi Tian (2002)) which are stored according to a descending order (Liyuan Li, Weimin Huang, Irene Yu-Hua Gu, Karianto Leman, Qi Tian (2003)) of $P(v_t^i|b,s)$ for each pixel (i.e. $P(v_t^i|b,s)\geq P(v_t^{i+1}|b,s)$). Then for a proper selection of features, there should be two percentage values T_1, T_2 (i.e. T_1=80%～90%, T_2=10%～20%) and a small integer N_1 which are satisfied with the following conditions:

$$\sum_{i=1}^{N_1(v)}P(v_t^i|b,s)>T_1 \quad \text{and} \quad \sum_{i=1}^{N_1(v)}P_s(v_i|f)<T_2 \qquad (5)$$

where N_1 is a small number of the principal feature vectors at pixel $s(x,y)$. It is important to cut down the computation and storage efficiently for this method's practical application.

Under the Bayesian framework, the following information should be formed for each pixel:

(1) Construct the feature vector set which can represent the background effectively. $v_t^i = [a_1^i, \cdots a_n^i]^T$, where $i = 1, \cdots, N_2$ （$N_2 > N_1$）, the feature vectors are selected differently for static and dynamic points: there are $v_t = [r_t, g_t, b_t]^T$ or $v_t = [r_t, g_t, b_t, \Delta r_t, \Delta g_t, \Delta b_t]^T$ separately.

(2) Established a table of statistics for the principle feature including the prior probability and conditional probability, such as $p_v^{t,i} = P(v_t^i | s)$ and $p_{vb}^{t,i} = P(v_t^i | b, s)$.

ALGORITHM DESCRIPTION

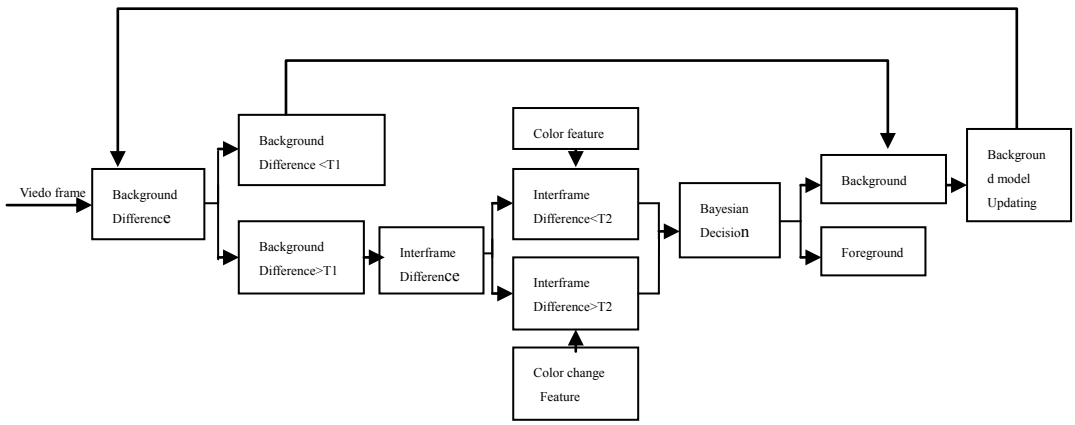

Figure1. Block diagram of the algorithm.

Arithmetic flow

Step 1: Initialize the probability of background pixels, and construct feature vectors set by learning.

Step 2: Classify each pixel by background subtraction $F_{bd}(s,t)$ and inter-frame difference $F_{td}(s,t)$. Meanwhile construct different feature vectors for static or dynamic pixels.

Step 3: Calculate the probability $P(b|s)$, $P(v_t|s)$ and $P(v_t|b,s)$ for all the stationary points and dynamic points as follows:

$$\begin{aligned} P(b|s) &= p_b^{s,t} \\ P(v_t|s) &= \sum_{i \in H(v_t)} k_i (v_i - v_t) \\ P(v_t|b,s) &= \sum_{i \in H(v_t)} k_i^b (v_i - v_t) \end{aligned} \qquad (7)$$

Suppose $v_t^{s,i}$ is the i th feature vector in the feature vector set at pixel $s(x,y)$, $H(v_t)$ is the matched feature set, where $H(v_t) = \{ i : \forall i \in \{1, \cdots N_2\}, |v_t - v_t^{s,i}| < \varepsilon \}$. The kernel function $k_i(v_i - v_t) = p_v^{s,t,i}$ and $k_i^b(v_i - v_t) = p_{vb}^{s,t,i}$, where $P(v_t|s)$ and $P(v_t|b,s)$ are probability kernel estimation functions. In this paper, the non-parameter kernel function (i.e. histogram) is to be adopted in the probability estimation.

Step 4: Decide if the pixel $s(x,y)$ is satisfied with the Bayesian rule

$2P(v_t|b,s)P(b|s) > P(v_t|s)$, and if it will be classified as background, let $s(x,y)$=0. Otherwise pixel $s(x,y)$ will be classified as foreground, in which case let $s(x,y)$=1.

Step 5: Utilize a morphological operation to remove the noise point.

Step 6: Update the probability tables and the background models.

Background and parameter updating

Probability Table Updating

$$p_b^{s,t+1,i} = (1-\alpha)p_b^{s,t,i} + \alpha M_b^{s,t,i},$$
$$p_v^{s,t+1,i} = (1-\alpha)p_v^{s,t,i} + \alpha M_v^{s,t,i},$$
$$p_{vb}^{s,t+1,i} = (1-\alpha)p_{vb}^{s,t,i} + \alpha(M_b^{s,t,i} \wedge M_v^{s,t,i}) \quad (8)$$

Where α is the learning rate, $\alpha \in [0,1]$, v_t is the feature vector at pixel $s(x,y)$. $M_v^{s,t,i}=1$ if v_t^i matches with v_t, otherwise $M_v^{s,t,i}=0$. If v_t doesn't match any vector in the feature vector set, the last vector in the feature vector set is replaced by a new feature vector, whose values are:

$$p_v^{s,t+1,N_2} = \alpha, \quad p_{vb}^{s,t+1,N_2} = \alpha, \quad v_t^{N_2} = v_t \quad (9)$$

Meanwhile, $M_b^{s,t}=1$ if the $s(x,y)$ is classified as the background by the Bayesian rule at last, otherwise $M_b^{s,t}=0$.

On the other hand, if $P(f|s)\sum_{i=1}^{N_1} P(v_t^i|f,s) > T$ (i.e. $\sum_{i=1}^{N_1} p_{vb}^{s,t,i} \cdot \left(1-\sum_{i=1}^{N_1} p_v^{s,t,i}\right) > T$ where $T \approx 90\%$), it shows that the background has sudden variations and the new features are becoming dominated immediately, the probability needs to be updated as follows

$$p_v^{s,t+1,i} = 1 - p_v^{s,t,i}$$
$$p_{vb}^{s,t+1,i} = \frac{\left(p_v^{s,t,i} - p_b^{s,t} \cdot p_{vb}^{s,t,i}\right)}{p_b^{s,t+1}} \quad (10)$$

where $i \in [1, N_1]$, $p_b^{s,t} = \sum_{i=1}^{N_1} p_v^{s,t,i}$, $p_b^{s,t+1} = \sum_{i=1}^{N_1} p_v^{s,t+1,i}$

Background Models Updating

Background subtraction has been used in the initial classification of pixels mentioned in section 2.1. To achieve this, an accurate and adaptive background is needed. So the background model should be updated in real-time.

If the background changes slowly, the background is updated as

$$B_c(s,t+1) = (1-\beta)B_c(s,t) + \beta I_c(s,t) \qquad \alpha_1 \in [0,1] \quad (11)$$

If the background changes suddenly to ($P(f|s)\sum_{i=1}^{N_1} P(v_t^i|f,s) > T$), the background is updated as $B_c(s,t+1) = I_c(s,t)$ (12)

Where, β is the updating rate of the background, $B_c(s,t)$ is the color value of pixel $s(x,y)$ in the reference background, and $I_c(s,t)$ is the color value at pixel $s(x,y)$ in the current frame.

EXAMPLES AND ANALYSIS

In order to verify the robustness and efficiency of this method, many real-time traffic surveillance videos each of whose size is 720 by 576 were tested on the VC++6.0 platform. In the experiments, the main parameters were initialized as $p_v^0 = 0$, $p_b^0 = 0$, $p_{vb}^0 = 0$. In terms of storage and computation, the number of the feature vector $v_t = [r_t, g_t, b_t]^T$ **was** set to 32, whereas the feature vector $v_t = [r_t, g_t, b_t, \Delta r_t, \Delta g_t, \Delta b_t]^T$ was set to 16. The two probability tables of every pixel of each frame can be calculated according its respective histogram. One is for stationary points and the other is for the dynamic points. The feature vectors were stored according to the descending order of $P(v_t|b,s)$. The learning rate was α. If it had been too small, the system would have been too slow to respond to the sudden background changes. In the experiment, we set the learning rate range from 0.005 to 0.01. β is the update rate of the background and ε is the match threshold. In the experiments α, β and ε are set to 0.02, 0.5, and 0.05 separately.

The following two figures show the results with different methods of foreground object detection. In Figure 2, employing mixture Gaussian models, the first column is raw video frame: 15, 46, and 110. The second column shows the background models corresponding to the first column generated by GMM. The third column is the detected foreground object. From the frame 15 to 46, the flasher is used to make the light change slightly. In frame 110, when the white car comes into the view of the camera, the light changes suddenly because of the strong light reflection. Seen from row 3, all the pixels change suddenly due to light reflection. These background pixels can be mistaken for the foreground. Thus the foreground object can't be extracted effectively from the image.

Figure 3 employs the method proposed in this paper, showing the achieved result of our proposed algorithm. The raw video frame is the same as that used in Figure 2. The first column is raw video frame: 15, 46, and 110. The second column shows the background models corresponding to the first column, but generated by the Bayesian framework both in gradual and sudden changes in their respective environments. The test indicates that the principal features are effective in representing the characteristics of their background.

The experiments were repeated under complex environments where they detected the vehicles effectively.

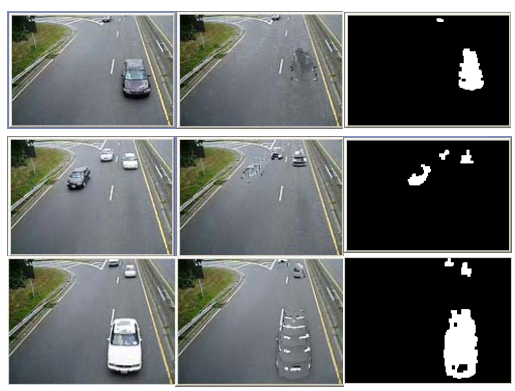

Figure3.Moving Object Detection Based on Bayesian Statistical Models.

CONCLUSIONS

In detecting foreground objects from complex environments, this paper proposed a novel statistical method for background modeling based on Bayesian decision theory. In the proposed method, different feature vectors are selected to represent the static and dynamic background pixels. From the statistics of their principal features, foreground objects are detected under a Bayesian framework. The experiments on vehicle detection were repeated with a variety of environments, and our research indicates that the proposed method using different features to model different parts of a vehicle's background is more effective than just using one type. The experimental results demonstrated a significantly improved performance in detecting foreground objects amid a complex background.

ABSTRACT

Research of the shortest path problem in time-dependent networks has important practical value. An improved pheromone update strategy is demonstrated here. Using this strategy, the residual pheromone of each path can accurately reflect the change of weighted value for each path. An improved ant colony algorithm for the shortest path problem in time-dependent networks based on our improved strategy is also presented here. The results of this experiment show that the improved algorithm has a greater probability to achieve an optimal solution, and the convergence rate of the algorithm is greater than that of a traditional ant colony algorithm.

INTRODUCTION

The shortest path algorithm plays an important role in many fields, such as communications systems and intelligent transportation systems. A large number of methods and algorithms to solve the shortest path problem have been proposed in many existing literatures, but most of them focus on a network with fixed weights, without taking into account time varying weights.

R W Hall (1986) firstly pointed out that the traditional shortest path algorithm cannot be used with time varying weight. The shortest path problem of some dynamic networks cannot be solved unless strict conditions of consistency have been established. A dynamic network model solved by the improved Dijkstra algorithm has been proposed by Tan Guozhen and Gao Wen (2002), but it has a high time complexity. A genetic algorithm has been adopted to solve the shortest path problem of dynamic networks by Liu Jianqiang and Liu Fenlin (2004), but this approach can easily lead to a premature convergence, and to a local optimal solution. A feedback

neural-network model has been used by He Hong, Zhu Daming and Ma Shaohan (2004), but it requires that the weight matrix must be symmetric and the link travel-time function must be continued and bounded. The traditional ant colony algorithm is used in time-dependent networks by Chen Lichao, Liu Jia and Lv Yanan (2007), but the pheromone update strategy cannot reflect changes in the weighted value of each side, so the efficiency of path choosing results is low.

This paper presents a pheromone update strategy of an ant colony algorithm applied to time-dependent networks, so that the residual pheromone of each path can accurately reflect its respective change of weighted value. An improved ant colony algorithm for the shortest path problem in time-dependent networks based on the improved strategy is presented below. This algorithm can be applied to both discrete and continuous networks effectively, and results not only in a fast convergence, but also greatly enhances the probability of finding a global optimal solution.

TIME-DEPENDENT MODEL

Model Description

Generally, dynamic networks are presented as (V, A, T), where $V = (v_1, v_2, ..., v_n)$ is a finite point set, A is the limited side set, and $A \in VxV$; $T = \{g_{i,j}(t) \mid (v_i, v_j) \in A, t \in [t_0, t_m]\}$ is the function of each edge (v_i, v_j), with the time extent $[t_0, t_m] \in R$. With $g_{i,j}(t)$ as a non-negative real number, this represents the time passed between joint v_i and v_j at the moment t; $t_0 \le t \le t_m, \forall t \in [t_0, t_m], t + g_{i,j}(t) \in [t_0, t_m]$.

The Shortest Path Model of Dynamic Networks

The model is described as:

$$\min \sum_{i=1}^{n-1} T_{v'_i, v'_{i+1}} \tag{1}$$

$$T_{v'_k, v'_{k+1}} = g_{v'_k, v'_{k+1}} \left(\sum_{i=1}^{k-1} T_{v'_i, v'_{i+1}} + t_s \right) \tag{2}$$

$$(v'_1, v'_2), ..., (v'_{n-1}, v'_n) \in A \tag{3}$$

$$v'_i \in V, i = 1, 2, ...n \tag{4}$$

$$0 < k < n, k \in N \tag{5}$$

With v'_0 as the starting point, v'_n as the ending point, and t_s as the departure time. The above equation (2) represents the time passed from the joint v'_k to v'_{k+1} by the path $(v'_1, v'_2, \ldots, v'_n)$ when starting off at the moment t_s. The constrained condition is (3) and (4) makes sure that the

path $(v'_1, v'_2, \ldots, v'_n)$ among the networks is connected, without any points of breakage.

THE INNOVATION STRATEGY OF A COLONY ALGORITHM

The Selection Strategy Between Adjacent Cities

The basic ant colony algorithm compares the taboo table with the other *n*-1 cities when an ant transfers from city *i* to *j*, computing the transfer probability of each city, which requires more expenditures of time.

In practical applications, ants must crawl in a network with a topology relationship. Ants cannot choose any city from all the cities in the non-taboo table, but only chooses a city with a direct path between them, and so must choose from the joints which have a path (v_i, v_j) between them. So, we only need to compute these cities' transfer probabilities, and, as a result, the calculation of the basic ant colony algorithm is greatly reduced, and our computing speed is greatly increased.

The Dynamic Pheromone Updates Strategy

There are two main points in the ant colony algorithm: one is the transfer probability computing strategy, the other is the pheromone updating strategy. The calculation of ants' transition probability also depends on the amount of pheromones we can detect. Thus in the ant colony algorithm, the pheromone update strategy is very important, since it determines the convergence speed of the algorithm.

In the basic ant colony algorithm, the pheromone update strategy can make sure that the corresponding pheromone concentrates in alignment with the path the ants chose, according to the edge weights that are unchanged after the ants accomplish a traversal.

In a time-dependent network, the edge weights are the functions of time, changing as the time changes. So a traditional pheromone update strategy cannot accurately reflect the corresponding pheromone alignment with the ants' choice of paths. Although this ant colony algorithm has a certain adaptability, and it can still lead to an optimal solution after several traversals, there is no doubt that it requires greatly increased computation time to do so.

Here we give a pheromone update strategy for an ant colony algorithm using a time-dependent network, so that we can accurately reflect the dynamic situation of the edge weights as well as the optimal solution of the chosen path.

$$\tau_{ij}(t+1) = \left[\ (1-\rho)\tau_{ij}(t) + \rho\Delta\tau_{ij} \ \right] * \lambda_{ij} \tag{6}$$

$$\lambda_{ij} = g_{ij}^{old} / g_{ij}^{new} \tag{7}$$

$$\Delta\tau_{ij} = \sum_{k=1}^{m} \Delta\tau_{ij}^{k} \tag{8}$$

$$\Delta\tau_{ij}^{k}=\begin{cases}\dfrac{Q}{L_k}, & \text{when ant k pass through the path ij}\\ & \text{between the time of t and t+1;}\\ 0, & \text{otherwise;}\end{cases} \tag{9}$$

g_{ij}^{old} and g_{ij}^{new} mean the time consuming on the road *(i,j)* before and after the update respectively.

Using this pheromone update strategy, the pheromone generated on each path after each traversal does not only reflect the optimal solution of the chosen path, but also the dynamic situation of the edge weights accurately.

The Optimal Individual Crossing Strategy

The basic ant colony algorithm leads both to the convergent solution and the local optimal one. In order to avoid such a situation, we combine the ant colony algorithm with a genetic algorithm. We first put the solution after each traversal together in the initial species, and then scanned the parents to see which ones had the same gene, and then chose the optimal gene among the gene pairs from the descendents which generated a single-point crossover in order to carry out their single-point crossovers.

This approach does not generate an unfeasible solution or enable a cross-operation with direction at the same time; not only can it speed up the convergence to a global optimal solution, but also helps avoid the local optimal solution to some extent.

The Steps of the Improved Ant Colony Algorithm

According to the improved strategy above, we propose the ant colony algorithm TDNACO, applying it to a time-dependent network. The details of this algorithm follows:

(1). At the beginning, every pheromone of the paths should be initialized by the following formula:

$$\tau_{ij}(0)=c \qquad (c \text{ is a constant}) \tag{10}$$

Set the iteration number at the same time;

(2). Put M ants on the initial node S;

(3). Calculate the transfer probability by the following formula:

$$p_{ij}^{k}(t)=\begin{cases}\dfrac{\left[\tau_{ij}(t)\right]^{\alpha}\left[\eta_{ij}\right]^{\beta}}{\sum_{l\in allow_k}\left[\tau_{il}(t)\right]^{\alpha}\left[\eta_{il}\right]^{\beta}}, & j\in allow_k\\ 0, & else\end{cases} \tag{11}$$

Where $tabu_k(k=1,2,...,m)$ means the cities that ant *k* has passed; $allow_k$ means the discrepancy between $tabu_k$ and the nodes connected with node *i* ; where $\eta_{ij}=g_{ij}(t)^{-1}$, $g_{ij}(t)$ is the time consumed on the path (v_i,v_j) when starting off at the moment *t*; then α, β shows how the pheromone and the inspiration information influence the ant's decision-making.

(4). If node *j* is not the destination node, then return to step 2, for a continued search; if *j* is the destination node, then ant *k* finds a path from the jumping-off point S to the destination, then identify the path and the time consumed as L_k.

(5). When all the M ants finish the searching task, there are M paths saved, and then the global update pheromone of each side is:

$$\tau_{ij}(t+1)=\left[\ (1-\rho)\tau_{ij}(t)+\rho\Delta\tau_{ij}\ \right]*\lambda_{ij} \tag{12}$$

$$\lambda_{ij}=g_{ij}^{old}/g_{ij}^{new} \tag{13}$$

g_{ij}^{old} and g_{ij}^{new} mean the time consumed on the path *(i,j)* before and after the update respectively.

$$\Delta\tau_{ij}=\sum_{k=1}^{m}\Delta\tau_{ij}^{k}, \tag{14}$$

$$\Delta\tau_{ij}^{k}=\begin{cases}\dfrac{Q}{L_k}, & \text{when ant k pass through the path ij}\\ & \text{between the time of t and t+1;}\\ 0, & \text{otherwise;}\end{cases} \tag{15}$$

ρ means the extent of the fading of the pheromone, $0<\rho<1$. $\Delta\tau_{ij}$ is the pheromone increment belonging to the path *ij*. *Q* is a constant, L_k is the length of the time consumed on the path from the starting point to the destination that ant *k* has passed.

(6). The M solutions need to be calculated as hybridized with each other; if the time consumed on the path is less than the result after hybridization, then the new path should replace the old one, and the pheromone should be updated for every corresponding path.

(7). Get the local optimal solution from the M solutions above according to the formula 16:

$$L_{k_{min}} = \min(L_k), (k = 1, ..., m) \quad (16)$$

(8) The minimal optimal solution from all the local solutions is the global optimal solution until now:

$$L_{min} = \min(L_{k_{min(l)}})(l = 1, 2, ..., \text{the current number of iterations}) \quad (17)$$

(9) If the number of iterations still does not reach the set number, then exit the procedure; otherwise add the number of iterations with one, then go to step 2.

THE SIMULATION RESULTS

To verify the algorithm, we needed to set up a topology network including 40 cities, and then calculate the edge weights with the TDNACO algorithm and the ACO algorithm. To simulate the actual situation of the change of the edge weights in the dynamic network, we needed to establish an independent thread, and then modified the weights randomly at a certain range every fixed time. The simulation results show that using the algorithm TDNACO makes it easier and faster to get the optimal solution than using the algorithm ACO with the same number of iterations. The simulation results are shown in Table 1.

Table 1. Simulation Results.

	TDNACO	ACO
Number of cities	40	40
Initial number of ants	8	8
Number of iterations	160	160
A	2	2
B	2	2
P	0.3	0.3
Q	1	1
Changing frequency of weights (ms)	5	5
Probability of optimal solution (%)	100	91
Average time of getting the solution (ms)	59.06	99.74

CONCLUSIONS

The research into the shortest path problem in time-dependent networks has increased practical value here, using an improved pheromone update strategy. Under this strategy, the residual pheromone of each path can accurately reflect the change of weighted value of each, as well as the optimal choice of the shortest path. Based on this improved strategy, an improved ant colony algorithm for the shortest path problem in time-dependent networks has also been presented here. The simulation results show that the algorithm TDNACO offers an easier and faster process to get the optimal solution than does the algorithm ACO with the same number of

iterations.

ABSTRACT

Extreme emergencies, whether caused by man or natural disasters, increasingly threaten urban life. Emergency traffic evacuation management is a complex procedure that includes routing evacuees, identifying exits, and designing traffic control. The evacuation routing models are vital to the evacuation planning problem. Real-time traffic evacuation management has become an increasingly attractive research topic, as a result of the rapid development and wide-spread deployment of a large number of applications for traffic data collection, processing, and dissemination.

In this paper we extend our existing work on developing Intelligent Emergency Traffic Evacuation System (IETES) as a spatial decision support system based on Exploratory Spatial Data Analysis (ESDA) technology for urban disaster environment traffic control. The IETES has been enhanced with the Dynamic Traffic Assignment (DTA) model and Real-time Evacuation Algorithm (REA) to solve emergency traffic resource distribution and dynamic existing problems. ESDA performs spatial traffic data mining and data analysis functions from urban Geographic Information System (GIS) databases to set up relation links between dynamic traffic flows and varying disaster environment, which could improve DTA and REA efficiencies. An inference engine designed on rules and cases could make IETES capable of thinking, learning, and decision supporting.

1. INTRODUCTION

Dynamic traffic assignment (DTA) models traditionally require a deterministically known time-dependent origin-destination (OD) demand matrix. However, traffic demand is rarely known in advance with certainty. At any given point in time, information is available on past and current demand levels (if a good monitoring system is in place), but future demands can, at best, only be probabilistically forecasted. However, notwithstanding this uncertainty, decisions need to be made on investment alternatives, traffic management, and control.

This paper focuses on the control of dynamic traffic systems through the development and real-time adaptations of the optimal routes for vehicles, when the OD demand is uncertain. Often, a single value for OD demand is employed for network analysis. However, if the goal of a particular DTA application is to develop route guidance and a certain demand level was used to develop an a priori path set, it

is unclear what action should be taken when predicted demand is not realized (Peeta and Ziliaskopoulos, 2002). It becomes necessary to design approaches that account for demand uncertainty and develop more comprehensive solutions that are less likely to fail under these extreme events and potentially reduce the variance of costs. The linkage between dynamic traffic flows and the environment is uncertain. How to discover the linkage for potential demand in uncertain and various extreme surroundings, the spatial decision support system with ESDA techniques maybe a possible solution.

2. DYNAMIC TRAFFIC ASSIGNMENT MODEL

The basic relationships of the cell transmission model that describe the propagation of traffic flow can be found in Daganzo (1994, 1995). The DTA model developed based on these relationships can be found in Ziliashopoulos (2000) and it is presented next for completeness. Table 1 summarizes the notations used in this model.

Table 1. Notation in Deterministic Model

SYMBOL	DESCRIPTION
k	Density
C	The set of cells: diverging cells(C_D), Merging cells(C_M), source cells(C_R) and sink cells(C_S)
T	The set of discrete time intervals
x_i^t	Number of vehicles in cell i at time interval t
N_i^t	The maximum number of vehicles in cell t at time interval t
y_{ij}^t	The number of vehicles moving from cell i to cell j at time interval t
E	The set of cell connectors: ordinary cell connectors(E_O), merging cell connectors(E_M), diverging cell connectors (E_D), source cell connectors(E_R), and sink cell connectors(E_S)
Q_i^t	The maximum number of vehicles that can flow into or out of cell i during time interval t
δ_i^t	The ratio v/w for each cell and time interval
$\Gamma(i)$	The set of successor cells to i
$\Gamma^{-1}(i)$	The set of predecessor or cell to cell i
d_i^t	The demand (inflow) at cell i in time interval t

$$\text{Minimize} \quad \sum_{\forall t \in T} \sum_{\forall i \in C/C_s} x_i^t \tag{1}$$

$$\text{Subject to:} \quad x_i^t - x_i^{t-1} - \sum_{k \in \Gamma^{-1}(i)} y_{ki}^{t-1} + \sum_{k \in \Gamma^{-1}(i)} y_{ij}^{t-1} = 0 \qquad \forall i \in C \setminus \{C_R, C_S\}, \forall t \in T, \tag{2}$$

$$y_{ij}^t - x_i^t \le 0, \quad y_{ij}^t \le Q_i^t, \quad y_{ij}^t \le \delta_j^t x_j^t \le \delta_j^t N_j^t \quad \forall (i,j) \cup E_O \quad \forall t \in T, \tag{3}$$

$$y_{ij}^t - x_i^t \le 0, \quad y_{ij}^t \le Q_i^t, \quad \forall (i,j) \quad E_S, \forall t \in T, \tag{4}$$

$$y_{ij}^t \le Q_j^i, \quad y_{ij}^t + \delta_j^t x_j^t \le \delta_j^t N_j^t \quad \forall (i,j) \quad E_D, \forall t \in T, \tag{5}$$

$$\sum_{\forall j \in \Gamma(i)} y_{ij}^t - x_i^t \le 0, \quad \sum_{\forall j \in \Gamma(i)} y_{ij}^t \le Q_i^t \quad \forall i \in C_D, \quad t \in T, \tag{6}$$

$$y_{ij}^t - x_i^t \le 0, \quad y_{ij}^t \le Q_i^t \quad \forall (i,j) \quad E_M, \forall t \in T, \tag{7}$$

$$\sum_{\forall i \in \Gamma^{-1}(i)} y_{ij}^t \le Q_i^t, \quad \sum_{\forall i \in \Gamma^{-1}(i)} y_{ij}^t + \delta_j^t x_j^t \le \delta_i^t N_j^t \quad \forall j \in C_M, \forall t \in T, \tag{8}$$

$$x_i^t - x_i^{t-1} + y_{ij}^{t-1} = d_i^{t-1}, \quad j \in T(i) \quad \forall i \in C_R, \forall t \in T, = x_i^0 \quad \forall i \in C, \tag{9}$$

$$y_{ij}^0 \quad \forall (i,j) \in E, \tag{10}$$

$$x_i^t \ge 0 \quad \forall i \in C, \forall t \in T, \tag{11}$$

$$y_{ij}^t \geq 0 \quad \forall (i,j) \in E, \forall t \in T, \tag{12}$$

Note that the boundary conditions consist of the states of the sink and source cells and the initial value x_i^0 of all cells $i \in C$, The sink cells are set to have infinite capacities ($N_i^t = \infty \quad \forall i \in C_S, \forall t \in T$) and allow infinite input flows ($Q_i^t = \infty \forall i \in C_S, \forall t \in T$). Thus, their occupancies are not constrained. The input flow to a sink cell will be determined by the state and characteristics of its predecessor cell. The source cells have infinite capacity ($N_i^t = \infty \forall i \in C_R, \forall t \in T$) but finite output flow. The basic relationship of the source cells is as follows:

$$x_i^t = x_i^{t-1} + d_i^{t-1} - y_{ij}^{t-1}, \quad j \in \Gamma(i) \forall t \in T,$$

Where d_i^t is the demand (inflow) at cell i in time interval t. The initial values x_i^0 can be set to initial traffic conditions in the network at the beginning of the time period of interest. In the following section, we relax the assumption of determinism d_i^t and instead we treat it as a random variable with known probability distribution. In general, for both planning and operational applications, it is unclear what action should be taken or what the cost is, when the forecasted demand is not realized.

It becomes necessary, therefore, to develop a systematic way of accounting for uncertain demand and to develop a more comprehensive solution, which is more likely to withstand extreme events. One such possibility is to run the deterministic model with a large number of randomly generated demand patterns, and to infer some rules and principles from results. Such an approach has been proposed by Peeta and Zhou (1999) to produce comprehensive DTA solutions. The only drawback with this approach appears to be the computational requirements of a single DTA run and the enormous amount of scenarios that need to be run to produce meaningful results and inferences.

3. EXPLORATORY SPATIAL DATA ANALYSIS MODEL

Data mining, or knowledge discovery in a database, is a technique of analyzing data to discover previously unknown information. The goal is to reveal regularities and relationships that are not easily found. This is accomplished through an analysis of the patterns that form in the data. Various algorithms have been developed to perform this analysis. Spatial data mining differs from regular data mining in conjunction with the differences between non-spatial data and spatial data. The attributes of a spatial objects stored in database may be affected by the attributes of neighbor objects. In addition, spatial location, and implicit information about the location of objects, may be the exact information extracted by spatial data mining.

Many spatial data mining methods are used for knowledge discovery from the GIS database. Compared with other methods, Exploratory Spatial Data Analysis (ESDA) technology is more suitable for IETES. ESDA technology matured from computational geography. Essential to ESDA is a kind of “data drive” analysis method. It put emphasis on spatial relations and differences of data. Null hypothesis is ESDA technology’s application condition. ESDA technology includes spatial weight matrix, variation chat, and spatial relation analysis technology. They are introduced as the following:

The definition of spatial weight matrix is the key difference between spatial

statistics and traditional statistics. That is also the foundation of utilizing ESDA. The goal of establishing a spatial weight matrix is to definite spatial objects' adjacent relationships. The formula of spatial weight matrix is as:

$$\mathbf{W} = \begin{bmatrix} W_{11} & W_{12} & \cdots & W_{1n} \\ W_{21} & W_{22} & \cdots & W_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ W_{m1} & W_{m2} & \cdots & W_{mn} \end{bmatrix} \tag{13}$$

Adjacent rule of above matrix (where i=1, 2, …, n; j = 1, 2, …, m):

$$W_{ij} = \begin{cases} 1 & \text{Position of } i \text{ is adjacent to that of } j; \\ 0 & \text{Position of } i \text{ is not adjacent to that of } j. \end{cases} \tag{14}$$

If we define distance "d" between two objects is the adjacent range, the rule will be:

$$W_{ij}(d) = \begin{cases} 1 & \text{Distance of } i \text{ and } j \le \mathrm{d}; \\ 0 & \text{Distance of } i \text{ and } j > \mathrm{d}. \end{cases} \tag{15}$$

Two rules mentioned above can be used together and separately. If two objects are not at adjacent physical position, but they are related closely, usually we regard they are neighbors. The spatial weight matrix is a prejudgment of spatial objects' relations.

Variation chat reflects the relations and changing trend of spatial data. Connotative knowledge can be discovered through variation chats. Theory variation chat, experimental variation chat, and cloud variation chat are often used in spatial data mining. Theory variation chat is presented as:

$$\gamma(h) = \frac{1}{2} E\left[\left(Z(x) - Z(x') \right)^2 \right] \tag{16}$$

x is an observation position, and x' is the other adjacent observation position. Further more $h = x' - x$ means the distance between the pair of observation position x and x'. Function $Z(x)$ is the value of target point Z at position x. So the theory variation $r(h)$ describes position relations of point Z at distance h.

To discover spatial objects' distribution mode, spatial relation analysis technology is be used. It includes Moran Iand Geary C statistics. Those are all core concepts of ESDA technology.

Moran I model has the definition of:

$$I(d) = \frac{\sum_{i}^{n} \sum_{j \neq i}^{n} w_{ij} (x_i - \bar{x})(x_j - \bar{x})}{S^2 \sum_{i}^{n} \sum_{j \neq i}^{n} w_{ij}} \tag{17}$$

Here $S^2 = \frac{1}{n} \sum_{i}^{n} (x_i - \bar{x})^2$, x_i means target observe value at position i. $\bar{x} = \frac{1}{n} \sum_{i=1}^{n} x_i$; w_{ij} is the spatial weight value.

The Moran I model can be used to measure spatial relativity to discover differences and relationships of observation. When observation values are adjacent within some distance "d", Moran I is prominent and positive. When they are not adjacent, it is negative. When the observation values distribute at random, Moran I is null.

Geary C model always included positive distribution in asymmetry. The model is as follows:

$$C(d) = \frac{(n-1)\sum_{i}^{n}\sum_{j}^{n} w_{ij}(z_i - z_j)^2}{2nS^2\sum_{i}^{n}\sum_{j}^{n} w_{ij}} = \frac{(n-1)}{2n^2}\sum_{i}^{n} C_1(d) \tag{18}$$

Assume Geary C statistics are the model average value. When there is no spatial correlation that value is 1. Low and prominent value (0, 1) indicates positive spatial correlation. High and Prominent value (>1) indicates negative spatial correlation (Cliff A D 1981).

4. IETES ESDA PROCEDURE

The goal of knowledge discovery is to find out hidden information from a mass of problems to help urban planning. Connotative knowledge can be discovered from a GIS database by ESDA technology. The general process of knowledge discovery by ESDA in data manager module is running like a loop (Fig. 1), which is called an Artificial Intelligence Learning Loop.

The loop is composed of three steps. The first step is called "needed connotative knowledge confirmation" based on null hypothesis. It determines whether we could find out useful information from raw data, and what kind of information could be discovered. It is the only constraint to stop the loop. IETES provides an interface program for users' interference.

The second step is the process of data mining is combined in two consecutive parts, discovery scope definition and ESDA performance. Discovery scope definition could be executed by GIS database filter with running general attribute mining programs. It aims at providing a definite spatial data mining scope matched with a problem description for ESDA. Within a definite scope and given environment, the ESDA program could perform spatial data mining process in a GIS database for knowledge discovery.

The last step of the loop is verifying results. Knowledge discovered by ESDA engine is unilateral and lacking in experience accumulation, so it is too rough to solve problems. According to planners' experiences and stored knowledge in the knowledge base, the raw results should be verified. New knowledge brings new understanding of those problems. The learning loop needs another run for further discovery. The loop would meet its end until the problems are solved or no more new discoveries could be found. Usually the loop would be stopped after several cycles according to the complexity of the problems.

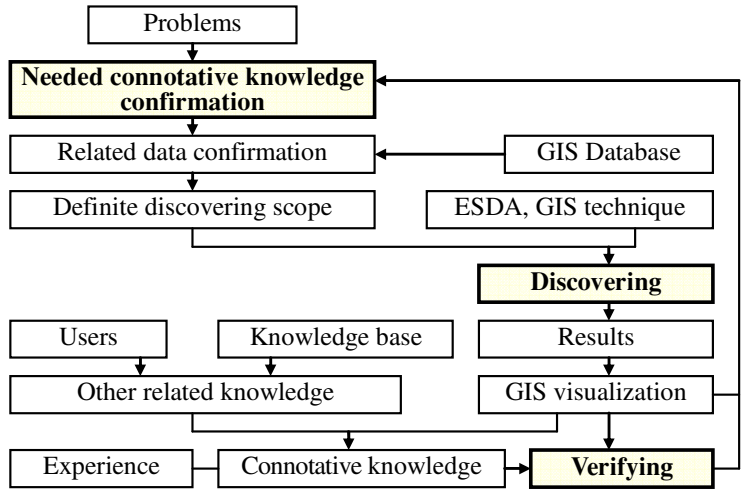

Figure 1. Framework of discovering knowledge from GIS database

There are two kinds of inference modes of IETES. One is based on rules and the other is based on cases. Inference based on rules indicates the action of deriving logical conclusions from regulations known or assumed to be true. The general idea of inference based on rules is setting up communications between the GIS database and knowledge base. Usually rules inference and cases inference (structure analysis and case models) work together for decision supporting and knowledge expression. A working mechanism of inference based on rules and cases is shown in Figure 2.

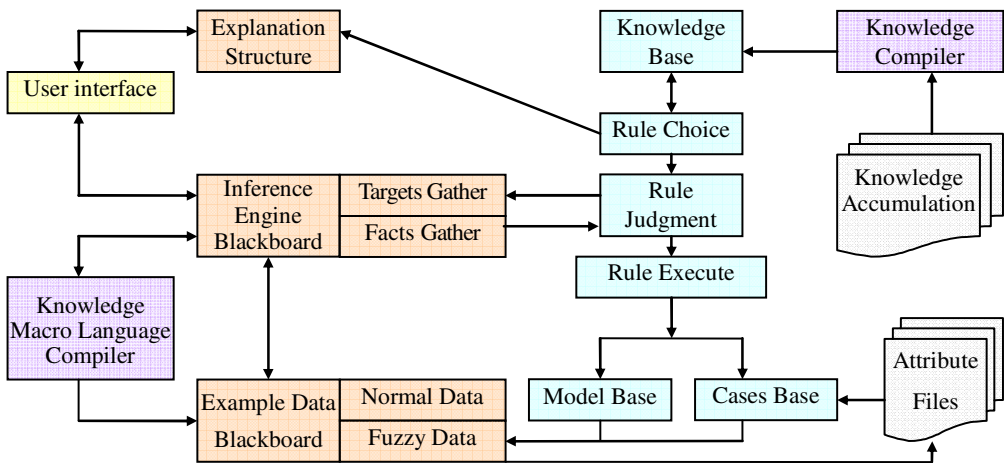

Figure 2. Working Mechanism of Inference Based on Rules and Cases in IETES

6. CONCLUSION

A combination of DTA and ESDA provides a reliable approach to solve temporal-spatial related problems for emergency traffic control. We developed an intelligent system, IETES, to perform an automatic procedure for emergency decision supporting. Real-time traffic flows' temporal-spatial relations could be discovered from the GIS database by the ESDA module in IETES. Such a relation makes it possible for the DTA module to fulfill traffic resource distribution for emergency use. Inference engines based on cases and rules endow IETES with the

capability of thinking like humans. As an intelligent system, IETES could "learn" from cases and "remember" by accumulating discovered knowledge.

ABSTRACT

In this paper, the estimation of origin-destination (OD) matrices for public traffic passenger flow is given. As the basis of transit scheduling, more accurate OD matrices mean more scientific operations and more rational utilization of staff and vehicles. In order to improve the estimation precision, characteristics of a passenger's trip, land use around bus stops, and transferring function are considered. Kolmogorov-Smirnov (K-S) Test method is adopted to analyze the trip stops. The result shows that it follows a Poisson distribution. According to passengers boarding and alighting, the OD estimation based on the trip's character is present. Attracting coefficient and weight are employed to estimate the OD matrices based on the land use around the stops. The stop significant coefficient, which relates to the route number of stations as starting, ending and midway, is also proposed to estimate the OD matrices based on transferring function. Analytic hierarchy process (AHP) is used to combine these three factors, and the last OD matrices are gained. Real data are applied to test the estimation methodology. Good agreement between predicted and observed matrices is found, and the results prove that the method is feasible to heighten accuracy.

INTRODUCTION

Large scale direct sampling of passenger OD is costly and it is prone to biases and errors. The estimate of OD matrix is an essential source of traffic demand information for most transit planning processes, and for the management and control of the transit system. A good deal of models and methods have been researched for the estimation of OD matrices in road networks, but to our knowledge, not many papers on the problem of transit passenger OD estimation had been presented in literature. Notable examples include the paper by Lam et al. (2003), who investigated the transit passenger OD estimation problem in congested transit networks where updated passenger counts and outdated OD matrices are available. Li and Cassidy (2007) presented an algorithm to generate estimates based upon passenger boarding and alighting counts at each stop along a route. In the statistical approach, Cascetta and Nguyen (1988) presented a broad review of statistical estimation procedures for the OD matrix, including maximum likelihood and Bayesian estimation. Wong and

Tong (1998) presented a maximum entropy estimator.

However, all the above studies had not considered using the land around bus stops and transferring function, even though both are important. The flow's character is analyzed by K-S Test method. AHP is introduced to combine the above three factors and to obtain the last OD matrices estimation. The scope of this paper is eminently practical, and this paper is organized as follows. In Section 2, on the basis of the surveyed data, the trip's character was drawn. Some useful concepts and notations are proposed. Section 3 describes the estimation formulation. A case study is provided in Section 4 and the conclusions are given in Section 5 together with suggestions for further studies.

PREPARATIONS

Distribution of trip. The survey route is 212 Road in Changzhou. It has fourteen stops. Taking one trip as an example (as shown in **Table 1**), it is analyzed by the single sample Kolmogorov-Smirnov test (K-S test), and the results are shown in **Table 2**.

Table 1. Statistics for passengers and stops

Stop	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Counts	6	8	13	16	14	10	4	8	5	2	3	3	2	1

It is well known that the traveler's distance is similar to following a normal distribution. It means that most of the travel time between origin and destination are concentrated in an area. Passengers, who travel by bus, get off the bus at one stop at the biggest probability, after having traveled a certain number of stops.

Table 2. K-S test result

		Data
Sample Size		95
Parameters of Poisson Distribution	Average	5.4842
Difference	Absolute Value	0.093
	Positive	0.093
	Negative	-0.070
Test Statistics		0.903
P Value		0.389

From **Table 2**, the value of P is 0.389, which is far larger than 0.05, and so it is accepted that the stops of trip follows a Poisson distribution.

Land use around stops. It is well known that different land uses correspond to different trip products and attractions. We quantitated the land use around stops by using boarding and alighting counts. As is eminently practical, there are seven classes of land use: living space, public facilities (including office administration, health, education, etc.), commercial space, industrial space, external traffic (railway stations, bus stations, etc.), streets and squares (parking, etc.), and others (Dou, 2006). Moreover, in urban public transit, work or school passengers are the majority, so attracting coefficients of living and industrial space are defined as one (as shown in

Table 3). Different routes have different attracting coefficients of any class, but the method of quantification is not change.

Table 3. Attracting coefficients of every land use

id	1	2	3	4	5	6	7
Land Use	Living	Public Facilities	Commercial Space	Industrial Space	External Traffic	Streets, Squares	Others
Coefficients	1.0	0.7	1.1	1.0	1.2	0.8	0.6

Transferring function. Generally, the more routes at a stop, the bigger possibility of transferring at the stop, and the more passengers attracted. It also means that, the larger scale of the stop, the more passengers.

FORMULATION

Maximum entropy (ME) method is adopted, for it is the best among the methods such as generalized least square method, maximum likelihood method, and information minimizing method (Chen et al., 2003; Liu et al., 2007). Suppose we have OD matrices along a route with *n* stops. Let $O(i)$ be the number of passengers boarding at the stop i. $X_1(i,j)$ is denoted as the OD matrix based on characters of passenger flow. The simultaneous probability of OD traffic flow is W, as follows, $W(X_1(i,j)) = X_1(i,j) * X_1(1,2)^{x_1(1,2)} * X_1(1,3)^{x_1(1,3)} \cdots * X_1(n-1,n)^{x_1(n-1,n)} / \prod_{i,j} X_1(i,j)!$, where $x_1(i,j)$ was surveyed. Because $\max W(X_1(i,j))$ equals to $\max \ln W(X_1(i,j))$, applying the Stirling's Formula: ln X!=XlnX-X, we get the mathematical model as follows,

$$\begin{cases} \max \ln W(X_1(i,j)) = -\sum_i \sum_j (X_1(i,j) \ln X_1(i,j) / x_1(i,j) - X_1(i,j)) \\ s.t. \quad \sum_i \sum_j X_1(i,j) P_k(i,j) = V_k, k = 1,2,...,2(n-1) \\ V_k = \sum_{j=i+1}^{n} X_1(i,j), k = 1,2,...,n-1 \\ V_k = \sum_{i=1}^{j-1} X_1(i,j), k = n, n+1,...,2(n-1) \end{cases},$$

and $P_k(i,j)$ is the coefficient correspond to V_k. Applying the method of Lagrangian Multipliers, we obtain the maximum entropy estimate of $X_1(i,j)$ as

$X_1(i,j) = x_1(i,j)\prod_k (\lambda^k)^{p_k(i,j)}$, where $\lambda^k = \exp(-\mu^k)$, μ^k is the Lagrangian operator.

$$V_k = \sum_i \sum_j [x_1(i,j)\prod_k (\lambda^k)^{p_k(i,j)}]P_k(i,j)$$

We adopt the solution presented by Liu (2007), because of the solution's simpleness and accuracy. For stop j, let S_{jl} be the land area of l ($l = 1,2,...,7$), and let X_l be the attracting coefficients. The attracting weight of stop j (Z_j) could be calculated. Let $X_2(i,j)$ be the OD matrix based on the land use around stops. $X_2(i,j) = O(i)Z_j / \sum_{i+1}^{m} Z_j = O(i)\sum_l S_{jl}X_l / \sum_{i+1}^{m}\sum_l S_{jl}X_l$, where $O(i) = \sum_{j=i+1}^{n} X_1(i,j)$. It is assumed that there are n_{1j} midway routes, n_{2j} starting routes, and n_{3j} ending routes at stop j. And the weight of j stop scale is defined as $T_j = n_{1j} + \lambda_1 n_{2j} + \lambda_2 n_{3j}$. λ_1, λ_2 are respectively given the coefficient as starting and ending stop).Let $X_3(i,j)$ be the OD matrix based on transferring function.

$$X_3(i,j) = O(i)T_j / \sum_{i+1}^{m} T_j = O(i)(n_{1j} + \lambda_1 n_{2j} + \lambda_2 n_{3j}) / \sum_{i+1}^{m}(n_{1j} + \lambda_1 n_{2j} + \lambda_2 n_{3j})$$

How to get a feasible OD matrix integrating the three factors? AHP is adopted. The last OD matrix is $X(i,j) = \eta_1 X_1(i,j) + \eta_2 X_2(i,j) + \eta_3 X_3(i,j)$.

By investigation from relevant experts, we give the three factors' impact coefficients, as follow:

$$A_1 = \begin{pmatrix} 1 & 3 & 3 \\ 1/3 & 1 & 1 \\ 1/3 & 1 & 1 \end{pmatrix}; A_2 = \begin{pmatrix} 1 & 2 & 7/3 \\ 1/2 & 1 & 8/5 \\ 3/7 & 5/8 & 1 \end{pmatrix}$$

Table 4. Combination coefficients

Characters of Passenger Flow η_1	Land Use Around Stops η_2	Transferring Function η_3
0.5570	0.2430	0.200

Consistency of the above two matrices' is tested by AHP, and the combination coefficients are shown in Table 4. In order to check the effectiveness of estimation,

ER is introduced (Eq. 10), and its value is between zero and one. The smaller theER's value, the better fit between estimation and measure. $x(i, j)$ is the measured number of passenger who board at stop i for stop j.

$$ER = \sqrt{\sum_i \sum_j (x(i,j) - X(i,j))^2} \,/\, (\sqrt{\sum_i \sum_j x^2(i,j)} + \sqrt{\sum_i \sum_j X^2(i,j)})$$

NUMERICAL EXAMPLE

Take 20 Road of Changzhou as an example (Chen Xuewu, 2008), one trip (start from 7:30 a.m., down direction) was surveyed. The data of 21 stops' boarding and alighting counts are shown in **Table 5**, and the results are shown in **Table 6**.

Table 5. Original data

Stop	1	2	3	4	…	18	19	20	21
Boarding	33	51	22	17	…	2	1	0	0
Alighting	0	2	1	3	…	9	7	12	25

ER (%)	18.32	28.17	39.65	9.24

CONCLUSIONS

In this paper, three factors are considered separately in advance, and then are integrated by AHP. A real example shows that the combination has a better result. It proves that the proposed method could indeed improve the estimation accuracy. However, some parameters are required to be investigated by the expert. The researchers will have a further study on the scientific decision of parameters' value.

ABSTRCT

Urban traffic control is a large and complex system. When traffic congestion occurs it generally cannot be resolved by the workings of a single intersection. Using a multi-agent system to set up a traffic control framework, we can simulate different control strategies. We have defined different kinds of traffic-control-agent classes while researching the interactions and dynamic adapting mechanism among agents. Utilizing self-organization and sliding window skills, we have designed an effective congestion control mechanism. In simulating the traffic environment, we obtained a valuable experimental result.

INTRODUCTION

The goals of an intersection's traffic signal include maximum traffic capacity, a shorter average delay, shorter length of waiting in queue, and so on (He et al, 2002, Wang et al, 2006,Wen et al, 2001). When traffic congestion occurrs, it generally cannot be resolved by the workings of a single intersection. A systemized approach is necessary, in order to analyze and describe a traffic system and then work out ways to control an ongoing traffic problem. To do so, we need to use a better research method than the class idea. As a result of the development of computing technologies, artificial evaluation systems based on multi-agents have proven to be an effective choice to analyze and control complex traffic systems (Zheng et al, 2006).

In this paper, both traffic control architecture and the coordination mechanism are determined by the agents. Using this framework, an intersection is defined as an intersection agent, and the road section is described as a road segment agent. Therefore, different kinds of agents and the relationship among them have mapped a complex traffic network. Under normal traffic conditions, the relationship between agents is light, but when an abnormal situation appears to affect one agent, it may either be resolved by itself or it may need the help of other, connected agents. Depending on the specifics of each incident and its effects, we have set up a self-organizing system to adjust to and address the problem.

THE TRAFFIC AGENT MODEL

First, some definitions follow in order to make this process clear.

Definition 1: Under ideal conditions, the speed of a vehicle is the constant v_0 while passing through the intersection, its passing time is t0, and t0 is decided by

$T0=S/V_0$

And *s* is the distance through the intersection, as shown in Figure 1.

This indicates that no delays exist when the vehicle passes through the intersection.

If a vehicle slows-down from v_0 to v_i while passing through an intersection, the vehicle's delay time is t_d, which is decided by formula (1); if there is a traffic queue, the vehicle's waiting time is t_w while waiting at the red light.

$$t_d = \begin{cases} 0 \quad ; \ v = v_0 \\ 2*((v_0+v_i)/(v_0-v_i))*(s/v_0) \quad ; \ a = (|v_i - v_0|)/t \quad is \quad cons\tan t \\ 2*(v_0+v_i)/(v_0-v_i)*(s/v_0)+(n*(d_s+d_v)+s)/v_0+t_w \quad ; \end{cases} \tag{1}$$

Where n is number of waiting vehicles in the queue, d_s is their inter-vehicle distance, and d_v is the standard length of each vehicle.

Definition 2: The length of a waiting queue q(t) is decided by the formulation (2)。

$$q(t+\Delta t) = \begin{cases} q(t)+u_a(\Delta t)*\Delta t - v_a(\Delta t)*\Delta t \quad , green \quad time \\ q(t)+u_a(\Delta t)*\Delta t \quad , red \quad time \end{cases} \tag{2}$$

Where $u_a(t)$ denotes a vehicle's speed of arrival at the intersection, $v_a(t)$ denotes a speed of departure from the intersection, and q (t) denotes the number of vehicles stopped until the time t.

An intersection and its lanes can be tracked so as to reflect their ability to respond to the traffic's status at given times and their ability to buffer conditions for a given vehicle. The length of a vehicle queue in an intersection is related to the speed of a vehicle's arrival, the speed of a vehicle's departure, and its previous status, but is not related to its future status.

Definiton 3: The first-in first-out server (FIFOS) is the vehicle which first arrives at the intersection and will first leave the intersection. Overtaking other vehicles and jumping the queue are not allowed.

Definition 4: (FIBS) is the first-in back server, this denotes a vehicle that arrives later but is first served.

One intersection-agent adopts the fuzzy control strategy. The longest queue and the maximum quantity of arrival vehicles in a lane are input parameters of the intersection, while the traffic signal phasing and signal timing scheme are determined by a fuzzy controller (He et al, 2002, Wang et al, 2006,Wen et al, 2001) in order to reduce the vehicles' mean delay time.

Intersection agent. Fuzzy control is one of the most effective methods to realize the control of an intersection signal (Liu and Wang, 2004, Ehlert and Rothkrantz, 2001). The intersection agent can make use of a fuzzy strategy to

model intelligence. Intersection agents need to control the intersection signal and to coordinate with other agents. Therefore, we have designed a two-fuzzy intelligent traffic control system of isolated intersections. A block diagram of an intersection agent is shown below, in Figure 1.

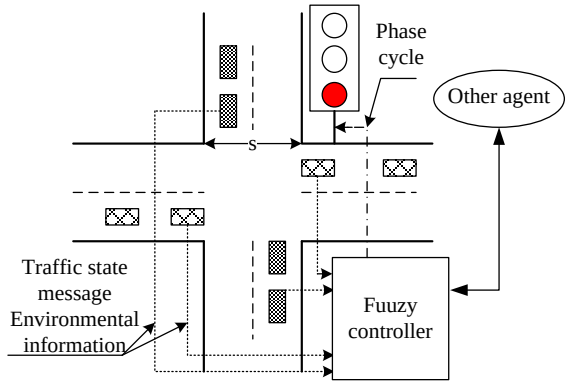

Figure 1. Block diagram of intersection agent.

The road segment agent. The goal of the road segment agent is to adjust the flow according to the traffic's status. It realizes this aim through restricting speed instruction. The speed is restricted by forecasts and statistical attributes of the flow and is then communicated via output to traffic speed signals. When the road agent receives another agent's request message to increase or reduce output speed, it can modify the traffic speed signal intelligently. A diagram of the Road section agent is shown below in Figure 2.

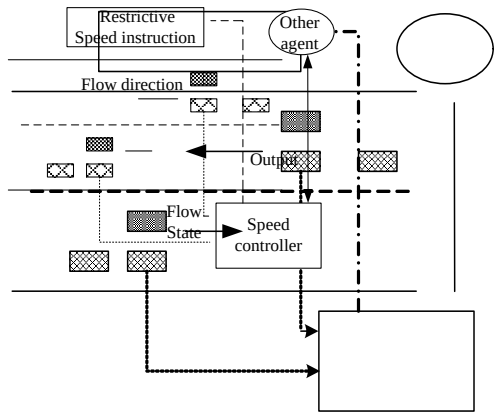

Figure 2. Road segment agent.

AREA TRAFFIC COORDINATION CONTROL

An area traffic network consists of a group of basic agent units. According to the statement above, the basic unit of an agent is divided into an intersection agent and a road segment agent. A intersection agent controls the traffic signal, including the phase, cycle and split, and the status information from that agent is communicated to the neighborhood agents. The road segment agent adjusts the speed and time occupancy rate of the vehicles, the status information of the agent notifies its neighborhood agents. The neighborhoods of an intersection agent are directly interconnected road segment agents, but when two intersections are very

close, we ignore the connection road and consider the neighborhood as being the next intersection.

Coordination process. Traffic flow queue length increases when the intersection's congestion is beginning to emerge. After some signal cycles, the intersection's congestion will become more serious if its status has not changed. At this moment, the agent needs to seek help from its neighborhoods, and multiple agents start to coordinate. When its neighborhood agents get a message requesting help, they take a series of steps to reduce the vehicle flow into the congested intersection. These steps include reducing the vehicle speed for an upstream road agent or improving the vehicle speed for a downstream agent, in order either to decrease green time or cycle for the upstream intersection agent or to increase green time or cycle for the downstream agent. Road segment agents take the FIBS to restrict speed, and intersection agents use the FIFO to improve capacity.

The size of a coordination domain and the number of agents needed to be enjoined are decided by the congestion level. Since the traffic parameters are time-varying, therefore, this multi-agent coordination is self-organizing.

A neural network based on unsupervised learning is self-adaptive to adjust the network by learned form samples, and the network can adapt to the new input samples. A self-organizing feature map can discern analogous input vectors from learning, and the neighborhood analogous inputs have the same answer.

Figure 3 shows the neural network model of a multi-agent self-organizing feature map in an area traffic control system.

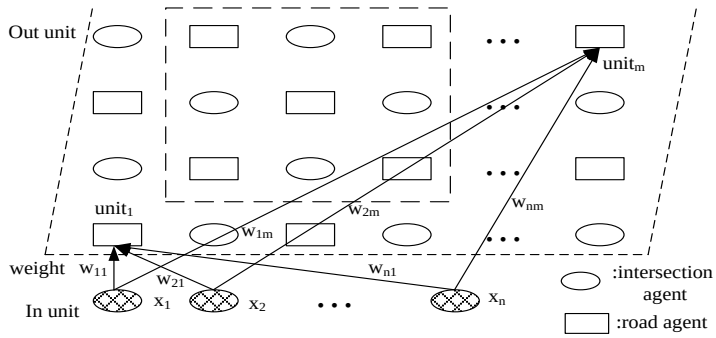

Figure 3. Self-organizing Feature Map Model.

Learning algorithm. The status parameters of a intersection agent represent the input vector of the control system, where X denotes input vector, $X=[x_1,x_2,\ldots,x_n]^T$, output unit is arranged on a 2-d grid, and W is the defined weight vector of the i^{th} output unit, $W=[w_{1i},w_{2i},\ldots,w_{ni}]^T$, (i=1,2, …,m);

The winner unit is decided by

$$q(x) = \min_{\forall i} \|x - w_i\| \tag{3}$$

Where q(x) points to the winner unit of its input x, it represents x and its neighborhood to emerge from an abnormal traffic state, according to the severity level of the incident we determine the neighborhood N_q (k), and to modify the

weight as formulation (4).

$$w_i(k+1) = w_i(k) + \eta_{qi}(k)[x(k) - w_i(k)] \tag{4}$$

Where focal functions $\eta_{qi}(k)$ are defined by

$$\eta_{qi}(k) = \begin{cases} \mu(k), i \in N_q(k), o < \mu(k) < 1 \\ 0, i \notin N_q(k) \end{cases} \tag{5}$$

Learning efficiency function $\mu(k)$ decreases with time.

Learning as traffic proceeds modifies the weight efficiency according to the facts, as vehicles resume a normal traffic state.

Improved algorithm. 1) In using the above method, the workload increases with an increase in the number of agents, with a position for a sliding window, and where l is size of the window, the input vector is written

$$x \in \{x1, x2, \cdots xi, \cdots\}, X = [x_i, x_{i+1}, \cdots, x_{i+l}]\text{，} \quad \text{i=0，1，2，…；}$$

2) The learning efficiency can be improved by designing a learning strategy. The status and action of the agent is used to grasp all the estimated results of status-action to decide which action to take next. Therefore, Q-learning [4] is a good idea with a higher convergence speed.

Interaction protocol. Protocol mainly includes message format and communication interaction processes.

The message is composed of an ID, the time, type of help, and level. ID shows the agent's physical position, and the time includes the incident's start time and end time, type of help and level describes the degree of severity and type of help sought.

Communication processes use a "handshake" idea. Firstly, the agent puts out a call for help, the neighborhood agents get the help message to adjust the program at their individual position, and they send a response. The process is repeated until normal traffic status reappears. If the neighborhood agent cannot help, it broadcasts the help message to its neighbors, and then repeats the above processes.

SIMULATION EXPERIMENT

In order to verify the view of multi-agent coordination, we set up an area of traffic coordination simulation architecture that included a 4x3 and 8x6 intersection using C^{++} language. Assuming the length of the road segment is 1 km, each intersection has 2 lanes, and its 4-phase max of cycle time equals 120s, the vehicle speed in each section is 30 km/s, and the simulation results compare to the fixed cycle, as shown in Table 1 and Table 2.

Table 1. Simulation results by 4x3.

	Intersection average value in area		
	Queue q(t)	Delay td(s)	Leave vehicle
Agent excellent	14	120	17
Agent bad	17	135	14
Fixed cycle	17	138	14

Table 2. Simulation results by 8x6.

	Intersection average value in area		
	Queue q(t)	Delay td(s)	Leave vehicle
Agent excellent	12	118	15
Agent bad	15	131	13
Fixed cycle	18	140	12

We compared Table 1 and Table 2, to discover the more effective process with the greater number of agents and area size of traffic coordination under a heavy congestion situation. Our simulation results found that agent coordination is frequently necessary when traffic congestion and multi-agent coordination control can relieve congestion effectively, but when the traffic is normal, traffic agents are related lightly and there is no obvious difference between using a multi-agent coordination system and a fixed cycle control model.

CONCLUSION AND FUTURE RESEARCH

In this paper, the intersection agent and the road segment agent are separately defined while the feature and function of different agents are more specifically described. We designed a traffic coordination model and simulation plan based on multi-agent coordination by means of a message system allowing agents to request and receive help. When traffic incidents emerge, the multi-agent coordination is available to respond. A position sliding window algorithm can reduce the computing scale. Further efforts can be pursued to improve the features of each agent and the specific coordination mechanisms of agents' actions.

ABSTRACT

Vehicle delay, stopping times, queuing length and API are selected as the evaluation vectors and a comprehensive AHP evaluation model is proposed to assess the constructed signal control method. Typical arterials are chosen to conduct the simulation tests by VISSUM, including Beixin Str. for passenger transport arterial, West Liaohe Rd. for freight transport arterial and Xuefu Rd. for mixed transport arterial. Comparison is done between the normal signal control method and the proposed one. The simulation result shows that the proposed signal method can decrease the vehicle delay and improve the average velocity significantly.

LITERRATURE REVIEW

City road traffic signal control systems are widely used in foreign countries so that the basic theories and algorithms have reached a mature state, which formed the offline systems TRANSYT represented and the adaptive systems SCOOT and SCATS represented. Either from the engineers' points of view or from the administrator's points of view, the evaluations of the systems' effect are important to discriminate test means, which are also the essential references for optimizing signal control parameters, and adjusting and perfecting the system.

Hunt et al. (1982) applied the analytical hierarchy process to study the assessment of the traffic control systems and analyzed the effectiveness of the indicators based on SCOOT. Chard and Lines (1987) systematically introduced the traditional traffic control evaluation model and methods. Papageorgiou proposed the evaluation indicators system of Rout Traffic Control Strategy for Real-time and chose a typical southern city of Paris as the case to verify its efficiency.

Aiming at serving the entire users, the assessment of coordinated signal control system is very important for controlling the size of facilities, saving investment and developing an appropriate traffic control measures at an acceptable

level in order to maximize the benefits of system and guide planning and designing a balanced system. For example, Shanghai successfully developed the Chinese-made adaptive signal control system, SUATS, based on the introduced SCATS system. However, fewer of these studies consider the complex issues existing in the motor vehicle itself, thus the effect of their controls should be studied further. This paper studied the - evaluation system, and proposed a single-criterion AHP model.

SINGLE-CRITERION AHP MODEL

Indicators Selection: Various factors on level of service of signalized intersections can be reflected relating delays, such as saturation rate, velocity ratio, the number of stops etc., Since delay is a main causation of additional fuel consumption and air pollution, this article selects vehicle delay, queue length, number of stops, and the Air Pollution Index (API) as indicators.

Mitigating vehicle delay, (s/veh) is always the traveler's request as to travel on a comfortable road network with less congestion and more rational traffic controls. Number of stops is defined as the ratio of actual journey time and the ideal (the free flow). The average queue length (veh) reflects the traffic operation conditions at intersection; API simplified several monitored air pollutant concentrations into a single conceptual-form index. The values of the first three indicators are obtained through the empirical formula projections. Table 1 gives the threshold criterion.

Table 1. Critical Value for Evaluation Indexes

Traffic conditions	Vehicle delay (s)	Queue length (m)	Number of stops	Air Pollution Index API
I	≤30	≤10	(0, 0.3]	(0, 50]
II	(30, 50]	(10, 25]	(0.3, 0.5]	(50, 80]
III	(50, 70]	(25, 40]	(0.5, 0.7]	(80, 90]
IV	(70, 90]	(40, 60]	(0.7, 0.9]	(90, 120]
V	>90	>60	>0.9	>120

Status Matrix Construction: Because of the significant differences between delays and queue lengths on the value and dimension, and avoiding the impact of dimension and value of the variables to ensure that the property variables in the analysis are equal, Standardized Processing of the attribute data should be taken before calculating of property variable distances. According to the characteristics of delay, queue length, journey time index and API, adapting Negative type is in Figure 1.

Considering that traffic artery makes up of some series form of intersection, finite element analysis is used for reference, traffic trunk is dispersed into intersections, and the whole traffic management effect is gathered at each intersection synthetically afterwards.

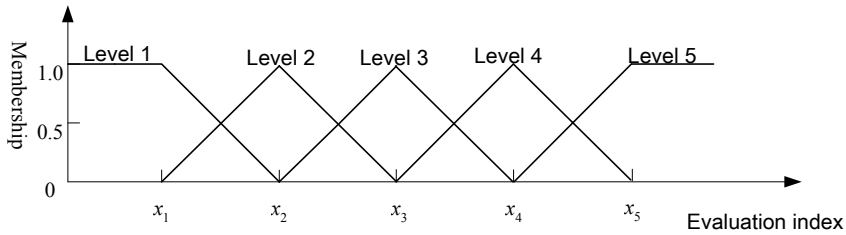

Figure 1. Membership function of grading index

Status matrix evaluates intersections separately, the degree of membership of the evaluation objects (intersection) and alternative sets of elements (five indicators) are determined then. Setting that the i artery, the j intersection and the l direction's evaluation is u_{ijl}, the degree of membership of evaluation object subjecting to the k index is r_{ijlk} (i=1,2…,m; j=1,2,……,n; k=1,2,……,4), then the status matrix of the intersection can be showed as:

$$R_{ijl} = \begin{bmatrix} r_{il11} & r_{il12} & \cdots & r_{il14} \\ r_{il21} & r_{il22} & \cdots & r_{il24} \\ \cdots & \cdots & \cdots & \cdots \\ r_{i\ln 1} & r_{i\ln 2} & \cdots & r_{i\ln 4} \end{bmatrix} \quad i = 1,2,\cdots,m \quad s = 4 \tag{1}$$

AHP Based Evaluation Model: In some intersections, setting the weight of the four traffic flow direction is w'_l ($l \in [1,4]$),the evaluation matrix of that intersection's traffic status can be showed in the augmented matrix in Equation (2):

$$R_{ij} = \begin{bmatrix} R_{ij1} & R_{ij2} & R_{ij3} & R_{ij4} \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \cdot \begin{bmatrix} w'_1 & 0 & 0 & 0 \\ w'_2 & 0 & 0 & 0 \\ w'_3 & 0 & 0 & 0 \\ w'_4 & 0 & 0 & 0 \end{bmatrix} \tag{2}$$

Set the weight distribution vector of the j intersection in the i artery satisfies w''_j , then the overall traffic conditions of the i artery can be showed as the matrix R_i, according with:

$$R_i = \begin{bmatrix} R_{i1_{grade1}} & R_{i2_{grade1}} & R_{i3_{grade1}} & R_{i4_{grade1}} \\ R_{i1_{grade2}} & R_{i2_{grade2}} & R_{i3_{grade2}} & R_{i4_{grade2}} \\ R_{i1_{grade3}} & R_{i2_{grade3}} & R_{i3_{grade3}} & R_{i4_{grade3}} \\ R_{i1_{grade4}} & R_{i2_{grade4}} & R_{i3_{grade4}} & R_{i4_{grade4}} \\ R_{i1_{grade5}} & R_{i2_{grade5}} & R_{i3_{grade5}} & R_{i4_{grade5}} \end{bmatrix} \tag{3}$$

Let the weight vector of the four evaluation index w_m , then the evaluation

model of the traffic management effect in the *i* artery can be vectored further:

$$R_i = \begin{bmatrix} R_{i1_{grade1}} & R_{i2_{grade1}} & R_{i3_{grade1}} & R_{i4_{grade1}} \\ R_{i1_{grade2}} & R_{i2_{grade2}} & R_{i3_{grade2}} & R_{i4_{grade2}} \\ R_{i1_{grade3}} & R_{i2_{grade3}} & R_{i3_{grade3}} & R_{i4_{grade3}} \\ R_{i1_{grade4}} & R_{i2_{grade4}} & R_{i3_{grade4}} & R_{i4_{grade4}} \\ R_{i1_{grade5}} & R_{i2_{grade5}} & R_{i3_{grade5}} & R_{i4_{grade5}} \end{bmatrix}^T \cdot \begin{bmatrix} w_1 & w_2 & w_3 & w_4 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{4}$$

Then further simplify the formula:

$$R_i = \left[\sum_{\tau=1}^{5} R_{i1_{grade\tau}} \cdot w_1 \ \sum_{\tau=1}^{5} R_{i2_{grade\tau}} \cdot w_2 \ \sum_{\tau=1}^{5} R_{i3_{grade\tau}} \cdot w_3 \ \sum_{\tau=1}^{5} R_{i4_{grade\tau}} \cdot w_4 \right] \tag{5}$$

Let λ represents Confidence level and if there is an undetermined object R_i, then ascribing R_i to the mode which has the shortest distance with it. In general, the criterion of confidence level is divided by the positive sequence, that is, stronger is much better, and the strong should occupy quite large proportion. In this paper, the confidence level is limited within 50%;at the same time, the management level is not under the secondary level.

$$k_0 = \min\left\{ \sum_{k=1}^{4} \sum_{\tau=1}^{4} R_{ik_{grade\tau}} \cdot w_k \geq \lambda, \ 1 \leq k \leq 4 \right\} \tag{6}$$

APPLICATION CASE

Simulation Experiment: West Liaohe Rd. in Golden Port Zone of DaLian is one of the important channels linking the main city of Dalian and Xiao yaowan Development Zone, the proportion of large vehicles is 14%, in which large trucks account for 10%. So the vehicle type of large trucks is chosen as a typical representative of the freight main road and VISSIM software was used to carry out the traffic simulation.

AHP method was used to determine the weight of the four intersections in West Liaohe Rd. According to many years studies, practical experiences, the references of the characteristics of intersections and traffic flow and other factors, 18 experts from Harbin and Dalian, who have been long engaged in the traffic design and management to fix the score of the intersections, then constructed judgement matrix to solve the maximum eigenvalue, so the weight can be determined, and the corresponding consistency check can be carried out.

There was a significant difference between the running states of traffic flow controlled by different conditions. In this paper, the first grade indexes (delay, queue length, number of stops and the Air Pollution Index API) were done for Single-level Sequencing by entropy weight method, using the Matlab to write simple calculation procedure, then analyzing the weight vector of first grade indexes under the optimize control scheme and conventional control program. The results are listed in Table 2.

Table 2. Intersection Weight of West Liaohexi Rd.

Intersection	I_1	I_2	I_3	I_4	w'_i
I_1	1	1/2	4/5	2/3	0.174
I_2	2	1	8/5	6/7	0.313
I_3	5/4	5/8	1	5/7	0.209
I_4	3/2	7/6	7/5	1	0.304

$\lambda_{\max}$=4.0189, *CI*=0.0063, *RI*=0.9, *CR*=0.007, pass the consistency check

$$\left[w_{Delay} \quad w_{Ququing} \quad w_{StopppingtimeS} \quad w_{API}\right]=\left[0.2748 \quad 0.2836 \quad 0.2001 \quad 0.2416\right]$$

$$\left[\overline{w}_{Delay} \quad \overline{w}_{Ququing} \quad \overline{w}_{StopppingtimeS} \quad \overline{w}_{API}\right]=\left[0.2761 \quad 0.2712 \quad 0.2001 \quad 0.2527\right]$$

Characteristics of the intersection and volume are the main considerations to determine the weight of different traffic flows in an intersection, and hierarchy general ranking is the ultimate referenced. The four direction of traffic flow cover from east to west, left of west to east, straight of south to north as well as left of south to north. The corresponding weights are (0.35, 0.15, 0.35, 0.15) for West Liaohe Rd &West Huanghe Rd, (0.2, 0.25, 0.15, 0.4) for West Liaohe Rd and Jinma Rd, (0.2, 0.35, 0.2, 0.25) for West Liaohe Rd and Liaoning St, and (0.15, 0.4, 0.25, 0.2) for West Liaohe Rd & Dongbei Da St.

Evaluation of Control Effect: According to the actual situation in each intersection, taking the weight vector w''_i in different directions of the West Liaohe Rd, the weight vector of the four intersections w'_i and the weight of single index w as consideration, data were integrated layer by layer, as Table 3.

Table 3. Weight of Traffic Flow Direction for West Liaohe Rd.

ID	Intersection	Optimized project	Normal project

	Evaluation vector	$R_{Per}=[0.5132 \quad 0.2156 \quad 0.1765 \quad 0.0738 \quad 0.0211]'$	$R'_{Per}=[0.4867 \quad 0.1748 \quad 0.2439 \quad 0.08800 \quad 0.0068]'$

Taking 70% as the confidence level, the optimize system get the secondary level of control, while the conventional control program is at the three-tier level. It indicates that the proposed trunk signal control scheme is effective. Similarly applying the single-criteria composite AHP model to evaluate the signal control effect of Xuefu Road and Beixin Street, the results verify the effectiveness of the proposed control program of this article.

CONCLUSION

As a multi-factor, multi-variable, multi-level complex system, urban road traffic system of traffic control technology develops extremely rapidly. Neural Network Control, Fuzzy Control and other intelligent control technology are gradually applied to the trunk road traffic control system. In this system, the differences of the objective things show similar characteristics that are hard to judge, so it is difficult to introduce absolute, fixed standards.

Based on the above research results, this paper selected vehicle delay, queue length, number of stops and API as evaluation index vectors and proposed the single-criteria compound AHP model to assess city trunk roads signal control effect, which solved the evaluation of multi-variables, discrete data. Use West Liaohe Rd. as a simulation object, results show that applying the allocation proposed in this paper can effectively reduce vehicle delay and improve the efficiency of vehicle travel at different traffic composition conditions.

ABSTRACT

Complexity is an obvious feature of the components of traffic in our country. The vehicles' operating speed declines because of complex vehicle composition, differences in vehicles' mechanical properties, and the different saturations of traffic flow on trunk freight roads. This paper argues that there are traffic delays which are influenced by the three aspects. We analyze the mutative regularity of traffic control parameters on a freight-traffic road and research applicable methods for traffic control on freight-traffic trunk roads which include the discussion of the timing of yellow lights, signal cycles and offset optimization. VVISSIM is applied to verify the optimized methods.

INTRODUCTION

Domestic scholars have made many efforts to improve methods for traffic control in complex traffic components (Zhao L et al. 2008), however most of these have been proposed to optimize a single intersection. The optimization of controlling traffic signals on trunk traffic has been seldom studied previously, especially in sections and intersections with high proportions of trucks, where traffic flow is significantly affected by them. And conventional approaches can't adapt to this situation (Luo X. et al. 2000).

ANALYSIS OF DELAYS ON FREIGHT-TRUNK ROAD

Influences of vehicle component on delays. The differences among vehicles impacts their operating speed on city roads, and because of the existence of intersections and traffic lights, traffic delays can differ according to traffic flows.

The velocity distribution of a single vehicle fits Normal Distribution if its slowest and fastest speeds are v_1, v_2 respectively. In the axis of time, the vehicle starts at t_0 travels at the speed of v_1 and arrives at $t_0 + l/v_1$; if the vehicle starts in the speed of v_2, it will arrive at $t_0 + l/v_2$, so the time cost should be $[t_0 + l/v_2, t_0 + l/v_1]$.

At a green light, if the flow rate is not saturated, the time range of a vehicle's arrival at the next intersection is reckoned according to the lowest speed of the last vehicle and the fastest speed of the first vehicle. If the first vehicle leaves the intersection at t_1 and the last one leaves at t_2, then the vehicles will arrive at the next intersection during $[t_1 + l/v_2, t_2 + l/v_1]$.

The number of vehicles waiting at the next intersection is shown as the

following :

$$m_i = \begin{cases} m_{i-1} + q_i - s_i, & m_{i-1} + q_i - s_i > 0 \\ 0, & m_{i-1} + q_i - s_i \le 0 \, or \quad redtime \end{cases} \tag{1}$$

where m_i is the number of vehicles waiting in the ith period of time, and m_{i-1} is the number of vehicles waiting in the $i-1$th period of time, q_i is the number of arriving vehicles in the ith period of time, and s_i is the rate of vehicles leaving at the ith period of time, which are all at the following intersection.

The delays in the vehicle team are shown as:

$$D = \sum_{i=1}^{p} t_i m_i \tag{2}$$

where m_i is the number of stopping vehicles at the ith period of time, t_i is the value of the ith period of time, and D is the delay of the vehicle team.

The upper and lower limit of D can be reckoned as follows: the upper limit and lower limit occur when the head vehicle arrives at the next intersection at the highest speed and the last vehicle arrives at the next intersection at the lowest speed, and there are no vehicles left in the rear.

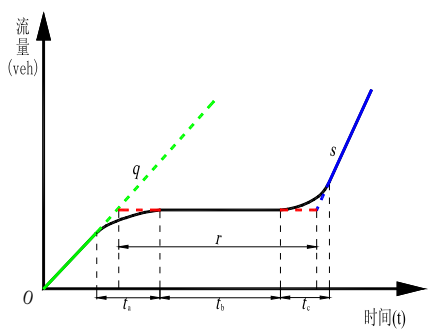
Influence of different vehicles' mechanical properties on delays. Delays are mainly due to the intersections of an urban artery, and the intersections of urban arteries are usually signalized intersections. The queue waiting time and dispersing time in signalized intersections constitute a major component of traffic delays. Assuming that the traffic flow arrives into an intersection at a uniform speed, and the traffic waits only because of a red light, the traffic flow passes through the intersection at a faster speed in effective green time and the queue dissipates gradually. Because of a light's restrictions, vehicles passing through the intersection usually have status such as equable motion, deceleration, stopping, acceleration, and resumed equable motion, as shown in Figure 1.

The deceleration time, stopping time and acceleration time are respectively t_a, t_b, t_c. After converting the process of deceleration and acceleration, the blocking time of the head vehicle is the red light time, and then the process of the car passing through the intersection is deceleration, stopping and acceleration, as shown in Figure 2.

In an ideal state, all vehicles have the same maneuvering performance. The blocking time of the head vehicle, the arriving flow rate and the saturation flow rate are respectively r, q, s. The delay can be shown as follows:

$$d = 0.5r \cdot H = 0.5q \cdot s \cdot r^2 / (s - q) \tag{3}$$

If there is a vehicle which experiences bad maneuvering performance in the traffic platoon, the delays of the entire traffic flow will change, as shown in Figure 3.



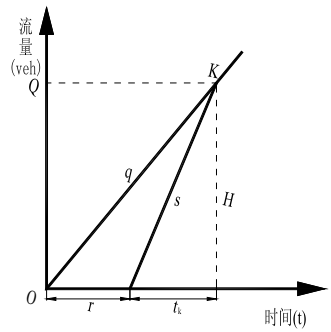


Figure 1. Actual vehicle's delay model. Figure 2. Delay model at ideal condition.

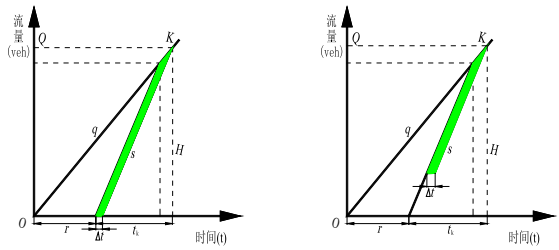

a) b)

Figure 3. Effects of a vehicle's capability difference in the delay model.

When the head vehicle experiences bad maneuvering performance, because of its longer starting time, the blocking time of the entire traffic flow will increase, as shown in Figure 3a. Use Δt to express the difference value of the starting time between bad maneuvering vehicles and normal vehicles. And the delay of the traffic is:

$$d_1 = 0.5(r + \Delta t) \cdot H_1 = d + 0.5(2r \cdot \Delta t + \Delta t^2) \cdot q \cdot s / (s - q) \tag{4}$$

If the vehicle in the middle of the traffic has bad maneuvering performance, that will increase the starting time of the subsequent vehicles, as shown in Figure 3b, then, the delay of the traffic is:

$$d_2 = d + 0.5q \cdot s \cdot \Delta t^2 / (s - q) + r \cdot q \cdot s \cdot \Delta t / (s - q) - s \cdot \Delta t \cdot \overline{h}_t \tag{5}$$

where $\overline{h}_t$ is the average headway if vehicles have the same maneuvering performance .

Influence of different saturation on delays. In a low saturation environment, the effects of each vehicle on other vehicles are minimal, and the relationship between traffic composition and traffic delay is weak. In a high saturation environment, the available space within which to freely travel is minimal, headway is limited within an invariable level, and the vehicles cannot choose freely where to go. In this situation, the difference between composition and delay is minimal. In a general saturation environment, the effect between vehicles is augmented simultaneously by headway changes at any moment, increases in lateral interference, and the rising effect between different roadways. Different vehicle proportions, especially those of larger vehicles, directly result in different saturation rates.

Denoting $s^{'}$ for our expression, the traffic delay is:

$$d^{'} = 0.5q \cdot s^{'} \cdot r^2 /(s^{'} - q) \tag{6}$$

At the same time, if the mobility of the vehicle differs from this, then according to the mobility of vehicle, the actual traffic delay in different locations can be showed as follows:

$$d_1^{'} = d^{'} + 0.5(2r \cdot \Delta t + \Delta t^2) \cdot q \cdot s^{'} /(s^{'} - q) \tag{7}$$

$$d_2^{'} = d^{'} + 0.5q \cdot s^{'} \cdot \Delta t^2 /(s^{'} - q) + r \cdot q \cdot s^{'} \cdot \Delta t /(s^{'} - q) - s^{'} \cdot \Delta t \cdot \overline{h}_t \tag{8}$$

SIGNAL CONTROL OPTIMIZATION

Yellow-light time. The "Traffic Engineering Manual" completed by ITE confirms the model of yellow-light time (y) and red-light time (r) (Institute of Transportation Engineer 1999)：

$$y + r = \delta_0 + \frac{v}{2a + G} + \frac{W + L_v}{v_{ip}} \tag{9}$$

where, δ_0 is reaction time (s), v is the vehicle speed in an import road (m/s), a is minus speed in import (m/s2), G is the import gradient, denoting in %, if declivity, then being negative, W is the intersection width (m), and the distance from the stop line to the conflict trajectory intersection L_v is the vehicle length (m), v_{ip} is the speed in the passing intersection (m/s).

In a freight artery, due to the decrease of a and v_{ip} in our formula (9), then the value of $y + r$ increases, and conflict flow in a non-freight artery can be divided absolutely within 3s yellow light time. Moreover in a freight artery, after researching the simulation of Synchro software and making practical observations, the following result is obtained：When the yellow light time's interval is 4-5s, the conflict flow can realize separation, and this interval can be mostly determined according to the intersection's size. For an intersection within 30 meters, the interval is 4s; for the other, it is 4-5s; for a freight artery, the recommended yellow-light time is 4s, and the red-light time is 1s.

Signal cycle. The best cycle time can yield a transportation benefit index at the maximum level in signal intersections (Wang J. G.. et al. 2000). The Webster method is the most classic, where the optimized cycle length is mostly reckoned from the lost time and the sum of flow ratio in the critical lane group; thus the flow ratio in the critical lane group is relative to the saturation ratio (Wang Y. G.. et al. 2008).

In the ideal situation, the best cycle time can be calculated by the Webster method:

$$c_0 = \frac{1.5 \times \sum (t_l + l / v + t_a - y) + 5}{1 - \sum \max(q_i / s_i)} \tag{10}$$

where c_0 is the best cycle time (s), t_l is the start-up lost time (s), y is the yellow-light time (s), v is the average driving speed (m/s), l is the distance from the stop line to the conflict dot (m), and t_a is the braking time (s).

In this paper, when we determine the optimum cycle time, the delay is the

benefit index with which to deduce cycle time, and the signal cycle of the freight roads intersection is:

$$\min(D) = \min[0.5q \cdot s' \cdot r^2 / (s' - q)] \quad (11)$$

Formula (11) shows that the value of the saturation flow rate is essential to obtain the optimal solution, and it is affected by large vehicles' correction coefficient which is closely related with the PCE. We observed traffic flow characteristics during our investigations of West Liaohe Road, Dalian City, and the straight lanes' vehicles discount coefficient and the left turn and right turn conversion coefficient are shown in Table 1 and Table 2, which are used to calculate the optimum cycle times.

Table 1. PCE of a straight lane.

Vehicle type	straight lanes vehicles discount coefficient
Small vehicle	1
Middle-sized vehicle	1.294
Large vehicle	1.775

Table 2. PCE of left-turning and right-turning lanes

lane	vehicles discount coefficient		
	small vehicle	Middle-sized vehicle	large vehicle
Left-turn	1	1.380	1.867
Right-turn	1	1.430	2.019

In formula (10), the saturation flow rate of a single freight road is shown, where as travel speed decreases, start time and braking time per cycle increase. Compared with a non-freight road, traffic demand in all directions of the intersection changes little (reduced to about 8-13%). This makes the optimum cycle time larger.

According to the survey data on the freight road, if the head and the tail end of traffic are large vehicles in an entrance driveway, the green time loss is 2.1s, yellow terminal loss is 0.2s, and the start time losses are 2.1s + 0.2 s = 2.3s; its traveling speed is 5.6 ~ 8.3 m/s, the average speed v value is 7.0 m/s, and the large vehicle braking time is 1.5s, while the optimum cycle time of the freight road is calculated below as:

$$c_0 = \frac{1.5 \times \sum (l/7 - 0.2) + 5}{1 - \sum \max(q_i / (1800 \times f_{hv} \times \prod f_i))} \quad (12)$$

where $\prod f_i$ is the product of a vehicle's modification coefficient excepting a large vehicle's.

After calculation, the optimum cycle time of a freight road is longer than that of a non-freight road by 12~31%.

Phase offset. This means that the offset time between two adjacent intersections start or end with the green light. In order to enable vehicles to pass more intersections with signal coordination control systems, phase offset must fit with their travel time, so the phase offset is a key parameter in reckoning signal coordination control systems (Lu K. et al. 2008).

Phase offset mainly depends on the distance between intersections and their

average travel speed. A vehicle's average speed on a freight road is lower than on a non-freight road, so the phase offset increases, and the increasing ratio is the reciprocal of the ratio of the two average speeds, which is calculated as follows:

$$O_v = (v_c / v_v) \times O_c \tag{13}$$

Where O_v is the phase offset in a large vehicle environment (s), v_v is the average travel speed with a large vehicle (km/h), v_c is the average travel speed in a smaller vehicle environment (km/h), and O_c is the phase difference in a smaller vehicle environment (s).

CASE ANALYSIS

West Liaohe Road (6 lanes of two-way traffic) at the Dalian Golden Port is an important channel. Its proportion of large cars is as much as 14%, and one of the large trucks on this road accounted for 10%, which is a typical percentage on the freight corridors. Table 3 shows our simulation result.

Table 3. Comparative Analysis Simulation Result

Intersection name	Direction	Flow (pcu/h)	Ordinary			Optimize		
			Delay (s)	Queue (m)	Stops (times)	Delay (s)	Queue (m)	Stops (times)

	S. L.	399	19.3	38.0	0.22	21.4	39.5	0.24
Average			27.48	37.281	0.289	27.31	33.500	0.281

Note: M. equals to main, St. equals to Straight, L. equals to Left, S. equals to Secondary

The major road intersections that cross West Liaohe Road are the Yellow River West Road, the Jinma Road, the Liaoning Road and Northeast Street. Separately for the two-way lanes 6, 8, 4, and 6, the intersection spacing is 739, 1038,

and 317 meters, respectively. Using VISSIM software to simulate the optimization method of this paper, the conventional method was considered separately.

In using this simulation analysis, compared with conventional traffic signal control, the most optimized control method can reduce vehicle delay, queue length and number of stops, so it can effectively improve the efficiency of the vehicle form.

CONCLUSION

We analyzed the impact of vehicles' composition and maneuverability on delays on a freight road, by investigating and analyzing road saturation and vehicle speed. We demarcated the PCE value of different functions of the freight lane, given the recommended value of yellow light time in traffic signal control for a freight artery. We deduced the calculation formula of the best cycle time and phase offset for an actual freight artery, using the Liaohe West Road in the Dalian Economic Development Zone as an example. Using VISSIM in the simulation and analysis with both optimized and conventional methods, we verified the effectiveness of the optimized method proposed in this paper.

ABSTRACT

In urban transportation networks, road flows may be unbalanced because of the difference of traffic demand in space (e. g. on/off duty). Aiming to make full use of the existing road resource and alleviate transportation congestion, a reserve capacity model of optimal lane allocating is proposed. The lane numbers in both directions of two-way roads and signal timing parameters of intersections are optimized to make the traffic distribution more balanced in lanes, so as to make the network accommodate more traffic demand. A bilevel programming model is proposed: the lower-level problem represents a network equilibrium model; the upper-level problem is to allocate lanes and optimize signal timing to maximize reserve capacity of road networks, taking account of drivers' route choice behavior. A numerical example is presented to illustrate the application of the model.

1. INTRODUCTION

In urban transportation networks, road flows may be unbalanced because of the difference of traffic demand in space (e. g. on/off duty). Generally, variable lanes approach is used to deal with that. However, the result may be counterproductive; that is, although it could help to alleviate local traffic congestion, it may lead the entire urban road traffic conditions to deteriorate, if the variable lanes program is based on only one or a number of roads (ZHAI Zhong-min, 2004). Aiming to make full use of the existing road resource and reduce transportation congestion, a reserve capacity model of optimal lane allocating is studied from the system point of view in this paper.

Webster and Cobbe (1966) brought up the concept of reserve capacity of a simple signal-controlled intersection. Wong and Yang (1997) extended the concept of reserve capacity to a general signal controlled road network, a bilevel programming model was set up, and presented a heuristic to solve the problem(Wong et al. 1997). But parameters optimized are green splits only. Ceylan and Bell(2004), Suh-Wen Chiou (2007) studied on reserve capacity of coordinated fixed-time signalized road network respectively (Ceylan et al. 2004, Chiou Suh-Wen 2007). Besides green splits, offsets and the common cycle time are also considered. However, the improvement of reserve capacity is very limited just simply by setting traffic signals.

Ziyou and Yifan (2002) combined the problem of reserve capacity of signalized road networks with that of the continuous equilibrium network design

(Gao Z Y et al. 2002). An integrated method has been presented to maximize the possible increase in travel demands of the road network while the minimization of investment in link capacity expansions is pursued with respect to the green splits at individual junctions. Tong and Ziyou (2004) combined the problem of reserve capacity with the discrete network design (Zhao Tong et al. 2004). The reserve capacity of road network is maximized by setting traffic signals at individual intersections and constructing new roads. Zhao tong (2006) suggested an approach of adding new roads to maximize the traffic capacity of the network to satisfy the increasing urban traffic demand, while still keeping that traffic demands within the environment constraint (Zhao tong et al. 2006). However, the parameters optimized on signal timing are green splits only in these studies, and the delay formulae are of simple BPR-like forms.

In fact, apart from the approaches of expansion or construction to existing road networks, the variable lanes control is also an effective measure to alleviate traffic congestion. Moreover, the investment is small and effect is fast (ZHAI Zhong-min, 2004). Reallocating of lanes not only changes the capacity of junctions, but also changes signal control delay of vehicles, which will affect drivers' route choice behavior. Therefore, it is necessary to make decisions from the system perspective, using systems analysis methods. A bilevel programming model is proposed in this paper: the lower-level problem represents a network equilibrium model; the upper-level problem is to allocate lanes and optimize signal timing to maximize reserve capacity of road networks, taking account of drivers' route choice behavior. The path impedance is composed of driving time and delay time at junctions.

This paper has been organized as follows. In the next section, some basic notions are defined. The capacity model of signal-controlled road network and its solution algorithm are presented in section 3 and 4. In section 5, a numerical example is given. Finally, conclusions are drawn in section 6.

2. BASIC NOTATION

The notations used in this paper are given as follows:

O: the set of all origin nodes; D: the set of all destination nodes; r: an origin node, $r \in O$; s: a destination node, $s \in D$; A: the set of links in the network; R: the set of signal-controlled intersections in the network; $n_{i\text{-}j}$: lane number of the link i-j from junction i to adjacent junction j(i-$j \in A$), $\boldsymbol{n}$ is a vector of lane numbers of all links; $\lambda_{i\text{-}j}$: green split of the link i-j from junction i to adjacent junction j(i-$j \in A$), $\boldsymbol{\lambda}$ is a vector of all green splits; C_j: cycle time of signal-controlled intersection j, $\boldsymbol{C}$ is a vector of all cycle times; L_j: total lost time per cycle of signal-controlled intersection j; K: the set of paths from original node r to destination node s; $\mathbf{q}$: the current O-D matrix; μ: the O-D matrix multiplier(suppose all demand multipliers between each O-D pair are the same); h_k^{rs} :flow on path k from original node r to destination node s; $f_{i\text{-}j}(\mu, \boldsymbol{C}, \boldsymbol{\lambda}, \boldsymbol{n})$: flow on link i-$j \in A$， it is a function of upper-level decision

variables μ, $\boldsymbol{C}$, $\boldsymbol{\lambda}$, $\boldsymbol{n}$; $\delta_{i-j,k}^{rs}$: takes a value of 1 if link *i-j* is on path *k* from origin node *r* to destination node *s*, and 0 otherwise; t_{i-j}: total journey time (or cost) function on link $i\text{-}j \in A$; $c_{i\text{-}j}(\lambda_{i\text{-}j}, n_{i\text{-}j})$: capacity of signal-controlled link *i-j* ($j \in R$.).

3. FORMULATION OF THE PROBLEM

Suppose that the lane numbers in both directions of all two-way roads are adjustable. The total lane number of a two-way road is fixed:

$$n_{i\text{-}j} + n_{j\text{-}i} = \mathrm{n_{ij}} \tag{1}$$

where $n_{i\text{-}j}$, $n_{j\text{-}i}$ are of positive integer, $\mathrm{n_{ij}}$ is sum of lane numbers in both directions ($i\text{-}j$, $j\text{-}i \in A$) of a two-way road.

In order to ensure that queues and delays at network intersections under equilibrium conditions be accepted by network users, flows on any signal-controlled links must be constrained so as not to exceed a prescribed maximum acceptable value, i.e., capacity constraints are given as follows:

$$f_{i\text{-}j}(\mu, \boldsymbol{C}, \boldsymbol{\lambda}, \boldsymbol{n}) \le x_{i\text{-}j} \cdot c_{i\text{-}j}(\lambda_{i\text{-}j}, n_{i\text{-}j}) \quad j \in R, \quad i\text{-}j \in A \tag{2}$$

where $x_{i\text{-}j}$ is the maximum acceptable degree of saturation for link $i\text{-}j (j \in R)$. Furthermore, the signal timing variables at signal-controlled intersections should satisfy some linear constraints which include cycle time, minimum and maximum green times. Signal timing variable constraints are given as follows:

$$C_{min} \le C_j \le C_{max} \quad j \in R \tag{3}$$

$$\lambda_{min} \le \lambda_{i\text{-}j} \le \lambda_{max} \quad j \in R \tag{4}$$

where C_{min} is minimum cycle time, C_{max} is maximum cycle time; λ_{min} is minimum green split, λ_{max} is maximum green split. Green split and lost time must satisfy the following relationship:

$$\sum_{n=1}^{N_j} \lambda_{nj} + L_j / C_j = 1 \qquad j \in R \tag{5}$$

where N_j is the number of phases of signalized intersection j, λ_{nj} is the green split of the phase n.

Therefore, the upper-level model has the following form:

$$\text{Max} \quad \mu \tag{6}$$

$$s.t. \quad n_{i\text{-}j} + n_{j\text{-}i} = \mathrm{n_{ij}} \quad i\text{-}j \in A, j\text{-}i \in A \text{且} n_{i\text{-}j}, n_{j\text{-}i} \text{ are of positive integer} \tag{7}$$

$$f_{i\text{-}j}(\mu, \boldsymbol{C}, \boldsymbol{\lambda}, \boldsymbol{n}) \le x_{i\text{-}j} \cdot c_{i\text{-}j}(\lambda_{i\text{-}j}, n_{i\text{-}j}) \quad j \in R, \quad i\text{-}j \in A \tag{8}$$

$$C_{min} \le C_j \le C_{max} \quad j \in R \tag{9}$$

$$\lambda_{min} \le \lambda_{i\text{-}j} \le \lambda_{max} \quad j \in R \tag{10}$$

$$\sum_{n=1}^{N_j} \lambda_{nj} + L_j / C_j = 1 \qquad j \in R \tag{11}$$

where $f_{i\text{-}j}(\mu, \boldsymbol{C}, \boldsymbol{\lambda}, \boldsymbol{n})$ is obtained by solving the following network equilibrium problem:

$$\min \quad \sum_{i-j \in A} \int_0^{f_{i-j}(\mu, C, \lambda, n)} t_{i-j} dx \tag{12}$$

$$s.t. \quad \sum_{k \in K} h_k^{rs} = \mu \cdot q_{rs} \qquad \forall r \in O, s \in D \tag{13}$$

$$f_{i-j} = \sum_{r\in O}\sum_{s\in D}\sum_{k\in K} h_k^{rs}\cdot\delta_{i-j,k}^{rs} \qquad \forall i-j\in A \tag{14}$$

$$h_k^{rs} \geq 0 \qquad \forall r\in O, s\in D, k\in K \tag{15}$$

where t_{i-j} is composed of the link driving time (for example, BPR-like form) and intersection delay. The average signal control delay per vehicle for a given link (i-j) entering a signal-controlled intersection is recommended by HCM2000 (initial queue delay is not included):

$$d = \frac{0.5C(1-\lambda)}{1-[\min(1,x)\lambda]} + 900T\left[(x-1)+\sqrt{(x-1)^2+\frac{8kIx}{cT}}\right] \tag{16}$$

For a detailed description, see HCM(2000).

Once n_{i-j}=0, and then c_{i-j}=0, t_{i-j}=∞. In this case, the two-way road is turned into a one-way road, and its direction is from j to i.

4. SOLUTION ALGORITHEM

In order to solve the problem we must evaluate the changes in equilibrium link flows caused by the changes in signal timing variable, O-D demand multiplier and lane numbers under the condition that all constraint conditions are not being violated. It is difficult to evaluate the changes in equilibrium link flows directly because of the implicit, nonlinear function form of equilibrium link flows. A good idea is to use the linear function to approximate the nonlinear function of $f_{i-j}(\mu, \boldsymbol{C}, \boldsymbol{\lambda}, \boldsymbol{n})$. Therefore, we must calculate the derivative of the link flows, with respect to signal timing variable($\boldsymbol{C}$ and $\boldsymbol{\lambda}$), O-D demand multiplier(μ) and lane numbers($\boldsymbol{n}$) (Wong and Yang 1997). But the lane numbers($\boldsymbol{n}$) are of positive integer, the difference of equilibrium link flows respect to $\boldsymbol{n}$ can be adopted as approximation of the derivative(Yi-fan and Zi-you,1998).

Let μ^*, $\boldsymbol{C}^*$, $\boldsymbol{\lambda}^*$, $\boldsymbol{n}^*$denote an initial solution to O-D demand multiplier, cycle time, green split and lane numbers respectively, and let $f_{i-j}(\mu^*, \boldsymbol{C}^*, \boldsymbol{\lambda}^*, \boldsymbol{n}^*)$ denote the corresponding equilibrium link flows, which are solved from lower-level problem.

$$\begin{aligned} f_{i-j}(\mu,C,\lambda,n) \approx f_{i-j}(u^*,C^*,\lambda^*,n^*) &+ \sum_{i-j\in A}\left[\frac{\partial f_{i-j}(\mu^*,C^*,\lambda^*,n^*)}{\partial\mu}\right](\mu-\mu^*) + \sum_{j\in R}\left[\frac{\partial f_{i-j}(\mu^*,C^*,\lambda^*,n^*)}{\partial C_j}\right](C_j-C_j^*) \\ &+ \sum_{i-j\in A,j\in R}\left[\frac{\partial f_{i-j}(\mu^*,C^*,\lambda^*,n^*)}{\partial\lambda_{i-j}}\right](\lambda_{i-j}-\lambda_{i-j}^*) + \sum_{i-j\in A}\left[\frac{\Delta f_{i-j}(\mu,C,\lambda,n)}{\Delta n_{i-j}}\right](n_{i-j}-n_{i-j}^*) \end{aligned} \tag{17}$$

When substituting (17) into the upper-level problem, the upper-level problem becomes an inter-nonlinear programming problem with the variable μ, $\boldsymbol{C}$, $\boldsymbol{\lambda}$ and $\boldsymbol{n}$. This inter-nonlinear programming problem can be solved by the well-known branch and bound method (Gupta and Ravindran, 1985), thus one can get a new improved point (μ, $\boldsymbol{C}$, $\boldsymbol{\lambda}$, $\boldsymbol{n}$) from which a new inter-nonlinear programming problem is again generated and again solved by the same method, and so on. Therefore, the method is in fact a sequence of linear approximations to the original bilevel problem.

5. A NUMERICAL EXAMPLE

The example network is shown in Fig. 1 This problem has three O-D pairs(1-4, 5-6 and 6-5), eleven links (arrows denote the directions of links, the figures next to links are driving times of free flows, and the unit is second) and six nodes, of which nodes **2** and **3** are of signal-controlled intersections(two-phase). There is only one lane on each link, and the saturated flow for all lanes is 1800 pcu/h. The link driving time is expressed as follow:

$$t_{i-j}^{1} = t_{i-j}^{0}\left[1.0 + 0.4\left(f_{i-j} \Big/ c_{i-j}\right)^{4}\right]$$

The average signal control delay per vehicle are expressed as formula(16), where only the signal-controlled links (j is 2 or 3) have signal control delay, T=0.25，k=0.4，I=1.

The current O-D: q_{56}=1000pcu/h, q_{65}=300pcu/h, q_{14}=500pcu/h; the current signal timing: C_2=60s, C_3=120s, L_2=L_3=10s, $\lambda_{5\text{-}2}$=$\lambda_{6\text{-}2}$=0.5, $\lambda_{5\text{-}3}$=$\lambda_{6\text{-}3}$=0.5; we can get the current distribution of traffic flow: $f_{1\text{-}2}$= $f_{2\text{-}3}$= $f_{3\text{-}4}$= 500 pcu/h，$f_{5\text{-}3}$= $f_{3\text{-}6}$=840 pcu/h，$f_{5\text{-}2}$= $f_{2\text{-}6}$=160 pcu/h，$f_{6\text{-}3}$= $f_{3\text{-}5}$=300 pcu/h. It can be seen that link 5-3 is congested, but other links are unoccupied. The reason is the difference of traffic demand in space (q_{56}> q_{65}) and the difference of traffic impedance between links ($t_{5\text{-}2}$> $t_{5\text{-}3}$). Then we use the model proposed by this paper to optimize lane numbers in both directions of two-way roads and signal timing parameters, the object is to maximize reserve capacity of the road network.

At the process of iterative calculation, the lost time of signalized intersections (2 and 3)is 10s. The lower and upper bounds of the green splits are 0.05 and 0.95 respectively. The lower and upper bounds of the cycle times are 20s and 180s respectively. The maximum degree of saturation for all signal-controlled links take the same value of x =0.85. Convergence criterion δ=0.005, initial points are: μ=1, C_2=60, C_3=120, $\lambda_{5\text{-}2}$=$\lambda_{6\text{-}2}$=0.5, $\lambda_{5\text{-}3}$=$\lambda_{6\text{-}3}$=0.5.

After optimized calculation, we get lanes' reallocation: $n_{5\text{-}2}$=2, $n_{2\text{-}6}$=2, as shown in Figure 2; the optimized signal timing: C_2=99s, C_3=180s, $\lambda_{5\text{-}2}$=0.3730, $\lambda_{5\text{-}3}$=$\lambda_{6\text{-}3}$=0.3197; the maximized O-D matrix multiplier μ=1.630. The maximized O-D demands between different O-D pairs are: q_{56}=1630pcu/h, q_{65}=489pcu/h, q_{14}=815pcu/h, and the distribution of traffic flow are: $f_{1\text{-}2}$= $f_{2\text{-}3}$= $f_{3\text{-}4}$= 815 pcu/h, $f_{5\text{-}3}$= $f_{3\text{-}6}$=489 pcu/h, $f_{5\text{-}2}$= $f_{2\text{-}6}$=1141 pcu/h, $f_{6\text{-}3}$= $f_{3\text{-}5}$ = 489pcu/h. It can be seen that the traffic flows on each links are more even, the road resources have been fully utilized.

It is worth mentioning that, if we increase the lanes of congested path 5-3-6($n_{5\text{-}3}$=2，$n_{3\text{-}6}$=2) in accordance with the common sense, the traffic pressure on this path can be alleviated, but the maximized O-D matrix multiplier μ=1.445<1.630. Readers can check on their own. The reason is that the impedance difference between two parallel paths (5-3-6 and 5-2-6) is further increased, so the traffic flows on each links are more uneven, road resources are not fully utilized.

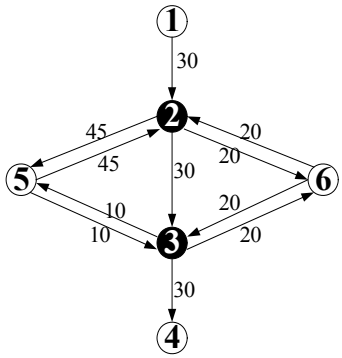

Fig. 1. Example network.

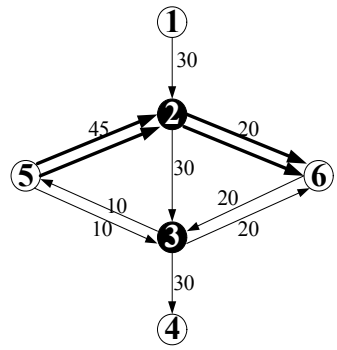

Fig. 2. Improved network.

6. CONCLUSION

A bilevel programming model of reserve capacity based on variable lanes is proposed in this paper. From the above discussion we can conclude that the traffic flows on each links are more even and the road resources can be fully utilized after the lane numbers and signal timing are optimized by this model, thus the reserve capacity of road network can be increased as much as possible.

ABSTRACT

To overcome the shortcomings in existing control mechanisms and adapt to domestic transit operation conditions such as high frequency and overlapped bus routes, many researchers work on various optimization methods. In fact, the effectiveness of priority control varies with side road traffic demand. If a side road is less congested, priority control has less of an impact, whereas otherwise the impact increases accordingly. There is still a lack of effective means by which to solve this problem.

Based on former studies, this paper analyzes how priority control impacts side road traffic, optimizes key parameter settings like minimum green time and maximum green time, and adopts conditional priority as well as appropriate compensation strategies. It is hoped that this transit signal priority system can alleviate excessive changes in side road traffic.

BACKGROUND

The study of Transit Signal Priority (TSP) started 40 years ago. In theory, TSP can raise bus speeds and increase the attractiveness of the transit system; it can also reduce transit operation expenses and improve efficiency. However much research and prior experiments have showed that the benefits of TSP change with traffic demands on side roads. Lee (2006) indicated that TSP increased side road delay by 14.17%; Ma (2006) found that exclusive priority control increased the vehicle delay of a non-priority phase from 29.8s/veh to 35.2s/veh.

Therefore this paper considers side road traffic endurance and optimized control logic such as the key parameter setup in the logic, the judgment criteria of granting priority, and the adoption of certain compensation strategies. We aim to create a control system that can realize transit priority control objectives and reduce the impact of side road traffic at the same time.

BASIC TSP CONTROL LOGIC

The basic control logic of TSP is shown in Figure 1. Key technologies include bus detection and location, short-period travel time forecast, TSP control logic and their combination.

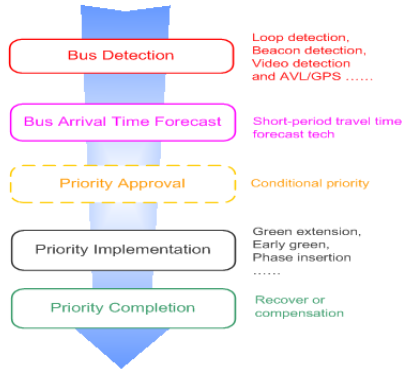

Figure 1. Basic control logic and key instruments of TSP.

This basic control logic focuses more on the provision of effective and exact priority for buses. It is less concerned with other traffic conditions in the network, especially side road traffic.

STUDY OF CONTROL PARAMETERS

TSP control uses **maximal green time** to determine the maximal green extension extent for priority requests and uses **minimal green time** to guarantee necessary travel time in the non-priority phase. Basic control uses an experienced calculation method. Lee (2006) used 25% of the whole cycle as a green extension in trials. Furth (2000) used an early green strategy in the experiment, where minimal green time is 6s of the non-priority phase. However, it is difficult to obtain an ideal and unified effect when these methods are applied to varying side road traffic conditions.

Consideration of side road traffic

TSP impacts side road traffic in the following ways:

- In peak hours, the green extension of the priority phase will cause an accumulation of queuing vehicles on a side road and those vehicles cannot be released in one cycle time. Then second stops may occur and vehicles can even spill over into the upstream intersection.
- In peak hours, the early green of the priority phase will occupy non-priority green time and many vehicles cannot pass through in the reduced green time (or minimal green time), so second stops and overspills occur.
- Frequent bus arrivals request TSP frequently. This can cause increased delays, second stops and even congestion that spreads to the whole network.
- If the local intersection is a part of whole coordinated system, TSP may break up or disrupt its coordination.
- Bicycle and pedestrian safety should be considered, but most basic control has already taken them into account, so this paper did not focus on them.

Concisely speaking, TSP will reduce the pass-through time of side road traffic and require more capacity to accommodate these queuing and arriving

vehicles. However, with ordinarily designed approaches, it is not always possible to widen the approach or add another lane, so the capacity of the existing approach can remain unchangeable. Conversely it will require minimal green time in the non-priority phase in order to limit the extent of TSP.

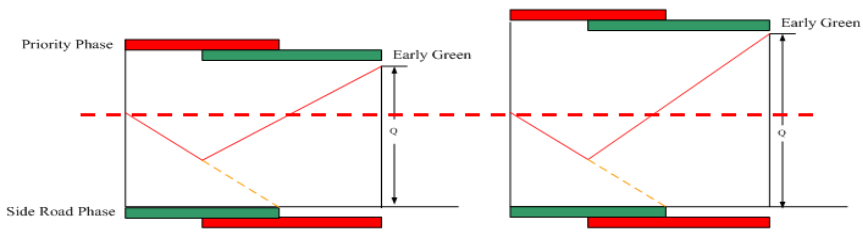
A prerequisite of this paper is that approach design and signal planning is matched to its actual conditions before the TSP application and the capacity of the approach is not changed.

Minimal green time

Minimal green time is related to an early green strategy. We know that traditional minimal green time takes into account the factors below:

- Safety: drivers need minimal green time to respond to signal changes.
- Basic pass-through demand: each phase should allow a certain number of vehicles through to reduce the average wait for a queue.
- Pedestrian: pedestrians need enough time to cross the intersection safely.

However, when the TSP is applied to an intersection, the minimal green time of a side road should satisfy more serious conditions during peak hours. When an early green is adopted, the back of the queue (Q) should be shorter than what this lane can accommodate (L).



a) Side road arrival rate is low b) Side road arrival rate is high

Figure 4. Queue increase during Early Green.

According to HCM2000, the average back-of-queue characteristics at signalized intersections are

$$Q=Q_1+Q_2 \tag{1}$$

where

Q = maximum distance in vehicles over which the queue extends from the stop line during an average signal cycle (veh),

Q_1 = first-term queued vehicles (veh)

$$Q_1 = PF_2 \frac{\frac{v_L C}{3600}\left(1-\frac{g}{c}\right)}{1-[\min(1.0, X_L)\frac{g}{c}]} \tag{2}$$

where

PF_2 = adjustment factor for effects of progression,

v_L = lane group flow rate per lane (veh/h),
C = cycle length (s),
g = effective green time (s), and
X_L = ratio of flow rate to capacity (v_L/c_L ratio).

And,

Q_2 = second-term queued vehicles (veh).

$$Q_2 = 0.25 c_L T[(X_L - 1) + \sqrt{(X_L - 1)^2 + \frac{8 k_B X_L}{c_L T} + \frac{16 k_B Q_{bl}}{(c_L T)^2}}] \quad (3)$$

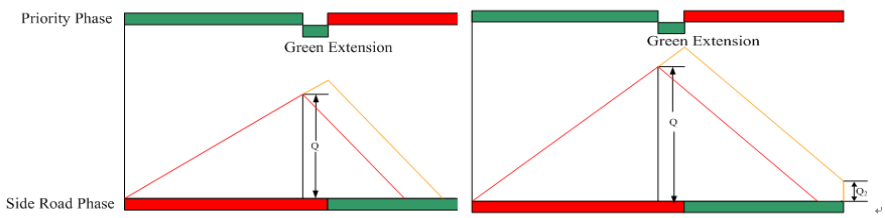
where

c_L = lane group capacity per lane (veh/h);
T = length of analysis period (h);
X_L = v_L/c_L ratio;
k_B = second-term adjustment factor related to early arrivals;
Q_{bL} = initial queue at the start of the analysis period (veh) ; and
C = cycle length (s)..

In the early green strategy, $Q_{bl} = Q_1(g' = g - t_b, C' = C - t_b)$ (t_b = early-start green time) because $Q_2 = Q_2$ (g', v_L), $Q_1 = Q_1$ (g', v_L), and $Q = Q1 + Q2 \leq L$
So minimal g' (minimal green time for the side road phase) is the function of L and v_L. It relates to parameters in the control logic with side road traffic and road conditions.

Maximal green time

Maximal green time is related to the green extension strategy. The maximal green time of the priority phase equals the maximal red phase of the non-priority phase. When a green extension is adopted, the queue remains after the completion of a whole cycle if the side road arrival rate is high and feeds into the initial queue in the next cycle (Figure 5). If the side road capacity has been determined, limits on maximal green time can insure that the back-of-queue will be shorter than the length of the lane.



a) Side road arrival rate is low b) Side road arrival rate is high

Figure 5. Queue increase of Green Extension.

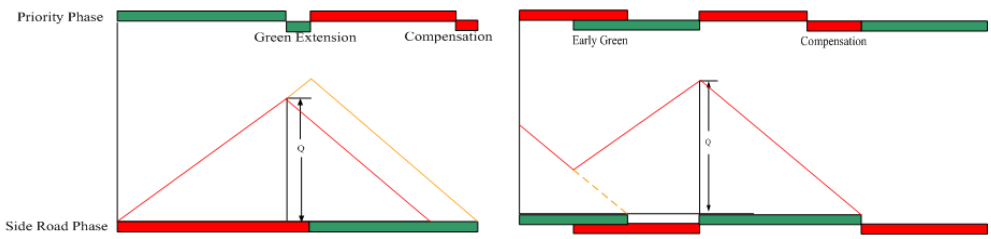
In a green extension strategy, $Q_{bl} = v_L t_a$ (t_a = extended green time), because

$Q_1(C'=C+t_a, v_L)+Q_2(v_L) \leq L$ so [t_a +g (the green time of the priority phase)] makes the maximal green time for the priority phase and is a function of L and v_L too. It ties the parameter of the control logic with the side road traffic and road conditions.

COMPENSATION STRATEGIES

Studies show that mainline benefits compared to side road drawbacks (measured in total hours per year) reveal a ratio of almost 9 to 1. Where a non-priority phase is curtailed due to a priority call, compensation can be afforded in two ways: the first is to compensate for the loss in exactly the next phase or to spread it over a period of time by simply increasing the normal green setting for the non-priority phase appropriately. However, compensation for time lost should be immediate and non-optimum normal maximums could lead to inefficient operation whenever the bus priority system is out of action (Muthuswamy, 2007).

In this paper, the compensation strategy is used as a standard function of TSP just after the priority phase (figure 6).



a) Green extension b) Early green

Figure 6. TSP with compensation.

In the green extension strategy, side roads can be compensated for lost time in TSP in the same cycle; in the early green strategy, side roads can be compensated in the next cycle. But if this time TSP is utilized again, it is the controller's task to determine whether or not to give compensation or TSP, balancing between the benefits of this side road's condition or the needs of buses (in a forecasted delay). This is the most effective compensation for side road traffic loss with the least impact on priority control continuity. In this way, intervals between requesting buses are required to be longer than at least one cycle and are easily met in most situations.

CONDITIONAL PRIORITY

The frequency of priority requests is important because an intersection may need some time to recover, i.e., to clear queues that have accumulated or to return to a background cycle to allow adequate traffic progress. If interruptions occur too frequently, the intersection may not get a chance to recover. By using conditional priority, the frequency of these interruptions will be responsively reduced.

Conditional priority systems can also be tailored to minimize their impact on

critical intersections by varying the "reliability" criterion from intersection to intersection. By using a looser criterion at the busiest intersections, the likelihood of interruption at those intersections goes down. Of course, accordingly, the likelihood of interruption at the succeeding intersections will go up. But by the same token, using a tighter criterion at one or two intersections upstream of a critical intersection will lessen priority requests at that critical intersection.

To evaluate the effects of conditional priority control in simulation, VISSIM and its VAP interface have been used to design and write the control logic (for the model setup, see Xu 2008). According to transit operation requirements, three reliability criteria are added to reduce TSP call frequency. Results are listed in Table 1.

Table 1. Summary of simulation result.

Criterions	Operation results	Side road impact compared to exclusive TSP
1 Transit speed	Average speed was 25.3km/h	Delay reduced by 15%
2 Schedule adherence	Performance improved by 22%	Delay reduced by 18%
3 Headway fluctuation	Headway variation contained in 15% (C1)	Delay reduced by 12%

*C1= coefficient of headway variation

CONCLUSION

This paper analyzed how priority control impacts side road traffic and ways to optimize key parameter settings like minimum green time and maximum green time. We also adopted conditional priority as well as appropriate compensation strategies. It is hoped that this transit signal priority system can adapt well to and alleviate excessive changes in side road traffic.

ABSTRACT

Urban road traffic is a non-linear, non-stationary, and uncertain process; its uncertainty increases rapidly when making short-term (five minute-long) traffic flow prediction. The state-of-the-art in traffic flow prediction is reviewed here, including Time-Series, Artificial Neural Network, Ada-Boost, and Support Vector Machine based algorithms. A novel prediction method is proposed for short-term (five minute-long) traffic flow prediction. The time interval between vehicles is treated as a stochastic variable and described with the Marked Point Process in the ARCH (autoregressive conditional heteroskedasticity) framework. Different point processes may generate a corresponding ACD (autoregressive conditional duration) model for the prediction of time intervals between vehicles in the traffic's flow. A particle filter is applied with measured vehicle speed data for traffic flow speed and density prediction. We apply this algorithm to the Traffic Guidance System of the Cross-River Tunnel, Lujiazui, Pudong, Shanghai. Nine congestion levels are proposed and the prediction error for short time (five minute-long) is within three levels.

INTRODUCTION

Traffic prediction (Lingras Pawan, 1999) uses a dynamically retrieved traffic data series to predict future traffic status. In general, the basic parameters include traffic flow density, average speed, and the road occupancy ratio. Predictions can be divided into long-term and short-term types. Long term refers to intervals including thirty minutes, one hour, one day or longer. Short-term refers to short intervals such as five minutes, normally no longer than fifteen minutes.

Since the traffic flow is a real time, non-linear, high-dimension, and unstable stochastic process, the shorter sample intervals display more stochastic and unstable characteristics. It is related to the past traffic flow status of a current road segment and the up/down flow of an investigation point. In addition, the weather, traffic accidents, and environmental factors also impact the traffic flow process.

The real-time data analysis based on short-term traffic flow prediction is one of the important foundations for traffic information, traffic diversion, and control. A major body of work has been previously done in this area.

The main traffic prediction methodologies (Lingras Pawan, 2000; Ye Zhirui, 2003; Sun HY, 2003; Weng XX, 2006; Turochy R.E. 2004; Chen SY, 2006; Attoor Sanju Nair, 2006) include linear system theories, knowledge based intelligence models, a non-linear system theory, a combined model based method, and a traffic simulation-based approach.

The models yield different types of performance in terms of accuracy, time, response, and compatibility. Linear system prediction is precise and easy to operate, but it cannot match the accuracy and dynamic response requirements for a complicated road network. A knowledge-based intelligence model has strong data fitting ability; it can provide good prediction when a traffic accident occurs by utilizing required data input. Its shortcoming is the complication of an algorithm, parameter choice, and applicability. A non-linear system responds to non-linear characteristics of traffic flow systems. It affords a high level of accuracy but it requires complicated calculations. Its theory foundation still requires further research. The combined model-based prediction method may well combine the strengths of each model, which requires further investigation in determining the consistency among different models. An unsuitable combination may lead to big variations. In addition, its application requires complicated calculation, which is not suitable for a large-scale traffic system.

This paper proposes a novel five-minute-based traffic flow prediction method: with the Vehicle Detector (VD) under the road surface to measure the stochastic process of the vehicle passing interval, under the ARCH framework, we use the marked point process to describe the process. Different point processes present different ACD models which can be used for the vehicle passing interval description. The practical filter used for an unstable dynamics system can be applied to the prediction of average speed and traffic density with the statistical data from the VD. This algorithm has been used for the sample analysis of a traffic diversion project in the cross-river tunnel at Lujiazui, Pudong, Shanghai.

ACD MODEL

The ACD Model (Engle R.F.,1994) is created for the analysis of an event whose last period is based on the passed samples. It can convert the time interval among the events to a temporal points system. Different points processes may have different ACD models, the most simple one being the Poisson process.

Defining the interval as: $x_i=t_i-t_{i-1}$, t_i is the ith event occurence time, Ψ_i is the conditional expectation of the ith interval:

$$E(x_i \mid x_{i-1}, x_{i-2}, \cdots, x_1) = \psi(x_i \mid x_{i-1}, x_{i-2}, \cdots, x_1; \theta) \equiv \psi_i$$

The key point of this model is the hypothesis that the existing relationship is determined by the information of a history-based conditional expectation function, in addition, x_i and Ψ_i is independent on random variables with the same distribution, where the interval x_i has the following relationship with Ψ_i :

$$x_i = \psi_i \varepsilon_i$$

where $\varepsilon_i \sim i.i.d$ is an independent temporal series with specific distribution. Its density is $P(\theta, \phi)$, where θ, ϕ are estimated parameters. The ACD model has one simple form where the conditional expected value is only based on its historical intervals. This may be presented in the following functions:

$$\psi_i = \omega + \sum_{j=0}^{p} \alpha_j x_{i-j} + \sum_{i=0}^{q} \beta_j \psi_{i-j}, \quad i = 1,2,\cdots$$

Where, $\omega > 0$, $\alpha = (\alpha_1, \alpha_2, \cdots, \alpha_p) \geqslant 0$, $\beta = (\beta_1, \beta_2, \cdots, \beta_q) \geqslant 0$, $\gamma = \alpha + \beta < 1$, the stability of the random process is guaranteed. In addition, $x_0 = \Psi_0 = 0$, p and q are the delayed orders of the model. The ith interval's conditional aspect is determined by its delayed p conditional expectation and q historical intervals.

Here, we apply the simple but successful EACD (1,1) model to describe the vehicle detection intervals, E present for the ε_i exponential distribution.

$$\psi_i = \omega + \alpha x_{i-1} + \beta \psi_{i-1}, \quad \alpha, \beta \geq 0, \omega > 0, i = 1,2,\cdots$$

The parameters estimation of the EACD model uses the following function:

$$L(\theta) = -\sum_{i=1}^{N(T)} (\log(\psi_i) + \frac{x_i}{\psi_i})$$

PARTICLE FILTER

The basic synthesis of the Particle Filter (Doucet, 1998) is achieved by using a randomly sampled series and a sample weight to calculate the posteriori probability distribution. By making the suggested density distribution match the a priori density distribution, the series applies particle filtering steps, as shown in the following equations (m=1,2,⋯M):

Generated Particle: $x_k^{(m)} \sim p(x_k \mid x_{k-1})$

Calculated Weight: $w_k^{*(m)} = w_{k-1}^{*(m)} p(z_k \mid x_k^{(m)})$

$$\text{Weight Normalization:}\quad w_k^{(m)} = \frac{w_k^{*(m)}}{\sum_{m=1}^{M} w_k^{*(m)}}$$

$$\text{Estimation:}\quad E(g(x_k \mid z_{1:k})) = \sum_{m=1}^{M} g(x_k^{(m)}) w_k^{(m)}$$

Since the series weight-based method has the problems of weight depravation and particle exhaust, a re-sampling method may solve these two problems, by replicating the particles relative to the weight and by taking the random samples:

$$\left\{ \tilde{x}_k^{(m)}, \frac{1}{M} \right\}_{m=1}^{M} \sim \left\{ x_k^{(m)}, w_k^{(m)} \right\}_{m=1}^{M}$$

Where, x_k is the sample of a status vector at time k, then z_k is the measured vector at time k.

SHORT-TERM TRAFFIC FLOW PREDICTION

In the traffic guidance project at the Lujiazui Cross-river tunnel, Pudong, Shanghai, the 49683 recorded event intervals of 6:00-20:00 during 16/02/2009-20/02/2009. These are analyzed below; precisely 500 points are presented in Figure 1.

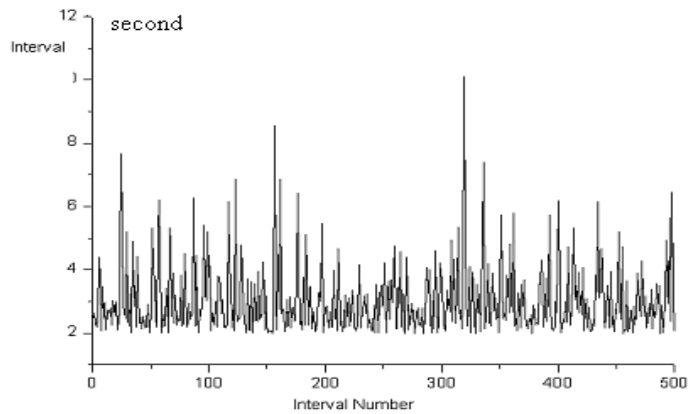

Figure 1. Vehicle Intervals.

The BHHH algorithm in the GAUSS system is used for EACD (1,1) parameters estimation, while the model may be written as: $\Psi_i = 0.126 + 0032 x_{i-1} + 0.932\ \Psi_i$, its validation is shown in Figure 2.

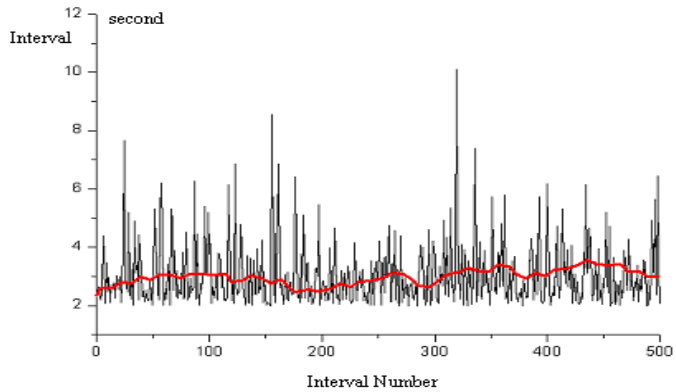

Figure 2. EACD (1,1) Model Fitting Result.

This model well describes the vehicle detection intervals, where the mean value is 3.5, five minutes are used as a traffic flow calculation unit. The short-term traffic prediction is the calculation for the intervals based on the EACD (1,1) model, where its status equation is:

$$x_i = \psi_i \varepsilon_i = (\omega + \alpha x_{i-1} + \beta \psi_{i-1})\varepsilon_i = (0.126 + 0.032 x_{i-1} + 0.932 \psi_{i-1})\varepsilon_i \,,$$

$$\varepsilon_i \sim Exp(1,1) \qquad 1)$$

Since it is the prediction of five-minute-based events in the future, without recorded data for validation, here the status value has a zero mean white noise which is used as the recorded value: $z_i = x_i + \mu_i$

Equation (1) is an non-linear status model which can only be well predicted with a PF method. Based on the algorithms presented in section 3, the result time series is $\{x_i/(x_1+x_2+\cdots+x_N) \leqslant 600\}$, where N is the predicted five-minute short-term traffic flow.

Figure 3 presents the recorded five-minute traffic flow data fit with the predicted value (the dot line is the recorded value):

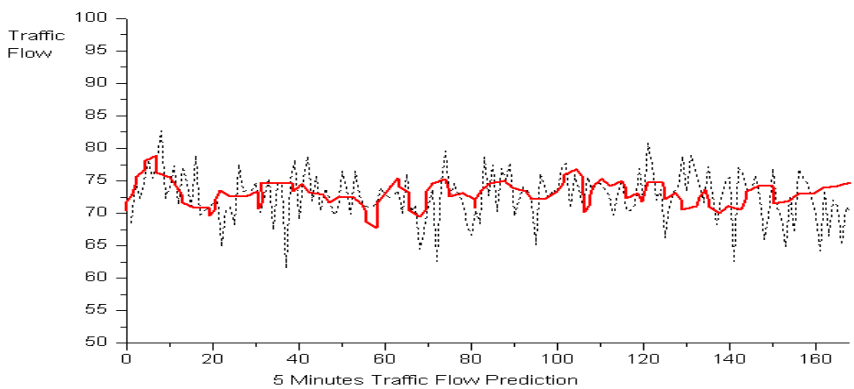

Figure 3. The prediction by particle filter.

The resulting well fitted recorded data may divide the road congestion to nine grades, where the five- minute traffic flow prediction error is within three grades, and may be used as the output of a guidance system.

CONCLUSION AND FUTURE WORK

This paper proposes the ACD model and PF combined approach for a short-term (five-minute) traffic flow prediction algorithm that was validated by using it with a city traffic guidance project. The desired effect was achieved.

Future research may be based on the choice between different ACD models for better description and prediction of traffic flow.

ABSTRACT

In response to on-ramp queue length and control-threshold restriction, an ALINEA-based local traffic-responsive metering strategy controls the Wuyi on-ramp in the Shanghai urban expressway network. The ALINEA parameter study results, integrating data analysis, determined the ALINEA parameter's values. The analysis of a local ramp's traffic-responsive metering mechanism fixes on its control-threshold parameters. The Wuyi on-ramp data analysis determines the control-threshold parameters and builds the Wuyi on-ramp control-threshold table. The queue-length subsection restriction model was built according to the analysis of an ALINEAR classic queue model given the Wuyi on-ramp's physical characteristics. The control-threshold and ALINEA algorithm and the queue length subsection restriction model constitute the Wuyi on-ramp local traffic-responsive metering strategy. The off-line simulation results show that this ramp metering strategy can not only even out the ramp volume's pulse characteristics but can also increase the mainline speed and relieve the mainline downstream congestion.

INTRODUCTION

Ramp metering, when properly applied, is a valuable tool for efficient traffic management on freeways and freeway networks (Emmanouil Smaragdis et al., 2004). Based on the results of several field implementations in European countries (M .Papageorgiou et al.,1991 and 1997), the ALINEA ramp-metering control strategy, proposed by Papageorgiou in the 1990s, has been shown to be a remarkably simple, highly efficient and easily implemented ramp metering application (Xu Yang et al., 2002). Simulation-based evaluation studies on a number of adaptive ramp-metering environments showed the competitive performance of ALINEA compared to other coordinated ramp metering systems (H.M.Zhang et al., 2001). Because of the high performance of this algorithm, ALINEA is an excellent tool when embedded into a coordinated ramp control or integrated control system (Xu Yang et al., 2002).

To ease the mainstream congestion caused by an urban expressway on-ramp pulse traffic stream and to mitigate the effects on the surface street caused by the

queue length at the on-ramp, it is necessary to undertake further study of the urban expressway on-ramp control strategy. The city's (internal) expressway on-ramp metering strategies may benefit from highway ramp control strategies and the experiences of other countries in reducing their urban expressway traffic congestion so as to improve the efficiency of our road networks. But the highway and the urban expressway have important differences, both in facility structures and in transport modes. So the Shanghai urban expressway on-ramp local-metering strategy cannot simply use the ALINEA algorithm but we here propose a control threshold and an extension of the queue length model to cooperate with the ALINEA algorithm. Simulation results and our analysis are presented in Section 4.

THE ALINEA STRATEGY

The ALINEA algorithm, a local feedback ramp metering strategy, attempts to maximize the mainline throughput by maintaining a desired occupancy on the downstream mainline freeway. The ALINEA strategy makes use of real-time traffic measurements in the vicinity of a freeway ramp, in order to calculate suitable ramp metering flows. It's activated at each time interval T. The metering rate, at the end of each running period T, is calculated based on the following formula:

$$r(k) = r(k-1) + K_R \times [O_{dir} - O_{out}(k-1)] \qquad (1)$$

Where r(k) is the ramp flow (in veh/h) to be implemented during the new period, k; O_{dir} is the desired occupancy (in %, typically, it is set equal to or slightly less than the critical occupancy) of the downstream detector station; then O_{out}(k-1) is the last measured downstream occupancy (in %), and K_R (in veh/h) is a regulator parameter.

The ALINEA algorithm has three parameters to be calibrated: the desired occupancy of the downstream detector station, the update cycle of each metering rate T, and a constant regulator K_R. The following is a summary of parameter settings used in previous research and implementations (Papageorgiou et al., 1990, 1991, and 1997; Xu Yang et al., 2002).

1. The desired occupancy can be equal to or close to the occupancy value at capacity, which can be found in the volume-occupancy diagram. Various values ranging from 0.18 to 0.31 have been found in previous applications.

2. Control results have been found to be insensitive for a wide range of values of the regulator KR, used for adjusting the constant disturbances of the feedback control. In real-world experiments, the algorithm has been determined to perform well for KR=70.

3. A wide range of values for the update cycle of the ramp-metering rate have been used: from 40 seconds to 5 minutes.

The ramp flow r(k) resulting from (1) is truncated if it exceeds a range [$MinR^T_{ramp}$, $MaxR^T_{ramp}$], where $MinR^T_{ramp}$ is the minimum admissible ramp flow and $MaxR^T_{ramp}$ is the ramp's flow capacity. This application of ramp metering may lead to the formation of an on-ramp queue. If it appears likely that the queue length exceeds a certain limit, such as that which interferes with the surface street traffic, ramp

metering is temporarily disengaged to allow a decrease of the ramp queue (Emmanouil Smaragdis et al., 2004). The ramp flow is truncated based on the following formula:

$$Max[d(k-1)-\frac{L_{\max}-l(k)}{T}, MinR_{ramp}^{T}] \le r(k) \le Min[d(k-1)+\frac{l(k)}{T}, MaxR_{ramp}^{T}] \quad (2)$$

Where d(k-1) is the ramp flow demand during the last period, k-1; L_{max} is the ramp maximum admissible queue length, and l(k) is the queue length at the beginning of the period k.

CONTROL THRESHOLD

The purpose of this study lies in the practical metering application of the Wuyi on-ramp in the Shanghai urban expressway network. The Wuyi on-ramp metering strategy cannot simply transplant the ALINEA strategy, which is successful in freeway ramp metering, but expands the ALINEA strategy according to the differences between the freeway and the urban (internal) expressway.

The differences between the freeway and the urban expressway may be classified as follows:

1) The mainline traffic flow and the ramp demand of urban expressways are clearly more than that of a freeway, especially the peak time ramp and mainline demand. Because the distances between the neighboring ramps of an urban expressway are much shorter than that of a freeway, the mainline traffic status of an urban expressway is more easily affected by its ramp flow.

2) The average trip distance on the Shanghai urban expressway network is less than five km, whereas drivers commonly use the freeway for long-distance travel. So the urban expressway users are more sensitive than the freeway users to the queue time. Though the urban expressway ramp length is shorter than the freeway's, the average ramp demand of an urban expressway is much higher.

Recent applications of ALINEA revealed a number of issues and needs that are not sufficiently covered by ALINEA or other available local ramp metering strategies (Emmanouil Smaragdis et al., 2004), including:

1) Use of upstream (rather than downstream) measurements.

2) Use of flow-based (rather than occupancy-based) set values and measurements.

The mainline traffic situation can be divided into three types: smooth traffic, traffic congestion and traffic jam. Therefore, the urban expressway ramp metering strategy may be divided into three types of control modes: no control, ramp metering and ramp closure. The control conditions, which decide the ramp status to be changed, constitute a control threshold table.

CONTROL CONDITIONS

No-control to ramp-metering

During the no-control status, ramp flow cannot commonly change the mainline status from free to congested. When the sum of the mainline upstream volume and the same time ramp flow exceeds a certain limit, such as the mainline

downstream capacity, the mainline traffic status can be changed to congested status. This control condition may be concluded from the following formula:

$$\begin{cases} q_{upstream} + q_{ramp} \geq CQ^{T}_{downstream} \\ o_{downstream} \geq O^{on}_{downstream} \end{cases} \quad \text{(no-control to ramp-metering)} \quad (3)$$

Where $q_{upstream}$ is the mainline upstream volume during the period T; q_{ramp} is the ramp flow at the same period T; $o_{downstream}$ is the real-time detecting occupancy of the downstream mainline; $CQ^{T}_{downstream}$ is the mainline downstream maximal admissible volume in the period T; and $O^{on}_{downstream}$ is the mainline downstream critical occupancy.

Ramp-metering to ramp-closure

When ramp-metering cannot ease the mainline downstream congestion and ramp flow may lead mainline traffic status to become worse, the on-ramp should be closed. For this control condition, the downstream mainline traffic situation is traffic congestion and the upstream mainline traffic demand is the main reason for downstream traffic congestion. The downstream mainline traffic congestion has affected the upstream mainline traffic. The ramp-metering to ramp-closure condition reads

$$\begin{cases} q_{downstream} \leq Q^{close}_{downstream}, o_{downstream} \geq O^{close}_{downstream} \\ s_{upstream} \leq S^{close}_{upstream} \end{cases} \quad \text{(ramp-metering to ramp-closure)} \quad (4)$$

Where $q_{downstream}$ is the downstream mainline volume during the period T; $o_{downstream}$ is the real-time detecting occupancy of the downstream mainline; and $s_{upstream}$ is the real-time detecting speed of the upstream mainline. For the ramp-metering to ramp-closure condition, $Q^{close}_{downstream}$ is the critical traffic volume of the downstream mainline during the period T, and $O^{close}_{downstream}$ is the critical traffic occupancy of the downstream mainline, and $S^{close}_{upstream}$ is the critical speed of the upstream mainline. These critical factors may be found through the traffic data analysis.

Ramp-metering to no-control

After the ramp is operating under metering status for some time, the downstream mainline traffic eases up again. If the ramp flow and the upstream demand meet certain conditions, the ramp status may change into no-control again. This control condition can be concluded by the following formula:

$$\begin{cases} q_{ramp} + q_{upstream} < CQ^{T}_{downstream}, o_{downstream} < O^{on}_{downstream} \\ s_{upstream} > S^{open}_{upstream} \\ t \geq N_{open} T \end{cases} \quad \text{(ramp-metering to no-control)} \quad (5)$$

Where t is the real-time detecting time; $S^{open}_{upstream}$ is the critical speed from the ramp-metering status to the no-control status; N_{open} is the minimum update cycle number when the ramp is at the ramp-metering status; and other factors are the same

with the formula (3) and (4).

Ramp-closure to ramp-metering

After the ramp is closed, the mainline traffic situation becomes increasingly better. Until the upstream speed and the downstream volume exceed these critical values and several update cycles have passed, the ramp may be changed into metering status again. This condition can be read:

$$\begin{cases} q_{downstream} > Q^{close}_{downstream}, o_{downstream} < O^{close-on}_{downstream} \\ s_{upstream} > S^{close}_{upstream} \\ t \geq N_{on} T \end{cases} \quad \text{(ramp-closure to ramp-metering)} \qquad (6)$$

Where $O^{close\text{-}on}_{downstream}$ is the critical occupancy of the downstream mainline, then N_{on} is the minimum update cycle number for the ramp-closure to ramp-metering control condition. Other factors are the same as in formula (3), (4), and (5).

Control Threshold Table

Through the analysis of the detecting data related to the Wuyi on-ramp metering strategy, from July 25, 2007 to July 31, 2007, these critical values were fixed and placed on the control threshold table of the Wuyi on-ramp metering strategy.

Table1. Control threshold about Wuyi on-ramp.

Control Condition	$o_{downstream}$	$q_{downstream}$	$s_{upstream}$	$q_{ramp}+q_{upstream}$	Time
No-control to ramp-metering					
Ramp-metering to ramp-closure	>30%	/	/	≥80pcu/**min**	/
	>45%	<30pcu/min	<20km/h		/
Ramp-metering to no-control	<30%	/	>40km/h	<80pcu/min	T≥5min

QUEUE LENGTH SUBSECTION RESTRICTION MODEL

The ALINEA classical queue restriction model has proven to be efficient for freeway ramp metering. While the ramp demand of an urban expressway is heavier than that of a freeway, and the ramp queue space of an urban expressway is shorter than a freeway's, a more sensitive queue restriction model should be proposed.

Both $MinR^{T}_{ramp}$ and $MaxR^{T}_{ramp}$ are used in the freeway ramp metering strategies with experienced values (Xiao-peng Zhou, 2006)), so the new extreme values for the urban expressway ramp queue control models should be fixed, based on the following formulas:

$$CQ^{T}_{upstream} + MinR^{T}_{ramp} \xrightarrow[\infty]{} CQ^{T}_{downstream} \qquad (7)$$

$$AQ^{T}_{upstream} + MaxR^{T}_{ramp} \xrightarrow[\infty]{} CQ^{T}_{downstream} \qquad (8)$$

where $CQ^{T}_{upstream}$ is the upstream mainline capacity; $CQ^{T}_{downstream}$ is the downstream mainline capacity; and $AQ^{T}_{upstream}$ is the upstream mainline peak period

average volume in one period T. Based on the analysis of the traffic data related to the Wuyi ramp, $MinR^{T}_{ramp}$= 4veh/T and $MaxR^{T}_{ramp}$=24veh/T。

The urban expressway ramp is divided into an inclined part and a horizontal part. Queuing vehicles expect to wait at the horizontal part from a secure point of view. The queue length of the Wuyi on-ramp's horizontal part is L_{hor} and L_{hor}=36veh, and the queue length of the Wuyi on-ramp is L_{end} and L_{end}=92veh. A separate part of the ramp's horizontal part is designated the expected queue section, and the entire horizontal part and a part of the inclined ramp constitute the maximal queue section.

So the queue length subsection restriction model reads:

$$Max[d(k\text{-}1)-\frac{L-l(k)}{T}, MinR^{T}_{ramp}] \le r(k) \le Min[d(k\text{-}1)+\frac{l(k)}{T}, MaxR^{T}_{ramp}] \qquad (9)$$

If l(k)<20veh, then L= L_{exp};

If 20veh=<l(k)<36veh, then L= L_{hor};

If 36veh=<l(k)<64veh, then L= L_{max};

If 64veh=<l(k), then L=L_{end}。

Where L_{exp} is the expected queue section and L_{exp}=20veh; L_{max} is the maximal queue section and L_{max}=64veh. Other factors are the same as in Formula (2).

As compared to Formula (2), the advantage of this queue restriction mode is its great sensitivity. When l(k) is short, L is short too. So the L's sensitivity to the change of l(k) is improved. The lower boundary of r(k) increases with the increase of l(k). When l(k) exceeds a certain limit, L is changed and L's sensitivity to l(k) decreases. So the lower boundary of r(k) can't be a sustained increase. The queue length subsection restriction model makes the r(k) lower boundary increase more smoothly.

SIMULATION AND ANALYSIS

This on-ramp metering strategy was tested in a simulation environment which was coded by VB. The utilized parameter values were K_R＝70 veh/h, O_{dir}＝30 %, and T=60 sec.

Impact on the downstream mainline traffic

Table 2. Speed and traffic volume compare of main line.

RAMP STATUS	SPEED OF DOWNSTREAM MAINLIEN			VOLUME OF DOWNSTREAM MAINLINE		
	MAXIMUM (km/h)	MINIMUM (km/h)	AVERAGE (km/h)	MAXIMUM (veh/min)	MINIMUM (veh/min)	AVERAGE (veh/min)
NO CONTROL	66.70	12.30	26.13	72	30	59.36
METERING	60.88	20.89	44.06	77	21	55.89

The following is our analysis of the results of Table 2.

1) Speed in the downstream mainline increases palpably under the ramp metering. The statistics of a seven day period shows that as against no control, with this method, the average speed of downstream mainline increases by

17.93 km/h.

2) The average volume of the downstream mainline is 55.89 veh/min, which is close to the no-control average volume.

Though the average volume of the mainline is slightly less than the no-control average volume, the average mainline speed is much more than the no-control speed. Results from the simulation show that this ramp metering strategy can improve downstream mainline traffic conditions as compared to no control.

Impact on the Wuyi on-ramp

Table3. Impact on the Wuyi on-ramp.

MAXIMUM QUEUE LENGTH (PCU)	AVERAGE QUEUE LENGTH （PCU）	METERING TIME（MIN）
48	3.2	332

From Table 3, although ramp metering improves the mainline traffic conditions, the Wuyi on-ramp traffic flow is also affected. The maximum queue length over seven days is 48 pcu, which does not go beyond the L_{max}. The average metering time is 332 minutes and the average queue length is 3.2 pcu. So the queue length subsection restriction model keeps the queue length at an expected length and avoids interference with surface street traffic.

CONCLUSION

In this paper, an extension of the feedback local ramp metering strategy ALINEA for urban expressways was proposed, allowing the urban expressway ramp to have three control models, including no control, ramp metering, and ramp closure. The ramp control model was changed according to the comparison of the control threshold and the real-time detecting traffic data. During the ramp-metering cycles, the queue length subsection constraint model was proposed to avoid the ramp queue length exceeding the ramp's capacity for queue length. So this local metering strategy for an urban expressway may be constituted with three parts: a ramp-model control threshold, an ALINEA algorithm and the queue length subsection constraint model. The off-line simulation results show that the ramp metering strategy can both increase the main line speed and relieve the urban expressway main line downstream congestion. This queue length subsection constraint model also avoids an on-ramp queue's interference with surface street traffic.

Abstract

In order to solve the parking problems in the metropolises, a new approach integrating active pattern for parking guidance information system including parking lots, cars, parking information service center and traffic management center is proposed. Active parking mode can avoid some inherent problems, such as low guidance obedience rate, low information resources utilization rate, as well as low overall system performance. Through implementing the self-interested negotiation among the functional entities of parking guidance system, an overall balance of interests can be achieved. Through using the intelligence, adaptability and collaboration of agents, the active parking guidance system can automatically execute park searching, parking price negotiation, parking space booking and parking routes negotiation and guidance.

Key words: Multi-agent System; Parking Mode; Active Parking Guidance; Negotiation Framework;

1. Introduction

During the fast-development of urban cites, the number of vehicles increase rapidly so that the parking demand is much greater than supply in metropolises. Thus the parking problem is serious than ever before. Currently, the Parking Guidance Information System (PGIS) is employed as a main technical measurement to solve the parking problem. The PGIS collects all the available parking information, and later releases all the processed information to the drivers with parking demand through various ways (radio, VMS, Web, telephone, short message). A typical architecture of existing PGIS is shown in Figure 1.

However, this general information-based guidance pattern can be defined as "passive parking guidance", which does not consider the activity, individual requirements, as well as the vital interests of the drivers and can't effectively solve the interests' conflicts problem between the whole traffic system and drivers, resulting in low parking obedience rate and weak collaboration performance.

This paper intends to apply the concept "activity" to establish an active parking guidance pattern which emphasizes the collaboration, interaction and negotiation between the PGIS and the drivers. It aims at providing a better connection for the two and thus maximizing the overall benefits of the PGIS and the parking

guidance service quality. Another contribution of our work is to establish the framework for the theoretical system of active parking negotiation.

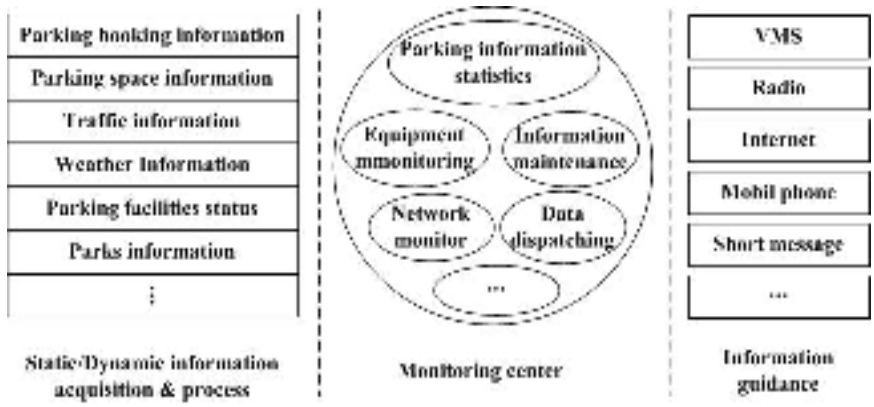

Fig. 1. A typical PGIS architecture

2. Limitations of traditional passive parking guidance

With the objective of the optimization of overall system, passive parking guidance pays more attention on the collection, processing, transmission, distribution of meta-information by parking and traffic, and treats the travelers as passive recipients in the whole parking-decision-making process, so this pattern neglects the activities, personal interests and individual needs of the travelers as active individuals.

Static parking routes guidance rarely considers traffic congestions. Even though dynamic parking routes guidance take into account the dynamic traffic assignment, due to the neglect of the travelers' personal interests, it cannot effectively solve the benefit conflicts (system optimum or individual optimum) between parking guidance system and the individual travelers, thus resulting in low parking obedience rate, weak comprehensive and collaboration performance.

To simplify these issues and data processing, the traditional passive parking guidance system adopts a number of idealistic assumptions conditions (travelers' behaviors are predictable or travelers all comply with the guidance information) to develop the traffic model and design of optimization algorithms (Chen O J W, 1998); however it is difficult to overcome the inherent shortcomings.

The processing of guidance information overly depends on statistical methods, fuzzy theory and mathematical programming model, which seldom takes into account the travelers' interests of. Even more, the characteristics of non-linear, dynamic time-varying and high distribution in the large-scale urban transportation system can also cause a rigid mechanism in passive parking guidance system.

3. Active parking guidance

3.1 Active traffic guidance

Active traffic guidance first appeared in the study of coordination between the urban traffic control system (UTCS) and urban traffic flow guidance system (UTFGS)

(Fisk C S, 1984). Traffic managers developed the control and guidance strategies for the transport network from the point of view of the entire system optimum, which conflicts with the individual traveler optimum. Therefore, in order to improve overall network performance, researchers began to study the coordination strategies between traffic managers and travelers while focusing on travelers by coordinating UTCS and UTFGS (Chen O J W, 1998), which is the initial active guidance mode with the participation of travelers.

However, such primitive coordination is based on the assumptions that travelers' behaviors are predictable or travelers all comply with the guidance information. Thus the methodologies, such as the evolutionary game theory, bounded rationality, artificial psychological and artificial emotion to study driver's response to the guidance information are applied. While the estimated traveler's demand is often inconsistent with the real situation and the travelers still accepted the information passively.

So, actually this primitive coordination is not an exact equitable negotiation between system managers and travelers' respective objectives. When the objectives of system and travelers are inconsistent, or even opposite, it is very difficult to achieve a valid coordination.

3.2 Active traffic guidance

Parking guidance system and the travelers are two different entities with different benefits seeking. They have a "competitive benefits" relationship in parking facilities, road resources, and time and space resources. The mode of coordination and cooperation in existing traffic systems cannot effectively solve the conflicts. Parking guidance system and the travelers need to start a negotiation based on their respective interests such that:

(1) Simultaneously improve user acceptance while enhancing net-work performance.

(2) Achieve an efficient reallocation of network capacity over time and space without seriously violating any individual user's preferences.

(3) Not to seriously affect the other parties and maximize their own interests.

Here, negotiation is also a kind of coordination, but put more emphasis on participants' activities in the coordination process, as well as the satisfaction of participants' interests. Therefore, the active parking negotiation between the parking guidance system and travelers needs deep negotiation, and can clearly demonstrate the self-interest of in the process of interaction, cooperation, thus conform to the real transport environment.

Negotiation theory has played an important role in intelligent UTCS and UTFGS. Negotiation will be the major activities in building the active parking guidance system. By using multi-agent technology for modeling traffic control systems, traffic management and decision-making can be easily implemented in the

form of interactive negotiation.

In recent years, new technologies, such as Vehicle Information Communication Systems (VICS), GPS, GIS, wireless communication, and mobile computing have gradually been applied into parking service systems. Agent technologies have the great potentials in solving the problems in the dynamic distributed and complex traffic environment (Hernandez, J. Z., 2002, Choy, M. C., 2003, Chen, B., 2008) and can be integrated with the new technologies mentioned before to provide a good solution and to establish the negotiation network and automation mechanism for the active parking guidance system with highly interactive and dynamic behaviors (Chou, S., 2008). The active agent-based parking negotiation network system architecture is shown in Figure 2.

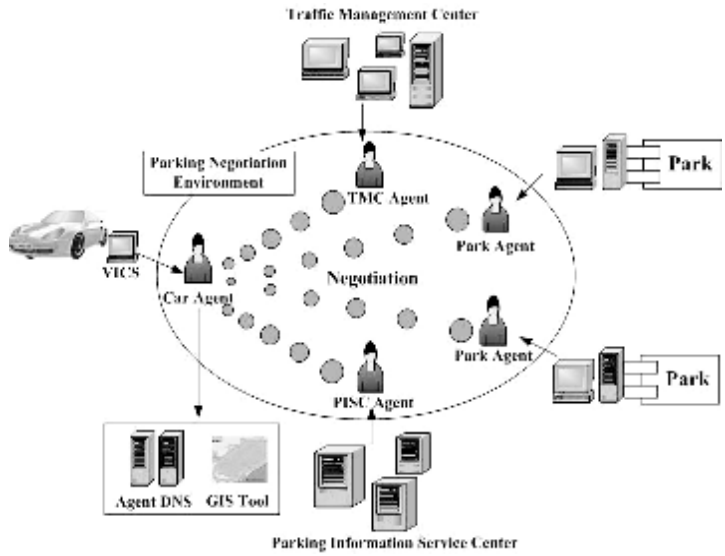

Fig. 2. Active parking negotiation network system

4. Negotiation framework system for active parking guidance

4.1 Negotiation activities under active parking guidance

Analyzing the negotiation demand of parking guidance system entities, including motor vehicles (Traveler), car parks, parking information service centers, traffic management centers, is the first step for designing the active parking guidance system. In order to study the internal parking guidance negotiation mechanism, parking system entities functions, behavioral characteristics, interactive mode, the characteristics of information, should be emphasized. The proposed active interaction among the functional entities is shown in figure 3.

4.2 Negotiation framework theory under active parking guidance

(1) Negotiation participants combining method

The determination of negotiation participants combining is the first step to ensure the effective negotiation functions. Before establishing all kinds of specific

negotiations, the challenge is to design a highly efficient, dynamic and flexible combination method for all the participants based on the participants' characteristics and negotiation environment.

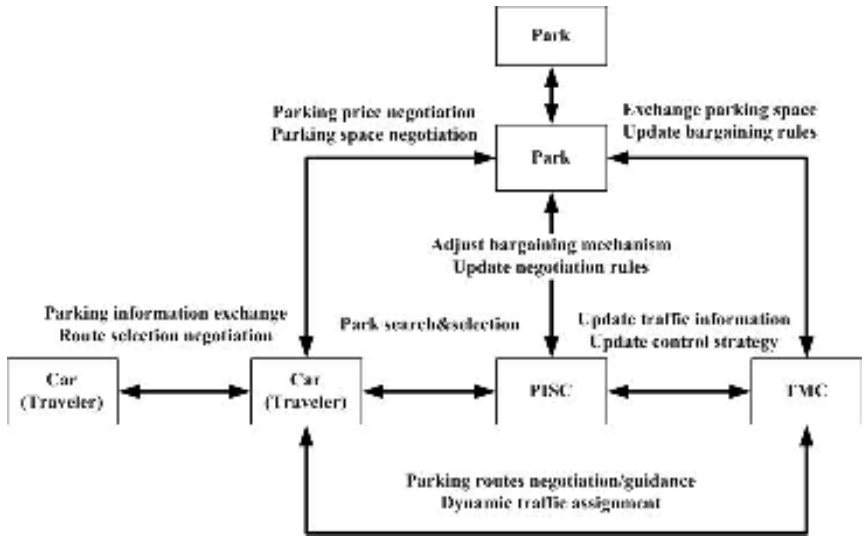

Fig. 3. Active interaction of the functional entities in PGIS

(2) Negotiation issue selection

Under different negotiation environment and information status, the selection of negotiation issue should base on the analysis of the characteristics and its impact on the overall parking guidance service standards, and specific negotiation activities.

(3) Negotiation primitive language design

Based on the characteristics of parking negotiation participants, contents and structure of interactive issues, interactive mode, specific scenes, and the specific information requirements of the participants, negotiation primitive language should be designed easily for the participant to clarify their intention.

(4) Negotiation protocol design

Effective negotiation protocol can improve the parking guidance efficiency, fulfill the requirements of real-time multi-point negotiation, speed up the flow of guidance information, reduce negotiation conflict, and finally ensure the efficient, safe and stable negotiation. To design the simple and efficient negotiation protocol, it should consider the characteristics and combining manner of all the negotiation participants, and the negotiation issue under specific negotiation activity.

(5) Negotiation strategies set design

Building of active parking negotiation strategies set requires a comprehensive analysis of the various possible negotiation combinations of participants and negotiation issue selection of active parking guidance under different specific negotiation environment and negotiation protocol.

(6) Negotiation decision-making model

Based on the negotiation combinations, characteristics of negotiation issue and the inherent complexity of parking guidance system, the design of negotiation utility computing model and evaluation model should include self-interest of participants (maximize their own interests), timeliness and non-precision in the processing of data, and to exactly express the true interests of participants.

5. Conclusion

Active parking guidance is an advanced method compared with traditional passive parking guidance. The concept of "Active" can avoid some inherent problems, such as low guidance obedience rate, low information resources utilization rate, as well as low overall system performance. The negotiation theory and method for active parking guidance proposed in this paper provides a theoretical support and a scientific basis for the active mode of parking guidance. Through realizing the self-interested negotiation among the motor vehicles (traveler), car parks, parking information service centers, traffic management centers, an overall balance of interests can be achieved. Intellectualization is the development direction for the parking guidance system. Integrating the "Active mode" with parking guidance system provides an absolutely new idea for the design and implementation of "intelligent" PGIS, and as well offers a targeted solution for the existing inherent problems in the PGIS.

ABSTRACT

A series of sensors on the pavements being used for traffic flow data detection have some disadvantages. With recent advances in high-resolution commercial remote sensing systems, detecting traffic flow data from remote sensing images over large regions is an attractive option in traffic information collection technology. The main goal of this research is exploring vehicle information from high-resolution satellite remote sensing images. A new method for vehicle detection based on object-oriented image analysis is developed and applied in this paper. Analyzing high-resolution satellite image characteristics, object-oriented segmentation is implemented here in order to generate image objects. Then feature space is created by extracting features of these objects, to be used for vehicle detection, classification, and traffic flow information analysis. Our experimental results as described and assessed here show how this method is effective. Our research provides a means of traffic flow information collection in ITS as compared to traditional approaches.

INTRODUCTION

Many studies reveal that advanced traffic data collection and traffic information extraction are a foundation for intelligent traffic guidance or reasonable traffic flow distribution in ITS. Since the 1970s, various technologies have been developed to explore traffic flow information from sensor data (Shi Zhongke, Cao Li, 2007). Recently more vehicle information has been extracted from traffic images using a ground-based video imaging system. However, due to the limited coverage of this method, we can't use it to access a wide range of traffic information at the scene. We expect to collect more valuable traffic data from a more distant perspective. With the development of commercial satellite remote sensing technology, we can use ideal image data to exploit traffic information for a global and detailed analysis (Eikvil, L., et al., 2008). The traffic data collection from satellite images has the potential to be a meaningful supplement for ground traffic monitoring systems in ITS.

The main goal of this research is to extract vehicle information from a high-resolution satellite image. This paper introduces a new method for vehicle detection based on object-oriented image analysis. By analysis of image characteristics, object-oriented segmentation is implemented to generate image objects, and the features of these image objects are extracted to build feature space, to be used for vehicle detection and classification, and furthermore for traffic information analysis. Lastly, the experiment is assessed, and the method for vehicle extraction proved to be valid.

METHODOLOGY OF OBJECT-ORIENTED IMAGE INTERPRETATION

Usually we use the naked eye to identify feature categories from images, and so-called visual interpretation. In this process, our eyes discern color, texture, shape and other characteristics of images. The higher the spatial resolution is, the more features we can analyze in detail, and the higher the accuracy of our classification will be. Yet most computer image analysis is based on pixels. A pixel's features, such as graying and texture, are analyzed, and the feature's differences are used to discriminate between categories of features in determining classification. For higher-resolution imagery, the differences increase not only among objectives but also in the internal parts of the objectives (Markham B L, et al., 1981). So pixel-based image analysis, applied in a high-resolution image, is very sensitive to noise and can lead to error classification.

Thus, to improve accuracy in classification, an image analysis unit becomes a homogeneity image unit (so-called image object), which is obtained by taking into account shape, texture and other characteristics. We can describe object-oriented image analysis to detect and classify vehicles from satellite remote sensing images as follows:

(1) Multi-segmentation under certain criteria creates image objects to build a hierarchical image object network;

(2) Extract image objects features to constitute feature space for classification;

(3) Execute classification algorithms to identify image objects in feature space.

VEHICLE INFORMATION EXTRACTION FROM A SATELLITE IMAGE

Segmentation

Image segmentation, the key step in image processing, is used to subdivide the entire image into regions to extract a target of interest. This paper takes multi-segmentation algorithm twice (see Figure 1), using bottom-up region merging technology from the pixel level to the entire image at different scales. Firstly, segment at large scale and create image object level-1 for road region identification, as this region is valid for traffic information extraction. Secondly, further segment at a small scale in the road region, which is identified on level-1 (see section 3.3). The second segmentation results, in the image object on level-2, are prepared for vehicle classification. Finally, the object network is constructed, affording the advantage that the object knows its neighborhood, its super-object and its sub-object (User Guide eCognition, 2007).

Figure 1. Multi-scale segmentation.

Segmentation criteria

The successful design of segmentation requires better criteria, including:

(1) Setting image layer weights w_L. It is necessary to expand differences among the objectives by increasing important layer weights (Jensen, J.R, 2005).

(2) Setting scale parameter. This depends on the classification task or the size of the objectives. For example, setting a larger scale can merge larger-difference image objects for road classification.

(3) Setting Composition of Homogeneity Criteria. A homogeneity Criterion is used as a synonym for minimized heterogeneity. Internally, three criteria are considered: color, compactness and smoothness. The relationship between them is shown in formula (1). Adjusting weights can create objects under different criteria. For example, adding color weight allows spectral-heterogeneity to the image so objects can emerge for the classification of bright vehicles, while a dark vehicle is distinguished by adding shape weight.

Multi-segmentation can be described using the following formula. Two image objects which have a lower difference f than a certain threshold T (determined by the scale parameter), can merge. So we adjust the w_{color} scale parameter, w_{color} and $w_{compact}$ to change the segmentation criteria (Ursula C Benz, etc. 2004).

$$\begin{aligned} f &= w_{color}h_{color} + (1-w_{color})h_{shape} \\ &= w_{color}h_{color} + (1-w_{color})[w_{compact}h_{compact} + (1-w_{compact})h_{smooth}] \le T \end{aligned} \quad (1)$$

The best segmentation criterion is not uniform because of its condition influence. To choose the best one, we have to compare segmentation results under different criteria.

Image objects

The primary segmentation produces objects with coarse heterogeneity on a large scale. We can identify some objects as part of the road because they are similar to it. After the road is identified, (see section 3.3), new information is generated to be used for the next segmentation. The second segmentation limited within the road region generates objects with more precise criteria for vehicle classification. In this way, the pixel level, the image object levels and the entire image compose a hierarchical object network.

Feature extraction

Features of the image object include color, shape and so on. In the hierarchical object network, the image object of each level corresponds to a feature vector, which constitutes the feature space (Guan Yuanxiu, 2008).

Depending on the demands of the road and the vehicle classification, both the Object Feature and the Class-Related Feature are extracted. The Object Feature is used to evaluate an image object itself as well as its location in the hierarchy object network. For example, using a "Mean" can identify both bright vehicles and road markings because of their more obvious mean range in good lighting conditions, while using a shape feature in the form of an external rectangular "Length", or by specifying the "Length/Width" feature, we can extract other artificial objects. Class-related features, constructed by referring to a classified image object (either in a vertical or neighbor relationship), can be used to classify the unclassified image objects. For example, using the above-mentioned Object Feature can easily classify part of the road surface but not all of it. In the rest of the region, the border and the road markings embedded in the road surface can be classified by class-related features. For example we can use the feature of "relative border to classified objects" in order to classify the border and the road markings with a value more than 0.5 or even close to 1.

Classification

Classification is the process by which we link image objects with a class hierarchy. Using a certain classification algorithm, we can classify each image object to a specific category (or unclassified), which is executed according to the difference of features in section 3.2.

For high-resolution remote sensing images, it is difficult to classify image objects as a particular type that only depends upon a single feature. Fuzzy classification is a powerful soft classifier that uses a membership function to replace its feature value with a membership value for a certain category (between 0-1 fuzzy values) (Benz, 2004). If the value is in the required range, the image object will likely belong to a certain defined class, and if it is out of range, it will of course not belong to that class. Considering different objectives to extract, here are two fuzzy classification algorithms, the Conditions Combination for bright vehicle classification and the Nearest Neighbor algorithm for dark vehicles.

Regional restriction for vehicle information extraction

Selecting "Ratio" and "Length/Width" features to identify the road region, the process is described as follows:

$$if\,[Ratio(object) \in RLR]\ AND\ [Length/width(object) \in RL/W],\ then\ land\ cover(object) = road \tag{2}$$

RLR, RL/W are allowed the "Ratio" and "Length/Width" ranges of the image objects of the road.

Formula 3 can classify part of the road's objects but not all the real-world road objects. In the rest of the unclassified objects, some objects can be classified further. This process can be described as follows:

$$if\,[rel.border\ to\ Road\ Region \in RB],\ then\ unclassified(object) = road \tag{3}$$

Using the "relative border to" feature, RB is limited within the range of another road region, such as its boundary or road marking.

Bright vehicle classification

On a small scale, bright vehicles contrast sharply with road objects, considering their spectral characteristics. So after extracting its features, a bright vehicle can be detected further with features, such as "Mean," "Area" and "Length/Width." So on the basis of the description above, the following process should be added:

$$\begin{aligned} &if\,[Length(road\ object) \in VL]\ AND\,[Width(road\ object) \in VW] \\ &AND\,[Length/Width(road\ object) \in VL/W],\ then\ road(object) = vehicle \end{aligned} \tag{4}$$

VL, VW and VL/W are used to limit the range of image objects' $Length$, $Width$, $Length/Width$.

Dark vehicle classification

With its low contrast, a dark vehicle can be identified by various features. The color and texture of a dark vehicle are not obvious and internal gray value is heterogeneous. If we use the Conditions Combination described in section *Bright vehicle classification*, it will result in error classification. Thus, we take advantage of the nearest neighbor algorithm to classify a dark vehicle in the feature space. First, we select a feature and edit the "Nearest Neighbor" membership function, and the slope of that function determines the membership value of its image objects. The image objects,

closer to the samples, are probably identified as being in a certain class, and then classified according to the category of the nearest sample.

EXPERIMENT AND DISCUSSION

Figure 4 shows a high-resolution image with a scene of a road link in a certain city. Orthorectified image data (after radiometric correction and orthorectification) was selected from QuickBird, including four spectral bands (red, green, blue and Near IR), and a panchromatic band. The spectral bands with 61cm (2ft) or 70m (2.3ft) resolution are suitable for texture analysis, and the panchromatic band with 2.44m (8ft) or 2.80 (9.2ft) resolution is fit for spectrum analysis (Digitalglobe Inc, 2009). We cut out part of the image as a study area, and combined layers of R, G, B bands to form a true color image after its histogram equalization (see Figure 2).

Figure 2. True color image after histogram.

Segmentation at large scale

We set the band layer weights to R: G: B: NIR: Pan = 1:1:1:0:1. The high-resolution image, especially the true color image, is more distinguishable （Jensen, J.R , 2005; Dai Changda, et al., 2004).

The segmentation results were analyzed to determine which parameters of criteria afford better results under these conditions (see Figure 3). Segmentation at a small scale, such as 100 or 300, yields a complicated result which is difficult to classify the road region. Segmentation at a 600 scale generates image objects, and some of them are similar or close to road objects, which are useful for classification. So we can set the scale parameter to 600, set the shape as 0.1, and the compactness as 0.5 respectively.

Figure 3. Segmentation at a 600 scale,Classification using Object Feature and Class-related Feature.

After the primary image segmentation, object features such as "Ratio" (the ratio of a green band layer) and "Length/Width" were extracted, so we could identify part of the road. The class-related feature such as "Relative Border to" was extracted for further road object classification. If the feature value was more than 0.4, the boundaries and the road markings within the road region were classified as a road category. We repeated this classification process twice, and then got the result.

Segmentation at small scale

In the road region, we executed a second image segmentation on a small scale. We could choose the best scale value by comparing all the segmentation results with different scale values and different heterogeneity values. It is important for bright vehicle identification to increase the color weight. However, an appropriate shape

parameter often improves the quality of the identification. We discovered that the best criteria settings are where scale, shape and compactness are respectively set at 80, more than 0.3, and 0.5, and the result can be seen in Figure 4.

Figure 4. Segmentation under certain criteria.

Vehicle information extraction

Bright vehicles with obvious mean and shape features contrast sharply with other image objects, which are marked with black pixels (see Figure 5). This image was obtained by applying the Conditions Combination classification algorithm.

Figure 5. Bright vehicles classification

Dark vehicles requiring more features for identification can be classified using the Nearest Neighbor classification in the feature space. As shown in the Nearest Neighbor membership functions (see Figure 6), the length membership function is wider than others, which implies that length is not the most important feature for dark vehicle classification. In Figure 6, the dark vehicles are marked in blue.

Figure 6. Nearest Neighbor membership functions and dark vehicle

Assessment

More tests were implemented, and a nearly 10% error ratio exists by comparing the automatic extraction with visual interception. The error-classification mainly occurs in the shadow region.

CONCLUSION

This study focused on vehicle information extraction from high-resolution satellite images by using object-oriented image analysis. Different features were used to extract bright vehicles and dark vehicles separately and acceptably accurate classification was obtained. However, there are still some error classifications, and the shadows of vehicles and buildings are the main reason. Thus, it will be necessary in the future to eliminate shadows in the pre-processing of satellite images. In addition, we extracted vehicle information from satellite images of a one-way street and did not include a two-way street. So both shadows and two-way traffic flow will be taken into account in further research.

ABSTRACT

Using a traffic guidance system, we studied the map-matching algorithms of a center terminal to monitor the probe vehicle real time and obtain vehicle traffic information when driving. Realizing that the GPS information period is too long in the center terminal, we are introducing the idea of partitioning the road network into grids and are proposing a map-matching algorithm. Our process is suited to a complicated road section in a big city, based on the road network's topological structure. The results of our simulation of real driving data show that this map-matching algorithm affords higher accuracy and can better solve the matching problem for complex road networks in cities.

INTRODUCTION

The development and maturity of GPS technology provides a powerful method of identifying vehicle's accurate positioning in real time。In intelligent transportation systems, the exploitation and application of vehicle navigation and monitoring systems are achieved gradually. Probe vehicle technology is a new kind of traffic information collecting technology It collects vehicle GPS data at a large scale and monitors the city's traffic condition. Creating a map-matching algorithm of a center terminal is the core problem of the probe vehicle technology. A map-matching algorithm of a center terminal has the following negative characteristics: the GPS data scale is big (about 14,000 vehicles), the adjacent GPS of the same vehicle signal period is too long (20s-60s), and relevant information between GPS points is poor. In this paper, we designed a map-matching algorithm of a center terminal based on the road network's topological structure, verified with the vehicle GPS data of Guang Zhou City. The results show that the map matching algorithm has a high level of precision and efficiency, which can meet the needs of Guang Zhou City's high-capacity.

GPS DATA ANALYSIS AND PROCESSING

The quality of GPS data is the basis of the map matching. GPS data is often lost or inaccurate in urban canyon environments where GPS signals are often blocked by high-rise buildings (Mohammed et al. 2007). For the data to be uploaded to the center terminal, we must first process the data. We put the abnormal GPS data into different categories and put forward corresponding methods of treatment. Abnormal data is mainly divided into static drifting data, incorrect data, and dynamic drifting data, as follows.

Static drifting data

If the vehicle drives at low-speed or stops, GPS data will be static drifting data. For a random drifting of GPS positioning errors, it makes the system give the vehicle positioning information at the current actual location for the center of a circular area with a random jitter. The method by which we can judge the drifting data is described as follows:

If the vehicle's speed is less than 2m/s, we can calculate the distance between the current point to pre-positioning points (for which the design admits 3). If the distance between these is less than the normal GPS positioning error upper limit, that indicates that the current vehicles are either driving at low-speed or stopping. Now the corresponding matching points of the current points should be the true location of the vehicle, (instead of being just the current positioning of the follow-up matching point). This should be the case until the vehicle speed is higher than 2m/s.

GPS signal interruptions and inaccuracies

GPS receivers can display some abnormal conditions, such as: continuously unchanging GPS information; lack of GPS information; or a vehicle's sudden increase in speed that is very high (more than 35m/s) and so on. The abnormal data are directly removed.

Dynamic drifting data

Since GPS signals are often blocked by high-rise buildings, it can render the distance of two adjacent GPS points as higher than a certain threshold. We consider the GPS data to be dynamic drifting data. The dynamic drifting data are directly removed too.

MAP-MATCHING ALGORITHMS

Fixing The Candidate Road Segment

The first step is to obtain the candidate road segment of map-matching. If we acquire the GPS positioning data, we can draw the candidate road segment from the digital map database by its error region. This way, we can reduce the number of candidate road segments and the computing time of map-matching. The selection of a candidate road segment should reduce its computational volume, conserve memory, and ensure the algorithm in real-time. We select the candidate road segment twice in order to reduce its computational complexity.

First Selection of the Candidate Road Segment

We introduced the idea of partitioning the road network into grids, in which the recorded road segment intersects with the grid or is contained in the grid. To increase the efficiency of this searching process, all grids are stored according to serial number order. After acquisition of the GPS data, we find the GPS location grid by half seeking. Since the GPS point may be in the border of the grid, we first select a 3 S * 3 S grid area in which nine grids link up together and we can obtain the road segment information that these grids store at the same time. The example in Table 1 follows. When the GPS is in grid 6, the sifted area finally includes the grids 1, 2, 3, 5, 6, 7, 9, 10 and ll (FU Mingjie et al. 2005).

Table 1. 3 S *3 S grids area.

1	2	3	4
5	6	7	8
9	10	11	12
13	14	15	16

We fix the candidate road segment by two different forms which are determined by the quality of the GPS data.

(1) When it contains the GPS initial matching points or when the last GPS data is removed as abnormal, we can fix the grid number which the GPS point is in and extract the candidate road segment which is stored in the grids at the same time.

(2) When the last GPS point can be matched as normal, we use the road network topology to determine the candidate road segment of the current GPS point. When the center terminal gathers GPS data of the same vehicle in a period interval, the vehicle may drive over some road sections. We need to do the depth searching for the two ends of the matching road in the road network. The algorithm begins with the two end points of departure, using a heuristic search for the information of adjacent points in a certain region. We then fix the candidate road segment which has topological connectivity to the matching road (Zhang et al. 2007). We control the heuristic searching number of adjacent points to control the scale of the region, which determines the number of candidate road segments. The example in Figure 1 follows.

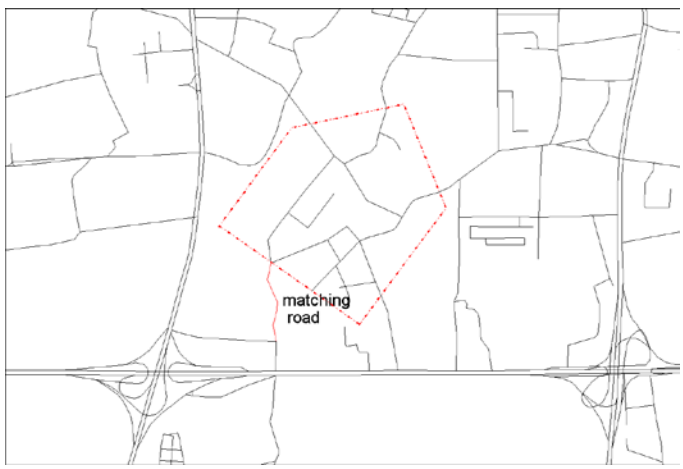

Figure 1. Candidate Road Segments by Heuristic Search.

The Secondary Selection of the Candidate Road Segment

We carry out the secondary selection of a candidate road segment based on previous accumulated experience.The rules are as follows:

(1) If the angle between the direction of a moving vehicle and the direction of a road exceeds the acceptable threshold, we regard the road as not appropriate for the candidate road segment.

(2) If the distance between GPS points and the candidate road segment exceeds the acceptable threshold, we regard the road as not appropriate for the

candidate road segment.

(3) We do perpendicularity projection from the GPS point to the candidate road segment. If the projection entirely matches the road, we regard the road as the candidate road segment. If the projection does not match the road (matching up to the road's extended line), we do not regard it as the candidate road segment.

(4) In the background database of the navigation electronic map, we confine the direction of traffic flow for each road. We select the candidate road segment by judging the vehicle direction according to the permitted direction of the road.

Elevation-Assisted Map-Matching Algorithm

Algorithm rules: when there is only one candidate road, we can directly match it. If the candidate road segments are more than one road, we cannot directly match them, since this requires the adoption of road network topology relations and GPS information to calculate matching degrees. In the map-matching algorithm, we calculate the degree of map matching, using three parameters: the angle between the direction of a moving vehicle, the direction of a road, its distance, and its elevation.

$$f(d,\theta,z) = w_d \bar{d} + w_\theta \bar{\theta} + a\bar{z}$$

Function $f(d,\theta,z)$ consists of the matching degrees of candidate road segments. w_d, w_θ and a represents respectively the weights of the angle, distance, and elevation of matching degrees, satisfying the formula $w_d + w_\theta = 1$ and a has a value of 0 or 1. When the vehicle is near a viaduct, a has a value of 1, otherwise a has a value of 0. When the vehicle is near an intersection, w_d has a value of 0.4 and w_θ has a value of 0.6, otherwise w_d has a value of 0.6 and w_θ has a value of 0.4.

$$\bar{d}_i = \frac{1/d_i}{\sum_{i=1}^{n} 1/d_i}, \quad \bar{\theta}_i = \frac{1/\theta_i}{\sum_{i=1}^{n} 1/\theta_i}, \quad \bar{z}_i = \frac{1/z_i}{\sum_{i=1}^{n} 1/z_i}$$

In the formula: n represents the number of the candidate road segment; d_i and θ_i represent the distance and angle of the candidate road segment in which the road segment is marked i. Normally, d_i and θ_i cannot be valued as 0. If d_i or θ_i equal 0, we define them with a very small value, where $\bar{d}_i$ and $\bar{\theta}_i$ represent the nuisance value of the distance and angle of the candidate road segment (Christopher et al.2000).

The matching process is as follows: first, we calculate all the matching degrees of candidate road segments. Second, we select the maximal matching degree f_m and the secondary maximal matching degree f_n. Third, we calculate the formula $f_m - f_n > f_{th1}$ (f_{th2} is introduced to distinguish the road segment which has close matching degrees and a value of 0.2) and $f_m > f_{th2}$ (f_{th2} is the credible matching degree with a value of 0.8).

Delay Map Matching

When the matching degree cannot satisfy the matching requirements, we do

not match the GPS at once and save the longitude and latitude of the GPS point and acquire the next GPS's point information. We then match the next GPS point. We repeat the above process until one GPS point can be matched. We match the GPS point using the topology between the GPS point whose point we did not match and the point we can match. If the GPS point still cannot be matched, we consider building the shortest path between the GPS point which we cannot match. The driver is able to choose the shortest path to the next point by empirical experience. The delay map-matching process is shown next in Figure 2.

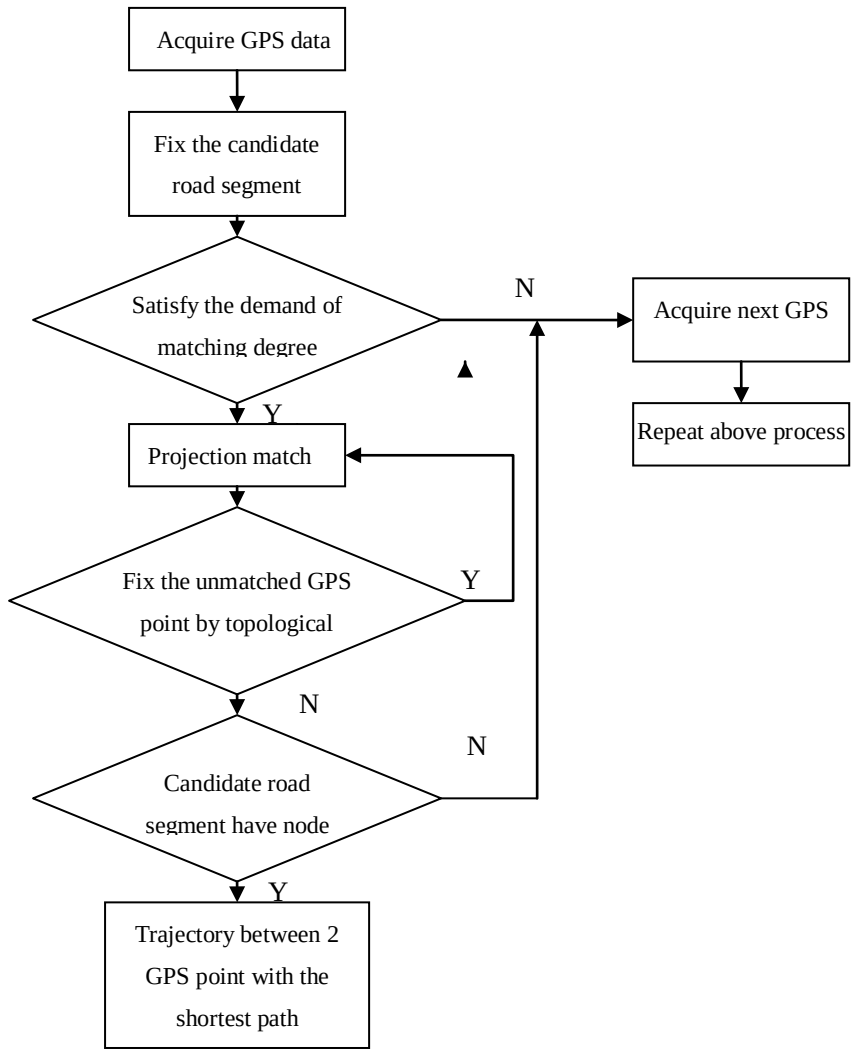

Figure 2. Delay map matching process.

Map-Matching Algorithm Process

The map-matching algorithm process is as follows:

(1) Acquire the GPS data information when time is T;

(2) Judge whether the GPS data is available or not. If the data is not available, go to 12;

(3) Judge whether the vehicle is moving at low speed or stops or not. If it is moving slowly, go to 12;

(4) Judge whether the GPS data is dynamic drifting data or not. If it is, go to

12;

(5) Judge whether the last GPS data is normal or not. If it is abnormal, go to 6, otherwise go to 7;

(6) Make sure the number of the grid where the GPS data is in, draw the road segment information and fix the candidate road segment. Go to 8;

(7) Fix the candidate road segment through heuristic searching and go to 8;

(8) If we do not get a candidate road segment, go to 9; If we get one candidate road segment, g to 10; If we get more than one candidate road segment, go to 11;

(9) Put the GPS point as the real position, go to 12;

(10) Carry out the projection match and acquire the latitude and longitude, go to 12;

(11) Calculate the matching degree of the candidate road segment. Judge whether the matching degree meets the necessary requirements or not. If the matching degree meets the requirements, go to 12. Otherwise, go to delay matching;

(12) Acquire the next set of GPS information.

ALGORITHM VALIDATION

We validated the algorithm using GPS data and a navigation electronic map for Guang Zhou. For the map matching of its center terminal, we analyzed the topology between the candidate road segments of adjacent GPS points for the same vehicle. We extracted the GPS data of one probe vehicle from the traffic information center and carried out map matching, using the algorithm we created. The effect in Figure 3 displays the drawing of our map matching when the vehicle is around the viaduct.

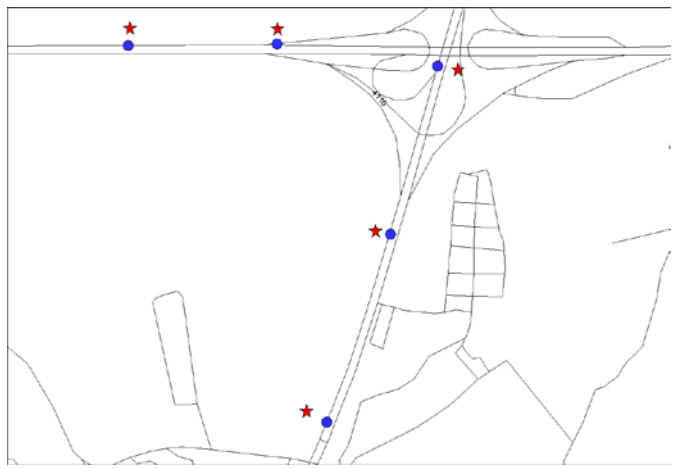

Figure 3. Map matching around viaduct.

CONCLUSION

The need for a map matching algorithm of the center terminal is the core problem of probe vehicle technology. In this paper, we created the complete map-matching algorithm of a center terminal based on the road network topology, which

is validated by the GPS data of a probe vehicle in Guang Zhou City. Our result shows that the algorithm can effectively fulfill the map matching of 14,000 cars equipped with GPS in real time with higher accuracy, to better solve the matching problem when the vehicle is in a complex road network and near a viaduct.

ABSTRACT

In an intelligent transportation system (ITS), route planning is very important for vehicle navigation. It is necessary to optimize the algorithm of route planning to meet the real time requirement of the system. Based on the analysis of the temporal complicacy and spatial complicacy of the A* algorithm, this paper proposes a modified A* algorithm which can run much more efficiently compared to the original A* algorithm. First, this paper adopts the data structure of a binary heap, not a linear array, to implement the operation of its priority queue and to successfully improve the efficiency of searching the minimum cost node. Secondly, according to the special spatial distribution feature of the road network, a search mechanism to restrict the search district is introduced here, which can greatly reduce the search data volume of the algorithm. Finally, this paper makes tests in a real road network in Xi'an. The tests also prove that the modified algorithm is workable and time-saving.

INTRODUCTION

The intelligent transportation system (ITS) is thought of as the best method with which to solve the problem of traffic congestion all over the world. Route planning is an important basic function of the system, and is also a popular area of research in this field.

The core of route planning is the search for the shortest route (Wang, 2007), and nearly twenty kinds of shortest route search algorithms have been discussed and are widely used at present. According to their search mechanisms, these algorithms can be divided into three kinds: breadth-first search, depth-first search and heuristic search (Lu, 2001).

Among these, the A* algorithm adopting the best-priority search mechanism is a relatively advanced heuristic algorithm, and it is highly effective in searching for the shortest route in a road network. However, because the route planning function is used frequently in the system and the computational complexity of its algorithm is high, it is necessary to further optimize the A* algorithm to meet the real time requirements of a practical system.

A*ALGORITHM (Zhao, 1999; Xia et al., 2001)

A distinct feature of the A* algorithm is to use a heuristic estimate function of cost. Cost can be distance, time, fees, etc. The estimated function of cost from current node i to the goal node can be defined as follows:

$$f'(i)=g(i)+h'(i)$$

In the above equation, $g(i)$ is the real cost from the start node to the current node i. $h'(i)$ is the estimated minimum cost from current node i to the goal node, and $f'(i)$ is the estimated minimum cost from start node to the goal node through node i.

The basic principle of the A* algorithm is: when meeting with a new node in the search course, calculate the minimum cost from the node to the goal node through the estimate function, and then continue to search from the minimum estimate-cost node. In a word, the aim of the A* algorithm is to minimize $f'(i)$.

In the A* algorithm, two lists are used to record operated nodes. *Openlist* stores the nodes that have been generated but not extended (and generates all successor nodes), and *Closelist* stores the nodes that have been generated and extended. At every step of the A* algorithm, extend the best node whose estimate-cost is the smallest in all generated nodes of *Openlist*, then move it to *Closelist* where its successor in put in *Openlist*. After checking every generated node to determine whether it has appeared, which ensures the node will be recorded only once in one of two lists, estimate its cost. Repeat the above process until the goal node is generated. In this way, the solution route can be obtained.

AN IMPROVED A* ALGORITHM

Using binary heap as a priority queue

The core step of the A* algorithm is to find the minimum cost node *BEST* in *Openlist*. This is a process of cycle comparison. If the nodes to be compared are stored in disorder, all nodes must be scanned one by one to find which one represents the minimum cost. With a large volume of data, this will undoubtedly become a bottleneck restricting the speed of calculation.

To solve this problem, the most effective way is to arrange these nodes in the order of their estimated cost and to construct a priority queue in an ascending order of estimated cost. Therefore the qualified node can be easily found out in every cycle and the efficiency of the algorithm will be greatly increased. As distinct from general algorithms using a linear array, this paper adopts a binary heap as the data structure of the priority queue.

Williams put forward the method of HEAPSORT in 1964, in which the heap, a specific data structure, is introduced. (Tang et al., 2000) Heap is defined as the following: if and only if a sequence of n elements $\{k_1, k_2, \ldots, k_n\}$ satisfies the following formula, it is called a heap.

$$\begin{cases} k_i \le k_{2i} \\ k_i \le k_{2i+1} \end{cases} \text{ or } \begin{cases} k_i \ge k_{2i} \\ k_i \ge k_{2i+1} \end{cases} \qquad \left(i = 1,2,...,\left\lfloor \frac{n}{2} \right\rfloor \right)$$

The binary heap can be considered to be a full binary-tree, which shows that the values of all non-leaf nodes are not larger (or not less) than the values of their left and right child nodes. So the element on the top of the heap (or the root of the full binary-tree) must be the minimum value (or maximum value) of n elements in the heap.

In this paper, the binary heap is used as an efficient data structure in the priority queue, which includes three main operations:

① Sift (h): Adjust the disorder sequence h to become a binary heap. First, put the minimum value on the top of the heap, and then from the top of the heap, put nodes on suitable sites by comparing the values of their left and right child nodes. This process of adjustment from heap top to bottom is called "Sift".

② Insert (x,h): Insert element x into heap h and cull the Sift to adjust h to become a binary heap. First add x into the bottom layer of the heap, then traverse the route from the node of the new leaf to the top to find a suitable site in which to put the new element.

③ Min (h): Find the minimum element of h and delete it in h, then adjust h to become the binary heap by using Sift(h). Its operation time is mainly spent on the adjustment of the binary heap.

Because the original A* algorithm adopts a linear array as the data structure of its priority queue, it is necessary to traverse all nodes in *Openlist* in every manipulation. Its time complexity is about $O(N^2)$. But the algorithm using the binary heap structure only needs traverse nodes from the top of the heap to the current node in the binary heap and its time complexity is about $O(E\lg N)$. Therefore it saves time and increases the efficiency of the algorithm.

RESTRICTING SEARCH DISTRICT

The shortest route algorithm derived from computer science only considers the topology feature of a net but neglects the spatial distribution feature of a road network, which means the search lacks specific direction and gets a shortest route tree in which the start node is the root and the goal node lies on the leaf. In the course of creating this route tree, there are still a lot of redundant calculations. This is mainly attributed to the unrestricted search district of the algorithm.

The node coordinate of the road network is of real significance, and it denotes the actual location of the node in mapped space. In the course of the route search, if the start node and goal node are given, the spatial distribution of the shortest route can be determined approximately. To determine whether a node should be involved in the search process one should consider the spatial relations among the node, the start node and the goal node. From the perspective of probability, the

shortest route is most likely composed of the nodes within the area around the line segment between the start node and the goal node.

As figure 1 shows, *A* is the rectangle formed by spread of the start node *s* and the goal node *e* and the search for the shortest route is limited in *A*.

In the process of searching for the route, determine the spatial relationship between node *n* and district *A* when meeting the node *n*.

Case 1: if *n* is in *A*, it means the node *n* can be the composition of the shortest route.

Case 2: If *n* is not in *A*, it means the node *n* cannot be the composition of the shortest route.

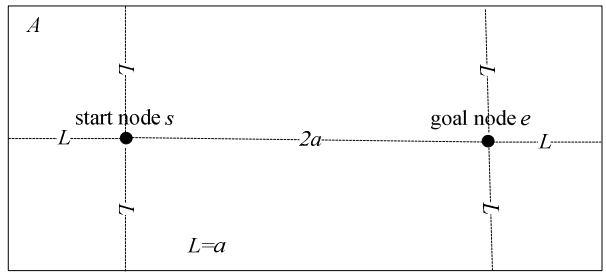

Figure 1. Restricted search district.

Restricting the search district can reduce the search space of the shortest route and raise the algorithm's efficiency. But because this method is incomplete, it needs to be further improved. After all the nodes in the restricted search district are operational, if the route cannot be obtained, the search district should be expanded properly.

The principle of optimizing the algorithm by restricting the search district operates as follows: in the process of searching for the route, analyze the spatial distribution relation among the nodes that can constitute the last search result, the start node, and the goal node, and sift the nodes that have almost no likelihood of forming the shortest route. Therefore, the search space and computation can be reduced and the algorithm can be optimized.

IMPLEMENTATION OF THE IMPROVED ALGORITHM

Use *Openlist* to store the nodes which have been generated but not extended and adopt the binary heap as the data structure of *Openlist*. Use *Closelist* to store the nodes that have been generated and extended. Take *s* as the start node of the search and take *e* as the goal node. Let *A* be the restricted search district formed from *s* and *e*. The cost of *s* is *g(s)*=0 and the costs of other nodes = ∞. Besides, in order to save the solution route, add a backward pointer in the data structure of the node. The search steps of the improved A* algorithm are as follows:

① Empty *Openlist* and *Closelist*.

② Insert (*s*,*Openlist*): put *s* in the binary heap *Openlist*.

③ If *Openlist*=*NULL*, turn to step ⑥.

④ *BEST* =Min*(Openlist)*: find the minimum estimate-cost node *BEST* ; move *BEST* to *Closelist* and judge whether *BEST* is the goal node *e*. If yes, it is successful and then turn to step ⑦, otherwise, extend *BEST* and produce the successor nodes according to the topology of the road network. Then judge every successor node *n*, if $n \in A$, operate *n* as follows:

a) Calculate the cost of node *n*: *g*(*n*)=cost of *BEST*＋cost from *BEST* to *n*.

b) If there is a node *m* same with node *n* in *Openlist* and cost $g(n) < g(m)$, then $g(m) = g(n)$ and turn the backward pointer of *m* to *BEST*.

c) If there is a node *m* that is the same as node *n* in *Closelist* and the cost $g(n) < g(m)$, then $g(m) = g(n)$. Turn the behind pointer of *m* to *BEST*, then delete *m* in *Closelist* and Insert (*m,Openlist*).

d) If *n* doesn't appear either in *Openlist* or in *Closelist*, turn the backward pointer of *n* to *BEST*, and calculate $f'(n)=g(n)+h'(n)$ and then Insert (*n, Openlist*).

⑤ Return to step ③.

⑥ Expand *A* and judge whether *A* exceeds the map space of the road network. If yes, that means failure, which means there is no route between start node *s* and goal node *e*. Otherwise, turn to step ①.

⑦ Track back from *BEST* node, which means to traverse all nodes from the backward pointer of *BEST* to the start node, and then get the solution route.

PERFORMANCE EVALUATION

In order to verify the performance of the proposed algorithm, a simulation program for searching for the shortest route based on this algorithm was designed with Embedded Visual C++ 4.0 and a series of related tests were performed on an embedded platform whose frequency was 200MHz and whose memory was 64MB with the operating system of Windows CE 4.0. We carried out 10 long-distance route search tests in the actual road network of Xi'an city, which contains 2709 nodes and 3769 arcs as Figure 2 shows, and the results are shown in Table 1. Table 1 lists the performance comparison of three kinds of algorithms: the original A* algorithm, the A* algorithm using a binary heap and the A* algorithm based on the binary heap and the restricted search district. In the table, N_1, N_2 and N_3 respectively denote the total numbers of operated nodes of three kinds of algorithms, and T_1, T_2 and T_3 respectively denote their run-time. The unit of run-time is second.

Table 1. Performance comparison of three kinds of algorithms..

	1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**
$\mathbf{N_1}$	2122	2046	1983	2055	2187	1789	2012	1645	2178	1965
$\mathbf{T_1}$	13	12	12	12	13	11	12	11	13	11
$\mathbf{N_2}$	2122	2046	1983	2055	2187	1789	2012	1645	2178	1865
$\mathbf{T_2}$	10	10	9	10	11	9	10	9	10	9
$\mathbf{N_3}$	1024	1014	1045	1023	1111	945	1035	1344	1687	1003

T_3	4	4	4	4	5	3	4	7	8	3

The test results can be summarized as follows:

(1) The mechanism of adopting the binary heap as a data structure for a priority queue can reduce the search for the minimum cost node, and therefore reduce the run-time of the algorithm.

(2) If the start node and the goal node are located in the center region of the map, the mechanism of restricting the search district can reduce the number of operated nodes, and then greatly improve the efficiency of the algorithm. However, if the start node and the goal node are both located in the border region of the map, the algorithm's efficiency may be relatively lower (as the results of the 8th test and the 9th test show), because the first restricted search region doesn't completely contain all the nodes of the solution route.

(3) In most cases, the improved A* algorithm has better overall performance than the original A* algorithm.

Figure 2. The road network of Xiàn city.

CONCLUSION

In order to meet real time requirements of route planning in ITS, this paper presents a novel improved A* algorithm which adopts the binary heap as the data structure for the priority queue. Using this method improves the efficiency of searching for the minimum cost node and restricts the search district to reduce the search space. Tests have shown that the improved algorithm is workable and time-saving.

ABSTRACT

Reliability is a key factor in ensuring the benefits of urban parking message signs. First, this paper seeks to define the reliability of parking guidance provided by urban parking variable message signs (VMS). By analyzing drivers' parking choices under guidance and in optional parking lots, our reliability model has been formulated. Then, the influence factors of guiding reliability are studied, and the results show that the locations of VMS, the changing of parking spaces, and parking flow are the most important factors affecting the reliability of guidance. We find that the parking guidance VMS product affords the greatest benefits within certain conditions of parking supply and demand. Finally, to improve guidance reliability, this paper proposes several suggestions to optimize the configuration of the parking VMS, which could help to systematically improve the effectiveness of urban parking VMS.

INTRODUCTION

With the development and application of information, the urban Parking Guidance Information System (PGIS) has become the most important method used to reduce the parking problem. The primary way to promulgate parking guidance information is via the Variable Message Sign (VMS) (Wardman, 1997, Chatterjee, 2002). The existing research demonstrates that parking flow can be guided best through optimizing the numbers and locations of VMS (Yan Kefei, 2006; Li Dongping, 2007). It also shows how optimal display can redistribute parking flow to minimize driving distance or queue length (Thompson, 2001, Chen Jun, 2006, Mei Zhenyu, 2008). In the process, VMS not only reflects the operating conditions of parking lots, but also forecasts available parking spaces. However, there are contrary conditions between the display information in VMS and the actual usable spaces in the parking lot (Chen Qun, 2007). This last issue constitutes the reliability problem in parking guidance. With less reliability, drivers' acceptance of the VMS is lessened, which ultimately impacts the efficacy of the PGIS. Reliability is often used to

evaluate the travel time and network capacity (Noland, 1998, Clark, 2005), and Lam (2003) uses reliability as a basis for evaluating parking time. This paper defines the reliability of parking guidance, using VMS, and analyzes its influencing factors, then puts forward a method to optimize the benefits of parking VMS.

FOUNDATION OF RESEARCH

Definition of the reliability of parking guidance

Drivers choose parking lots, using parking guidance information, and then they arrive at parking lots under two conditions: usable space and unusable space. This paper's definition of parking guidance reliability includes: the destination, the location of parking lots and their guidance information, the drivers' choice of parking lots, the timing of drivers' arrival at parking lots, and the ratio of parking flow with usable spaces, and the total parking flow. The following can be denoted as ψ:

$$\psi = Q_m / Q \quad (1)$$

Where, ψ is the guiding parking reliability of VMS; where ψ is greater, the reliability is better. Q_m is the parking flow in chosen parking lots with parking guidance information. Q is the total parking flow.

Basic assumptions

The research is based on some assumptions, including:

(1) All drivers passing the message signs observe the displayed information and believe them to be correct.

(2) Drivers decide on a parking choice once they see the message signs, and once they have made a decision, they do not change their minds. After they arrive at parking lots, drivers wait for spaces if there is no availability of spaces, and the service rule is first come,first served.

(3) All drivers in the parking zone can see the parking guidance information, so that all can be guided by it.

(4) All vehicles in the chosen parking lots drive along a common route and do not make a detour or drive the wrong way, and road traffic conditions are otherwise normal.

(5) The display variety cycle ΔT is longer than the maximum driving time t_m from the deciding node to the parking lot.

PARKING GUIDANCE RELIABILITY

Parking choice model

Drivers always choose parking lots to minimize disutility (van der Waerden, 2003), and the parking choice model is given as the following:

$$P_{ijk} = \frac{l^{kj} \cdot \exp(-\theta U_{ijk})}{\sum_{k=1}^{K} l^{kj} \cdot \exp(-\theta U_{ijk})}, \quad (i = 1, \cdots, I; j = 1, \cdots, J; k = 1, \cdots, K) \qquad (2)$$

$$U_{ijk} = \alpha_m t_m^{ik} + \alpha_w t_w^{kj} + \alpha_f f^k / t_f \qquad (3)$$

Where, P_{ijk} is the probability of selecting parking lot k from deciding node i to destination j. And U_{ijk} is the utility for drivers from deciding node i to destination j, in choosing parking lot k. And t_m^{ik} is the driving time from deciding node i to parking lot k, which can be calculated from the VMS to the parking lot. And t_w^{kj} is the walking time form parking lot k to destination j; f^k is the fee at parking lot k, and t_f is the value of time. $\alpha_m, \alpha_w, \alpha_f$ are the relative importance weighting coefficients. θ is the scale parameter. I, J, K are the sets of the deciding nodes, drivers' destinations and the parking lots. Available parking lots are defined as those for which the walking time from parking lot k to destination j is in the range of a maximum acceptable walking time T_w. And l^{kj} denotes the efficiency of parking lots:

$$l^{kj} = \begin{cases} 1, & t_w^{kj} \le T_w \\ 0, & t_w^{kj} > T_w \end{cases} \qquad (4)$$

With the parking guidance information, when VMS displays that parking lot k is full, the parking lot is not available, so the available variable of the VMS display δ^{ik} is adopted to revise the parking choice utility (Thompson, 1998):

$$P_{ijk}(o) = \frac{\delta^{ik} l^{kj} \exp(-\theta U_{ijk})}{\sum_{k=1}^{K} [\delta^{ik} l^{kj} \exp(-\theta U_{ijk})]} \qquad (5)$$

Where, $P_{ijk}(o)$ is the probability of selecting parking lot j form deciding node i with destination k using the parking VMS. δ^{ik} is the Boolean variable:

$$\delta^{ik} = \begin{cases} 1, & \text{if message sign i displays parking lot k available} \\ 0, & \text{other} \end{cases} \qquad (6)$$

When all the effective parking lots displayed on the VMS are "Full," all the vehicles may queue to park. Here, parking choice behavior is consistent with behavior absent parking guidance information.

Amount of parking flow

First, the amount of parking flow in parking lot k is deduced, given the driving time delay from the deciding node with VMS i to parking lot k. When time is t, the vehicle from the deciding node i has to reach the parking lot k at $t + t_m^{ik}$, so we can assume that $\Delta T > \max\{t_m^{ik}\}$. Thus, the arrival parking flow is $r^k(t)$ between the variety cycle $\Delta T = T^{N+1} - T^N$ as shown in the following:

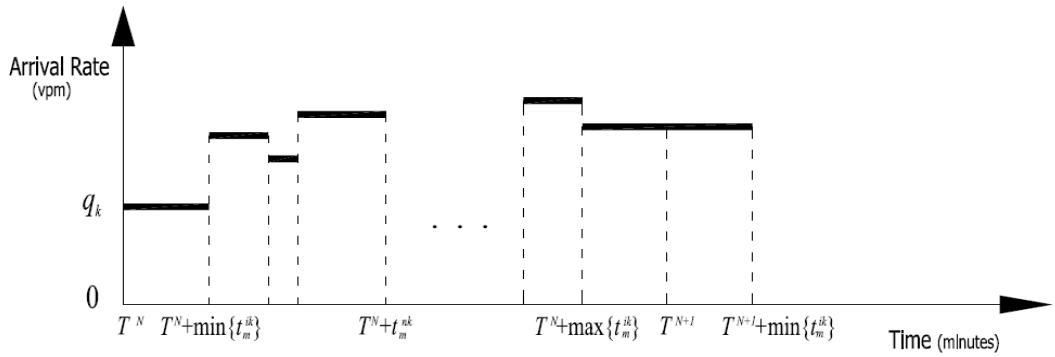

Figure 1. Arrival parking flow between $T^N \sim T^{N+1}$ in parking lot k.

At time T^N, each message sign changes the display in VMS. In the time $T^N \sim T^N + \min\{t_m^{ik}\}$, the arrival rate at parking lot k is influenced by the last variety cycle of redistributed parking. From the time $T^N + \min\{t_m^{ik}\}$, the arrival rate is dually affected by the last and the parking is redistributed with parking guidance information, till time $T^N + \max\{t_m^{ik}\}$. And from $T^N + \max\{t_m^{ik}\}$ to $T^{N+1} + \min\{t_m^{ik}\}$, the arrival rate at parking lot k is only affected by this parking guidance information. Sequencing t_m^{ik} from lesser to greater, the arrival rate at parking lot k is affected by parking flow from each of the deciding nodes, one by one, in this variety cycle. So, the arrival rate at parking lot k ($r_k(t)$) in time $T^N \sim T^{N+1}$ can be deduced as following:

$$r_k(t) = \begin{cases} \sum_{i=1}^{I}\sum_{j=1}^{J} q_{ij}^{N-1} P_{ijk}^{N-1} & t \in (T^N \sim T^N + \min\{t_m^{ik}\}) \\ \sum_{i=x+1}^{I}\sum_{j=1}^{J} q_{ij}^{N-1} P_{ijk}^{N-1} + \sum_{i=1}^{x}\sum_{j=1}^{J} q_{ij}^{N} P_{ijk}^{N} & t \in (T^N + t_m^{xk} \sim T^N + t_m^{(x+1)k}) \\ \sum_{i=1}^{I}\sum_{j=1}^{J} q_{ij}^{N} P_{ijk}^{N} & t \in (T^N + \max\{t_m^{ik}\} \sim T^{N+1}) \end{cases} \quad (7)$$

Where, $x = 1,2,\cdots,I$, and t_m^{xk} is sequenced t_m^{ik} from lesser to greater, $\min\{t_m^{ik}\} = t_m^{1k} \le t_m^{2k} \le \cdots \le t_m^{Ik} = \max\{t_m^{ik}\}$. So, in a variety cycle of VMS, the number of the arrival rate might be $I+1$. And q_{ij}^N is the parking flow rate from the deciding node i to destination j in the variety cycle N.

The amount of arriving parking flow at parking lot k is ($R_k(t)$) from T^N to $T^N + t$ can be calculated as

$$R_k(t) = \int_{T^N}^{T^N+t} r_k(t)dt \quad (8)$$

Secondly, the departure rate from parking lot k is $d_k(t)$, the departure amount of the parking flow from parking lot k is ($D_k(t)$) from T^N to $T^N + t$ can be calculated as:

$$D_k(t) = \int_{T^N}^{T^N+t} d_k(t)dt \quad (9)$$

Lastly, the amount of the parking flow of parking lot k ($S_k(t)$) from T^N to $T^N + t$ is the amount of arriving vehicles $R_k(t)$ less the amount of departing vehicles $D_k(t)$:

$$S_k(t) = R_k(t) - D_k(t) \quad (10)$$

This time, the number of total parked vehicles in parking lot k ($Q_k^N(t)$) is:

$$Q_k^N(t) = Q_k^N(0) + S_k(t) \quad (11)$$

Where, $Q_k^N(0)$ is the number of parked vehicles at the beginning of variety cycle T^N.

Parking guidance reliability model

Due to the variety cycle of VMS and PGIS, this paper measures the parking reliability guidance of a one time cycle from T^N to T^{N+1}.

According to Formula (11), the availability of spaces in parking lot k at $T^N + t$ is as follows:

$$V_k(t) = C_k - Q_k^N(t) \quad (12)$$

Where, $V_k(t)$ is the number of vacant spaces. When $V_k(t) > 0$, there are vacant spaces, achieving parking reliability; and when $V_k(t) \le 0$, there are no vacant spaces, lacking parking reliability. This is denoted as $\psi_k(t)$:

$$\psi_k(t) = \begin{cases} 1, & V_k(t) > 0 \\ 0, & V_k(t) \le 0 \end{cases} \quad (13)$$

According to Formula (7), there might be $I+1$ arrival rates at parking lot k in $T^N \sim T^{N+1}$. The parking flow achieves parking reliability at parking lot k in $T^N \sim T^{N+1}$ which is calculated:

$$Q_m(k) = \int_{T^N}^{T^{N+1}} r_k(t)\psi_k(t)dt \quad (14)$$

In the parking guidance zone, the parking guidance reliability in the variety cycle $T^N \sim T^{N+1}$ of VMS can be shown as follows:

$$\psi = \frac{\sum_k Q_m(k)}{Q} \quad (15)$$

Combining Formula (2) ~ (15), parking guidance reliability in variety cycle $T^N \sim T^{N+1}$ of VMS can be calculated, which can optimize the configuration of VMS and PGIS.

According to Formula (12) ~ (14), as the number of vacant spaces decreases, especially when the parking supply can't meet the demand, the system's parking guidance reliability decreases. To depict more precisely the guiding benefits of parking VMS, the relative parking guidance reliability is adopted as follows: the relative parking reliability with and without VMS ϕ is denoted as follows:

$$\phi = \frac{\psi - \varphi}{\psi} \qquad (16)$$

Where ϕ is the relative parking guidance reliability of parking VMS, ϕ is larger when the benefit of parking guidance is higher, whereas φ is the parking reliability without parking guidance information. As contrasted with ψ, the calculation of φ adopts parking choice model Formula (3) which does not need to be revised with Formula (4).

Model algorithm

The key to solving the above model is to construct the connections between the models. After gradually solving the models, the parameters can be calculated, and their reliability can be obtained. The calculation flow chart is as follows:

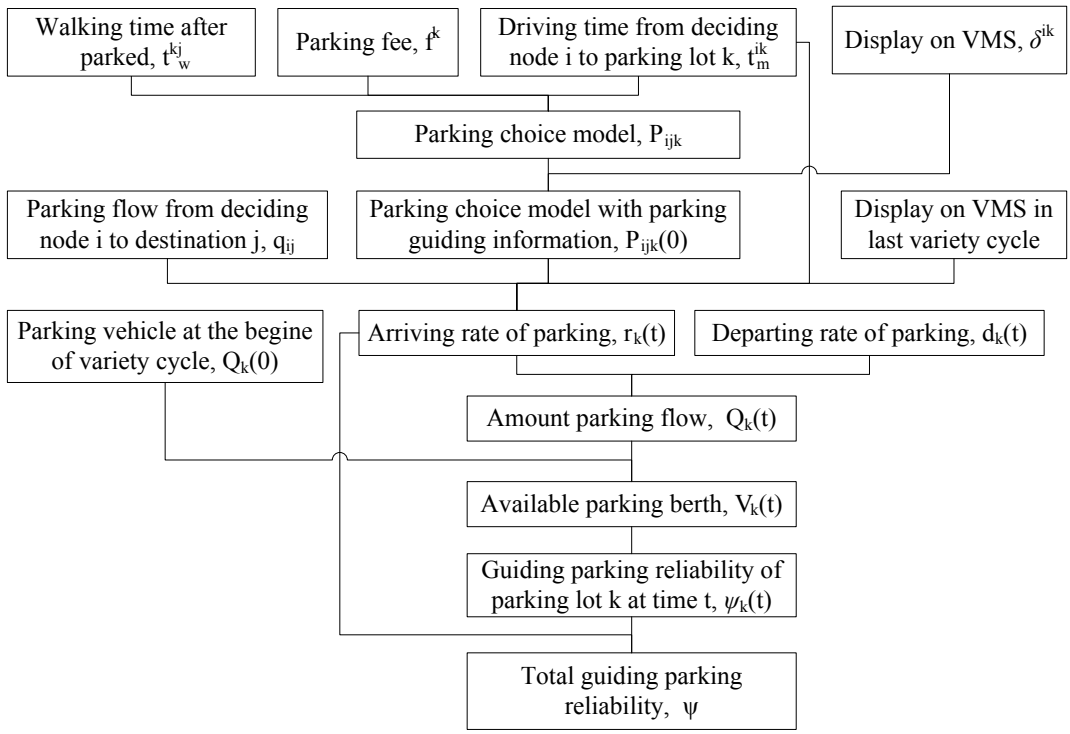

Figure 2. Calculation flow chart of parking guidance reliability.

From Figure 2, the key influence factors in parking guidance reliability are the driving time from deciding node i to parking lot k (t^{ik}_m), the display information on VMS (δ^{ik}), the parking flow (q_{ij}), and the departure rate ($d_k(t)$).

NUMERICAL EXAMPLE

The paper uses a simple numerical example network to explain how to calculate parking guidance reliability and to determine the effect of influencing

factors. The numerical example network is shown in Figure 3. Where, S is the deciding node, the location of VMS is A, and B are the parking lots, which are all in walking distance limitation $1^{AD}=1^{BD}=1$. D is the destination. The values of basic variables and parameters are as follows: $t_m^{SA}=5\min$, $t_m^{SB}=3\min$, $t_w^{AD}=2\min$, $t_w^{BD}=3\min$, $f^A=f^B=\$1$, $t_f=4\$/h$, $\alpha_m=1$, $\alpha_w=0.7$, $\alpha_f=0.05$, $\theta=1$, $\Delta T=T^{N+1}-T^N=10\min$, $C_A=50$, $C_B=100$.

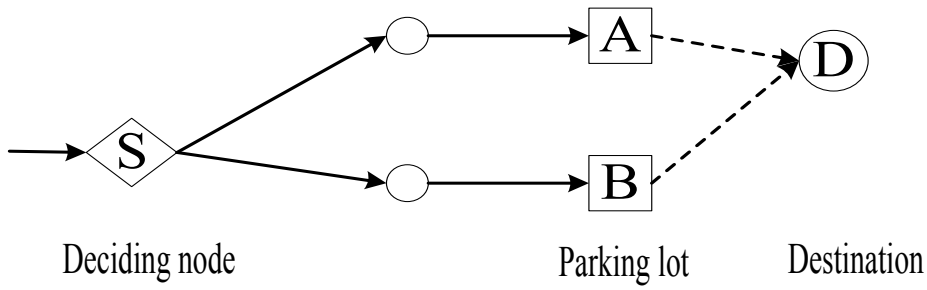

Figure 3. Numerical example network.

The parking arrival rate in the last variety cycle is assumed to contrast as ($q_{N-1}=6veh/\min$), and the availability of each parking lot in VMS is usable. To explain the effect of the influencing factors, the reliability under different conditions of parking supply and demand, and the display of VMS are calculated in Table 1.

Table 1. Parking reliabilities under different conditions.

Q(0)	q_N VMS	1	2	3	4	5	6	7	8	9	10
		Parking reliabilities									
$Q_A^N(0)=40$	(1,1)	1	1	1	1	1	1	1	0.924	0.841	0.783
	(1,0)	1	1	1	0.853	0.752	0.696	0.661	0.636	0.618	0.604
$Q_B^N(0)=80$	(0,1)	1	1	1	1	1	0.840	0.705	0.624	0.570	0.532
	NO	1	1	1	1	1	1	1	0.924	0.841	0.783
$Q_A^N(0)=20$	(1,1)	1	1	1	1	1	0.851	0.725	0.666	0.620	0.575
	(1,0)	1	1	1	1	1	1	1	0.944	0.884	0.839
$Q_B^N(0)=90$	(0,1)	1	1	1	0.920	0.610	0.507	0.410	0.348	0.307	0.277
	NO	1	1	1	1	1	0.851	0.725	0.666	0.620	0.575

Annotate: (1,1) means that parking lot A and B are available. (1,0) means that parking lot A is available and B isn't available, and (0,1) is the inverse. "NO" means that there is no VMS.

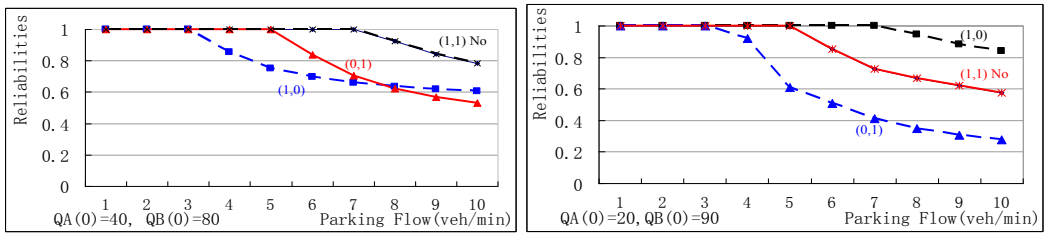

Figure 4. Chart of parking reliability under different conditions.

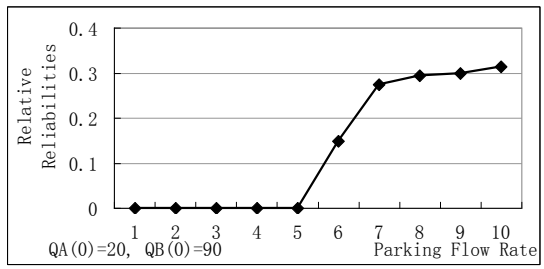

Figure 5. Relative guiding parking reliability under different parking supply and demand.

From the numerical example, we can reach the following conclusions:

(1) The key factors affecting the parking guidance reliability of VMS are the variety of parking spaces (parking vehicle arrival rate and departure rate) and the display conditions of VMS. When there is no optimization of the VMS display, its reliability may be lower than where there is no VMS, which shows that poor parking guidance information leads to poor results.

(2) When the parking supply is much greater than the parking demand, the parking guidance benefits are minimized. When the parking supply is less than or equal to the demand and the use of parking lots are unequal, the parking guidance benefits are maximized.

CONCLUSIONS

This paper analyzed drivers' parking choice behavior using the parking guidance of VMS, for which we studied the parking arrival flow rate. The parking guidance reliability model shows that driving time, VMS display, parking arrival rate and vehicle departure rate are key factors in parking reliability. The best guidance benefit was produced when the use of parking lots were unequal and VMS was optimized. This research can lead to a maximum benefit in the use of parking VMS.

ABSTRACT

The disequilibrium between traffic supply and demand leads to unbalanced traffic flow in urban transportation networks. By analyzing the mutual influence between the traveler route selection and signal timing, a bi-level program model is proposed in order to optimize transportation network efficiency. In light of the similarity between the game theory and the bi-level program, some simple changes are made for the purpose of simplifying the computation of the problem. Finally, a practical network is designed to validate the bi-level program model. Results indicate that the model can improve road network efficiency and decrease vehicle delays.

INTRODUCTION

Traditional signal timing design is carried out in a given traffic flow mode and does not consider the mutual influence between traffic flow and signal timing. So Allsop (1974) suggested that traffic control and path selection must be considered to analyze the impact which signal timing has on the traffic flow distribution pattern. The derivatives of this include the balanced signal control problem. Smith (1979) proved that Webster's saturation control strategies and traffic assignments are not the optimal control strategies. Bentley and Lambe (1980) proposed user-optimal piecewise linear objective function as the signal timing standard. Chen (1989) considered the issue as a Bi-level mathematical programming problem, the upper part reflecting the traffic signal control manager or the control objectives (such as minimum delay), and the lower part describing the behavior of user-optimal path selection. Chen applied this model to a large network with a heuristic algorithm successfully in Chicago. Smith (1990) studied the combination of dynamic traffic assignment with the conditions of a progressive introduction of the dynamic concept. Owen Jianwen Chen and Moshe E. Ben-Akiva (1998) placed dynamic traffic control and dynamic traffic assignment in combination as traffic managers in a traveller's non-cooperative game.

Domestic research about balance network traffic signal control started a little late, but the principle can be summarized with the following aspects: (1) Summary of research results from abroad; (2) improvement of road resistance function; (3) improvement of the distribution of the lower balance model; (4) development of the research model algorithm.

MODEL FOUNDATION

Basic Theory

The internal mechanism of traffic control aims are shown in Figure 1. The decision-making process consists of two levels and two policy-makers: traffic managers and travelers. Comprehensive consideration of the interactions among these groups should be made before the scientific and systematic ultimate decision in order to achieve system optimization. The problem is a typical bi-level planning and decision-making problem, so the bi-level programming model is described as an ideal tool to solve the problem. The upper planning presents the problem that when the section flow is *y*, solving the optimal signal control variable, this plan reflects the driver's considerations of path selection behavior at traffic control. The lower planning at the signal control presents variables for *x* with the equilibrium assignment problem, and the plan reflects the driver's considerations of traffic control parameters in the selection of a path. In this way, the bi-level programming model can describe the traffic control strategy based on the balance of networks toward the goal of an optimal system.

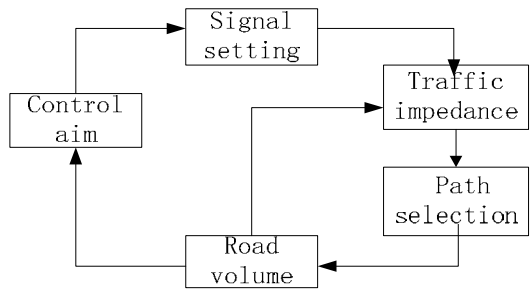

Figure 1. Traffic control aim inter-mechanism.

Basic Model

Upper Programming

Confirmation of the objective function is made by selecting an appropriate indicator to describe which network is running. On the single road sections as shown in Figure 2, the flow-speed relationship diagram under the assumption of the Greenhill rule is in a non-crowded region, while the flow is increased and the speed is reduced until the road reaches maximum capacity. In a crowded region, the flow and speed are decreased. Traffic managers expect to maximize the number of vehicles through the road in per unit time, while the driver would expect to maintain a high speed in order to reduce the travel time. So we consider the maximum product of flow and speed as the objective function to describe the network traffic flow's optimal state.

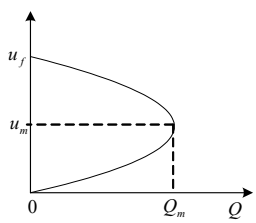

Figure 2. U-Q in Greenshields.

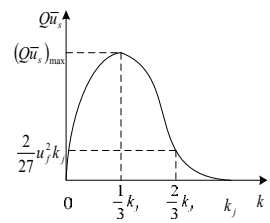

Figure 2. $Q\bar{u}_s - k$ in Greenshields

Taking the Linear relationship of velocity and density as $\overline{u}_s = u_f\left(1-k/k_j\right)$ which is rendered by Greenshields as an example, in order to get the maximum product of volume and velocity, we map the graph of $Q\overline{u}_s - k$ as shown in Figure 3, $\frac{1}{3}k_j$ and k_j are the extreme point, $\frac{1}{3}k_j$ is the maximum point , k_j is the minimum point, and $\frac{2}{3}k_j$ is inflection point. Using this as an analogy for a traffic network, according the sum of all the volumes of each turn in the maximum network, the aim-function of which is built on the upper programming model, we can describe the control object of the traffic managers.

To sum up, the upper programming model can be expressed as follows:

$$\begin{aligned} \max F &= \sum_i\sum_j\sum_h q_{ijh}u_{ijh} = \sum_i\sum_j\sum_h q_{ijh}\frac{l_{ij}}{t_{ijh}} = \sum_i\sum_j\sum_h q_{ijh}\frac{l_{ij}}{r_{ijh}+d_{ijh}} = \sum_i\sum_j\sum_h F(q_{ijh},g_{ijh}) \\ s.t. \quad & q_{ijh}\left(g_{ijh}\right) \le X_{ijh}^{\max}C_{ijh}\left(g_{ijh}\right) \\ & g_{ijh}^{\min} \le g_{ijh} \le g_{ijh}^{\max} \\ & c_j^{\min} - L_j \le \sum_{i\in I_j}\sum_{h\in H_{ij}} g_{ijh} \le c_j^{\max} - L \end{aligned} \tag{1}$$

Where q_{ijh} is the turning volume from the intersection i after intersection j to intersection h; u_{ijh} the travel speed of turning (i,j,h); l_{ij} is the distance between intersection i and intersection j. And $t_{ijh}(\cdot)$ is the impedance function of turning (i,j,h), where $t_{ijh}(\cdot) = r_{ij}(\cdot) + d_{ijh}(\cdot)$; $r_{ij}(\cdot)$ is the running time, if the node i and j are non-adjacent, then $r_{ij}(\cdot) = \infty$; $d_{ijh}(\cdot)$ is the delay time of turning (i,j,h) at the signal intersection j. And $X_{ijh}^{\max}$ is the maximum allowable saturation of the phase whose turning is (i,j,h); and C_{ijh} is the capacity of the lane whose turning is (i,j,h); where $g_{ijh}^{\min}$ and $g_{ijh}^{\max}$ are the minimum and maximum effective green times of the phase whose turning is (i,j,h); $c_j^{\min}$ and $c_j^{\max}$ is the shortest and longest cycle time at the intersection j; then L_j is the total loss time at intersection j.

Lower Programming

If it is assumed that travelers have determined their own path choice behavior using the UE principle according to control measures that have been developed as well as the road network traffic conditions, then the lower problem can be denoted in the transformation formula of Beckmann. Considering the impact of intersection delay on calculating the resistance of the road and the selection of a route as well as

the distinctness of delay at various turnings, we can transform the transformation formula of Beckmann into the following model (2):

Where： q_{ij} is the volumes of link (i,j); h_k^{rs} is the volumes of route k between r and s; f_{rs} is the volumes between r and s; $\delta_{ij,k}^{rs}$ is the relationship of route/link, if link (i,j) is on the route k which connecting the OD, then $\delta_{ij,k}^{rs}=1$, or else $\delta_{ij,k}^{rs}=0$.

$$\begin{aligned}
&\min\ Z=\sum_i\sum_j\int_0^{q_{ij}} r_{ij}(\mu)d_\mu+\sum_i\sum_j\sum_h\int_0^{q_{ijh}} d_{ijh}\left(u,g_{ijh}\right)d_u\\
&s.t.\qquad \sum_k h_k^{rs}=f_{rs}\\
&\qquad q_{ijh}=\sum_r\sum_s\sum_k h_k^{rs}\delta_{ijh,k}^{rs}\\
&\qquad q_{ij}=\sum_i\sum_j\sum_h q_{ijh}\\
&\qquad h_k^{rs}\ge 0
\end{aligned}\tag{2}$$

Math Expression

Via an analysis of the upper programming and lower programming model above, we integrate upper programming and lower programming into a model. Then the bi-level programming model based on the efficiency of the road network optimal signal control problem can be shown as formula (3):

$$\begin{aligned}
&U3:\\
&\max F=\sum_i\sum_j\sum_h q_{ijh}u_{ijh}=\sum_i\sum_j\sum_h F(q_{ijh},g_{ijh})\\
&s.t.\qquad q_{ijh}\left(g_{ijh}\right)\le X_{ijh}^{\max}C_{ijh}\left(g_{ijh}\right)\\
&\qquad g_{ijh}^{\min}\le g_{ijh}\le g_{ijh}^{\max}\\
&\qquad c_j^{\min}-L_j\le\sum_{i\in I_j}\sum_{h\in H_{ij}} g_{ijh}\le c_j^{\max}-L_j\\
&L3:\\
&\min Z=\sum_i\sum_j\int_0^{q_{ij}} r_{ij}(\mu)d_\mu+\sum_i\sum_j\sum_h\int_0^{q_{ijh}} d_{ijh}\left(u,g_{ijh}\right)d_u\\
&s.t\qquad \sum_k h_k^{rs}=f_{rs}\\
&\qquad q_{ijh}=\sum_r\sum_s\sum_k h_k^{rs}\delta_{ijh,k}^{rs}\\
&\qquad q_{ij}=\sum_i\sum_j\sum_h q_{ijh}\\
&\qquad h_k^{rs}\ge 0
\end{aligned}\tag{3}$$

Thus, $q_{ijh}\left(g_{ijh}\right)$ is determined by lower programming. By inference, the optimal conditions of model (3) are equal to the math expressions which Beckmann used to describe the Wardrop equilibrium state. Model (3) is a strictly convex programming problem, which has the only optimal solution concerned with route volumes.

Model Improvement

Generally speaking, solving the bi-level programming problem is very

complex, which is one of the reasons is the bi-level programming problem is an NP-hard problem. The non-convex aspect of the bi-level programming problem also shows that even if a double-layer solution can be found, usually the optimal solution is only a partial rather than a globally optimal solution. To improve on this, we take both bi-level programming and game theory with the same basic features into account, by using some approaches of game theory to describe the traffic signal control problem based on the operational efficiency of the road network, in order to simplify the model solution.

According to game theory, if we consider that the upper and lower decision-makers control their decision-making variables respectively and independently, then the bi-level programming problem can be showed as:

$$
\begin{aligned}
&U4: \\
&\max F = \sum_i \sum_j \sum_h q_{ijh} u_{ijh} = \sum_i \sum_j \sum_h F(q_{ijh}, g_{ijh}) \\
&s.t. \qquad g_{ijh}^{\min} \le g_{ijh} \le g_{ijh}^{\max} \\
&c_j^{\min} - L_j \le \sum_{i \in I_j} \sum_{h \in H_{ij}} g_{ijh} \le c_j^{\max} - L_j \\
&L4: \\
&\min Z = \sum_i \sum_j \int_0^{q_{ij}} r_{ij}(\mu) d_\mu + \sum_i \sum_j \sum_h \int_0^{q_{ijh}} d_{ijh}(u, g_{ijh}) d_u \\
&s.t \qquad \sum_k h_k^{rs} = f_{rs} \\
&q_{ijh} = \sum_r \sum_s \sum_k h_k^{rs} \delta_{ijh,k}^{rs} \\
&q_{ij} = \sum_i \sum_j \sum_h q_{ijh} \\
&h_k^{rs} \ge 0
\end{aligned}
\qquad (4)
$$

In upper programming U4, the link volumes $(\cdots, q_{ij}, \cdots)$ and the turning volumes $(\cdots, q_{ijh}, \cdots)$ are determined by the lower programming L4. Therefore, in model (4), the lower decision variable q_{ijh} is no longer a function of the upper decision variables g_{ijh}.

Example Design and Result Analysis

As the road network shows in Figure 4, we assign 1,3,7, 9 as the occurence and attraction points of traffic, and the trip volumes between OD pairs are shown in Table 1.

Table 1. Initial values among OD.

O	1	3	7	9
1				380
3			360	
7		380		
9	390			

In the network, 4-5-6 is a two-way, four-lane main road, where the designated speed is 50km/h. The others are secondary roads, which are also bi-directional four-lane roads, where the designated speed is 40km/h. The practical capacity of sections is 1350 veh/h. The distance between the intersection (m) as shown in Figure 4, the Free travel time of the links of the various sections in the transportation network, as shown in Figure 5.

There are five signal control intersections in network transportation, thus intersections 5 use four phases, with the phase settings shown in Figure 6, where the minimum and maximum effective green time of each phase is 17s, 12s, 17s, 12s and 45s, 40s, 45s , 40s. The intersection 2,4,6,8 uses three-phase phase settings as shown in Figure 7, where the minimum and maximum effective green times of each phase are 17s, 12s, 12s and 60s, 50s, 50s. Assuming that each phase of the green light loss time is 3s, all right-turn traffic volume is unrestricted by the red light, so the saturation flow rates of straight and left turn intersection imports are 1600veh/h and 1400veh/h.

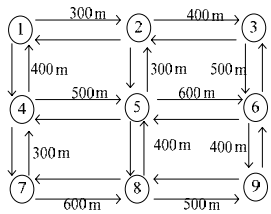

Figure 4. Distances among links in the example

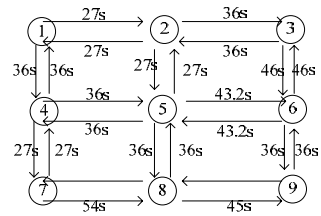

Figure 5. Free travel time of links.

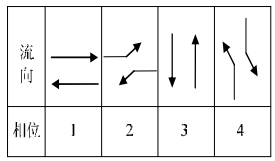

Figure 6. Phase of No.5 intersection

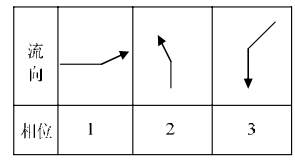

Figure 7. Phase of other intersections

The initial signal timing parameters of each phase in the signal control intersection are shown in Table 2.

8	0	0	0	0	595	0	671	0	767
9	0	0	0	0	0	797	0	726	0

Through our calculations, the initial solution of the corresponding objective function value is 96,625, and the total delay of all vehicles within the transportation network is 733,640. According to modes built for this paper, the optimal solution corresponding to the objective function value is 99,076, and the total delay of all vehicles in the transportation network is 636,680. That is, through the optimization of this algorithm, the total delay of vehicles in this network decreases by 13.22%.

CONCLUSIONS

According to the balanced distribution of network traffic flow, this paper proposed bi-level programming models which can reach network optimal efficiency. At last, we designed a practical network to validate the bi-level program model based on network efficiency optimization. The results indicate that the model can improve road network efficiency and decrease vehicle delays.

ABSTRACT

First of all, according to the studying and analysis of the existing travel time prediction model, the idea for prediction is acquired based on the analysis of the surveyed travel time data. The improved prediction model should focus on the benefits of the existing model as much as possible. Besides that, the improved model should choose different parameters for travel time prediction. The thesis gives the improved travel time prediction model in order to improve the existing model according to the ideas for travel time prediction. At last, according to the test for the improved model, the thesis can find that the improved travel time prediction model has a higher forecast accuracy and practicality.

INTRODUCTION

With China's rapid socio-economic development, transportation systems have quite an effect on the appearance of a new socio-economic development's "bottlenecks", showing serious congestion in big cities. In this regard, China has already made the development of urban public transport a priority, improving the proportion of residents' travel in order to alleviate the stress which urban bus traffic has faced. Although China has already offered to "give priority to the development of urban public transport" as a transport policy for more than ten years, the effect is not obvious. A lot of cities' public transport has undergone slow development or even serious recession. Taking Nanjing as an example, public transportation's contribution rate to all means of transport in the town in 2005 is 22.6%. However, in 2006 only 18.61 percent of residents in Nanjing's main city chose public transit for their trip. China's major cities' public transport is in an annual decline in the proportion of travel, which is mainly due to the low level of public transport service and the public transit punctuality rate. Therefore, the ability to facilitate economic and efficient access to public transport vehicles at urban road travel time in our country has become a constrained quasi-urban bus departure and arrival points of improved bottlenecks.

In recent years, domestic and foreign scholars have carried out a series of research on the travel time prediction of urban public transport, made some research results. The freeway travel time prediction model(Nam Do H et al. 1996) which takes into account random queuing theory and the number of vehicles on roads and so on had been set up; the signal control section of the vehicle on the distribution of travel times based on macro-delay Model(Rauphail et al. 1995)had

been predicted; a method which can predict travel time easily and efficiently(Zhang et al. 2003) had been proposed in 2003; travel time prediction of the basic formula(Yang et al. 1999,2004) based on Kalman filtering theory and Markov queuing model theory had been set up from 1999 to 2004; travel time prediction algorithm(Wen et al. 2006) based on gray correlation analysis of real-time has been studied in 2006.

Based on the analysis of domestic and foreign research results in the field of city public transport travel times forecasting, this thesis sets up an easy and accurate travel time prediction to improve the model, followed by the detailed description of the model. At last, a precision test to this model is given.

URBAN BUS TRAVEL TIME SURVEYS AND ANALYSIS

The paper investigates urban bus travel time of the No.3, No.47, No.52, and No.114 buses between Nanjing Xuanwu Lake Park and Shanxi Road. The survey time is 9:00am-12:00am from August 15, 2008 to August 29, 2008. The travel time investigation takes into account the different times of business days and holidays.

A 15 day survey data collation (10 minutes per vehicle travel times for an average of measured values) is shown below. As can be seen from Figure 1: the public transport travel time curve is obviously divided into two parts; the upper part of the curve contains bus travel times of the measured value during holidays, and the lower part of the curve contains measured values of bus trip time during a normal working day, indicating that sections holidays investigate bus travel times higher than the general working public transport travel times, which investigate the nature of sections of the zone.

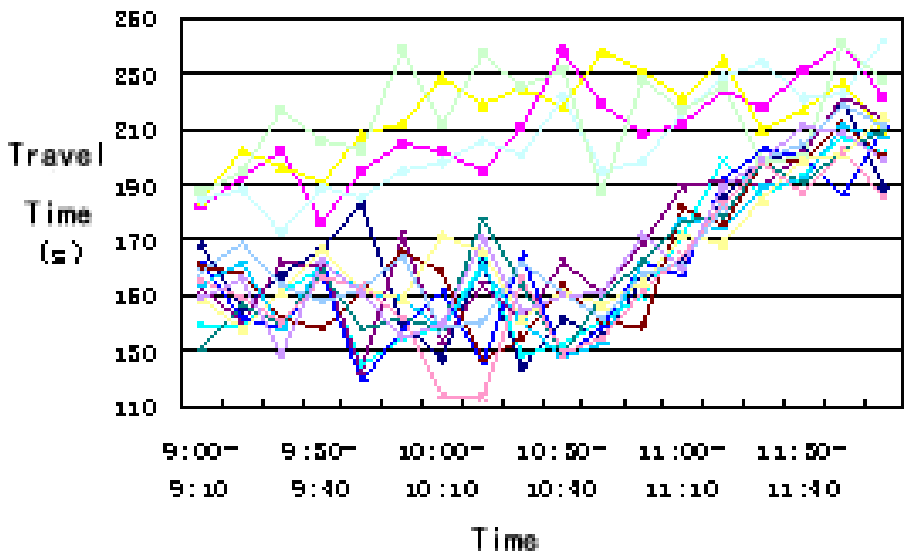

Figure1. Bus travel time (measured)

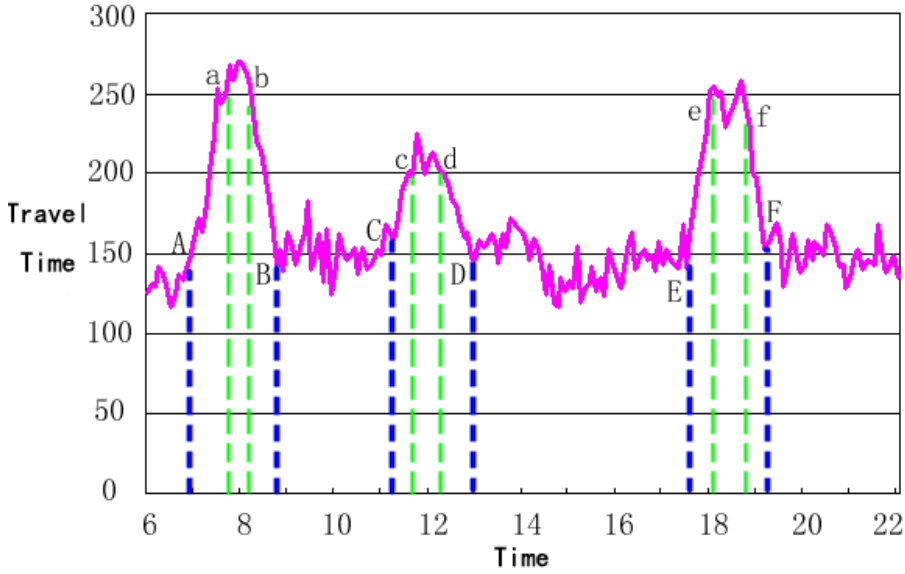

Figure 2. Bus travel time calibration stage (one day)

Figure 2 shows the Nanjing bus tours through a whole day.

According to the observation of the whole day of Nanjing city bus travel time, we can see that the travel time can be divided into peak hours and peace hours. Bus travel time is very stable at these times, but travel time is less stable when travel time is converting between peak hours and peace hours. Therefore, the travel time curve will be divided into the phases of stable changes in travel time and phases of dramatic changes in travel time. The stability of link travel time is shown, including changes in phase a-b, B-C, c-d, D-E, e-f. The link travel time phases of dramatic changes are also shown, including A-a, b-B, C-c, d-D, E-e, f-F.

MODEL

Taking into account the existing vehicle travel time prediction model, there are many inadequacies. This paper establishes a travel time prediction model based on the characteristic of urban buses and can reflect the different travel times throughout the whole day. In the paper, the prediction model will be divided into two separate parts for prediction. The first part of prediction uses the simple moving average method for prediction of travel time, and the result of the prediction reflects the approximate range of travel times. The second part of the trend prediction uses the moving average method for prediction of travel time, but this part of the process of predicting travel time mainly reflects the recent trend. Then it uses the weighted average of the result of the two parts, the integration value of prediction for different prediction periods, and its prediction model prediction value of the various parts of the share of different weights. Specific model is as follows:

$$\hat{z}_{(t)} = \omega_1 \hat{z}_{1(t)} + \omega_2 \hat{z}_{2(t)} \qquad (1)$$

$$\omega_1 + \omega_2 = 1 \qquad (2)$$

$\hat{z}_{1(t)}$ and $\hat{z}_{2(t)}$, respectively, for the first part and second part of the travel time prediction value, ω_1 and ω_2, respectively, on behalf of its weights.

$$\hat{z}_{1(t)} = \frac{z_{(t-1)} + z_{(t-2)} + \cdots + z_{(t-N)}}{N}, \quad t \geq N \qquad (3)$$

i for the first one of $z_{(i)}$ period of travel time measured data, N is the number of measured data.

Travel time prediction value of the second part of the trend of $\hat{z}_{2(t)}$ using the moving-average method of travel time changes in the process of prediction, the second part of $\hat{z}_{2(t)}$ is determined mainly by the first $M_{2(t)}^{(1)}$ moving average and the second moving average $M_{2(t)}^{(2)}$ consisting of the calculation formula:

$$\hat{z}_{2(t+T)} = a_{(t)} + b_{(t)}T, \quad T = 1 \qquad (4)$$

$$\begin{cases} a_{(t)} = 2M_{2(t)}^{(1)} - M_{2(t)}^{(2)} \\ b_{(t)} = \dfrac{2}{N-1}(M_{2(t)}^{(1)} - M_{2(t)}^{(2)}) \end{cases} \qquad (5)$$

$$M_{2(t)}^{(1)} = \frac{z_{(t)} + z_{(t-1)} + \cdots + z_{(t-N+1)}}{N}, \quad t \geq N \qquad (6)$$

$$M_{2(t)}^{(2)} = \frac{M_{2(t)}^{(1)} + M_{2(t-1)}^{(1)} + \cdots + M_{2(t-N+1)}^{(1)}}{N}, \quad t \geq N \qquad (7)$$

$a_{(t)}$ is the intercept; $b_{(t)}$ is the slope; $M_{2(t)}^{(1)}$ and $M_{2(t)}^{(2)}$, respectively, are the prediction processes of the second part of the first period of a moving average t and the second moving average.

Determination of model parameters is divided into the moving average value N and the determination of the weight values. The travel time prediction model for the first part of the number of moving average can take a large number; for the city bus lines. It can take an hour or a period of time, namely time to research their trip, so that the average journey time will be more precise. The travel time prediction model for the second part of the number of moving average can take a small number. In general, it can choose 10 minutes before the forecast period. The prediction model in the first part of the forecast model and the second part of the forecast model regarding the choice of weights, in general obey the

following principles: the stability of travel time to predict changes in stage, the first part of the right to a significant predictive value in the second part of the forecast weight value; in dramatic changes to the travel time prediction stage, the second part of the right to a significant predictive value of the predictive value in the first part of the weight. The prediction model of the right to re-value the main section of the projected range of the actual situation, the forecast interval, creates the need for public transport travel times above a certain understanding of the situation. In this paper, the "test method" determines the prediction model in the first part of predictive value and predictive value of the second part of the weight value. Weights are based on the value of options, primarily on the basis of predicted travel time $\hat{z}_{(t)}$ and the degree of measured values of the fitting.

MODEL TEXT

Because public transport travel times to improve the model contain four kinds of situations (working travel time dramatic changes in phase, changes in phase stability as well as dramatic changes in holiday travel time, and stability of phase change stage), so the test process model separately carries out inspection of the above four kinds of circumstances. Test time parameter selection is in the following Table 1:

Table1 Observed time

	Business Day, Dramatic phase	Business Day, stable phase	Holiday, Dramatic phase	Holiday, stable phase
Time	August 28, 11:20-11:30	August 28, 9:40-9:50	August 24, 9:50-10:00	August 24, 11:10-11:20

Because of space limitations, this only highlights the dramatic changes in working stages of the travel time on public transport travel time of the inspection process.

Use of survey data as a prediction model to improve prediction data source calculation model process is divided into Part I, Part II, and weight to calculate the three parts:

According to the first part of the model to improve the prediction formula, the second part of the formula of working travel time prediction phase of dramatic changes in the data source are calculated, respectively, to have been dramatic changes in travel time working stage. The second part of the first part of the predictive value is as follows:

Table 2 Prediction of travel time prediction model part Ⅰ on August 28

Time	$\hat{z}_{1(t)}$(s)	Time	$\hat{z}_{1(t)}$(s)
11:20-11:21	185.6	11:25-11:26	189.7
11:21-11:22	186.4	11:26-11:27	190.5
11:22-11:23	187.2	11:27-11:28	191.3
11:23-11:24	188.0	11:28-11:29	192.2
11:24-11:25	188.9	11:29-11:30	193.0

Table 3 Prediction of travel time prediction model part Ⅱ on August 28

Time	$\hat{z}_{2(t)}$ (s)	Time	$\hat{z}_{2(t)}$ (s)
11:20-11:21	200.7	11:25-11:26	183.6
11:21-11:22	197.0	11:26-11:27	189.1
11:22-11:23	193.7	11:27-11:28	194.8
11:23-11:24	188.5	11:28-11:29	201.9
11:24-11:25	182.7	11:29-11:30	211.9

Because of dramatic changes in phase, travel time prediction values of the second part of the prediction results for the impact are higher, so the second part of prediction values corresponding to the weight value should be greater than the first part of the corresponding weights. Mining test value method of weights to choose eventually determines the working phase of dramatic changes in travel time on public transport travel times the weight of the value of ω_1, ω_2, respectively, 0.3 and 0.7.

The above three parts organizing the process of prediction have been dramatic changes in travel time working phase bus travel times as follows:

Table 4 Prediction of travel time prediction model on August 28

Time	Prediction result(s)	Time	Prediction result(s)
11:20-11:21	196.2	11:25-11:26	185.4
11:21-11:22	193.8	11:26-11:27	189.5
11:22-11:23	191.8	11:27-11:28	193.8
11:23-11:24	188.4	11:28-11:29	199.0
11:24-11:25	184.6	11:29-11:30	206.2

For public transport travel times to improve the prediction model of evaluation, this thesis compares the simple moving average method and the trend of moving average method, as well as comparing measured data to determine its prediction accuracy.

Table 5 Bus travel times and the comparison between several models

Real Time (s)	Improved Model			Simple Moving Average Method			Trend Moving Average Method		
	Predict Time (s)	Absolute Error	Relative Error (%)	Predict Time (s)	Absolute Error	Relative Error (%)	Predict Time (s)	Absolute Error	Relative Error (%)
193	196.2	3.2	1.7	185.6	7.4	3.8	200.7	7.7	4.0
186	188.4	2.4	1.3	188	2.0	1.1	188.5	2.5	1.3
185	184.6	0.4	0.2	188.9	3.9	2.1	182.7	2.3	1.2
186	189.5	3.5	1.9	190.5	4.5	2.4	189.1	3.1	1.7
207	206.2	0.8	0.4	193	14	6.8	211.9	4.9	2.4

From the other three kinds of situation prediction results, the prediction model to improve prediction results are generally better than the above two

methods.

CONCLUSIONS

This paper investigates Nanjing bus travel time and outlines its rules. Then, the paper offers the ideas of the urban bus travel time prediction model. At last, the travel time prediction model is offered According to the test, the improved model offered in this paper can predict the urban bus travel times more precisely than the other method; therefore, it should be promoted widely.

ABSTRACT

A numerical simulation model was applied to study the characteristics of an off-ramp junction's traffic flow, based on analyzing the traffic flow of a Chinese urban expressway. In the course of this study, we constructed lane-changing rules with which to analyze special traffic flow characteristics. This construct was based on influences such as traffic volume parameters; the mainline rate; acceleration and deceleration values; and the length of the deceleration lane. Finally, we developed a new cellular automaton simulation model for the off-ramp junction of a Chinese urban expressway. Additionally, we analyzed the mainline traffic volume rate with different operation speeds, off-ramp junctions with different deceleration lane lengths, and the tendency chart of the mainline flow with different inflow probabilities. The results showed significant disturbance occurring between the outflow rates, mainline flow, and the operation speeds of mainline vehicles. By contrast, our new cellular automaton model was an efficient tool in the study of traffic flow from off-ramp junctions

INTRODUCTION

Traffic behavior for a single vehicle can't be represented in macroscopic models of traffic wave and gap-acceptance theory. However, as a microscopic and discrete model, the cellular automaton model focuses on the individual vehicle's kinestate of traffic flow. Furthermore, its updating rules can be changed easily, so this model can be suited to different traffic flow simulations as well as actual road and traffic conditions.

The NS model (1992) was put forward by Nagel and Schreckenberg, which proposed a one-dimensional stochastic cellular automaton model describing traffic flow on a highway. Lighthill and Whitham (1995) first brought forward hydro-dynamic theory and developed a simple continuum model, and later researchers applied this theory to study road ramp areas' traffic flow characteristics. Banks (1990) reported that queues first form in the median lane at a location well in

advance of the on-ramp. Cassidy and Bertini (1999) reported that bottlenecks activated some distances downstream of on-ramps, which could be explained by lane-changing behavior. Helbing, Dietrich, and While (1999) as well as Dong Li-yun (2002) used cellular automata doing traffic flow simulation experiments. Cassidy, Shadi, and John (2002) studied the freeway traffic near an off-ramp, where the ramp's queues were confined to the right-most exit lane, and where non-exiting drivers reduced their speeds upon seeing these queues. They found that this diminished flows in all lanes, and that the lengths of these exit queues negatively correlated with the discharge flows in the freeway segment's adjacent lanes. Robert, Bertini, and Cassidy (2002) used surveying data to study queue discharge features at a freeway bottleneck downstream from a merge.

Here, a two-dimensional cellular automaton model was used to simulate the traffic flow for an off-ramp junction of a Chinese urban expressway, which was based on special lane-changing rules. So, traffic flow characteristics for the off-ramp junction was studied with different acceleration lengths, levels of mainline traffic volume, and off-flow rates.

THE TRAFFIC FLOW SIMULATION MODEL

The Mathematical model with simplified representation. In the deceleration lane at off-ramp junctions, the traffic conflict is actually the vehicles' lane changing problems within a too-limited space. That's to say, shoulder lane vehicles change lanes from the deceleration lane to the ramp, and then travel along the off-ramp. Thus, as simplified in Figure 1, we just consider the shoulder lane of the mainline. Briefly, the upstream and downstream sections of the off-ramp junctions are marked by U and D, and the ramp section for R. In this paper, the length of deceleration is L_w and vehicles diverge in this limited length following corresponding lane-changing conditions. Otherwise, vehicles' update their status within the rules of the single lane NS model beyond the speed-down area.

Lane-changing behaviors include mandatory lane-changing, so they meet very simple lane-changing conditions. Each time step can be subdivided into two sub-steps in the two-lane model by the procedure of updating the location. In the first sub-step, parallel lane-changing is done by way of the lane-changing condition being satisfied. In the second sub-step, vehicles update locations under the rule of the single-lane NS model. The Imperative operation is applied to deal with the lane-changing of the ramp traffic's flow, so that all vehicles meeting the above-mentioned lane-changing principle transfer to the deceleration lane at road section L_w.

Simulation parameter selection. The length of a cell just equaled 1/7 of the average space headway, which was 1 meter for a cell. In other words, seven continuous cells had the same states and contained one vehicle. The length of a cell

was one of the key parameters in the simulation model.

Vehicles in an off-ramp junction were always influenced by off-flow from the mainline, whose operation speed always lowered the design speed, and the maximum speed approximately equaled the free flow speed. Therefore, the maximum speed in this simulation model was 90 km/h. In other words, the maximum speed of the cellular automaton v_{max} equaled 25L/s, where the range of speed was between 0 and v_{max}.

In this simulation model, the values of the maximum acceleration and deceleration $\pm a_{max}$ equaled $\pm$7m/s^2. This means that the maximum acceleration and deceleration values of the cellular automaton equaled ± 7 L/s^2, where the range of acceleration and deceleration was between -a_{ma} and a_{max}.

We selected a time step of 0.5 seconds, in this paper, given the actual traffic flow situation and its values for vehicle speed and acceleration. If the updating time step was longer, both acceleration and deceleration would change rapidly.

In order to guarantee the stability of the traffic flow simulation and to achieve a good effect from the special research expressway segment, a closed expressway system was selected for the boundary conditions of the NS model.

In this model, the simulation system was an unblocked expressway system with both sources and exports. Vehicles were generated in the mainline from the left boundary of the mainline, and they weren't subject to investigation outside the research area.

Simulation operation rules. At time t, if $v_n(t) \leqslant gap_n(t)$, the vehicle accelerated, so that:

$$a_n(t) = \begin{cases} gap_n(t) - v_n(t), & gap_n(t) - v_n(t) < 7 \\ 7, & gap_n(t) - v_n(t) \geqslant 7 \\ 0, & v_n(t) = v_{\max} \end{cases} \quad (1)$$

Where $v_n(t)$ was the speed of a self-vehicle at the time t; $a_n(t)$ was the acceleration of the self-vehicle between time t and t+1; and $gap_n(t)$ was the interval between the self-vehicle's head and the front vehicle's tail at time t, so that: $gap_n(t) = x_{n-1}(t) - x_n(t) - 7$.

At time t, if $v_n(t) > gap_n(t)$, the vehicle decelerated, so that:

$$a_n(t) = \begin{cases} gap_n(t) - v_n(t), & v_n(t) - gap_n(t) < 7 \\ -7, & v_n(t) - gap_n(t) \geqslant 7 \end{cases} \quad (2)$$

At time t, the acceleration of a present vehicle was known, and the deceleration we supposed for the front vehicle was the maximum deceleration -7 L/s^2, so at that at the time of t+1:

If $v_n(t+1) \leqslant gap_n(t+1)$, then acceleration for the present vehicle was still $a_n(t)$;

If $v_n(t+1) > gap_n(t+1)$, then $a_n(t) = a_n(t) - 1 \geqslant -7$, and didn't compute $v_n(t+1)$ and $gap_n(t+1)$ until $v_n(t+1) \leqslant gap_n(t+1)$. The $a_n(t)$ at the moment was the modified actual acceleration for the present vehicle at the time of *t*.

In the condition of probability of P_b, vehicles made adjustments such that adjustment rules would still reduce the speed, where the deceleration incrementation was $\triangle a \in [-7, 0]$. Additionally, the adjustment deceleration plus $\triangle a$ advanced to a maximum deceleration.

Cells would update continuously according to the speeds available from that lead time.

$$v_n(t+1) = v_n(t) + a_n(t)/2 \text{ , } x_n(t+1) = x_n(t) + v_n(t+1)/2 \tag{3}$$

where $x_n(t)$ was the location of the present vehicle at the time of *t*.

We assumed the location $x_0(t)$ was the target vehicle A, and the front and rear vehicles in the left or right lane locations were $x_{n\text{-}1}(t)$ and $x_n(t)$, respectively. If the target vehicle satisfied the following conditions:

$$\begin{cases} x_{n-1}(t) - x_0(t) - 7 \geqslant 0 \\ x_0(t) - x_n(t) - 7 \geqslant 0 \end{cases} \tag{4}$$

where $x_0(t)$ was the location of the vehicle in the acceleration lane at the time of *t,* then $x_{n\text{-}1}(t)$ was the location of the front vehicle at the time of *t.*

SIMULATION SYSTEM DEVELOPMENT

The procedure for traffic flow simulation of cellular automata contained five steps: network setting; initial state setting; cells' speed and location updating; simulation image generation; and traffic flow analysis.

Vehicle generation model. We first needed to satisfy demand for adequate actual traffic flow input. That was the vehicle generation model. At the time of the simulation, vehicles were continually generated at the left boundary cross-sections of the mainline. This reflected the randomness of system initialization, with both the vehicles themselves and their arriving time.

The generation model was divided into two parts: the vehicles' random generation and the initially produced status. First, a constant *P* was set belonging to [0, 1], and generated a random number according to weibrnd (0.8, 2.6, 10000, 1). Finally, comparing the two values and judging the front n cells, if the all n cells were full, a vehicle would be generated with a speed assigned in the range of [0, V_{max}].

Status updating model. Because of the different characteristics of operation speeds for different design speeds, the values for maximum speed and deceleration were set, and also for lane-changing and random probabilities. Utilizing the updating time step setting, the speed, deceleration and location updating for every cell were set.

In this paper, cells in the mainline and the deceleration lane had different maximum speeds, and according to different ramp areas, vehicles in different lanes had different lane-changing directions and probabilities.

The simulation image model. The output for simulation results was shown in both image and numerical value, so that the simulation image model could also help us judge our rationale for the simulation model, either way.

Because of the simulation updating time step, the simulation image dealt with noncontinuity, and the system yielded a critical image for every time interval, so we could realize the process of vehicles moving forward.

Traffic operation analysis model. The traffic operation analysis model was set for calculating the traffic flow rate, speed, and density after every time interval. So in this paper, we analyzed traffic flow variabilities for upstream, downstream, and off-ramp flows, as well as for the densities and speeds of both passing lanes and mainline lanes.

SIMULATION RESULTS

Before doing simulation experiments, several parameters had to be set, such as the length of the ramp junctions, the updating time step, the vehicles' generation rate, their lane-changing rate, their maximum acceleration and deceleration, their maximum speed, etc.

The actual inputs were as follows

a) The length of the ramp junctions were between 330 and 680 meters, i.e., the length of the passing lanes were between 50 to 400 meters;

b) The design speeds for the mainline were 60, 80 and 100km/h, which means that the maximum speeds for cells in the mainline and ramp were [19,22,25] and [11,14,20] L/s;

c) The maximum acceleration was 7 L/s^2;

d) The probability for vehicle generation and lane-changing belonged to [0,1];

e) The random changing probability was 0.2; and

f) The updating time step was 0.5 s, where the simulation time was 1800 s.

After doing several experiments, we developed an actual traffic flow rate diagram for different speeds, where the vehicle generation rate is 0.3, the lane-changing rate for the mainline is 0.2, the lane-changing rate for deceleration lane is 1, and the length of the ramp junction is 500 m.

Additionally, we constructed an actual traffic flow rate diagram for the different lengths of the deceleration lanes, which is based on the probability for the vehicle generation rate and lane-changing rate, which are 0.2. From the diagram, the length of the deceleration lane has an obvious affect on its capacity for off-ramp junctions.

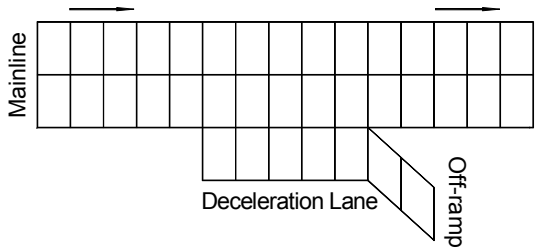

Figure 1. A celluar frame for off-ramp junction.

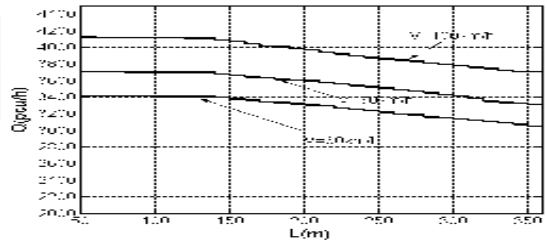

Figure 2. Traffic flow simulation results for off-ramp junctions.

In this paper, the outflow volume for the mainline is shown by the number of vehicles through a cross section of mainline downstream, and marked Q_o. Figure 4 is the relationship between generation probability and out-flow probability where the maximum speed for the mainline is $V_{\max} = 22$ and the ramp is $V_{\max} = 14$.

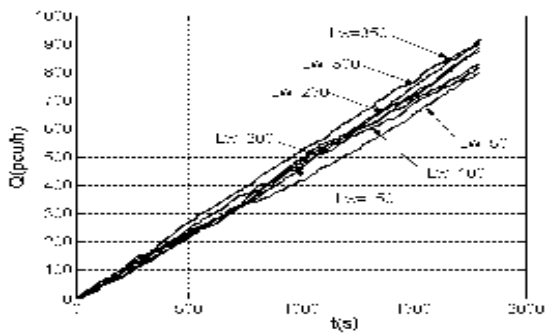

Figure 3. The influence with different lengths of deceleration lane.

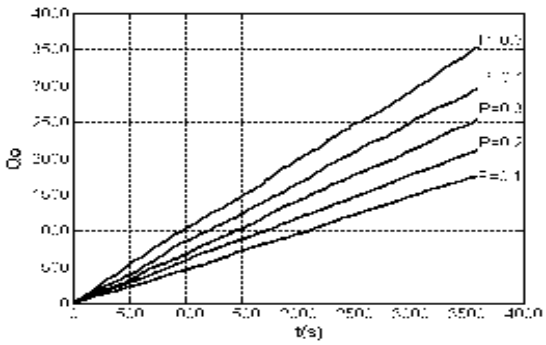

Figure 4. The flow tendency chart of mainline downstream.

The data demonstrates that with the increasing of inflow rate *P*, as well as the increasing of flow on both the ramp and the mainline, the ramp outflow gradually increases because of lane-changing over time. The mainline inflow rate increases when the volume of vehicles on mainline lanes is not heavy ($P \leqslant 0.3$), but when the vehicles' volume on the mainline lanes are very heavy, as more and more vehicles of the ramp change lanes, the downstream traffic on the mainline makes it more difficult to proceed, so the inflow gradually decreases, and when $P = 0.9$, the outflow falls to only about 200 veh/h, which is almost traffic jam condition.

CONCLUSIONS

A new cellular automaton simulation model was set up for an off-ramp junction in a Chinese urban expressway; it can be used to analyze traffic flow, level of service, etc. The simulation results showed that there was a significant disturbance between the outflow rates and the mainline flow, as well as in the operation speeds of

mainline vehicles. Our research showed that our new cellular automaton model was an efficient tool in the study of traffic flow for off-ramp junctions.

ABSTRACT:

This paper presents a procedure for constructing and calibrating a detailed model of a freeway weaving section using VISSIM5.0. This is applied to the Wuning on-ramp in the Inner Ring Elevated Roads of Shanghai. This test site provides several challenges for microscopic modeling: the contact between the road surface and the freeway, traffic characteristic of a weaving section, and the influence of the next off-ramp fifty meters away. A qualitative set of goals was established for the calibration. These were met with relatively few modifications to VISSIM's driver behavior parameters. A manual methodology calibration using Latin orthogonal square experiment for weaving section is presented in this paper. The actual data obtained by loop-detectors is used to demonstrate the feasibility, application, and benefits of the proposed methodology.

INTRODUCTION:

It has long been recognized that simulation modeling is a very useful tool for the design of improvements to urban freeway systems. However, there is something wrong with the simulation model. This is because the parameters used to describe driver behavior and vehicle performance characteristics are immeasurable. Engineers often use default values for parameters such as car-following sensitivity and gap acceptance because it can be difficult to obtain accurate estimates for these parameters. The procedure by which the parameters of the model are adjusted so that the simulated response agrees with the measured field conditions is what is known as model calibration.

Field data used as input for the model was compiled from two separate sources: loop-detectors on the on-ramps and mainline, and a manual survey of on-ramps and mainline using cameras. The model construction procedure consists of: 1) combination of weaving section and flat signal intersection, 2)identification of important geometric features, 3) collection and processing of traffic data, 4) analysis of the mainline and onramp data to identify the reason of bottleneck, and finally

5)VISSIM coding. Calibration and validation was then made based on collected data.

This work is part of a larger project that has as its central goal the design and implementation of an improved on-ramp control system for Shanghai Urban Elevated Roads. As is described above, the Wuning on-ramp is a typical test site, and presents three complicating features. Although this paper is based on a single test-case, practitioners wishing to use microsimulation to study unidirectional freeways may find many of the details on how certain features were implemented and how problems related to incomplete data were overcome to be useful.

THE VISSIM MODEL DEVELOPMENT

Overview of the program

VISSIM5.0 is the microscopic traffic simulator that was used to create the detailed model of the Wuning on-ramp. Its traffic model is based on the work of R.Wiedemann, The behavioral model for the driver involves a classification of reactions in response to the perceived relative speed and distance with respect to the preceding vehicle.

Coding of the network geometry

The site and time period chosen for the simulation study is the Wuning on-ramp in the Inner Ring Elevated Roads of Shanghai including the close flat signal intersection, between 4:30 pm and 5:30 pm (Figure 1). This is a single point on the Freeway system which can reflect the traffic condition in its entirety. It sustains heavy congestion during the afternoon peak. The site is equipped with a complete set of loop-detectors which helps us collect traffic data. Simulation models require a detailed and complete description of the layout of the site in order to produce a realistic output.

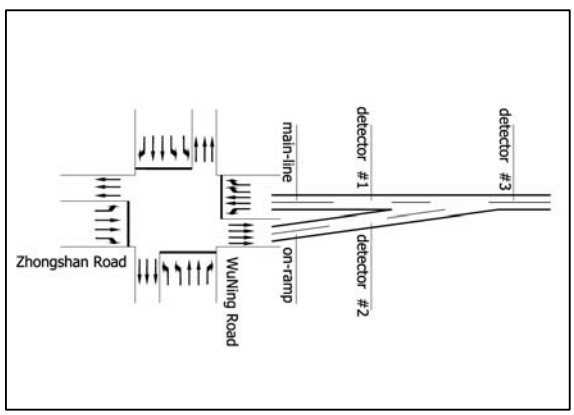

Figure 1: Test Site for Simulation

The relevant features of the test site were marked with the scaled aerial CAD-graphs including both freeway and surface road obtained from Government. Links and link connectors were then traced on this background image in VISSIM. In addition to the freeway geometry, coding of the supply side of the model also entailed the placement of the control hardware elements:

loop-detectors and signal heads including the flat intersection.

Coding of traffic demands

The traffic demand in this paper is to use aggregate vehicle sources, and to direct traffic using turning percentages. The data of flat intersection is collected by manual investigation, and that on the freeway is given by loop-detectors. The vehicle population presented in this paper is categorized into vehicles types. A single type gathers vehicles that share common vehicle performance attributes.

THE VISSIM MODEL CALIBRATION

Pre-checking

The purpose of pre-checking model is investigating whether the traffic characteristics in the model are in accordance to the actual situation. In this paper, it can be observed mainly through the three control points to control the model data credibility: the main line before the weaving section, the onramp before the section and then end of section. The positions of three control points are corresponding to the actual detector-loops. The elements of pre-checking are given in **Table 1**.

Table 1. List of Pre-checking elements

Num	Characteristic Description	Accomplish or not
1	Both main-line and onramp vehicles have deceleration behavior	Yes
2	Vehicles entering into the weaving section have obviously acceleration phenomenon.	Yes
3	At peak hours, the vehicle speed on main line and ramp is closed to the measured data obtained from the loop-detectors.	Yes

Minimum simulation number

According to experience, the minimum simulation number is 6 times in the beginning. Different random number seeds are selected to run the test model 6 times. Accounting to the actual needs of simulation objects, the desired confidence interval is ± 10%. Initial simulation results are given in **Table 2**.

Table 2. Minimum Stimulation Number

Random seeds		5	15	25	35	45	55	Standard deviation	t-Distribution	N	confidence interval	Desired the largest confidence interval
VI FLO	1	1279	1284	1232	1180	1206	1218	41.18	2.5705818	6	86.44	103.02

	2	636	706	712	702	708	720	30.66	2.5705818	6	64.36	70.73
	3	1907	1996	1921	1855	1904	1941	46.62	2.5705818	6	97.84	159.72
	1	21.6	21.4	21.5	21.5	21.4	21.6	0.09	2.5705818	6	0.19	1.79
SPEED	2	30.6	31.3	31.2	31.1	31.4	31.1	0.28	2.5705818	6	0.58	2.59
	3	61.2	70.9	72.4	72.9	69.8	68.8	4.27	2.5705818	6	8.97	9.79

*ps：In this t- distribution, confidence is 95%, and freedom is 5。

It can be seen that in the data above three points meets the demand when the desired confidence interval is twice the standard deviation. It is appropriate that 6 times is the selected number of the smallest simulation.

CHANGEABLE MODEL PARAMETERS

Drivers might behave differently on weaving section. Thus, the parameters described in this section apply equally to all vehicle types, but were adjusted for each link type. Link types are analogous to vehicle types. The driver behavior parameters that were changed from their default values to define each link type are described in Table 3.

Table 3. Classification Parameters

Parameters	CC0（m）	CC1（s）	CC2（m）	DLCD（m）	MDCB（m/s^2）
Level 1	1.00	0.5	3	50	-2
Level 2	2.00	1.0	5	100	-3
Level 3	3.00	1.5	7	150	-4
Level 4	4.00	2.0	9	200	-5

CC0: Standstill distance **CC1**: Headway time **CC2**: Following' variation

DLCD：Desired Lane Change **MDCB**：Maximum deceleration for cooperative barking

SIMULATION EXPERIMENT

This paper uses a Latin orthogonal square experiment to calibrate the driver behavior parameters. According to the parameter selection, it use $L_{16}(4^5)$ orthogonal table to experiment. The experiment is repeated 6 times with each parameter group, taking the average of test data as a result. First of all, detected flow gaining from detector #2 is selected for calibration targets. The experimental results are given in **Table 4**:

Table 4. Initial Calibration

	CC0（m）	CC1（s）	CC2（m）	DLCD（m）	MDCB（m/s^2）	Traffic capacity
1	4	2	9	200	-2	420
2	4	0.5	7	100	-5	560
3	3	1.5	7	150	-2	449
4	4	1	3	150	-4	559

5	2	2	7	50	-4	279
6	1	2	5	150	-5	276
7	1	0.5	3	50	-2	679
8	2	0.5	9	150	-3	663
9	2	1.5	3	200	-5	341
10	4	1.5	5	50	-3	341
11	3	1	9	50	-5	334
12	1	1	7	200	-3	593
13	1	1.5	9	100	-4	332
14	3	0.5	5	200	-4	660
15	3	2	3	100	-3	352
16	2	1	5	100	-2	642
Ⅰ	1880	2562	1931	1633	2190	
Ⅱ	1925	2128	1919	1886	1949	
Ⅲ	1795	1463	1881	1947	1830	
Ⅳ	1880	1327	1749	2014	1511	
Range	130	1235	182	381	679	

Based on the above analysis data, the following judgment is developed：

- The results of test 8,14,16 are better than others
- Based on range analysis, parameter changes on the results of the impact from strong to weak are as follows:CC1>MDCB>DLCD>CC2>CC0.

According to the experiment above, new parameter combinations are generated with the three groups for speed calibration. In the same measure, 6 times simulation is experimented, and a T test is the Statistical method of this experiment. The combinations and experiment results are given in **Table 5**.

Table 5. Simulation Results with T test

NO.	CC0（m）	CC1（s）	CC2（m）	DLCD（m）	MDCB(m/s²)	Traffic capacity	T-test （<2.015?）
1	2.00	0.50	9.00	150.00	-3.00	663	1.668
2	1.00	0.50	9.00	50.00	-3.00	643	-0.723
3	1.50	0.50	9.00	100.00	-3.00	662	1.234
4	3.00	0.50	5.00	200.00	-4.00	660	0.995
5	3.00	0.50	7.00	150.00	-4.00	642	-0.518
6	3.00	0.50	9.00	100.00	-4.00	551	-7.485
7	2.00	1.00	5.00	100.00	-2.00	642	-0.614
8	1.00	1.00	5.00	100.00	-2.00	680	4.250
9	1.50	1.00	5.00	100.00	-2.00	665	1.927
10	2.00	1.00	7.00	150.00	-2.00	501	-11.947

CALIBRATION TAGET

Three possible combinations (No.2,5,7) are selected by the experiment above. Simulation speed and flow is collected by using these parameters, then compared to the measured value (half hour). The results are given in **Table 6**.

Table 6. Verification Value

Group		Detector #1		Detector #2		Detector #3	
		Flow	Speed	Flow	Speed	Flow	Speed
Desired value		1200	23.8	600	5.5	1800	41.7
2	simulation	1207	21.5	603	5.6	1809	49.7
	deviation	0.56%	9.80%	0.56%	1.82%	0.50%	19.26%
5	simulation	1207	21	603	6	1802	50
	deviation	0.56%	10.29%	0.50%	1.82%	0.11%	20.42%
7	simulation	1207	21	603	6	1805	45
	deviation	0.56%	9.80%	0.56%	2.12%	0.25%	8.71%

The final selection of driver behavior parameters is group 7 as shown in **Table 6**. This parameter set is the most parsimonious among those sets that also met the calibration goals. Through the Latin orthogonal square experiment, the analyst can calibrate the driver behavior parameters of a simulation model.

SUMMARY AND CONCLUSIONS

This document has outlined a complete methodology for constructing and calibrating a simulation model of a unidirectional freeway with on-ramp control. The procedure included gathering and processing of field data from the database, microscopic simulation with VISSIM, and calibration of simulation model with a Latin orthogonal square experiment. Deficiencies in the field data were dealt with by assembling a composite typical day using data from several different days. A successful calibration of the VISSIM model was carried out based on the comprehension of driver behavior. In conclusion, this study has shown that the VISSIM simulation environment is well-suited for freeway studies involving complex flat interactions. With few and well reasoned modifications to its driver behavior parameters, the simulation model is capable of reproducing the field-measured response on the on-ramps and mixed-flow lanes.

Research will now continue using the calibrated VISSIM model to investigate a wide variety of ramp control strategies for the Inner Ring Elevated Roads of Shanghai during the peak period. Ramp control strategies will include local and system-wide alternatives. Caltrans will consider implementing improved ramp control strategies based on their assessment of the predicted results.

ABSTRACT

For probe vehicle system, there are only few travel time data (sample) available for real-time link travel time estimation due to limited number of probe vehicles. However, the population of link travel time (travel times of all vehicles) has large variance. In this circumstance, it is difficult to reliably estimate the population mean by the sample mean directly. In this paper, the population is redefined by the link travel times of such vehicles which have through movements at upstream and downstream intersections. However, there are still two groups of vehicles (without delay and with delay) with significantly different travel time. The relationship between the three variables (two means of the groups and the portion of the first group) is analyzed and an estimation method based on the relationship is proposed. The comparison between the new and the conventional method shows that the proposed method can provide more precise estimation result.

Keywords: probe vehicle, sample size, signalized link, travel time estimation

1 INTRODUCTION

For probe-based real-time link travel time estimation, the population of link travel time is defined by link travel times of all vehicles traveling a link during a time interval. And the sample is the travel time data from probe vehicles (PVs) on the link in the time interval. The cost and the capacity of the communication between PVs and the operation center impose the restrictions on the number of PVs. Hence the

* Supported by National Natural Science Foundation of China (ID:50808108)

number of PVs in the road network is limited and the sample size is very small. For a typical signalized link which has four-way intersections on both ends, there are nine distinct subpopulations associated with each combination of access and departure movements (left turning, right turning and through). These subpopulations have different travel time characteristics. Further more, the population also can be divided by intersection delay (some vehicles will experience the intersection delay at downstream intersection of the link, while the others will depart without intersection delay) and the two subpopulations also have significant different travel time. Therefore, the population has large variance and is seriously non-normal.

Various approaches have been developed to estimate the adequate number of PVs (e.g., Chen and Chien, 2000; Cheu et al., 2002; Hellinga and Fu, 1999; Quiroga and Bullock, 1998; Srinivasan and Jovanis, 1996). In these studies, sample mean is directly used to estimate the population mean. If the sample size is very small (less than 5) while the population has large variance and is seriously non-normal, it is difficult to reliably estimate the population mean by the sample mean directly. However, for probe-based estimation, it is still expected that a reliable estimation can be obtained by a small-size sample. Therefore, it is necessary to develop a new estimation method for probe-based estimation and it is the primary objective of this paper.

This paper is consisted by four sections. The next section describes the properties of link travel time which are useful for probe-based link travel time estimation. And then, the proposed estimation method is introduced and is compared with conventional estimation method. Finally, conclusions are drawn.

2 PRELIMINARY ANALYSIS FOR LINK TRAVEL TIME

In a previous study by the authors (Li et al., 2008), the properties of link travel time are discussed and some conclusions that are useful for probe-based link travel time estimation are made.

A corridor that consists of four links (link 2 ~ link 5) and the adjacent links are simulated for 3 hours using VISSIM – a microscopic traffic simulation software developed by PTV AG (http://www.english.ptv.de/). Figure 1 shows the road network (Traffic in Japan keeps left), origin zones (1~12), signal scheme and turning rate. Vehicles are generated at each origin zone with Poisson distribution. The imaginary time period is morning. The base vehicle input of each zone and the temporal variation are set as Table 1. Each intersection is controlled by a two-phase fixed-time

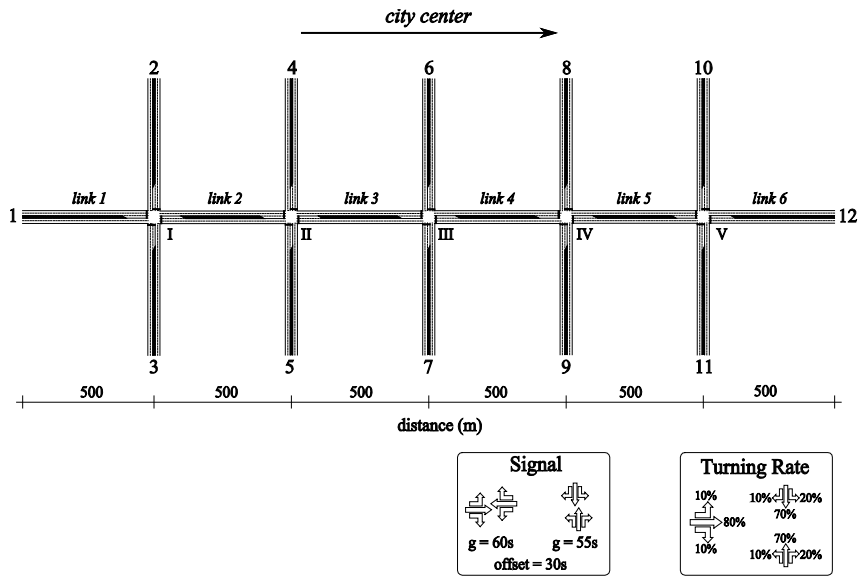

Figure 1. Simulation Network (adapted from Li et al., 2008)

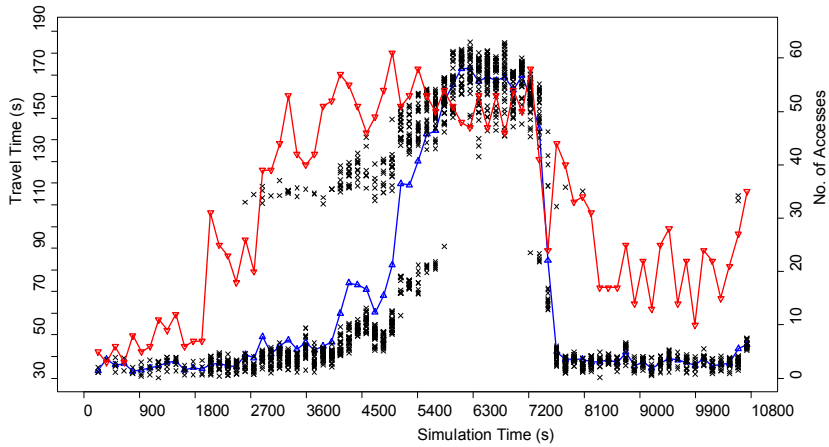
Table 1. Vehicle Inputs

Base Vehicle Inputs (Veh/h)		Temporal Variation	
Origin Zone	Vehicle Inputs	Time (s)	Proportion of Base Vehicle Inputs
1	1000	0 ~ 900	0.1
2~11	800	900 ~ 1800	0.2
12	500	1800 ~ 2700	0.5
		2700 ~ 3600	1
		3600 ~ 4500	1.2
		4500 ~ 6300	1.5
		6300 ~ 7200	1
		7200 ~ 8100	0.8
		8100 ~ 10800	0.5

signal with a cycle length of 140 s. The offset time of two consequent intersections is 30 s. The imaginary network is a corridor towards city center. Hence the turning movements towards city center are emphasized in turning rate setting.

For each link in the corridor, we are only interested in the travel times reported by the vehicles which have through movements at upstream and downstream intersections (abbreviated as TT). The link travel times and the flow (only through movement at upstream) are aggregated by signal cycle. Figure 2 shows the aggregation result of mean link travel time and flow for link 5. The figure also shows the individual travel time reports from the vehicles with TT (×) and the temporal variation of vehicle inputs (dot line).

The aggregation results are discussed in two stages divided by the traffic



conditions at upstream intersection.

During undersaturated conditions, all vehicles that access a link in a signal cycle at upstream can depart the link in a signal cycle at downstream. The travel times of such vehicles will be small and similar. Consequently, mean link travel time will be stable at a relatively low level over time (time period 0 s ~ 3600 s in Figure 2).

Under saturated/oversaturated conditions, the arrival distribution is close to uniform over green time and the queue length at downstream intersection increases over time. Then mean travel time also increases over time (time period 3600 s ~ 7200 s in Figure 2). As shown in Figure 2, in this stage, travel times can be divided into two groups: one without delay (Group 1) and the other with delay (Group 2). Further, as mean travel time increases, the average travel time of the two groups (μ_1 and μ_2) increase and the proportion of Group 1 (p) decreases. That is, μ_1, μ_2 and p have some relationship.

3 PROPOSED ESTIMATION METHOD

For arterial road, the subpopulation with TT is usually dominant in the nine subpopulations and the mean travel time of vehicles with TT can represent the traffic condition of the link in an interval. Thus, the population is redefined as the link travel times of all vehicles with TT during a time interval in this paper.

3.1 Relationship between μ_1, μ_2 and p

Under saturated/oversaturated conditions, there will be some vehicles queued

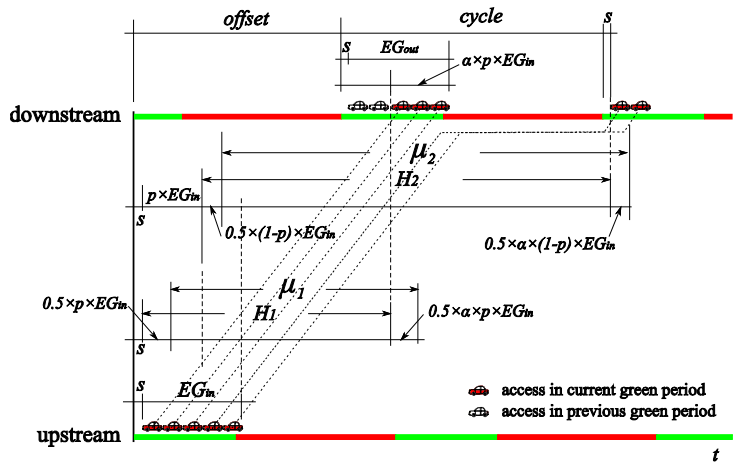


Figure 3. Vehicles that Access a Link in a Green Period

at downstream and thus the vehicles that access a link in same signal cycle will not be able to depart the link in the same signal cycle and some vehicles will experience the intersection delay. Then, under uniform assumption which is reasonable during saturated/oversaturated conditions, the access time and departure time of these vehicles can be illustrated as Figure 3. This figure is a time-space diagram and color bars at upstream and downstream intersection present the green and red periods of traffic signal. The vehicles with TL/TR (through access movement and left/right departure movement) access the link together with the vehicles with TT and will queue in left/right turning lanes at downstream intersection. That is, the length of the queue of vehicles with TT at downstream will become shorter than the length at upstream. The parameter α in the figure reflects the reduction of the length and is dependent on the turning rate at downstream intersection. The notation in the figure is described in the next paragraphs.

The relationship between μ_1, μ_2 and p can be obtained from Figure 3 and Eq. 1 and 2 show the relationship. Eq. 3 shows the formulation for calculating mean travel time and Eq. 4 shows that the difference between μ_1 and μ_2 is independent from p.

$$1 \quad \frac{H_1 \quad 0.5 \quad (1 \quad) \quad p \quad EG_{in}}{offset \quad EG_{out} \quad p \quad EG_{in} \quad 0.5 \quad (1 \quad) \quad p \quad EG_{in}} \qquad (1)$$

$$offset \quad EG_{out} \quad 0.5 \quad (1 \quad) \quad p \quad EG_{in}$$

$$_2 \quad \underline{H_2} \quad 0.5 \quad (1 \quad) \quad (1 \quad p) \quad EG_{in}$$
$$\underline{offset \quad cycle \quad p \quad EG_{in}} \quad 0.5 \quad (1 \quad) \quad (1 \quad p) \quad EG_{in} \tag{2}$$
$$offset \quad cycle \quad 0.5 \quad (1 \quad) \quad EG_{in} \quad 0.5 \quad (1 \quad) \quad p \quad EG_{in}$$

$$p \quad _1 \quad (1 \quad p) \quad _2 \tag{3}$$

$$_2 \quad _1 \quad cycle \quad 0.5 \quad (1 \quad) \quad EG_{in} \quad EG_{out} \tag{4}$$

where

p the proportion of Group 1
H_1, H_2 travel time of head in Group 1 and Group2
$_1, \ _2,$ mean of Group1, Group 2 and all
$cycle, offset$ signal length and signal offset between upstream and downstream instersection
EG_{in}, EG_{out} effective green time of upstream and downstream intersection for through movement
reduction rate of length of vehicles with TT between downstream and upstream

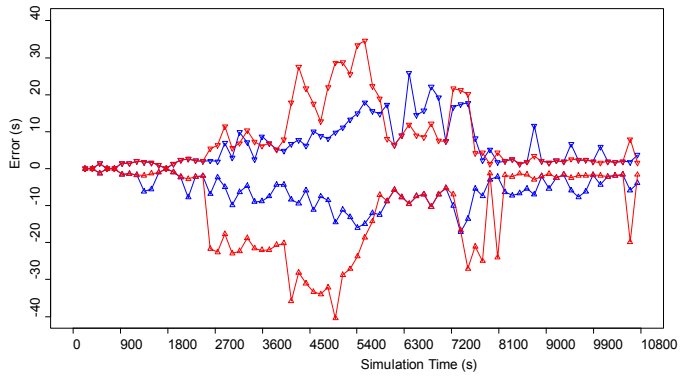
3.2 Procedure of Proposed Estimation Method

Under saturated/oversaturated conditions, since the two groups have relatively small variances, μ_1 and μ_2 can be estimated by small size sample reliably. Obviously, estimating μ_1 (or μ_2) and then obtaining μ_2 (or μ_1) and p by the relationship and finally calculating mean travel time by μ_1, μ_2 and p is a possible method to estimate mean travel time, which is the proposed method of this paper.

The pseudocode for the proposed estimation method is the following.

```
1   divide sample x to two groups x1 and x2
2   if size(x1) > size(x2)
3         x2 = x2 – diff_μ1_μ2
4         estimating μ1 by mean(x1, x2)
5         calculating μ2 and p
6         if p>95% p=1
7         calculating μ
8   else
9         x1 = x1 + diff_μ1_μ2
10        estimating μ2 by mean(x1, x2)
11        calculating μ1 and p
12        if p<5% p=0
13        calculating μ
```

As shown in Figure 2, link travel time becomes one group when undersaturated conditions at upstream intersection and when the queue length at downstream is relatively long (see 6300 s ~ 7200 s in the figure). The primary target of the proposed method is the population with two groups. The accuracy of the



proposed method declines when the population has only one group. However, the modification of p in step 6 and step 12 can improve the accuracy of the proposed method when the population has one group.

3.3 Comparison with Conventional Methods

The travel time reports in each signal cycle on link 5 from the simulation described in section 2 is treated as a population. Then, the estimation results by the proposed method and the conventional method, in which the sample is directly used to estimate, are compared at three levels of sample size n = 3, 5.

For each sample size, 1000 times of sampling are performed. Figure 4 illustrates 0.05 quantile and 0.95 quantile of the estimation errors by these two methods of three sample size levels. As shown in the figure, for almost every signal cycle, the proposed method can provide more precise result, especially when the link travel time has two groups (3600 s ~ 6000 s). For 6300 s ~ 7200 s, the performance of the proposed method is lower than the conventional method. However, in this period, the mean is relatively large and thus the large error is not so critical.

4 CONCLUSIONS

A new link travel time estimation method is proposed in this paper. The comparison between the new and the conventional method, in which the population mean is directly estimated by sample mean, shows that the proposed method can provide more precise estimation results, especially when the distribution of the travel time has two groups.

In the proposed method, it is assumed that (1) the traffic signals are constant and known; (2) the vehicles with TT account for a considerable part of the total nine movement pattern; and (3) the parameter α which is relevant to turning rate is constant and known. For real arterial link, if the majority of the vehicles get across the link with TT, there is a method that can estimate the signal time and turning rate. The proposed method can be used to estimate the mean travel time with small sample size. However, it is necessary to conduct a field test to verify the proposed method.

ABSTRACT

Ordinarily, an actuated-coordinated signal control intersection has a fixed phase whose order is settled. Each phase has a minimum and maximum green time to fit the traffic's randomicity and fluctuation. But if the traffic of some phases fluctuate remarkably and if there is little or no traffic comes in certain cycles or periods, the intersection runs the same phase number and order and sets the minimum green time accordingly. This would render the green time as obsolete and increase traffic delays in other phases. This paper considers the influence on drivers as caused by changing phase, optimizes the phase number and order of actuated-coordinated signal control intersection based on fuzzy control theory. It uses the intersection of Daxin Street and North Fourteen Street in Harbin as an example, simulates the intersection's traffic signal control with Vissim, and estimates the result thus validating the optimized method's availability and usability.

INTRODUCTION

In recent years road mileage, number of vehicles and drivers has been on the rise. As a result there has been an increasing demand for infrastructure to allow smooth traffic flows. Traffic jams and accidents occur frequently and many studies search for effective measures to solve existing traffic problems based on traffic control theory. Today, the actuated-coordinated signal control technique is well-developed in some developed countries (Chen et al. 2007), but it is in its primary stages in our country, and its application rate is poor. Compared to pre-timed signal control, the actuated-coordinated signal control is more adaptable to traffic's randomicity and nondeterminacy, and it could improve traffic capacity at intersections, reduce delays, and parking numbers. Much of the research conducted in this area applies fixed phase number and order at signal intersections, but this method is not the best timing scheme at some intersections with traffic changing obviously (Gao et al. 2003).

TRAFFIC DETECTING METHOD AT INTERSECTION

Consider the typical crossroads. The detectors' setting is shown in Figure1. There are four inlets in each direction, and each inlet has left turning, straight, and right turning driveway. Each driveway has two detectors; namely the upper detector and the stop-line

detector. The detectors check the incoming and outgoing traffic volume, and the information acquired could include cars' running speed, capacity, saturation flow rate, and headtime in green time (Wang et al. 2008).

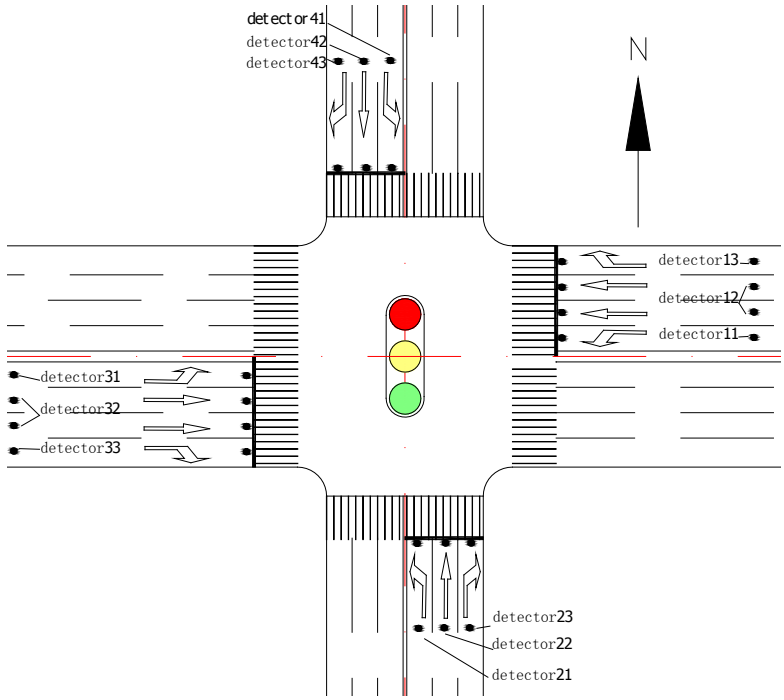

Figure 1. Detectors setting at actuated-coordinated signal control intersection

The traffic quantity data received from upper detectors set at left turning, straight, and right turning driveway of each direction are named as follows: Q_{IEL}, Q_{IES}, Q_{IER}, Q_{ISL}, Q_{ISS}, Q_{ISR}, Q_{IWL}, Q_{IWS}, Q_{IWR}, Q_{INL}, Q_{INS}, Q_{INR}.

The traffic quantity information received from stop-line detectors set at left turning, straight, and right turning driveway of each direction are named as follows: Q_{OEL}, Q_{OES}, Q_{OER}, Q_{OSL}, Q_{OSS}, Q_{OSR}, Q_{OWL}, Q_{OWS}, Q_{OWR}, Q_{ONL}, Q_{ONS}, Q_{ONR}.

Setting l is the distance between upper detector and stop-line detector, Q_{max} is the maximum number of detected vehicles at this driveway, h is the minimum headway, then $Q_{max}=l/h$ (Peng et al. 2001).

In order to acquire more information of flow direction at intersect detectors could be set at each outlet to judge the flow direction, and this would provide traffic information for the next intersection (Peng et al. 2001).

OPTIMIZING PHASE AND TIMING

The main parameters of conventional actuated-coordinated signal controls are: initial green time G_{min}, unit extended green time G_0 and maximum green time G_{max}. In the optimized method G_{max} is not a main parameter any more. The particular flow of optimized control method is shown in Figure 2 and the steps are as follows:

① G_{min} is calculated according to the distance between the stop line to the farthest conflict point which the car needs to pass in the green phase, and the speed of the car passing the intersection. The G_{min} should be long enough to ensure the first car could pass the

intersection. Set G_{min} to a certain phase.

②When G_{min} counts down to 0, search phases which have vehicles waiting.

③Judge phases if there are cars waiting over time in these phases. If so, then compare the former green phase's weight of right-to-pass with other phases according to overtime waiting, choose the phase with largest weight, and give the pass right to this phase; If the phase with largest right-to-pass weight is the former green phase, then extend the green time according to the queue length; if the phase with largest right-to-pass weight is not the former green phase, then give this phase G_{min}.

④Turn to step ②.

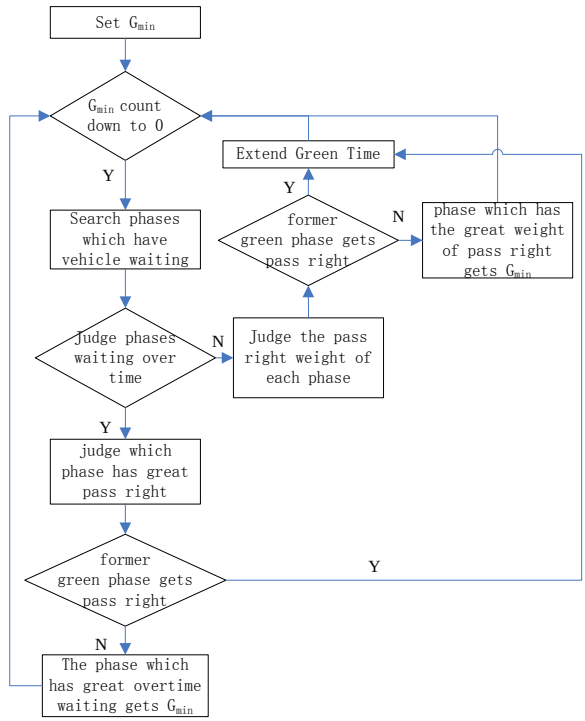

Figure 2. Flow chart of optimized actuated-coordinated signal control method

Estimate the phase which has the largest pass right, according to the waiting overtime or queue length. We now need to consider the yellow time coming after changing phase to clear cars left on the stop line (Wang 2008), and we also need to pay attention to the great influence on driver behavior caused by changing phase.

When the right-to-pass according to overtime waiting has been estimated, the main comparison factor is waiting time between the former green phase and other phases which has vehicles waiting. In fact, we just need to compare the waiting time between the former green phase and the phase which has the longest waiting time. Unlike the common actuated-coordinated signal control method, the driver cannot judge the next green phase by his general driving knowledge and needs to pay attention to the lights changing randomly, and this would cause a delay when vehicle start. We call the delay T_e in this paper. If T_{ot} is the former green phase's waiting-overtime while getting right-to-pass, G_{omin} is the former green phase's G_{min}; T_c is the time clearing cars left the stop line; T_{tmax} is the maximum overtime waiting of other phase's vehicle. The rules of right-to-pass are as follows:

①If T_{ot}-G_{omin}+T_c+T_e<T_{tmax}, then change the green phase and the phase which has the

greatest weight of right-to-pass gets green light.

②If T_{ot}-$G_{o\min}$+T_c+T_e≥$T_{l\max}$, then the former green phase still keeps the green light, and sets an extend green time.

If there is no vehicle waiting overtime, judge the right-to-pass based on the vehicle's queue length. We only need to compare the weight of right-to-pass between the former green phase and the phase which has the longest queue length. By using the data derived from the upper detectors and stop-line detectors, we can set parameters as the in queue number of i phase's cars Q_i, the cars' average speed V_i, the average headway h_i The time for cars of i phase in queue passing the intersection is calculated as T_i=$Q_i h_i$/V_i. If T_{ol} is the time for cars of former green phase in queue pass the intersection, the maximum T_i is T_{lmax}, T_{lmax} =max{T_i}, then the judging rules of right-to-pass are as follows:

①If T_{ol}-$G_{o\min}$+T_c+T_e<$T_{l\max}$, then change the green phase. The phase which has the greatest weight of right-to-pass gets green light.

②If T_{ol}-$G_{o\min}$+T_c+T_e≥$T_{l\max}$, then the former green phase still keeps the green light. Set an extended green time according to vehicle queue length of former green phase.

If the traffic volume is low and all detectors get no signals of incoming cars, set all lights to yellow flashing signal in order to warn drivers.

The differences between common and optimized actuated-coordinated signal control method are as follows:

①No limit to $G_{\max}$. If the vehicles in one phase come in continually and other phases do not witness vehicles for long periods, then this phase keeps green lights till other phases have vehicle waiting.

②$G_{\min}$ setting. The $G_{\min}$ calculation of common actuated-coordinated signal control method is based on traffic in each direction and thelost time phase. But with the optimized method, the $G_{\min}$ only provides a time to make sure the first car in the traffic flow could pass intersection. $G_{\min}$'s influence factors are then car's speed and the distance between stop line and the farthest conflict point.

③No fixed phase number and order. Signal cycle means a period of time between one main phase and the green light phase. With the optimized actuated-coordinated signal control method, the cycle could have two phases or more. If cars come symmetrically at intersection, the cycle usually has four phases. The phase's order is not fixed in a single form like east-west straight→east-west left→north-south straight→north-south left, but applies the method of instantaneously judging a phase's right-to-pass.

④The method of instantaneously judging phase's right-to-pass could reduce the green time of phases in which there are no incoming vehicles. However, the drivers have to observe the signal changes, and this would cause driver fatigue. In order to reduce delays caused by drivers judging the lights changing randomly, we could set a yellow light after the red light to provide a next green phase information to drivers.

CASE STUDY

Consider for example, the intersection of Daxin Street (east-west direction) and Northfourteen Street (north-south direction) in Harbin. Traffic flow in each direction and flow of intersection which occured between 7am and 8am on April 5th, 2006 is shown in **Table 1**.

Each inlet of this intersection has a right-turn lane, so the right turning vehicles have little influence on other cars, and there is no necessity to set a right turning phase.

The cars' starting to lose time on east-west straight, east-west left, north-south straight, north-south left is 2.7s, 4.1s, 3.0s and 3.8s; the average speed of vehicles is 25km/h; the average headway is 6m; the delay caused by drivers' judgment is 1s. According to the former conditions, $G_{\min}$ calculated is 8s, 10s, 7s and 8s (ignore the influence of pedestrians and non-motorized vehicles).

Table 1: Each Direction Traffic Flow on Daxin Street and North Fourteen Street Intersection

Inlet direction	East			South			West			North		
Flow direction	Left	Straight	Right	Left	Straight	Right	Left	Straight	Right	Left	Straight	Right
Average traffic	85	565	86	167	143	56	56	504	66	79	154	25
Minimum traffic	68	452	72	80	116	40	32	308	28	56	96	12
Maximum traffic	104	704	108	236	160	68	76	624	84	120	220	36
Saturation traffic	1621	3243	1621	1044	1044	1044	1653	3306	1653	1174	1174	1174

By simulating and analyzing with Vissim, a comparison is drawn of conventional and optimized actuated-coordinated signal control and is shown in **Table 2**.

Table 2: Comparison Result of Conventional and Optmized Actuated-coordinated Signal Control

Items	Conventional method(s)	Optimized method(s)	Effect(%)
Delays	12.4	10.7	13.7
Stops	0.54	0.43	20.4

According to the delay shown in **Table 2**, if we ignore pedestrians and non-motorized vehicle and contrast the optimized method with the conventional, the optimized method we could reduce the delay by 1.7s delay and 0.11 stops. This would mean an overall reduction of about about 13.7% and 20.4%. This gives good reason to believe that the optimized method could improve the intersection's passing efficiency remarkably.

CONCLUSION

①The method of instantaneously judging a phase's right to pass is considered from the angle of reducing the green time of phases which have few or no incoming vehicles .By simulating and analyzing with Vissim, the optimized method has some practicability.

②When contrasted with the conventional actuated-coordinated signal control, the optimized method gives a new concept, namely overtime waiting, and increases the phase order's flexibility. However, the phase order of this method would change the drivers' conventional thinking, and cause driver tension.

③This optimized method is still in the theoretical step, and ignores the influence of pedestrians and non-motorized vehicle. We need combine this method with practice in order to research further.

ABSTRACT

When traffic volume is distributed proportionally on a road network, it can relieve the traffic congestion of partial road nodes and make full use of road capacity. This article sets up an equilibrium model for regional signal coordination control according to the origin and destination demand between road nodes in small regions. This model is set up using the traffic equilibrium principle and dynamic traffic assignment theory. By coordinating the split of the signal between the intersections in the region, this model adjusts the turning volume at road intersections, distributes the traffic flow proportionally on the road network, avoids the vehicles crowding at some road intersection, effectively promotes road network efficiency, reduces delay in the road intersection, and alleviates traffic congestion. The model applies the traffic flow equilibrium theory to the region coordination control, makes the traffic flow in accordance with the optimization pattern movement, and realizes the traffic flow distribution proportionally.

INTRODUCTION

The urban road network is divided into many sub-networks by the urban expressway, and the optimization control of the intersections to each sub-network is the base of whole road network optimization coordination and control. It is an important means of improving efficiency in the whole network. Through coordination and optimization control the traffic congestion caused by the control of intersections can be reduced, distribution of the traffic flow on the road network can be balanced, and traffic flow can, as a result, run in a more efficient and orderly manner.

The region's traffic optimization control is one of the important areas for traffic control research and application. Since Webster proposed the simple point control timing method, the research of intersection optimization control has been one of the key research areas. Hong (Hong et al. 2001) used the genetic algorithm to establish the road intersection dynamic optimization control model. Chiou (Suh-Wen Chiou

2005) used the Wardrop theory as the basis and established a bi-level planning model to optimize the control of traffic networks. X.-H.Yu, (X.-H.Yu et al. 2006) used the stochastic process to establish the discrete time of network auto-adapted optimization control model. Chiou (Suh-Wen Chiou 2008) built a network balance control method on the basis of considering the user route choice. At present, the road intersection control delay computation has many kinds of models, The main choices include the model computation method (Gao Yang-bin, 2004) and the simulation analytic method (Zhuang Yan,2006). The difficulty of signal control and assignment of traffic flow at intersections does not allow for the impedance of intersections to be reflected easily. Brian (Brian et al. 1999) proposed a road intersection dynamic delay model based on the SCATS system, but did not solve the problem that transportation plan and the signal intersection control delay parameter coordinated each other. The dynamic traffic assignment combines with the intersection turning delay and uses the green ratio as variable, obtains the parameters of signal control through the balanced traffic assignment，realizes the region's road intersection balanced control.

SMALL REGION SIGNAL CONTROL OPTIMIZATION GOAL AND RESTRAINT ANALYSIS

The arterial road coordination control is mainly aimed at minimizing traffic flow direction vehicles.and ,as far as possible getting through the intersection in the green bands if cars run according to the design speed. This can reduce the signal control delay and interference to the main direction of the traffic flow.

The small region traffic control distributes traffic flow on the road network reasonably based on systematic perspective; it combines traffic control signal design with traffic flow equilibrium theory, enables the path to obtain the full use, and avoids the individual road intersection crowding which in turn causes traffic congestion in the region.

TARGET ANALYSIS OF SMALL AREA BALANCED TRAFFIC CONTROL

The small region balanced traffic control aims to minimize the total travel time on the road network. Each route of OD (Origin-Destination) pair's which has been used by cars has the same travel time and impedance according to the traffic equilibrium theory. The model considers the dynamic traffic assignment and the green ratio design of intersection turning directions together. The signals of each direction at intersection adjusts the balanced distribution of traffic flow on the road network, and then reaches the state of the intersection optimum control and small area traffic flow balanced distribution.

IMPEDANCE RESTRAINT OF SMALL AREA BALANCED CONTROL

The time impedance of vehicles on road network is composed of two parts The first one is the time impedance caused by vehicles travelling on the road section. The other is the impedance which is produced by the vehicle traveling on the road intersection. The road section travel time impedance research has many achievements. The mature impedance function has the BPR function and its function equation is: $t_a = t_{a,0}[1+\alpha(v_a/c_a)^{\beta}]$, of which t_a is road section impedance of link a, $t_{a,0}$ is free travel time of link a, v_a is traffic volume of link a, c_a is capability of link a, α, β is impedance parameter. They are calibrated by the traffic flow investigation data.

Traffic impedance which is produced in the road intersection is mainly the time delay while the vehicle gets through the intersection. Currently there are many methods used to compute the signal intersection's delay computation including the sample investigation computational method, the HCM (Highway Capacity Manual) computation method, the Webster delay computation method, and the Australian ARRB method (Zhang, 2002). The result of above computed models is vehicles' average delay which enter the road intersection. However, the intersection balanced control needs each turning direction time impedance to carry on the computation.

The road intersection impedance computation model is referred to in **Figure 1**.

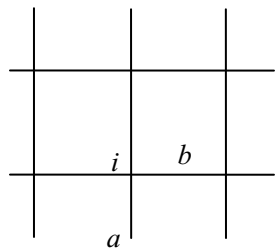

Figure 1. Node traffic turning impedance computation model

The road network model（N，A）like Figure 1 demonstrates that N is the set of nodes in the network and A is the set of links in the network. Road intersection $i, i \in N$ is a road intersection in the small control area, path *a*, *b* connected by road intersection *i*, the turning impedance from link *a* to link *b* is calculated by the ARRB model which has been improved as follows:

$$t_{a,b}(x_{a,b}) = T \cdot (1-\theta_{a,b})^2 / 2(1-x_{a,b}/c_{a,b}) + n_0 \cdot x_{a,b}/c_{a,b} \qquad (1)$$

$x_{a,b}$ —traffic volume from link a to link b, $a \neq b$,a,b belongs to A which is the set of links of small area road network.

T —signal cycle of the intersection i. T is constant

$\theta_{a,b}$ —green ratio from link a to link b in road intersection i.

$c_{a,b}$ — lane capacity from link a to link b, $c_{a,b} = \frac{3600}{T} \cdot \frac{\theta_{a,b} \cdot T - t_s}{t_0}$, t_s is green time lost , t_0 is the average headway when the vehicles continuously pass the stop line, t_s, t_0 is constant.

n_0 — the number of overflow vehicles in the intersection which entrance lane from link a to link b.

OPTIMAL CONTROL MODEL OF TRAFFIC FLOW BALANCED DISTRIBUTION

Assume that the driver should be able to choose an optimal route and cause total traffic cost to be the smallest, its mathematical programming question is the UE model. According to the shown in figure 1, the optimum balanced control model would be as follows:

$$\min Z = \sum_i \sum_b \sum_{a(a \neq b)} \int_0^{x_{a,b}} t_{a,b}\left(x_{a,b}\right) dx + \sum_b \int_0^{x_b} t_b(x_b) dx \qquad (2)$$

$$s.t. \quad \sum_k f_k^{rs} = q_{rs} \quad \forall r, s$$

$$f_k^{rs} \geq 0 \ \forall k, r, s$$

$$x_b = \sum_{rs} \sum_k f_k^{rs} \delta_{b,k}^{rs} \ \forall a$$

$$x_{a,b} = \sum_{rs} \sum_k \sum_{a \neq b} f_k^{rs} \delta_{b,k}^{rs} \delta_{a,k}^{rs}$$

$$0 \leq \theta_{a,b} \leq 1, \quad a,b \in A, \quad i \in N$$

In the model, $q_{r,s}$ —the OD traffic flow from node r to node s in the small area;

$f_k^{r,s}$ —the traffic volume belongs to OD pair r –s, which gets through route k.

$\delta_{a,k}^{rs}$ —state variable, if route k from node r to node s gets through link *a*, its value is 1, otherwise is 0.

Other variables' meaning is the same as above. $x_{a,b}, \theta_{a,b}$ is variable of the model to be solved . The green ratio of each turning direction and each link's traffic volume under balanced control can get by solving the model.

THE ALGORITHM OF THE MODEL

The method of small area traffic balanced control realizes the traffic flow

distribution proportionally on the network by adjusting the green ratio of each turning direction at the intersection. It reduces the total travel time to a minimum which cars in the network expend. The traffic flow reaches optimal state. The solution method of equation (2) is as follows:

Step 1: Initialization: according to $t_{a,b} = t_{a,b}(0)$, $t_b = t_b(0)$ $\forall a,b,a \neq b$, implement all or nothing assignment, obtain each link and intersection traffic volume x_b^1, $x_{a,b}^1$, $\forall a,b,a \neq b$,set n=1.

Step 2: Renew each link and intersection impedance: $t_b^n = t_b(x_b^1)$, $t_{a,b}^n = t_{a,b}(x_{a,b}^1)$, $\forall a,b,a \neq b$.

Step 3: Seek for the next iterative direction: According to $\{t_b^n, \forall b\}$, $\{t_{a,b}^n, \forall a,b,a \neq b\}$ Implement all or nothing traffic assignment, obtain a group of additional traffic volume $\{y_b^n, \forall b\}$, $\{y_{a,b}^n, \forall a,b,a \neq b\}$.

Step 4: Determine the iteration distance : Calculate λ_b, $\lambda_{a,b}$ by dichotomy following

$\sum (y_b^n - x_b^n) t_b(x_b^n + \lambda_b(y_b^n - x_b^n)) = 0$, $\sum (y_{a,b}^n - x_{a,b}^n) t_{a,b}(x_{a,b}^n + \lambda_{a,b}(y_{a,b}^n - x_{a,b}^n)) = 0$.

Step 5: Determine the new iterative beginning: $x_b^{n+1} = x_b^n + \lambda_b(y_b^n - x_b^n)$, $x_{a,b}^{n+1} = x_{a,b}^n + \lambda(y_{a,b}^n - x_{a,b}^n)$.

Step 6: Astringent examination criteria: If

$$\sqrt{\sum_b (x_b^{n+1} - x_b^n)^2} \Big/ \sum_b x_a^n < \varepsilon, \quad \sqrt{\sum_b \sum_{a,a \neq b} (x_{a,b}^{n+1} - x_{a,b}^n)^2} \Big/ \sum_b \sum_{a,a \neq b} x_{a,b}^n < \varepsilon_1 \text{（}\varepsilon, \varepsilon_1\text{）},$$

stop calculation, otherwise set n=n+1, and return to the second step.

APPLICABLE CONDITION AND SCOPE OF THE MODEL

Balanced Control model of regional intersections is based on small areas which are divided by primary roads. Each small area is an optimal balanced control unit. The input datum of the balanced control model need intelligent transportation system collect and supply. The control parameters which the balanced control model had figured out require coactions with intelligent information guidance system to guide the traffic flow distribution proportionally in accordance with the model expectation. Then, traffic flow realizes well-proportioned distribution in the control areas. The coordination and optimization between control areas can use arterial road line control method, reach optimal arterial route and intersection coordination operation, achieve the concordant control condition of each control unit, and the entire traffic network optimization.

CONCLUSION

The small area intersection balanced control model uses the traffic equilibrium theory to calculate the intersection signal parameters and distribute the traffic flow. It utilizes the green ratio as model variable, integrates the dynamic traffic assignment, distributes the traffic flow proportionally in the road network, and improves the travel condition in the road network while avoiding some excessively congested intersections. The model calculates the control parameters by using intersection turning impedance. This may make traffic plan and traffic management more coordinated and can alleviate traffic congestion more efficiently. But the traffic impedance model of intersection control needs further study. The balanced control model needs the intelligent guidance information system to help drivers plan the route correctly.

ABSTRACT

This paper presents a novel method of road shape describing, in which the real time sequence road images are shot by cameras fixed on Autonomous Navigation Vehicles (ANV) placed on a structured road. Through the pre-processing of real time images, the road lines in images are extracted in real time. Further, a parameterized road shape describing method is also proposed. All parameters' meanings are indicated and the real time parameter calculating problem is settled. The experiment results present that accuracy of real time parameter obtaining is above 99.1%. This method will provide basic data sustainment for research on Initiative Safety Technology (IST) of ANV which require real time road information, such as Vehicle Deviation Warning System, etc.

INTRODUCTION

An increasing amount of attention has been paid in recent years to the research on vehicle Initiative Safety Technology. Presently, there are a great many new technologies on IST like: Lane Deviation Warning System, Anti-drowsiness System, Speed Recognition Systems, Tire Pressure Monitoring System, and Vehicle Distance Control System (E.D.Dickmanns,1992.). In comparioson to Passive Safety Technology, the research significance of IST lies in preventing accidents and reducing casualties.

Vehicle and the road are the two core objects inevitable to study in IST. Relationship between vehicle and road is the basis and premise for the study of other technologies. Among those new technologies, road line shape description and position relationship between lines and vehicle are the foundational investigations. It is well known that the road line detection technique is mature and there are also some road line shape describing models(E.D.Dickmanns,1986.), however, rare existing methods can model simply and calculate description parameters accurately in real-time.

In this paper, we address the problem of real-time road shape describing and parameter obtaining. Based on modeling of some coordinates and preprocessing of images, a fully automated real-time road shape describing and parameter obtaining method is proposed. Researches in this paper are all based on prototype HONGQI Autonomous Land Vehicle (**Figure1**). The main vision sensor is a video camera mounted on the top left corner of the windshield.

Figure.1. HONGQI prototype

COORDINATE SYSTEM TRANSFORMATION

In this paper，we define the coordinate system as follows: the vehicle coordinate system $V_{(x_V, y_V, z_V)}$， the camera coordinate system $C_{(x_C, y_C, z_C)}$， the image coordinate system $I_{(x_I, y_I)}$ and the image-in-memory coordinate system $B_{(c,r)}$ (N. Apostolo,2003.). Firstly, we use

$$C = {}^{C}_{V}R(V - {}^{V}_{C}T) \tag{1}$$

to illustrate the rotation and translation transforms from the vehicle coordinate system to the camera coordinate system. The listing angle ψ, pitching angle θ and the rotating angle φ are used to define the rotation transformation. Order of rotation transformation is defined as:

$${}^{C}_{V}R = R_Y(\psi)R_X(\theta)R_Z(\varphi) \tag{2}$$

The pin-hole model for camera imaging is also utilized here：

$$x_I = f\frac{x_c}{z_c}, \quad y_I = f\frac{y_c}{z_c} \tag{3}$$

Lastly, transformation from image coordinate system to image-in-memory coordinate system is described as:

$$B = \begin{bmatrix} N_r & 0 \\ 0 & N_c \end{bmatrix}\begin{bmatrix} x_I \\ y_I \end{bmatrix} + {}^{B}_{I}T \tag{4}$$

N_r and N_c denote numbers of rows and columns of pixels corresponding to length in unit in image coordinate system respectively.

IMAGE PREPROCESSING

After construction of coordinate systems, it is necessary to follow some image preprocessing steps for aiming of obtaining road lines in image frame(Zhencheng Hu,2004):

Step 1: Choose region of interesting (ROI) in the image shot by the camera. As in **Figure 3** and **Figure 4**, the image size is 1024*256.

Step 2: Make use of the Sobel operator to do edge detection in the image.

Step 3: Automatically set the gray thresh to get binary image. Even on conditions of different illumination, threshold which is set via taking some fixed percent of the highest pixel value among the whole image can be easily chosen by equalizing bar graph.

Step 4: Use Hough transform to extract two brightest points which represent two sides of the road, as in **Figure 2** and **Figure 3**. By means of looking over continuous points in image space which are corresponding to peak values in Hough transform, the start and end points of two straight lines are obtained. **Figure 3** lines out two straight road lines extracted from original image by making use of start and end points' coordinates.

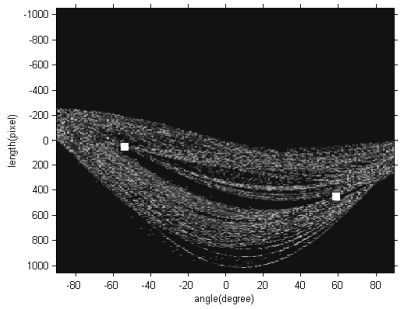

Figure.2.(left) Hough transforming
Figure.3.(right) Detected road lines and their start, end points

Step 5: Calculate the vanishing point according to start and end points' coordinates and draw the two road lines, as in Figure 4.

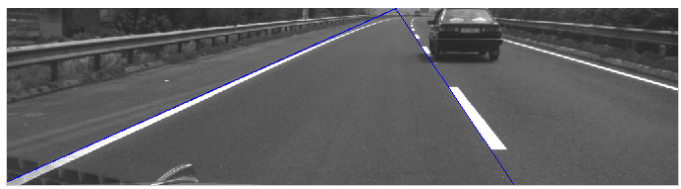

Figure.4. Extracted two road lines

ROAD SHAPE DESCRIPTION IN IMAGE

To describe road line shape, line model building is necessary. Given camera parameters $\varphi = 0$, $\theta = \pi/2$, $\psi = \pi/2$, ${}^{V}_{C}T = (0,0,-h)$, coordinates in image-in-memory frame ${}^{B}_{I}T = (0,0)$,utilizing (1)~(4) to calculate point coordinates from (x,y,z) in vehicle frame to (r,c) in image-in-memory frame, we have relations

$$r = \frac{z+h}{r_f x}, \quad c = \frac{y}{c_f x}.$$

Given $\varphi = 0, \theta = \frac{\pi}{2} - \theta_0, \psi = \frac{\pi}{2} - \psi_0$, we have

$$r = \frac{-x\theta_0 + y\psi_0\theta_0 + z + h}{r_f(x - y\psi_0 + z\theta_0 + h\theta_0)}, \quad c = \frac{x\psi_0 + y}{c_f(x - y\psi_0 + z\theta_0 + h\theta_0)}. \tag{5}$$

$c_f = \frac{1}{N_c f}$ and $r_f = \frac{1}{N_r f}$ are ratios of focal length f to length and width of a pixel respectively. On condition of only considering the level curvature diversion of highway, the road curve in the tangent plane can be presented as

$$\kappa(l) = 2c_{h2} + 6c_{h3}l$$

When the curvature is small, after twice integrals, we obtain the description form of the road curve in the vehicle frame as

$$\begin{aligned} x_V(l) &= l \\ y_V(l) &= c_{h0} + c_{h1}l + c_{h2}l^2 + c_{h3}l^3 \\ z_V(l) &= 0 \end{aligned} \tag{6}$$

From the equations in fore-mentioned camera modeling, when φ = 0, θ = 0, ψ = 0, we may take out the parameter *l* and we have

$$c = \frac{c_{h0}r_f}{c_f h}r + \frac{c_{h1}}{c_f} + \frac{c_{h2}h}{c_f r_f}\frac{1}{r} + \frac{c_{h3}h^2}{c_f r_f^{\,2}}\frac{1}{r^2} \tag{7}$$

when road shape is straight or a curve, viz. $c_{h3} = 0$, (7) in simpler form is

$$c = \frac{c_{h0}r_f}{c_f h}r + \frac{c_{h1}}{c_f} + \frac{c_{h2}h}{c_f r_f}\frac{1}{r}$$

Put equation (6) into (5) and eliminate parameter *l*, then we have

$$c = \frac{c_{h0}r_f - c_{h1}r_f h\theta_0}{c_f h(1 - c_{h1}\psi_0)}(r + \frac{\theta_0}{r_f}) + \frac{c_{h1} + \psi_0}{c_f(1 - c_{h1}\psi_0)}$$

We can finally unify 2D road parameter depiction when parameters are in different conditions as

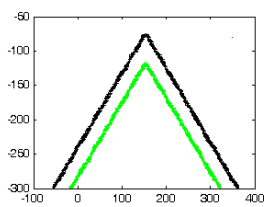
$$\begin{aligned} c_r &= (p_2 - p_1)(r - p_0) + p_3 + p_4\frac{1}{(r - p_0)} + p_5\frac{1}{(r - p_0)^2} \\ c_l &= (p_2 + p_1)(r - p_0) + p_3 + p_4\frac{1}{(r - p_0)} + p_5\frac{1}{(r - p_0)^2} \end{aligned} \tag{8}$$

so left and right side road curves are expressed as (8).

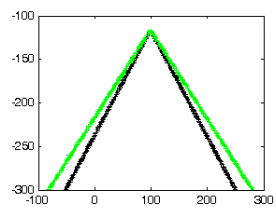
RELATIONS BETWEEN ROAD SHAPE AND PARAMETERS

Equation (8) above defines the road shape model, but the physical meaning of those parameters in (8) are unknown. Assuming the initial values of (8) as $p_0 = -128$, $p_1 = 1.20$, $p_2 = 0$, $p_3 = 128$, $p_4 = 0$, and $p_5 = 0$, we can see the actual meaning of these parameters through displacing their values.

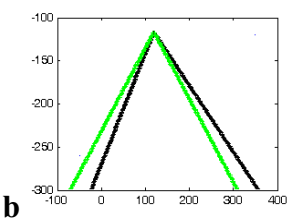
From **Figure 5a** to **Figure 5f**, the light lines denote the road when the parameters are equal to the initial values, in contrast, the dark lines denote the road when the value of some parameter has changed. **Figure 5a** shows the vanishing point becoming farther with the sole displacement $p_0 = -98$; **Figure 5b** shows the road width becoming narrower with the sole displacement $p_1 = 1.0$; **Figure 5c** shows the road deflects from the original location with the sole displacement $p_2 = -0.3$; **Figure 5d** shows the road departure in horizontal direction with the sole displacement $p_3 = 100$; **Figure 5e** shows the road turning left with the sole displacement $p_4 = 120$; **Figure5f** shows the road turning right with the sole displacement $p_5 = 400$.



a



b



c

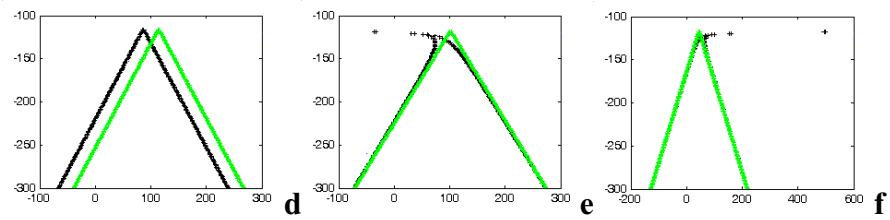


Figure. 5a-5f .The actual meaning of the road parameters

OBTAINING OF ROAD PARAMETERS FROM IMAGE SEQUENCE

From the physical meaning of parameters in equation (8), when (8) describes a straight road, it can be simplified as

$$\begin{cases} c_r = (p_2 - p_1)(r - p_0) + p_3 \\ c_l = (p_2 + p_1)(r - p_0) + p_3 \end{cases} \tag{9}$$

Compared with a general using straight line equation

$$y = k(x - x_0) + b$$

It is obvious that we can obtain the road parameters in (9) in image frame directly or indirectly from detected lines by Hough transform. p_0 is the position of vanishing point, so we can take cross point of two road lines as its value. p_3 can be calculated utilizing known start and end points of left or right line at will, it controls the road's horizontal displacement. p_2 and p_1 can be gained through calculating $p_2 - p_1$ and $p_2 + p_1$ from the slope of left and right lines，where p_2 controls angle offset, p_1 controls road width.

So that p_0，p_1，p_2，p_3 values can be obtained from sequential images. In **Figure 6**, calculating results of p_0，p_1，p_2，p_3 from continuous 2560 frames images are shown. Through the analysis of comparing with 2560 road images and the calculating results, the angle offset of only 23 frames present positive and negative pulsate of the same absolute value and further more, the pulsate do not influence the calculation results of other parameters. As in left-down figure of **Figure 6**, parameters obtaining accuracy in real-time is above 99.1%. Experiments illustrate that parameters of exact road shape information can be gained in real time by making using of road shape description model viz. equation (8) and this simple and convenient calculating method.

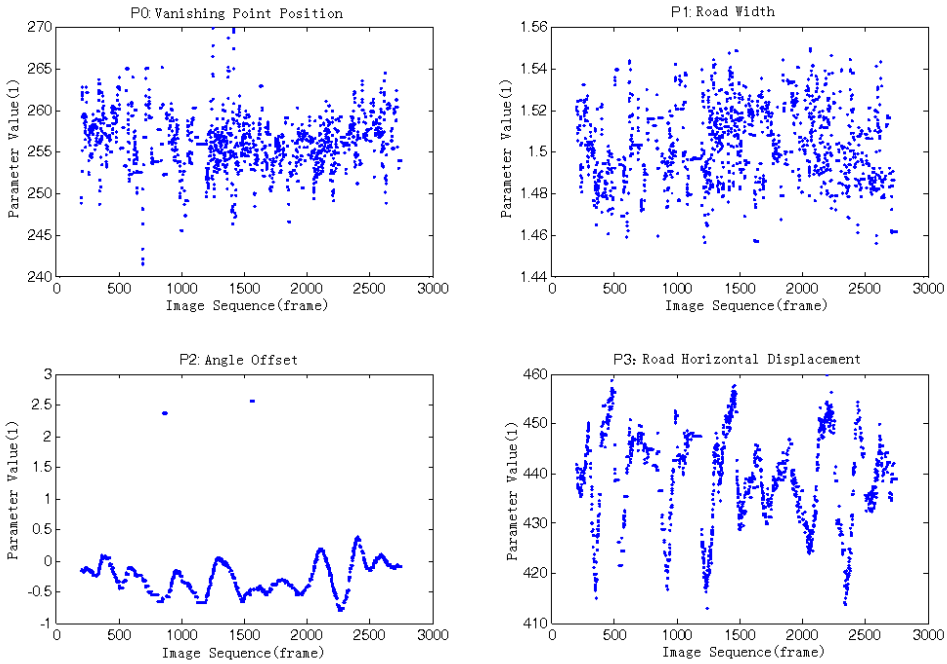

Figure.6. Obtaining road parameters from sequential images

CONCLUSION

Using the projection modeling and image preprocessing, we propose a novel road shape describing model. Through the research on relationships between road line shapes and parameters in the model, the representation and meanings of the road parameters in image frame are gained. Finally, a novel method of road shape describing and calculating parameters in real time are presented. Experiments illustrate that the validity of the method is well established. This simple way of modeling is accompanied by an excellent performance----accuracy of better than 99.1% and can be applied to engineer practice. This research will be followed by further study on the application of parameters calculation method in real time when road lines are of large curvature.

ABSTRACT

Adaptive signal control methods have the ability to improve operations at isolated intersections. However, most of these experiences mainly focus on one specific traffic status, so other traffic characteristics are not fully considered. In this paper, the traffic status of an isolated intersection is identified using a two-dimensional fundamental diagram divided into four levels. An adaptive traffic signal control method based on traffic status identification is proposed. Different signal control performance indexes (PIs) are chosen in different traffic levels. Appropriate evaluation parameters are selected for the PIs according to real-time traffic characteristics. An enumeration algorithm is put forward to solve the optimized model of PIs. Then, a signalized intersection in Shenzhen city is studied through theoretical calculation and simulation evaluation via a microscopic traffic simulation software, Paramics. The results indicate that the signal strategy derived from the proposed method is more effective than the original F. Webster method strategy, because the proposed PIs outperform those of F. Webster on all four traffic levels.

Keywords: Adaptive signal control; Traffic status identification; Signal timing; Traffic simulation.

1 INTRODUCTION

The F. Webster signal timing method developed by F. Webster and B. Cobber has been adopted in traditional fixed-time intersection management. This method takes under-saturated traffic flow into account, and selects delay as performance index (PI) (Webster & Cobbe, 1966). But the timing strategy derived from this method does not perform well in high traffic flow. Time loss increases as the result of insufficient cycle time, which is caused by static cycle time and split assignment (Quan, 1989). Akcelik and Kimber's researches have clearly modified the F. Webster method by revising evaluation parameter models (delay, stop times, capacity) and PI. They studied the parameter models in circumstances of high-saturation and over-saturation (Kimber, 1976; Akcelik, 1980, 1981). But the PI in the Akcelik method is still mainly determined by delay. This proves to be a weakness in a busy traffic status, because the capacity is the most important factor in PI for the intersection in an over-saturated status.

The real-time, traffic-responsive, multi-object signal optimization methods have

evidently demonstrated the ability to reduce the stops while delaying and improve capacity at isolated signalized intersections (Bullock, 2000; Yu, 2004). To meet real-time traffic demands, these methods make evaluation parameter coefficients adapt to the change of traffic flow. These methods mainly include two types. One typically has single fixed PI, decided by the delay, stops or capacity (Hong, 2004). The PI is decided by fixed control object, but traffic flow characteristics at intersections are not entirely considered. The other type proposed respectively by Denos and Li is based on traffic status identification. In their research, the traffic status is identified by saturation, and is divided into high saturation and low saturation (Denos, 1964; Li, 2006). These methods provide two different PI models to high saturation and low saturation respectively. However, two levels cannot explicitly consider the lower and over-saturated flow, and evaluation parameters are mostly based on F. Webster method, but the delay and stop index value cannot reflect how the actual traffic performs when the traffic flow at intersections increases.

Identifying different traffic status from different traffic parameters is to discuss in this paper. The recent progress of research in traffic flow theory indicates that traffic states distribute in two-dimension areas rather than lie exactly on the curve in the fundamental diagram, which is specifically the *y*-*O* diagram (total traffic flow rate of intersection; average time occupancy of intersection) in this paper (Kerner, 1996, 2002). In the light of that, this paper identifies the traffic status of isolated intersections into four levels with the combination of *y* and *O*.

This paper differs from the earlier work of Bullock, Hong, and Denos. Based on two-dimensional identification, a multi-object adaptive signal timing method is proposed, which selects different PI and appreciates evaluation parameters according to different real-time traffic status. The optimal control strategy of the proposed adaptive method is searched by the enumeration algorithm. Finally, to validate the rationality and effectiveness of the proposed method, a case study of the signalized intersection in Shenzhen is carried out, and simulation evaluation is done via Paramics.

This paper is organized as follows. Four traffic levels of intersection status, the proposed adaptive method and the solution of enumeration algorithm are described in Section 2. Section 3 presents the calculation of evaluation parameters in Shenzhen intersection. Section 4 shows traffic simulation and the comparison of control effects.

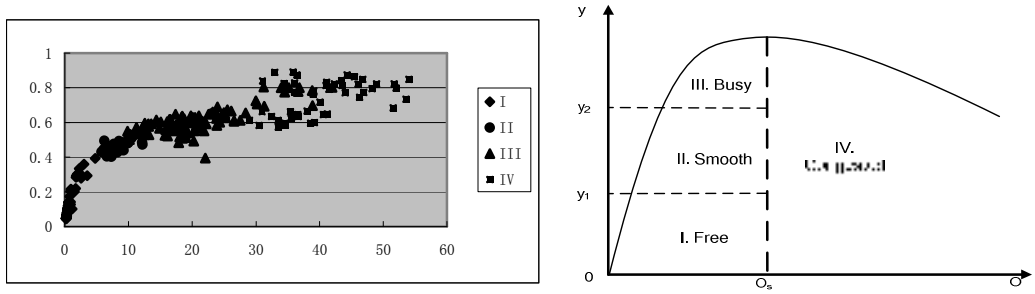
2 ADAPTIVE MODEL BASED ON TRAFFIC STATUS IDENTIFICATION

2.1 Traffic status

The *y*-*O* diagram in **Figure 1(a)** shows the distribution of traffic data at Hongli-Xinzhou intersection of Shenzhen during a month (March 1st, 2008 to March 31st, 2008). From the diagram, four distinct patterns can be identified: the linear Area I with low traffic flow rate, the linear Area II with high flow rate, the nonlinear Area III and the plateau Area IV.

The *y*-*O* diagram can be simplified as shown in **Figure 1(b)**, and four levels of traffic status are identified accordingly. In figure 1-b, O_s stands for the time occupancy of key lane in phase *i*, corresponding to saturated flow. When *O* is over O_s, the intersection is surely over-saturated and the traffic status is labeled as congestion. Otherwise, the under-saturated status is identified to three traffic levels by y_1 and y_2. Thus, the traffic status at intersection is

divided into four different levels: free, smooth, busy and congested. y_1 and y_2 are determined by the actual characteristics of signalized intersection. Taking Hongli-Xinzhou intersection as an example, the advised experimental y_1 is 0.6 and y_2 is 0.72.



(a) The O and y distribution **(b) The changing trend of O and y**

Figure 1. The principle of traffic status identification

2.2 The signal timing optimization model

Adaptive signal timing is decided by maximizing the PI, which lies on the control objective. In this paper, considering safety, economic and management demands at isolated intersection, promising control objects are proposed for different levels. The adaptive signal control objectives in four traffic levels are shown in **Table 1**.

Table 1. The control objectives of four traffic levels

Traffic level	Traffic characteristics	Management objectives
Free	Free flow	Safety & Delay minimum
Smooth	Uniform arrival	Comfort maximum
Busy	Markedly increasing	Economic benefits maximum
Congested	Forced-flow	Management efficiency maximum

First, in free level, drivers expect to pass intersections without stopping, but traffic safety is as important as delay minimization. Therefore the minimum constraints of cycle and green time are brought in to guarantee traffic safety. Second, according to the smooth and comfortable control aim at a smooth level, the objective function is to obtain a control strategy with the minimum of delay and stop times. Third, in the busy level, inadequate capacity will produce long queues and spillbacks in the high flow rate phases. So the capacity of each phase should be considered in the objective function to ensure adequate capacity. Fourth, delay and stop times are always high for every phase in the congested level. The best way to improve management efficiency in congested level is to increase the capacity of each phase. The capacity should then, be the most important factor in the objective function.

Previous researches have clearly verified the following points. First, PI is decided by delay, stops rate or capacity models (Nagui, 1999). Second, steady-state delay and stop rate model in F. Webster method have better performance if intersection saturation is under 0.6. Third, delay model in HCM2000 and Steady-state stop rate model in Akcelik method are more suitable for the traffic flow between low and high saturation. Fourth, when saturation is high, Transient Function delay and stop rate model, considering high-saturated and over-saturated traffic status, could make up for the lacks of the models above (Li, 2004;

HCM2000, 2000).

Based on the analysis of the control objectives in **Table 1** and the analysis of evaluation parameter discussed above, the objective functions (PI), weight coefficients and constraints for these four levels are shown in **Table 2** (Pitu, 2001; Akcelik, 1980; Li, 2006).

Table 2. The objective functions, weigh coefficients and constraints

Level	Objective function	Weight coefficients	Constraints
Free	$\min f(C,g_i)=\sum_{i=1}^{n} D^W \Big/ \sum_{i=1}^{n} q_i$	None	$C_{\min} \le C \le C_{\max}$ $g_i^{\min} \le g_i \le g_i^{\max}$
Smooth	$\min f(C,g_i)=\sum_{i=1}^{n}(k_i^1 D_i^H + k_i^2 H_i^W)$	$k_i^1 = 2Y \cdot \sqrt[7]{S_i}$ $k_i^2 = \sqrt[7]{S_i} \cdot \frac{1-Y}{0.9}$	$C_{\min} \le C \le C_{\max}$ $g_i^{\min} \le g_i \le g_i^{\max}$
Busy	$\min f(C,g_i)=\sum_{i=1}^{n}(\frac{k_i^1 D_i^H + k_i^2 H_i^A}{k_i^3 Q_i})$	$k_i^1 = 2(1-Y)$ $k_i^2 = 1.1 \cdot (1-Y)C/n$ $k_i^3 = 2Y(\frac{3600}{C})$	$C_{\min} \le C \le C_{\max}$ $g_i^{\min} \le g_i \le g_i^{\max}$ $x_i < 0.9$
Congested	$\min f(C,g_i)=-\alpha \sum_{i=1}^{n} Q_i \Big/ \sum_{i=1}^{n} D_i^T$	α : Adjustment coefficient. Generally: α =1000	$C_{\min} \le C \le C_{\max}$ $g_i^{\min} \le g_i \le g_i^{\max}$ $x_i < 0.95$

The meanings of parameters in **Table 2** are as follows:

i: Phase i.

l_i: Loss time of phase i;

g_i: Effective green time;

Q_i: Capacity of phase i;

D_i^W: F. Webster total delay;

D_i^T: HCM2000 total delay;

D_i^H: Transient total delay;

H_i^W: F. Webster total stops;

H_i^A: Akcelick total stops;

k_i^1 : Weight coefficient of delay;

k_i^2 : Weight coefficient of stops;

k_i^3 : Weight coefficient of capacity;

$g_i^{\min}$: Smallest effective green time;

$g_i^{\max}$: Largest effective green time;

$C_{\min}$: Smallest cycle time;

$C_{\max}$: Largest cycle time.

The detailed description of the delay and stop rate models is presented in Li's research (Li, 2004) and the coefficient modeling principle is studied in Xu's research (Xu, 2005). Note that drivers enhance the patience in higher traffic flow. The timing thresholds of high saturation level could be larger.

2.3 The solution of adaptive timing models

In the adaptive signal timing models above, y_i, q_i and l_i are known variables, and C and g_i are unknown variables. Based on an equal saturation assignment of effective green time, leaving just one variable C, the proposed signal timing models are solved and the best signal timing strategies are found by the algorithm shown in **Figure 2**.

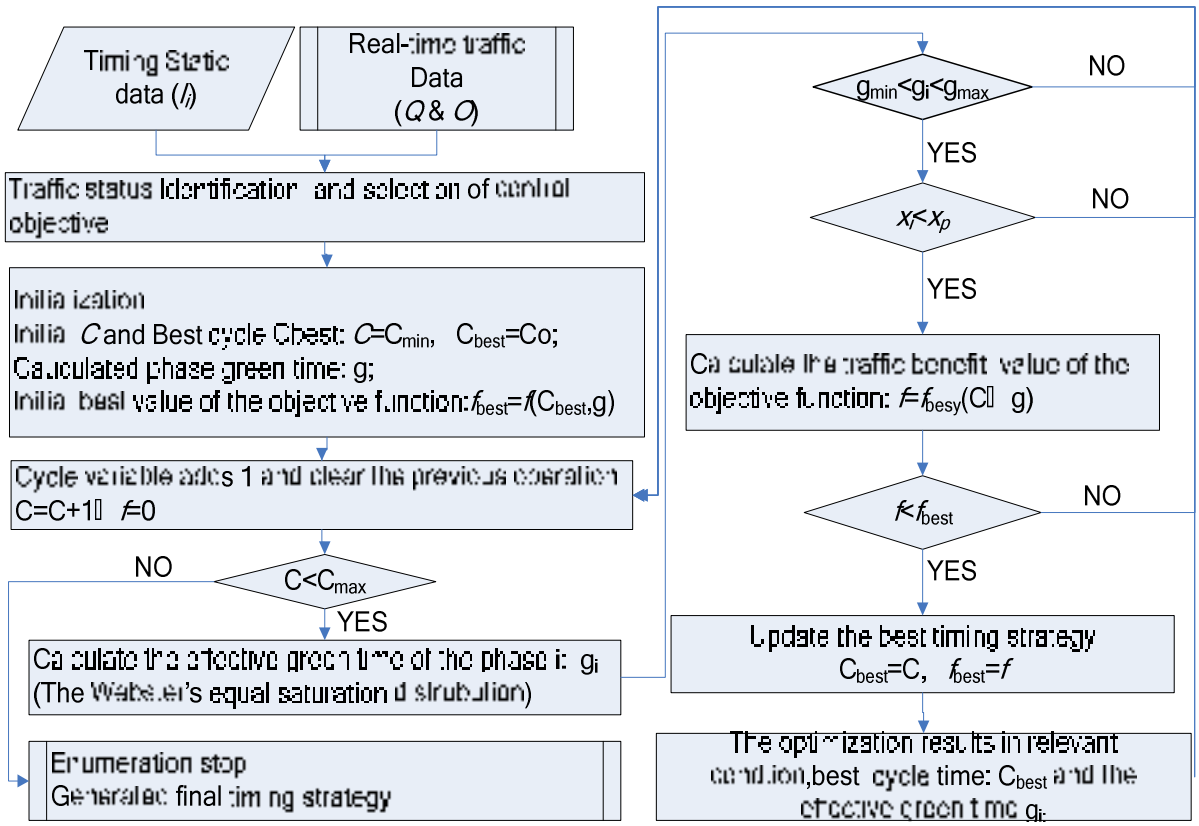


Figure 2. The adaptive timing optimization flow based on enumeration algorithm

Considering that the constraints of cycle time and effective green time are presented and the searching area is not large in these models, this paper solves the optimization model by the enumeration algorithm in order to enhance accuracy. The enumeration algorithm enumerates every integral value of C in its finite solution set and gets the best solution through comparing the calculated objective value.

3 CASE STUDY

Hongli-Xinzhou intersection in Shenzhen is a typical urban isolated signal control intersection (**Figure 3**). The eastbound, southbound, westbound and northbound entries are widened and the intersection is under four-phase signal control (the right-turn vehicles are not under the signal control). The data of phase, containing flow and the average traffic volume in four different levels are shown in **Table 3**. In **Table 3**, NS means northbound straight, NL means northbound left turn.

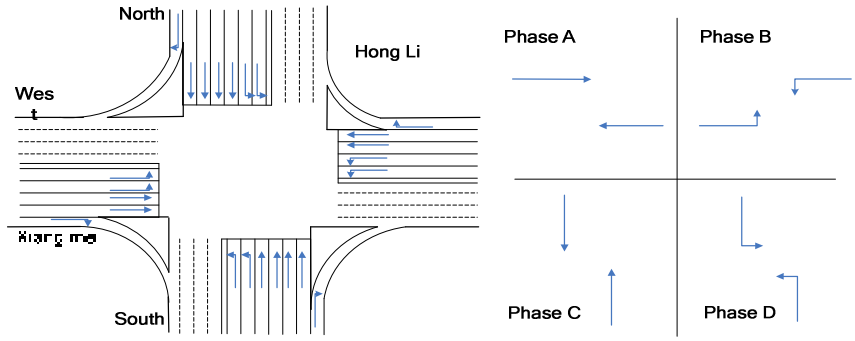

Figure 3. Traffic flow distribution and phase-graph

Table 3: Traffic data of Hongli-Xinzhou **intersection**

Phase name	A	B	C	D
Containing flow	ES,NS	EL,WL	NS,SS	NL,SL
Free flow volume: q	126,76	52,64	271,325	28,120
Smooth flow volume: q	475,365	287,250	847,1142	144,406
Busy flow volume: q	604,494	404,317	1107,1389	236,530
Congested flow volume: q	822,642	513,384	1619,1764	252,529
Phase saturated flow volume: S*	6600,6600	3100,3100	6600,6600	3100,3100

*The straight saturated flow volume is 1650 while the left-turn saturated flow volume is 1550.

Based on the experiential values researched by Guo (Guo, 2008) and the traffic characteristics of HongLi-Xinzhou intersection, signal timing constraints and thresholds of traffic status identification are shown in **Table 4**.

Table 4. Constraint limits and timing thresholds in four levels

Traffic level	l_i(s)	y_i	O_i	x_p	g_{min}(s)	g_{max}(s)	C_{min}(s)	C_{max}(s)
Free	4	[0,0.5]	[0,0.5]	0.90	10	30	30	90
Smooth	5	(0.5,0.72]	[0,0.5]	0.90	10	40	40	120
Busy	6	(0.72,0.9]	[0,0.5]	0.90	15	60	40	160
Congested	6	(0.9,1]	(0.5,1]	0.95	15	80	40	250

In order to evaluate the adaptive signal timing performance, this paper compares the adaptive signal timing proposed with F. Webster timing, which is widely used in isolated signal control. The calculated evaluation parameters contain the cycle time(C), the average delay (d), the average stops time (h), the intersection capacity (Q) and the phase effective green time (g_1-g_4).The statistical results are shown in **Table 5**.

Table 5. Performance comparison between adaptive timing and Webster timing

Level	Timing	C(s)	d(s)	h	Q(veh/h)	g_1(s)	g_2(s)	g_3(s)	g_4(s)
Free	Adaptive	63	20.71	0.743	3702	10	10	15	12
	F. Webster	63	20.71	0.743	3702	10	10	15	12

Smooth	Adaptive	105	44.49	0.845	3946	13	18	30	24
	F. Webster	88	47.63	0.871	3751	10	15	24	19
Busy	Adaptive	190	69.40	0.862	4351	29	38	60	39
	F. Webster	152	67.37	0.887	4199	22	29	47	30
Congested	Adaptive	241	87.46	0.88	4494	37	49	80	51
	F. Webster	247	90.14	0.88	4486	39	51	80	53

The calculation results in **Table 5** indicate that compared with F. Webster timing method, the adaptive timing decreases the delay and stops rate and increases the capacity in high saturation level. Especially at a busy level, the decrease of stops and the increase of road capacity are obtained with sacrificing some delay and this is consistent with the management objectives. In free level, as the traffic flow rate is low, the adaptive timing and F. Webster timing are the same.

4 Simulation Experiments

Traffic simulation is an effective way to analyze the effects of signal timing. Paramics is a microscopic traffic simulation software developed by QuadStone in UK. Signalized intersections could be well modeled and simulated via Paramics (Quadstone, 2003). This paper models Hongli-Xiangmei signalized intersection via Paramics's Modeller module. The signalized model of Paramics simulation is shown in figure 4, and considering the traffic flow characteristics and safety demands at signalized intersection, simulation parameter settings are as follows. Driver reaction time is 1.5s, target headway is 2.5s, the queue gap distance is 10m, the queuing speed is 7.2kph, the simulation seed is from one to ten and heavy vehicles weight is 3.0 (Wang, 2000).

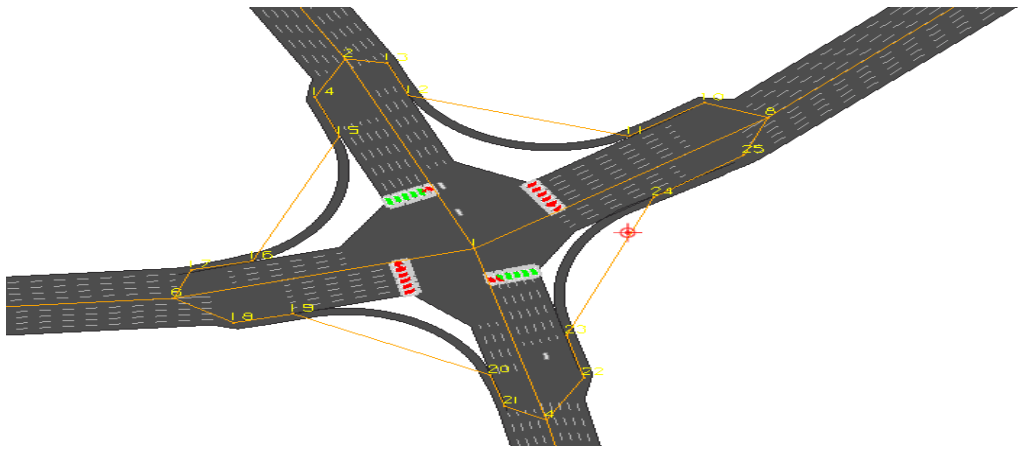

Figure 4. Paramics simulation model of HongLi-Xiangmei intersection

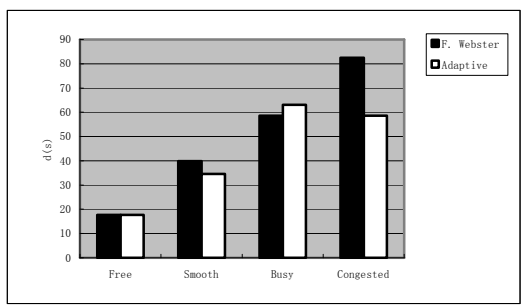
For each level, F. Webster signal timing and optimized adaptive signal timing, generated by optimized timing program, are set in Paramics's Modeller signalized unit. Then, to simulate real-life traffic arrival, different simulation seeds are selected for every time simulation. As a result, the 10 simulations for each timing strategy are carried out respectively in Paramics' Modeller module. Considering the actual valuation demands for isolated signalized intersection, the evaluation parameters extracting from Paramics' Analyzer module include the average delay (d), the average stops time (h), the average queue length

(N), the average OD flow volume (q) and the average speed (V). The statistical results are shown in **Table 6**.

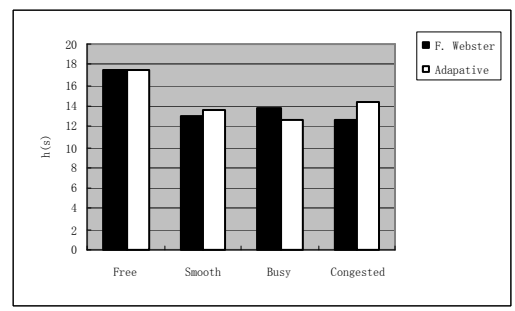
Table 6. Performance comparison based on Paramics modeling and simulation

Level	Timing	d (s)	h (s)	V (km/h)	N (Veh/s)	q (Veh/h)
Free	Adaptive	17.73	17.56	15.93	0.33	256
	F. Webster	17.73	17.56	15.93	0.33	256
Smooth	Adaptive	34.61	13.51	9.99	1.79	1230
	F. Webster	39.82	13.05	8.84	2.06	1222
Busy	Adaptive	63.13	12.69	6.53	3.64	1433
	F. Webster	58.63	13.70	6.47	3.56	1349
Congested	Adaptive	58.60	14.30	4.99	3.56	1433
	F. Webster	82.50	12.60	6.50	4.80	1368

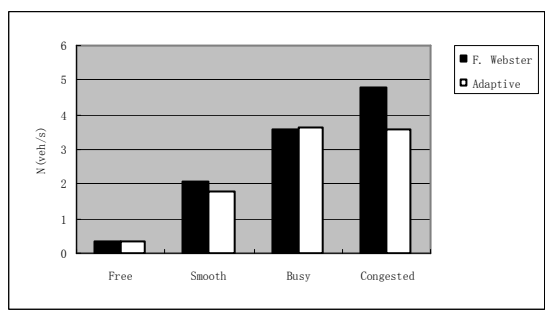
In **Table 6**, for four levels, the adaptive method makes majority evaluation parameters better by giving up one parameter, while the F. Webster method makes most parameters worse. The evaluation parameter comparisons under four different levels are shown in **Figure 5**. The analysis results of adaptive method are listed as follows: (i) In smooth level, the delay and queue length reduce by 13%, the larger capacity and speed are increased slightly, while the stops time nearly stay stable. (ii) In busy level, the capacity increases by 6.2%, delay decreases by 8% and stops drop by 7%, which is consistent with control objectives. Queue length and speed almost remain steady. (iii) In congested level, the delay sharply decreases by 28%, the queue length greatly declines by 25% and the capacity increases by 4.8%, but stop time rise and speed falls correspondingly. (iv) In free level, the control effects of two methods are the same because of the same timing caused by low flow rate.



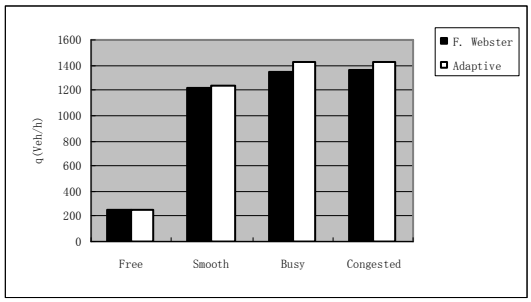
(a) The delay comparison of four levels

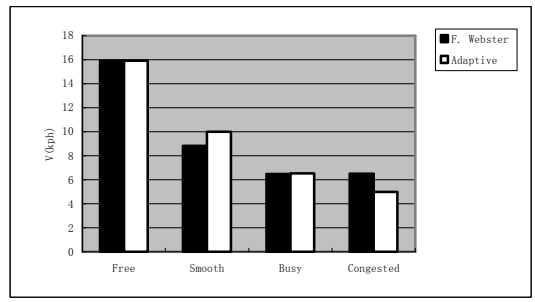


(b) The stops comparison of four levels



(c) The queue comparison of four levels





(d) The OD comparison of four levels **(e) The speed comparison of four levels**

Figure 5. The evaluation parameters changes between two timings

However, in busy level, there is a defect that delay increase is considerably larger for capacity increase. But this situation does not take place in congested level. That is because phase delay constraint is considered in PI model in congested level. Therefore, when priority is given to heavy phase flows at busy level, the delay of remaining flows rises greatly and leads to the delay of signalized intersection increases.

5 CONCLUSION

An adaptive signal timing optimization method of isolated intersections is proposed, which is based on traffic status identification with the combination of flow rate and time occupancy. Different control objects and appropriate evaluation parameters are chosen for four different traffic levels according to the characteristics of traffic flow. An enumeration algorithm is used to find out the optimal strategy. To compare the proposed adaptive signal control method with F. Webster method, a typical intersection in Shenzhen is taken as a case study and simulated via Paramics. The calculation and simulation results show the following conclusions. (i) The signal control objectives of the four levels can be achieved in simulation, and the proposed adaptive method based on traffic status identification contributes to the traffic management at busy signalized intersections. (ii) To avoid magnifying the effects of heavy phase flow, delay constraint should be taken into account in busy and congested level. (iii) In low flow rate level, the results of adaptive method is the same as those of F. Webster method, so PI model and constraints need further research.

A Collaborative Software Framework Design in Supporting GLITS I-75 Integrated Freeway & Arterial Operation Project

Ken Yang[1]

[1]Iteris Inc., 1120 East Long Lake Road, Suite 222, Troy, MI 48085 USA; PH (248) 740-8720 X 202; FAX (248) 740-8701; email: kyang@iteris.com

ABSTRACT

This paper summarizes the software design within the GLITS (Great Lakes ITS) I-75 Freeway and Arterial Integration project. The GLITS I-75 Project was a pilot project of the Integrated Corridor Management (ICM) aimed at coordinating freeway and arterial operations to quickly release freeway bottlenecks by optimizing the parallel arterial road's capability to accommodate traffic diversion from the freeway. This software framework links two different types of traffic management systems (freeway and arterial) and smoothly integrates corresponding functions together, minimizing the changes of their existing architectures. The paper will include the following aspects: 1) Functions requested to coordinate the freeway and arterial operations within GLITS I-75 Project; 2) Existing software architecture analysis for both freeway management and arterial management; 3) Concept of the collaborative software framework; and 4) GLITS I-75 Project software design summary.

INTRODUCTION

According to the previous study, 70% of freeway congestion is caused either by traffic bottlenecks (40%), by incidents (25%), or by special events (5%) (1). It is obvious that the existing freeway management system could not eliminate congestion alone without considering the potential impact of freeway traffic diversion on the parallel arterial roads. Here comes the concept of the Coordinated Freeway / Arterial (CFA) Operations, which is intended to optimize the corridor level freeway /arterial operations for many purposes, such as (1)(2)

- Traffic Incident Management;
- Work Zone Management;
- Planned Special Events Management, and
- Day-To-Day or Recurring Operations.

As a pilot CFA type project, the GLITS I-75 Project is focusing on the integration of freeway/arterial "Traffic Incident Management" and "Planned Special Events Management" functions. The goal of the project is to verify whether or not there could be certain carefully pre-defined signal timing plans that could be arranged along the arterial roads to better divert nearby congested freeway traffic and relieve the freeway congestion rapidly.

One of the core issues of the GLITS I-75 Project's design work is to develop an "expert system" to coordinate the existing freeway and arterial traffic operations in dealing with various freeway lane restriction scenarios. At the real world, there are two different types of ATMS software systems are running at the region, one is the MITSC's (Michigan ITS Center) freeway management system, and one is the RCOC TOC's (Road Commission for Oakland County Traffic Operation Center) arterial management system. The challenge of this design work is how to build an add-on software system, which will cross the boundary of two existing ATMS

software systems, and will smoothly integrate their relating functions together but minimize affecting the existing operations.

To achieve this, a collaborative software framework is proposed. This paper will be organized in the following manner. First, a summary of the CFA function requests within the GLITS I-75 Project. Second, the existing software architecture analysis for both freeway management and arterial management is presented. The concept of the collaborative software framework is discussed. Finally, the GLITS I-75 Project software design is summarized.

CONCEPT OF THE GLITS I-75 PROJECT

Before the concept of CFA, the freeway and the arterial management systems are working separately most of the time, even though, they maybe share certain information and device controls. The coordinated traffic signal controlling on the arterial roads majorly focuses on the coordination of arterial intersections without considering its impact on the nearby freeway traffic. The major concept of the CFA is to involve the "corridor" plan to target the integrated freeway/arterial corridor performance. It is based on the assumption that there would be certain carefully designed signal timing plans that could be pre-determined along the arterial roads; Once the nearby freeway suffers traffic congestion because of the traffic demand highly exceeds the capacity, the different corridor operational strategies will be triggered depending on the different combinations of the freeway and arterial traffic patterns, with a series of pre-determined operations such as DMS message displaying, diversion sign igniting, as well as special arterial signal timing plan activation (1)

Scope of the GLITS I-75 Project

Oakland County, Michigan, is one of the most affluent counties in the United States. It is located in southeast Michigan about 20 miles north of Detroit. The GLITS I-75 Project is scoped along 6 miles of the interstate I-75 corridor within the Oakland County, from Square Lake Road to Lapeer Road, including the Opdyke Road, a short portion of Lapeer Road, and crossing roads at interchange areas (e.g., M-59, Square Lake Road and University Drive). (Please refer to Figure 1). The I-75 freeway has 4 lanes in each direction within the GLITS I-75 Project area. Opdyke Road runs parallel to I-75 for the length of the project and has two lanes in each direction with an additional center turning lane. The project will include only the northbound (NB) direction of travel, with four interchanges in project vicinity. In addition, as shown in Figure 1, there is a sports stadium within the project area (Palace of Auburn Hills), which means there would be periodical sports or entertainment related special events occurring within the project corridor area.

Along the GLITS I-75 corridor, MDOT houses the extensive freeway traffic control system via MITSC. MITSC's freeway ITS components within the project region include CCTVs, detector stations and a CMS. On the other hand, RCOC is in charge of arterial traffic signal operations within Oakland County (with 650 SCATS equipped intersections and more than 600 fixed timing intersections). There are 18 SCATS intersections that cover the project defined major arterial road – Opdyke Road – along the GLITS I-75 corridor. As the advanced adaptive signal system, SCATS can support various levels of signal timing implementations that could either be pre-programmed, or could work in dynamic mode, where the signal timing plans are automatically adjusted by the SCATS system itself.

New Software Framework Required by the GLITS I-75 Project

Based on the existing MITSC and RCOC TOC software systems, the GLITS I-75 Project will include certain software enhancement for integrating freeway and arterial control functions on the GLITS I-75 corridor. The software framework of the GLITS I-75 is expected to be capable of "closely" merging the two existing ATMS (Advanced Traffic Management System) software systems, which shall be featured at least as the followings:

- The software framework shall take the maximum advantage of the existing two ATMS software systems with minimum changes of their existing operations.
- The software framework shall support smoothly data exchange / integration between the existing two ATMS software systems.
- The software framework shall coordinate related functions between the two ATMS software systems to fulfill the goal of the integrated freeway / arterial operations
- The software framework shall support integrated GLITS I-75 corridor traffic information access capability for other agencies (authorized users), as well as the general public.

CONCEPT OF THE COLLABORATIVE SOFTWARE FRAMEWORK

As we know, most of the current enterprise computing environments are featured as "Distributed Computing", which majorly based on the "client/server" model. This is also the common solution of ITS ATMS software systems, such as the existing ATMS software systems running at the MITSC and the RCOC TOC.

The concept of the "collaborative" software framework is initially coming from the intension of migrating / upgrading of the existing enterprise-wide software system. The basic idea is very simple, in order to make numerous software functions/components (including existing and new) to work coordinately and effectively, this type of the software framework should at least have the following features:

- Effective data sharing / exchanging mechanism;
- Supporting "Loosely-coupled" software structure;
- Supporting abundant data exchanging patterns;
- Standardizing communication and data exchanging protocols, and
- Scalable and flexible architecture for easy deployment and later maintenance.

Eventually, the "collaborative software framework" is particularly useful when building a software system upon previously existing software system; and it will stand for maximizing the software integration and minimizing adaption cost at the same time.

GLITS I-75 PROJECT SOFTWARE FRAMEWORK

Existing TMC Software Framework within GLITS I-75 Project

The existing ATMS software framework at both MITSC and RCOC TOC subscribes to a traditional "client/server" model, which normally relies on the "Request/Response" data operation approach for data retrieval, with a central database server and distributed clients.

The MITSC houses the freeway traffic control system for the region. The MITSC already provides extensive surveillance and motorist information functions along the freeway part of the

GLITS I-75 corridor. The existing MITSC ATMS software already provides most of the surveillance and management functions for freeway operations, such as device operations (CCTV cameras, CMS signs), traffic status monitoring, incident / special event management, as well as ATIS information distribution. Figure 2 illustrates the existing MITSC system software framework.

On the other hand, Road Commission for Oakland County (RCOC) is in charge of arterial traffic signal operations within Oakland County. At the RCOC TOC, besides SCATS signal control system, the existing RCOC's ATMS software system provides similar functions as those provided by the MITSC software but for arterial management. **Figure 3** illustrates the TIMS software architecture in the RCOC TOC. Most importantly, the RCOC TOC's ATMS system maintains several external interfaces that tie the RCOC TOC with external agencies. One of the most important interfaces is the link between the RCOC TOC and the MITSC. It enables the RCOC and MITSC to exchange real-time traffic information and share a certain level of device (CCTV) control.

Add-on Function Needs in the GLITS I-75 Software System

In details, for purposes of the integrated freeway/arterial operations, the following software enhancements are needed within the GLITS I-75 Project:

- New software interfaces need to be developed, such as
  - The interface that ties the MITSC software system with the SCATS "Event Manager" – the SCATS application is used the adjust signal timing plan.
  - The interface that retrieves new SCATS information.
- New software components that could smoothly merge the MITSC ATMS software system and the RCOC TOC ATMS software system together, providing on demand data exchange capability.
  - Freeway and arterial MOE (Measure of Effectiveness) data exchanging between MTISC and RCOC TOC.
  - Device status and alarm data exchanging between MITSC and RCOC TOC.
  - Automatic notification function to the RCOC traffic engineers for any activation/deactivation of special arterial signal timing plans.
- New software applications that provide data archiving / processing capability, such as
  - Data archiving capability for both freeway and arterial (SCATS) data;
  - Data mining and fusion capability of diversion detection and tracking in supporting of the semi-automatic operation mode, and
  - Rule-based response plan decision support capability.
- New web interface for presenting the integrated traffic information of both freeway and arterial roads.

The GLITS I-75 Project's Software Framework

The attached **Figure 4** gives the diagram of the GLIST I-75 software framework. As we can see, this software framework is build based on the existing MITSC and RCOC ATMS software system, with the following "collaborative" features:

- It smoothly bridged two existing ATMS software systems.
- It included build-in on-demand data sharing services.

- It added the additional required functionality, such as the data archiving/fusing functions, and decision support functions.

In details, the followings software components played the core role in this software framework to make it works collaboratively.

- "Data Exchanger" – The "Data Exchanger" manages the data sharing functionality at the both systems. In work with the lower-level "Message Server" component, it is in charge of processing and publishing new traffic data at each system.
- "Message Server" – The "Message Server" component acts as a low-level data buffer layer between the MDOT system and the RCOC system in supporting of the "Publish and Subscribe" data sharing mechanism. In corresponding with the "Data Exchanger" component, any data updating on one side could be rapidly reflected on the other side.
- "GLITS Data Fusion Application" – The "GLITS Data Fusion Application" is a server-side application that is in charge of archiving and fusing data from both freeway (MITSC) and arterial (RCOC TOC) systems to generate
  - Corridor level congestion report;
  - Diversion opportunity identification, alerts, and tracking information, and
  - Diversion condition monitoring
- "Diversion Alert Application" – The "Diversion Alert Application" is a thin, front-end application that displays diversion alert information and response plans for the operator's decision support purpose.
- "GLITS Corridor Web Site" – "GLITS Corridor Web Site" is at dedicated web site to present the integrated corridor traffic information to the external authorized agencies and general public.

The major benefits of this "collaborative" software framework are:

- Maximum leveraging of existing software architecture;
- Flexibility of adjustment;
- Message-base mechanism that adds stability of the software system and loosens the tight connection with a database, and
- Minimal new software development efforts.

SUMMARY

This paper presents the "collaborative" software framework design in supporting GLITS I-75 Integrated Freeway and Arterial Operation Project. This software framework links two different types of traffic management systems (freeway and arterial) and smoothly integrates corresponding functions together, minimizing the changes of their existing architectures.

ABSTRACT

Based on the development of Chinese Intelligent Integrate Transportation Systems, this paper shows the problems found in the process of the investment and finance of urban Intelligent Integrate Transportation Systems, especially when the problem faces the planning and Decision-Making process. In addition, this paper introduces some good examples that happened in the U.S. and other developed countries, besides the experience of success and failure in the construction of the highways in our country, and the expectations of finding a suitable way to develop our country, based on the last experiences. Afterwards, this paper shows the way to settle the problem of how to tighten the cooperation of the reform and administration, public and private investment departments. The major findings and lessons from this application are discussed, together with conclusions and Observations regarding further potentials and refinements.

INTRODUCTION

ITS (Intelligent Transportation System) is not a new word for us, especially in the big city. Nowadays, when the cities (Urbanization) of China have become bigger and bigger (Metropolitan Overspread), the Chinese Government faces the current situation, such as irrational economic structure, severe land wastage, intensive land-use-pattern, huge energy consumption, and so forth. These issues make the transport and logistics fee high, and the further deterioration of the living environment, as well as a large number of traffic emissions and sound pollution. The transportation time and fee for an ordinal people (Population Explosion) becomes high, and the traffic and transportation issue is no longer a construction problem but a control and management transportation systems issue.

Nowadays, the analysis for the economical benefit of transportation is difficult because of its public attribution. However, when it comes to the ITS, the city has come to a crucial period speeding up the construction of ITS. Therefore, we must face the investment and finance process, like it happened some years ago when we started to improve our national highway system.

DEVELOPMENT OF ITS

Intelligent Transportation System is a set of advanced information technology, data communication technique, electronic control technology and computer processing technology effectively applied to the management of transportation systems, people, vehicles and road close cooperation and harmony. Therefore, ITS plays a role in creating a framework of large, all-round, real-time, accurate and efficient transport management systems. Nowadays, in the 21st century, when United States, Europe, Japan and other countries and regions, are widely using ITS technology in an integrated transport system to improve traffic information, intelligence has become a modern transport development orientation.

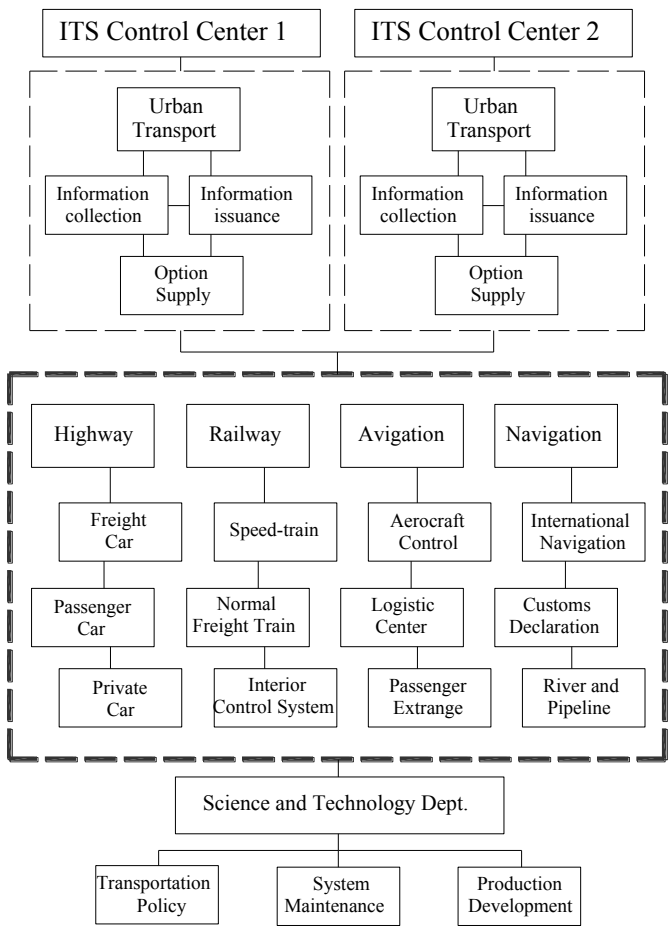

Figure 1. Framework for ITS Control Center .

Intelligent Transportation Systems uses widely information and communication technology to improve traffic management and operation of the system, providing a better way for the majority of those who travel, in order to integrate a variety of modes of transport, and improving the overall efficiency of transport.

Europe, the United States and Japan's experience shows us the ITS characteristics: 1) Developed rapidly. The progress of product research and development is rapid, from design to production to market, the cycle is becoming shorter and shorter; 2) Applications of integrated high-tech. The core technology called real-time traffic forecasting applies advanced detection, communications, remote sensing and computer technology into integrated transport systems, on behalf of the newest traffic technology; 3) Unprecedented huge scale. The scale and investment is huge. The U.S. Ministry of Transportation invests 1 billion dollars each year in research and development of highways and advanced intelligent traffic management systems.

DILEMMA OF ITS DEVELOPMENT IN CHINA

The urban infrastructure includes roads, bridges, rail transportation, public transport, water, electricity, coal, afforestation, environment, public health and other municipal and public infrastructures. As public goods, ITS infrastructure, like others, is basic, huge, public sharing, and should be planned in advance.

In China, the project policy is formed like a plan made by the government. As a result, the State Government and its development have both the obligation to have the right management, which needs to be planned in a more careful and flexible way to make a more relaxed investment policy. Therefore, the normal process is followed by Strategic Plan, Long-term plan, Middle-term Plan, Short-term Plan, and Dynamic Plan. In different levels of the investment policy making and planning, the participants and tasks are different, so as it is the development methods and support systems.

In other facets, technically speaking, although ITS has been developed rapidly in foreign countries, it has its problems and difficulties in China: ①ITS exceeds the start-up phase to development phase, but far from maturity phase; ② ITS is still focusing in information and communication technology; the real Intelligent Transport is also little; ③Lack of theoretical research, results are not mature enough and the application is not wide enough; ④Standardization should also be improved.

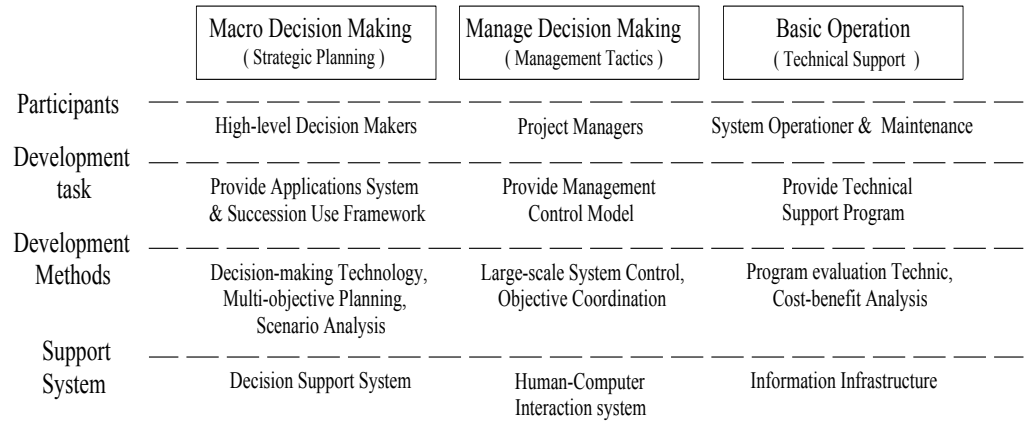

Figure 2. Investment Decision -Making Level Task in China .

Consequently, the process of the development of the ITS is a long way for us, and this puzzle is the investment step; it does not matter that the problem is a policy making or a technical one, despite that, we should do some research about this in order to know more about the dilemma.

FOREIGN INVESTMENT AND FINACING SYSTEM

Even though the ITS requires a huge investment, the recovery period is long, and even in some projects, funds cannot be recovered at all. Therefore, all countries with ITS on the financial arrangements use a number of policies and provision of the relevant budget to support their projects.. Take the United States, Japan and Sweden for example, they have been targeted for specific budget of the ITS.

Country -Scale-Budget Investment :

The Netherlands take the ITS development plan into the whole country Transport Policy. The Sweden put the transport policy making power & responsibilities to the Ministry of Communications. It follows Swedish National Road Administration (SNRA) and Swedish Road Information & Traffic Management Department (SRITMD) to coordinate government activities related to ITS units. SNRA annually deals with about 1.05 billion Swiss Currency (about 132,500,000 U.S dollars) ITS-related budget. SNRA as well, cooperates with local governments to improve local traffic signal control systems, plans to improve 3500 signal control cross, and conforms these crosses' information into a sharing network. The scheme will last for about 10 years, and the annual investment will be 130,400,000 Swiss Currency.

Private -capital -Budget Investment :

Investment and financing for ITS projects are similar to other transport facilities projects; they are constrained by the national capital shortage dilemma. As a consequence, the country encourages private investments in a participatory way to

build ITS facilities. To encourage private investments, government should relief taxes threshold and strengthening the legal system. In Japan and USA, the budget makes the scale of the ITS investments, and the capital can come from the company which is interesting in these projects, and the ownership of the ITS facilities can rely on the one who invests in them.

Government subsidies, business income tax reliefs, civil construction of national recognition, can be means to enhance the credibility of the participating units, and other ways of making access to private capital. At the same time, an integrated ITS program evaluation system should also be surfaced.

MIXED-METHOD INVESTMENT AND FINANCE IN CHINA

Reference to Chinese highway construction and operation mode, a government funded construction and commissioning should be an operated corporate mode, besides private enterprises operating modes if there is no fund construction budget. The great mode improves Chinese infrastructure development and promotes security of Chinese economic development. Therefore, based on ITS systems and development projects, it is a good way to use a different method of finance, access to sufficient funds to encourage community involvement and promote the development.

In order to achieve ways to link with each other, exchange data with each other and get co-operation, the Government has to intervene in private investment, avoiding the attention and the profit, in order to draw a clear relationship between rights and obligations. ITS plans on the construction, government and non-governmental cooperation in the specific way of relevant experience at China and abroad can generally be summarized as Table 1 shows.

Table 1. Mixed Investment and Finance Mode .
(I: Investment; C: Construction; B: Build; O: Operate; T: Transfer; R: Rehabilitate)

Mode	I-C-O Body	Ownership
BOT	Non-governmental Organization	Government.
BTO	Government-entrust Non-governmental investors	Government ownership first, then operation right.
ROT	Non-governmental organizations, Expanded and operate the leasing facilities	Government.
OT	Government Investment and constructed first, Non-governmental operate then	Government.
BOO	Non-governmental organizations	Non-governmental organizations
BOOT	Non-governmental organizations, operate itself then.	Government
BT + OT	One Non-governmental investors first, another operate then	Government ownership first, then operation right.

Government funding or private investment participation should be in line with Chinese financial law regulations and policies. Regarding of support for the ITS industry, we should also put forward specific regulations and policies for the entrance of government and non-governmental capital to prepare the way to long-term steady source of funds for ITS, through establishing a legal basis.

ITS construction costs are often very large; they have a very long recovery period, and the project may last for many years. The operating profit is also high, besides the Department's own profits, it may also include government subsidy, business Incentive such as tax relief. Through the participation of the country and the private capital, we should also enhance the credibility of the participating units to encourage their active participation.

However, grant awards and incentives should be strictly assessed and the adoption of a system should be regulated by the application of specific conditions and targets in order to avoid controversy or create unfairness.

CONCLUSION

ITS covers a wide range of promotion, in addition to the technical requirements to ensure the standardization of data can be exchanged with each other, the device can be linked with each other, the facilities can be operated by each other, the administrative unit for communication and coordination mechanisms, and even re-organization for the business mode can be done. As a whole, regulations and policies must be appropriate to distinguish, with a clear division of powers and responsibilities vested in the transport management policy and strategy formulation implementation to improve the efficiency of the ITS.

The Chinese Government clears the various powers and responsibilities between departments, but to achieve a complete and efficient ITS, it is bound to bring a lot of need for the integration of administrative functions. Investment conflicts various sub-systems, one department conflicts others, the government conflicts enterprises, so the program may face many difficulties and contradictions, when the apparent different government and private capital investors are put together. As a result, there is an urgent need to establish appropriate laws and regulations to establish coordination across the industry, providing industry responsible for the jurisdiction of each other and opening up the problems to solve them, otherwise, the building of Intelligent Transportation Systems will be delayed.

Abstract

Traffic congestion was inevitable because of the reduced capacity caused by the construction zone activities. In rural or suburban areas, highway network is not as permeable as urban areas, thus making advance traveler information more critical. The study investigated truck drivers' route choice behavior under the Advanced Traveler Information System (ATIS) using before and after traffic count collected at a number of locations in and around a suburban work zone in Wisconsin, USA. Variable message signs were used to inform approaching motorists of existing delays ahead by publishing real-time delay messages and divert trucks to alternative routes when congested. After including variables such as total traffic, truck percentage and time of day, delay information, however, is no longer statistically significant in the Multinomial Logit Models (MNL). The findings suggest that motorists may rely more on their own perception of congestion or upcoming congestion than the delay messages. The results help to understand the heavy vehicle driver behavior and develop more efficient and effective work zone management strategies.

Key Words: Truck Route Choice; Traveler Information; Multinomial Logit Model (MNL).

Introduction

Moving people and goods efficiently and safely on the nation's highways continues to challenge transportation researchers and practitioners with better solutions. Among all the factors accounting for delay and safety, work zones are constantly listed as one of the top public concerns. In order to mitigate work zone congestion by diverting traffic to alternative routes to an appropriate level without compromising their pavement and safety conditions, an in-depth understanding of heavy vehicles route choice behavior is indispensible. Work zones are usually congested because of the lower operating speed and reduced capacity. Work zones are also the places where many conflicts are taking places: conflicts between safety and mobility, conflicts between construction schedule and travel demand, conflicts between road users and workers, and conflicts between enforcement and driver compliance. Conflicts, on

the other hand, create opportunities for applying innovative technologies to ease the pain of traveling through and around work zones. Among these, intelligent transportation systems (ITS) technologies involving the use of electronics, computers, and communications equipment to collect, process, and analyze information are appealing solutions that make the work zone travel safer and more efficient. One of the ITS applications is the Advanced Traveler Information Systems (ATIS).

ATIS is beneficial in terms of providing drivers information ahead that may assist them in taking appropriate actions. Previous research shows that motorists' route choices can be affected by the provision of real-time traveler information (Abdel-Aty and Abdalla, 2004, Liu and Mahmassani, 2000). However, it is driver's decision that finally determines the actual surface traffic distribution and travel time. Substantial studies reveal that the process of individual decision-making is complicated, depending on the alternative route availability, route preference, value of time, traveler information reliability, driver's gender, age and other socio-economical factors (Abdel-Aty and Abdalla, 2004, Khattak, et al. 1993A, Khattak, et al. 1993B, Jou, et al. 2004, Benson 1996, Polydoropoulou et al. 1996, Lotan 1997).

Traveler information has proved to be an effective means to mitigating congestion in urban areas (Levinson and Huo, 2003, Chu et al. 2005, Lee and Kim 2006). Minnesota researchers developed a route choice model for predicting how drivers respond to the information provided by Variable Message Signs (VMSs) and whether drivers will divert to avoid incidents (Levinson and Huo, 2003). Empirical traffic and occupancy data were collected from loop detectors on both freeway mainline and ramps, as well as the messages on VMSs and a detailed incident log. The outcome of the weighted probit-based model showed that the diversion rate was significantly impacted by factors such as: alternative exit availability, nature of incident, time period, type of message, and the interaction between alternative exit availability and type of message. In Southern California, two separate studies evaluated the effectiveness of Advanced Work zone Information System (AWIS) and its resulting traffic diversion and safety impacts (Chu et al. 2005, Lee and Kim 2006). Using the detector data, Chu et al. observed the decrease in the maximum mainline delay and further suggested that AWIS improved safety by smoothing traffic flow (Chu et al. 2005).

Equally important, the congestion issues caused by work zones or incident circumstances in rural environment were studied and real-time information systems implemented were evaluated (Horowitz et al. 2003, Tudor et al. 2003). The influence of VMS on alternative route selection for rural Wisconsin freeways was examined through the Travel Information Prediction System (TIPS) (Horowitz et al. 2003). TIPS provided drivers with real-time travel time information through a collection of PCMSs. Each sign had two message frames publishing the distance to the end of the work zone and estimated travel time, along with three alternative routes. The impact was determined by traffic volume variations before and after the implementation of TIPS. The study reported little changes in alternative route selection far upstream of the work zone but a 7-10 percent increase in near upstream of the work zone. One of the weaknesses of the study is that it did not distinguish truck drivers from passenger car drivers. It is known that truck percentage is normally higher in rural or suburban areas than in the urban freeway system. Hence,

a work zone located on a freight corridor should be planned with extra cautions to avoid any negative impacts caused by excessive heavy vehicles.

The objective of the study was to investigate truck driver behavior under the effect of ATIS through their route choice decision-making process in a congested state along a suburban interstate highway. Using MNL models, a number of route choice decision-making contributing factors as well as their magnitude of influence were studied. It was assumed that truck drivers would take one of the two alternative routes (one designated detour and one without being signed as a detour) to avoid unreasonable delay and congestion on the interstate highway. The results help to understand the heavy vehicle driver behavior and develop more efficient and effective work zone management strategies.

Work Zone Description

Work zones unfortunately create bottlenecks on the Interstate highways which normally carry large volume of commercial vehicles. The congestion issue may become even more poignant on rural Interstate highways where the road network is not as permeable as urban freeway system. Extra concerns such as the diverted truck impact on alternative routes and their communities are valid and necessary. To fully investigate the route choice issues directly connected to the drivers especially truck drivers, the study location selection is the key. The premise is that the location has to have comparative alternative routes. In other words, the alternates should be attractive to drivers who are willing to consider diversion if delayed. Although no work zone is perfectly designed to fit the laboratory condition, the work zone I-39/90 crossing of the Rock River has many desirable features for observing routes choice activities.

Wisconsin Department of Transportation (WisDOT) performed $1.8 million bridge repair project on I-39/90 over the Rock River in northern Rock County, near Edgerton, where traffic was reduced to one lane in each direction. This segment of I-39/90 is a 4-lane divided roadway carrying over 54,000 vehicles per day with considerable amount of truck traffic of over 15,000 per day, about 28% of total traffic. During the rehabilitation, the northbound bridge was closed, and traffic was reduced to one lane in each direction and routed to the southbound side of the roadway by a median crossover (the capacity was reduced to half, which inevitable creates significant congestion).

Figure 1 shows that WisDOT provided an alternative route allowing drivers to divert from the freeway to avoid excessive delay. The designated alternative route, called alternative 1 in the study, includes US 14 and US 51, which are both two-lane undivided highways. Northbound drivers can take an exit ramp to US 14 and return back to I-39/90 via entrance ramp from US 51. Another alternate, called alterative 2 in the study, winds through Milton on the east side of I-39/90 including part of STH 26 and STH 59. Alternative 1 and 2 have approximate travel times of 21 minutes (13.4 miles) and 26 minutes (16.9 miles) respectively during normal conditions, as compared to 11 minutes (12.2 miles) on the mainline. Highway facilitates on both routes can accommodate heavy trucks but alternative 2 crosses two business districts: Milton and the east side of Janesville. More business activities happen on the east

Figure 1. Work zone and alternative routes.

side of I-39/90 compared to the west side. Another concern is safety for having large truck and high traffic volume appearance near school zones located on STH 26 and STH 59. Therefore alternative 2 was intentionally not signed as a detour but local commuters knew the alternatives. In short, alternative 1 carries less traffic and has much lower v/c ratio than alternative 2.

Data Collection and Processing

A total of eight data collection points were selected on three routes in and around the work zone: two detectors were on the mainline (No.5 0506 and No.6 0512 Sensors); two were on the off-ramps leading to the alternative routes (No.7 0601 and No.8 5623 off ramps), two were on the on-ramps returning to the mainline from the alternates

(No.1 5630 and No.2 5625 on ramps), and two were on the alternative routes (No.3 0602 and No.4 0604 Sensors). All detectors collected volume, speed, occupancy and vehicle classification. The data were time stamped and aggregated on 15-minute intervals. The detector locations are listed as follows and their approximate locations are depicted in Figure 1.

Data collection started one week before the construction and continued throughout the entire work zone period as listed in Table 2. Besides the traffic data, published delay time which was recorded or logged by the ATIS system was also recorded. The data used in the study include total traffic volume approaching work zone (T), truck percentage (PT), approaching traffic operating speed (S), day of week (DOW), time of day (TOD), and delay time on the message board (D).

Table 1. Work Zone Schedule.

Schedule	Dates	Traffic Control Description
I	Before May 6 (Sun)	Before the work zone, no traffic control
II	May 15 (Tue) ~ May 22 (Tue)	Work zone with traffic control, real-time delay system in operation

Work Zone Delay Time

A real-time traveler information system was operated through a contracted vendor. The delay time was defined as the difference between the estimated travel time based on real-time traffic data and the travel time under free-flow condition in the approaching area. Remote traffic microwave sensors (RTMSs) continuously collected speed data and reported to the master controller. The algorithm in the master controller calculated the instantaneous travel time based on the collected speed data from which the delay time was derived as the difference between the congestion and free-flow conditions. The approaching area was divided into several segments by the sensors. For each segment, the travel time was calculated by dividing the distance between two sensor locations with the average speed of the sensors. The total travel time before entering work zone was the sum of all the travel times in individual segments. The delay time is expressed in the following equation:

$$D = \sum_{i=1}^{n} \frac{l_i}{(v_i + v_{i-1})/2} - \sum_{i=1}^{n} l_i / v_f \qquad (1)$$

Where:
D – Delay time
l_i – Length of segment i
v_f – Free flow speed
v_i – Speed in ith segment
v_{i-1} – Speed in (i –1)th segment

Relative Difference (RD) of Traffic Volume

Data collected during schedule I without traffic control and work zone activities were

considered as baseline data. The difference of traffic volumes on each route between schedules I and II for each time interval (15 minutes) was used to explain the driver's decision on choosing different routes. Because traffic varies during different time of day, the difference was normalized by the baseline (traffic volume from schedule I) to standardize the scale along with the time line, called relative difference (RD).

$$RD = \frac{V_{Schedule\ II} - V_{Schedule\ I}}{V_{Schedule\ I}} \quad (2)$$

Where V is the observed traffic volume during 15-minute time period

RD was transformed to a value between 0 and 1 that is appropriate for a logistic model. The value of the response variable reveals the driver preference to choosing one of the routes, for example, if alternative 1 has a value of one, it means that in the same 15-minute interval, largest change (increase traffic) was observed on this route compared to normal conditions. It indirectly measures that more drivers prefer alternative 1 to others. For example, in Figure 2 we can easily observe that truck drivers prefer to take the alternative routes over the main route on Friday if the approaching traffic volume is above the average volume of the day. Furthermore, if so they prefer alternative route 1 to alternative route 2.

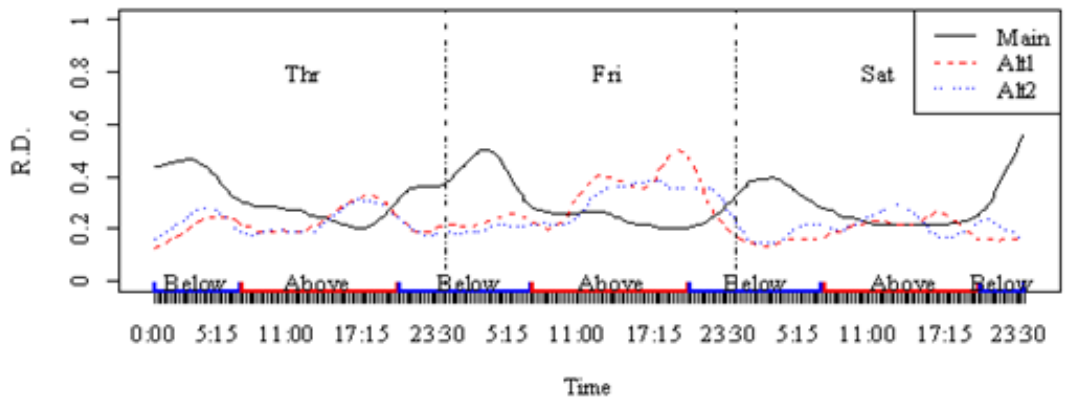

Figure 2. RD between Schedule I and II*.

* . "Above" represents the times of a day when traffic volume is *above* the average and "Below" for the opposite.

Despite the prearranged periodical trips to inspect the conditions of detectors and recover any incidents during data collection, some data were still lost due to such reasons as low or dead battery, damaged hoses, and detector memory overflow.
The most complete and comparative dataset includes only Thursday and Friday. Table 2 shows the summary statistics for the variables. All the statistics were calculated based on 15-minute interval data. To be more homogenous, data were split by average daily traffic volume. There were some variations in the total approaching traffic.

Table 2. Variable Summary Statistics (15-minute).

Variable	Schedule		I		II	
	Time of Day (TOD)		Above*	Below*	Above	Below

		Range			[8.00, 10.50]	[9.50, 15.50]

Truck Driver Route Choice Models

Truckers' route choice decisions are heavily affected by their traveling environment in addition to individual preferences. The environmental factors can be approximately categorized into:

1) Perceivable information: drivers' perception of traffic congestion that can be described as real-time traffic conditions such as traffic volume, truck percentage, operating speed;
2) Temporal information: drivers' trip purposes that can be replaced by such factors such time of day, day of week; and
3) Advisory information: posted delay time on the PCMSs.

In this study, the placement of the delay message was 8 miles away from the

work zone activity area. It was possible that the back of the queue had not reached the message sign by the time drivers read the delay message. Hence, the delay information was an advisory message. It either conformed to drivers' observation, reinforcing their decisions of taking detours, or conflicted with what drivers have seen, dividing drivers' into two groups: the group of compliance and the group of ignorance.

To construct route choice models using before and after traffic data, a multinomial logistic (MNL) model was designed to examine the factors that were significantly associated with the diversion. First, some notations are defined at 15-minute intervals:

p_{i1}= the probability that truckers at ith 15-minute prefers to choosing alternative 1.
p_{i2}= the probability that truckers at ith 15-minute prefers to choosing alternative 2.
p_{i3}= the probability that truckers at ith 15-minute prefers to choosing mainline.

Let $\boldsymbol{X}$i be a vector of explanatory variables for the characteristics of traveling environment at each 15-minute interval.

$$\log\left(\frac{p_{i1}}{p_{i3}}\right) = {}_1\mathbf{X}_i \tag{3}$$

$$\log\left(\frac{p_{i2}}{p_{i3}}\right) = {}_2\mathbf{X}_i \tag{4}$$

$$\log\left(\frac{p_{i1}}{p_{i2}}\right) = \log\left(\frac{p_{i1}}{p_{i3}}\right) - \log\left(\frac{p_{i2}}{p_{i3}}\right) = ({}_1 - {}_2)\mathbf{X}_i = {}_3\mathbf{X}_i \tag{5}$$

Where ${}_3 = {}_1 - {}_2$
Therefore:

$$p_{i1} = \frac{e^{{}_1\mathbf{X}_i}}{1 + e^{{}_1\mathbf{X}_i} + e^{{}_2\mathbf{X}_i}} \tag{6}$$

$$p_{i2} = \frac{e^{{}_2\mathbf{X}_i}}{1 + e^{{}_1\mathbf{X}_i} + e^{{}_2\mathbf{X}_i}} \tag{7}$$

$$p_{i3} = \frac{1}{1 + e^{{}_1\mathbf{X}_i} + e^{{}_2\mathbf{X}_i}} \tag{8}$$

Where

$\mathbf{X}$ – vector of predictor variables
– vector of coefficients.

Analysis and Discussion

Driver's decision-making is a complicated process which is in no way decided by a single factor such as delay time. Especially when delay message conflicts with driver's observation, the faith in the accuracy and reliability of the delay information dominates driver's route choice. By incrementally adding other variables to the

model, we can have a better understanding of how the factors as well as their interactions work together. Some variables are notably correlated in the model such as delay time, total traffic, truck ratio, and time of day. When two variables are highly correlated, only one of them remains in the model. To simplify the model, only two-way interaction is considered.

A set of models were tested with different variables of interest that help to understand and quantify the odds of truckers to choose alternative routes instead of mainline. The univariate models test the statistical significance of each variable in affecting driver's route choice independently. The significant variables then constitute multivariate models to improve the model performance. Examining the p-values from the MNL models in Table 3, we see that almost all the variables are statistically significant except for the one containing speed variable. One plausible explanation is that speed is highly correlated with total traffic and truck percentage. The addition of speed variable to the model with total traffic and traffic percentage does not gain extra benefit in the goodness-of-fit.

Table 3 MNL Route-choice Models.

Model	AIC	Deviance	Test Stats.*	p-value*	Significance
Null	13677	13673	-	-	-

* Tests and p-values are based on the likelihood ratios using the differences of deviances which are known to follow the Chi-square distributions with corresponding degrees of freedom.

With a three-category outcome (three routes) there are implicitly two equations. For each variable, the first coefficient is for the first equation that estimates the preference of choosing alternative 1, and the second coefficient is for the second equation that estimates the preference of choosing alternative 2. The coefficients in the MNL models are directly related to the odd ratios that quantify the change of the odds with the increase of 1-unit in the variable. Note that the estimated coefficients are in a format of natural logarithm and the odds ratio can be obtained by exponentiating them. A few important observations can be made from the estimates of the parameters listed in Table 4. First, neither alternative route is favored compared to the mainline if no other factors are considered. Second, temporal variables such as day of week or time of day are consistent in affecting truckers' route choice decision in which the mainline is still preferred over the alternative routes. Third, traffic conditions influence truckers in such a way that more approaching traffic (a stronger indicator of possible congestion) encourages truckers to take alternates though the preference of one over the other is marginal.

Finally, higher truck percentage leads to more reluctance to take the detour. It may be caused by the concerns from truck drivers about the pavement or traffic conditions on alternative routes.

Table 4 MNL Model Parameter Estimates.

Models	Route	Intercept	Thu.	DayTime (Below)	PT	T	S	D
Null	Alt1	-0.086						
	Alt2	-0.180						
D	Alt1	0.238	-0.523					
	Alt2	-0.013	-0.395					
TOD	Alt1	1.490		-4.830				
	Alt2	1.350		-4.720				
PT	Alt1	0.278			-0.765			
	Alt2	0.101			-0.559			
T	Alt1	-1.100				0.002		
	Alt2	-0.950				0.001		
S	Alt1	-7.980					0.122	
	Alt2	-7.310					0.111	
D	Alt1	-0.192						0.014
	Alt2	-0.255						0.010
DOW+TOD	Alt1	-0.860	-0.358	0.353	-1.060	0.002		
	Alt2	-1.320	-0.228	0.611	-1.020	0.002		
DOW+TOD+PT+T	Alt1	-0.860	-0.358	0.353	-1.060	0.002		
	Alt2	-1.320	-0.228	0.611	-1.020	0.002		

The last model is recommended as the best one for predicting heavy vehicle route choices because of the smallest AIC value. Its explicit model specification for Alt 1 is Equation 9 and the model for Alt 2 can be obtained by replacing all s in the model with the coefficients in Alt 2. Most of the coefficient estimates in this model are fairly similar to other models except that the delay time is no longer included. The delay information becomes statistically insignificant after the model includes other variables; it is plausible that the delay information is correlated with other perceivable traffic variables.

$$log\left(\frac{p_{i1}}{p_{i3}}\right) = \quad _0 + \quad _1 \cdot T_i + \quad _2 \cdot PT_i + \quad _3 \cdot TOD_i + \quad _4 \cdot DOW_i \qquad (9)$$

Conclusions and Future Recommendations

The study investigated the truck driver route choice decisions under the effect of ATIS implemented in a work zone on I-39/90, a major truck corridor connecting Chicago, IL, Madison, WI, and Twin Cities, MN. During the construction, the northbound was closed, and traffic was reduced to one lane in each direction and switched to the southbound side of the roadway via a median crossover. Traffic congestion was

inevitable because of the reduced capacity. To mitigate the congestion, two alternative routes have been planned, one with detour signage and the other without. In addition, to facilitate drivers' route choice decision-making, real-time delay message system was implemented.

The preliminary analysis shows that during the congestion, delay time message had statistically significant impact on truck drivers' decision-making in taking alternative routes if it was tested alone. An extensive model comparison was followed. In particular, we have found through the study that heavy vehicle driver's route choice decision was affected by 1) time of the day, a strong trip purpose indicator; 2) total approaching traffic to the work zone, a perceivable signal for congestion or upcoming congestion; and 3) truck percentage. High truck percentage discourages truckers themselves to take detours. The plausible reason may be due to the extra concerns from truck drivers of the pavement or traffic conditions on alternative routes. The study provides crucial information for traffic engineers whose objective is to alleviate mainline congestion by diverting traffic to alternative routes whose capacity is underutilized to an appropriate level without compromising the alternative highway pavement conditions as well as its traffic safety by the surge of truck traffic. By understanding the limitation of ATIS, the trucker route choice behavior as well as the similarities and dissimilarities between truckers and car drivers, a congestion mitigation plan can be designed more effectively and efficiently.

A discrete choice study is suggested in future research where every truck driver will be tracked in regard to their route choice decisions. The results can also be verified through a stated preference type of survey. The disaggregate level research may reveal other factors in motorist's route choice behavior and provide more definitive conclusions.

ABSTRACT

Traffic diversion and emergency traffic management strategies call for integration of not only advanced information colleting/disseminating devices such as Changeable Message Sign (CMS), video-detection and loop detection, and control system, but also appropriate roadside signing route guidance systems. Well signage-equipped alternate routes could play a vital role in supporting the congestion alleviation and incident management, especially in a mixed roadway network consisting of freeways, arterials, and local streets. While many researchers claimed the importance of dynamic routes for en route drivers, geographical, geometric and environmental conditions and the category of a specific roadway may objectively define its role as a "permanent" alternate route to certain freeways or major traffic generators/attractors. This raises several issues in identifying such "permanent" alternate routes and integrating a signing route guidance system into the implementation of local intelligent transportation systems. This paper attempts to develop a methodology to identify the "permanent" alternate routes for traffic diversion strategies, and to prioritize Intelligent Transportation Systems (ITS) element candidate locations in the concerned network. A scenario of incident management and operation is demonstrated to discuss how a "permanent" alternate route guidance system could be identified and integrated with ITS, using a mixed network near Los Angeles International Airport as an example. Finally, types of diagrammatic alternate route signs are addressed with design samples.

INTRODUCTION

Utilizing real-time traffic situation and route guidance advisory information to divert traffic from heavily loaded roadways to lightly loaded roadways has been long identified as one of potential solutions to alleviating urban traffic congestions. A Mixed roadway network consisting of freeways, arterials and other local streets is commonly located in an urban area. Terrible congestion frequently happens on freeways while some arterials or other local streets are lightly loaded. In Southern

California's mixed roadway networks, for instance, drivers are frequently trapped in severely congested freeways due to myopic decision making while possible alternate routes in local streets are not heavily loaded. Such a flow distribution underutilizes the overall network's capacity. Integrated with advanced traffic information/management systems (ATIS/ATMS), route guidance, and driver information systems may be employed to improve the network efficiency via disseminating alternate routes information (Papageogiou et al. 2003). In this way, relative traffic equilibrium over the roadway network is expected to be reached. However, the implementation of ATIS technologies in real life, especially of the real-time route guidance information into a real roadway network, is currently limited (Abdel-Aty et al. 2004). In addition to the computational effort needed for validated algorithms, difficulties in making consistent interactions between information and drivers' routing diversion behavior and a lack of route signing guidance systems are limiting the efficiency of ATIS.

An investigation (Wardman et al. 1997) discloses too wide a range of variables in estimating the proportion of drivers following en route real-time information via changeable message signs (CMS) to divert routes, namely, 5 to 80%. Clearly this range is hardly convincible to support the use of CMS for fine tuning the pattern of demand. A key weakness is the CMS' inability to display messages that are consistent with driver diversion response attitudes in the relevant roadway network (Peeta et al. 2001).

In the analysis of operation concept (Iteris 2003; 2004) with intelligent transportation systems (ITS), an alternate route guidance system is envisioned to play the role of supporting the implementation and operations of ATIS/ATMS. It requires integration of advanced information colleting/disseminating devices such as CMS, video-detection or loop detection, and control system. Ideally a genuine control strategy can optimize the network traffic conditions to avoid traffic congestion on alternate routes due to drivers' overreaction (Abdel-Aty et al. 2004). For the sake of fiscal constraints, however, it is not feasible to install surveillance detectors over all roadways in the entire network. The authors' practical design experience and literature review indicate that an appropriately designed static signing or trailblazer guidance system has proven cost-effective in supporting the implementation of ATIS/ATMS. To a specific trip attractor (e.g., airport, employment center), there usually are several alternate routes in existence. To determine such "permanent" alternate routes, important or vulnerable links or nodes of the roadway network should be identified at first. Vulnerability should explicitly account for the availability of alternate routes' excess capacity and travel time (Iteris 2001). For non-crossed freeways (e.g., freeways 1-210, SR-710, and SR-110 within the City of Pasadena roadway network), arterials and local streets could be used as connectors between freeways while continued guidance signs are needed along the routes.

This paper attempts to build up a methodology to identify important or vulnerable locations from the standpoint of its "importance to the network", and to prioritize ITS element candidate locations in the network. This approach was derived from our participated ITS deployment projects (Iteris 2001; 2003; 2004) most of which were conducted in Southern California areas. The paper then

discusses how a "permanent" route signing guidance system could be determined and integrated with ATIS/ATMS, which is presented with a scenario of incident management and operation in a mixed network near Los Angeles International Airport. Finally, the paper addresses the issue in building up a route guidance system with the use of special features of local streets (e.g., one-way) as a connector between freeways. A typical example of such connectors linking I-210, SR 101 and SR 710 in Southern California area is exhibited in the discussion. Several types of alternate route guidance signs are briefly discussed based on the authors' practical experience and literature review.

TRAFFIC DIVERTION ROUTES IN A MIXED ROADWAY NETWORK

Prioritizing Corridors and Key Locations for ITS Elements

A number of cities' roadway networks in Southern California are mixed with freeways, arterial corridors, and other local streets with severe traffic congestion problems. Inglewood, for example, a city located in the South Bay region of Southern California on the southern tip of the Los Angeles city limits, has 200 miles of streets, about 140 signalized intersections surrounded by two major freeways, I-405 and I-105, as shown in **Figure 1**. The City is a regional transportation hub and attracts traffic from numerous venues including the Great Western Forum, Hollywood Park Race Track, Hollywood Park Casino, Los Angeles International Airport (LAX), and two major Medical hospitals – Centinela Hospital Medical Center and Daniel Freeman Memorial Hospital. Due to its important location in the urban flow of Greater Los Angeles, Inglewood is faced with the "big city" challenges of traffic congestion, pollution, and special event managements. Inglewood has always experienced very high daily traffic levels on freeways and major arterials.

To solve these problems caused by heavy traffic, ITS solutions have been recommended for the traffic congestion alleviation and incident management in this area. As part of the ITS strategies, a route guidance system along pre-determined (or "permanent") alternate routes is viewed as a key element to support the implementation of the City's ATIS/ATMS. Effective alternate routes are expected to bear some throughput from multi-regional cut-through traffic heading to various traffic generators/attractors such as LAX, the traffic impacted by freeway incident along freeways I-405/I-105 and the vicinity of the freeway interchanges in that area. To determine alternate routes, key locations (links and nodes) that are important to the network need to be identified and prioritized for ITS elements deployment (Iteris 2001). In the meantime, most of such important links/nodes are viewed as vulnerable links/nodes (Murray-Tuite et al. 2004). A location's "importance to the network" can be evaluated with the following aspects (Iteris 2001; 2003; 2004):

- High Accident History;
- Critical Signal Timing to Coordination;
- Key Point to Routing – cameras and/or detectors placed in the vicinity of other field elements of the signal system, such as changeable message signs and traffic signals, can be used for an overview of their operation.
- High Frequency of Queuing;
- Special Traffic Generators;

- Intersections with Poor Level of Service;
- High Volume; and
- Proximity to Traffic Generator.

Practical experiences in network operational assessments ((Iteris 2001; 2003; 2004; Wei 2000) revealed that above features are usually used to evaluate criticality of a location with respect to its functional importance to the network. In other words, those nodes possessing those features mostly stay at worse level of service or bear heavier traffic. Thus, they are usually evaluated as critical nodes. It is therefore assumed that results from evaluations of those critical nodes can be used to represent the critical performance status of the entire network, provided that no sufficient ITS field elements cover the entire network of investigation.

Selection criteria proposed in the study combined all above analyzed aspects and the various agency needs and requirements in order to develop one uniform ranking system. **Table 1** presents the proposed quantitative criteria to initially prioritize ITS field surveillance locations by using the following equation (Iteris 2001):

$$P_j = \sum_{i=1}^{6} k \times f_i \times w_i$$

Where, P_j = priority ranking of detector type j; k = detector type factor; f_i = feature weight for criteria i; and w_i = importance weight assigned to criteria i.

Table 1. Criteria to Prioritize Field Elements Locations and Their Weights.

i	Criteria	Range	Feature Weight (*f*)	Important Weight (*w*)	Detection Type Factor *k*	
					Video Detection (*j*=1)	Data Detection (*j*=2)
1	Average number of accidents per year over a 5 year period	> 20	4	5	1	0
		10 ~ 20	3			
		5 ~ 0	2			
		< 5	1			
2	Intersection Level off Service (LOS)	F	4	4	1	1
		E	3			
		D	2			
		C, B, or A	1			
3	Average Daily Traffic Volume (ADT)	> 60,000	4	3	1	1
		45,000 ~ 60,000	3			
		30,000 ~ 45,000	2			
		< 30,000	1			
4	Proximity to Freeway On-ramp	Adjacent	4	2	1	1
		Not adjacent	0			
5	Proximity to Traffic Generator	Adjacent	4	1	1	1
		Not adjacent	0			
6	Type of Traffic Control	No CCS (TBC)	0	2	1	1
		TOD CCS	2			
		ATC	4			

Source: Iteris, Inc. Preliminary CCTV and System Detection Master Plan for South Bay ITS Project. October 26, 2001 (Iteris 2001)

- No CCS (TBC) = no Central Control System (Time Based Control)
- TOD CCS = Time of Day Control (TODC) using computerized Traffic Control
- ATC = Adaptive Traffic Control (ATD) with Traffic Responsive Plan Selection
- Operating characteristics of intersections are often described by use of the concept of level of service (LOS). LOS is a qualitative description of an intersection's performance based on traffic

delays. An intersection's LOS could range from A representing free-flow conditions, to F jammed conditions.

- Average Daily Traffic represents the average total number of passenger vehicles, trucks and busses that pass an intersection in a 24-hour period.

After the locations of detection elements are initialized, selected intersections are ranked based on the corridor rankings in which they are located. The corridors are ranked in principal, major and minor priority corridors. Usually freeways providing regional and interstate services, principal arterials providing regional access, and end-to-end traffic signal controlled corridors crossing multi-jurisdictions are ranked the top, or called principal priority corridors. Major arterials with intermediate capacity roadways providing local access to major commercial and industrial parcels and some regional access are ranked the second, or termed major priority corridors. Collectors with intermediate capacity roadways providing access between local streets and the arterial streets as well as local streets are ranked the third, or termed minor priority corridors. Critical locations are divided into principle important location, major important location and minor important location, depending on their improvement priority determined by following the above analysis procedure and method. **Figure 1** illustrates an example of such a classification and identifications in the City of Inglewood roadway network, Southern California.

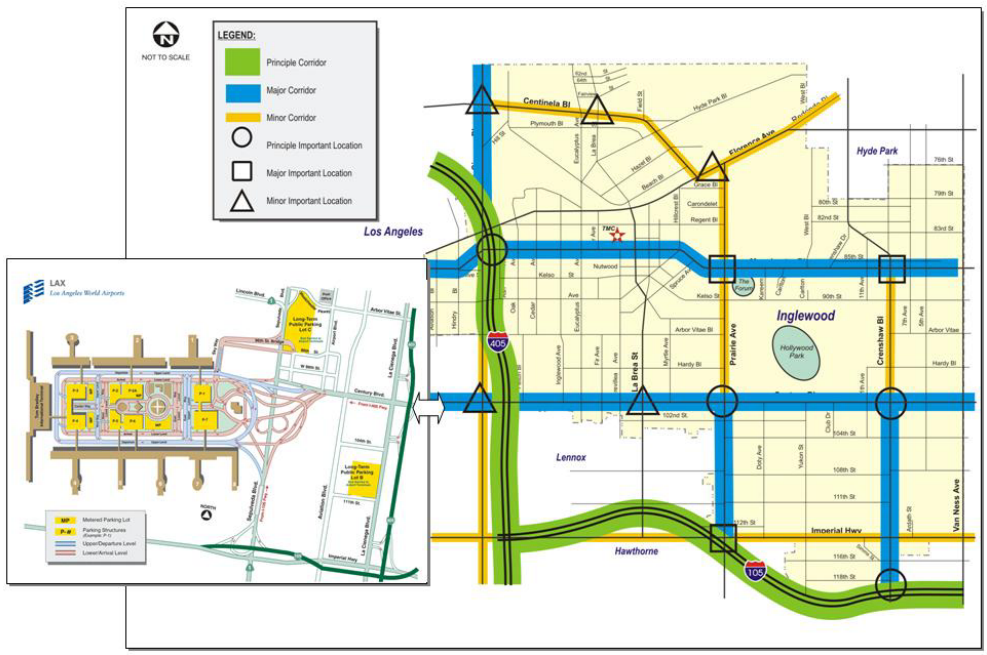

Figure 1. Priority Arterial Corridors Example Surrounding California LAX An Incident Management Scenario using Alternate Routes.

Upon compiling the rankings, an initial cutoff was established to identify those intersections that warrant deployment of ITS elements (e.g., CCTV cameras, video/data detector, signal controller upgrade, CMS and static directional signs) under immediate- and ultimate-term, depending on the discussions among related

city traffic engineers and planner as well as projects consultants (which is beyond the paper's focus and will not be discussed in details).

As a result of comprehensive analysis using the above method, priority corridors and important locations are identified, as shown in **Figure 1**. A high-level strategy for deployment of ITS elements are suggested and presented by an area ITS plan, as illustrated in **Figure 2**. Traffic analysis using Synchro indicates that most segments of the identified alternate routes (represented by dot line in **Figure 2**) for traffic leading to LAX are currently operating at the level of service C, meaning that those routes have capacity to accommodate diverted traffic from freeways I-405/I-105 as an incident or congestion occurs. When an incident happens on a priority corridor, ATMS could be implemented to divert traffic trapped in congestion to other alternate routes. Static roadside directional signs and limited number of CMS or Trailblazer Signs (TBS) to be installed along those routes constitute a signing route guidance system. The following scenario attempts to present how the signing route guidance system supports the implementation of ATIS/ATMS with incident management. **Figure 3** illustrates the concept of operations with an example of operating scenarios, which are envisioned to operate in a three-step fashion:

1. Traffic detection technology collecting traffic flow data from system detectors and calculates volume, occupancy and speed on a real-time basis.
2. Incident detection algorithms that interpret changes in certain traffic-flow parameters for determining the presence of capacity-reducing incidents.
3. Information dissemination and divert traffic via route guidance system and alternative signal control strategies.

Traffic Detection: There is an assumption that the system detectors installed on priority corridors are continuously measuring and collecting traffic flow data, as shown in **Figure 3**. Traffic flow data measured by loop detectors consist of 30-second counts of both volume and occupancy measured 24hr/day for each travel lane. Volume and Occupancy data is used to derive traffic flow speeds. A front-end-processor (FEP) and controller keeps transmitting field traffic flow data into a data processing server in which the traffic-detection system resides, as shown in **Figure 4**. In the meantime, operators in the TMC are monitoring the traffic flow via Closed Circuit Television (CCTV) cameras installed along the corridors as well as the Geographical Information System (GIS) map interface module imbedded in ATMS. Detector data containing such anomalies as missing values and unreasonably high or low values will be filtered to ensure "smoothed" data for data aggregation. The level of data aggregation must be therefore treated specifically concerning the cyclic nature of traffic at signal-controlled junctions along arterials, or simply by a certain period of time (e.g., aggregation by minute). Data measured in the format of volume and occupancy as well as speed is received by the incident detection subsystem through data acquisition on a certain time interval, as shown in **Figure 4**.

Incident Detection: An automatic incident detection algorithm embedded in ATMS automatically detects incoming traffic volume and occupancy as well as the derived speed from the traffic detection subsystem. If variables at a particular detector and its downstream detector have abnormal or over-threshold changes, depending on the type of incident detection algorithm that is being used, a potential incident somewhere between the upstream detector and the downstream detector

may be inferred.

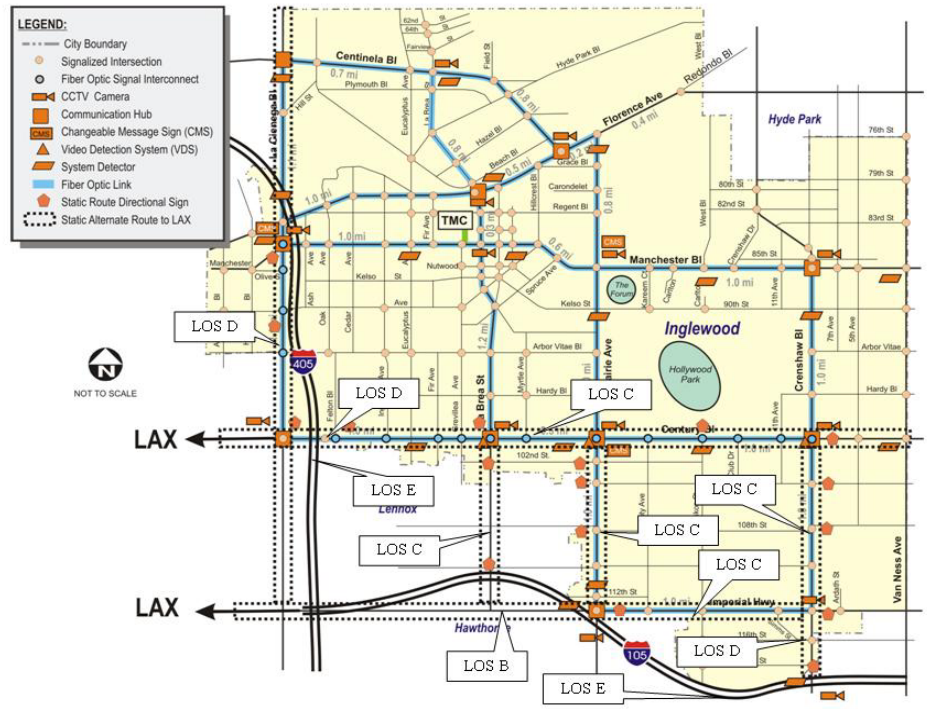

Figure 2. Proposed Alternate Routes to LAX and ITS Elements.

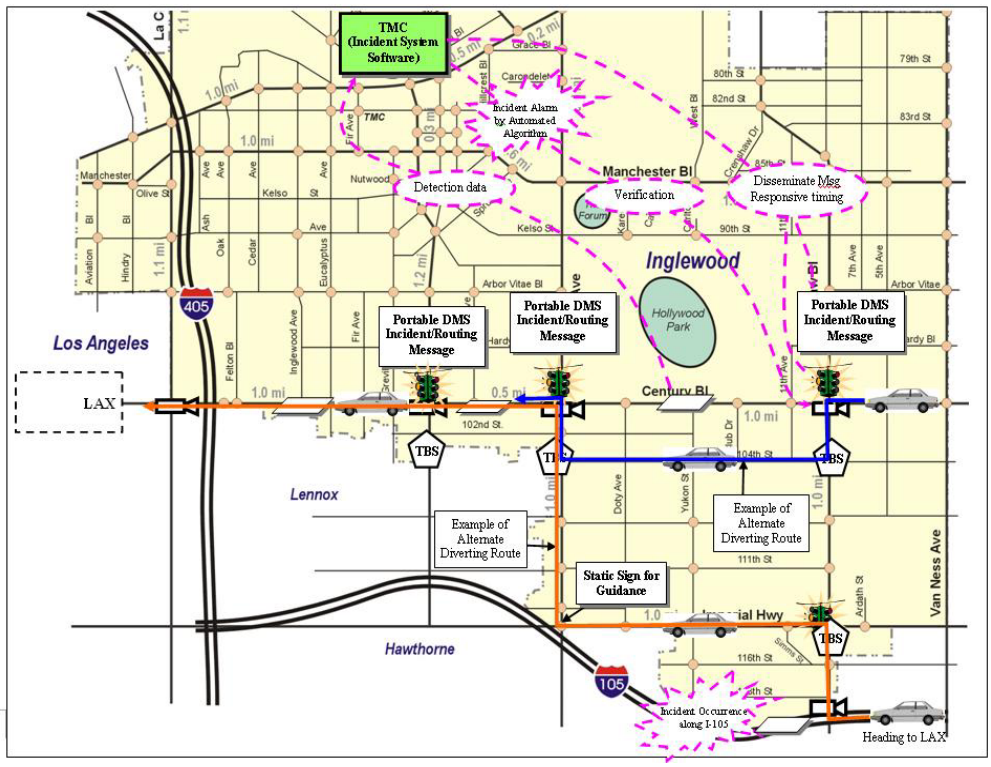

Figure 3. Operational Scenario of Route Guidance with ATIS/ATMS.

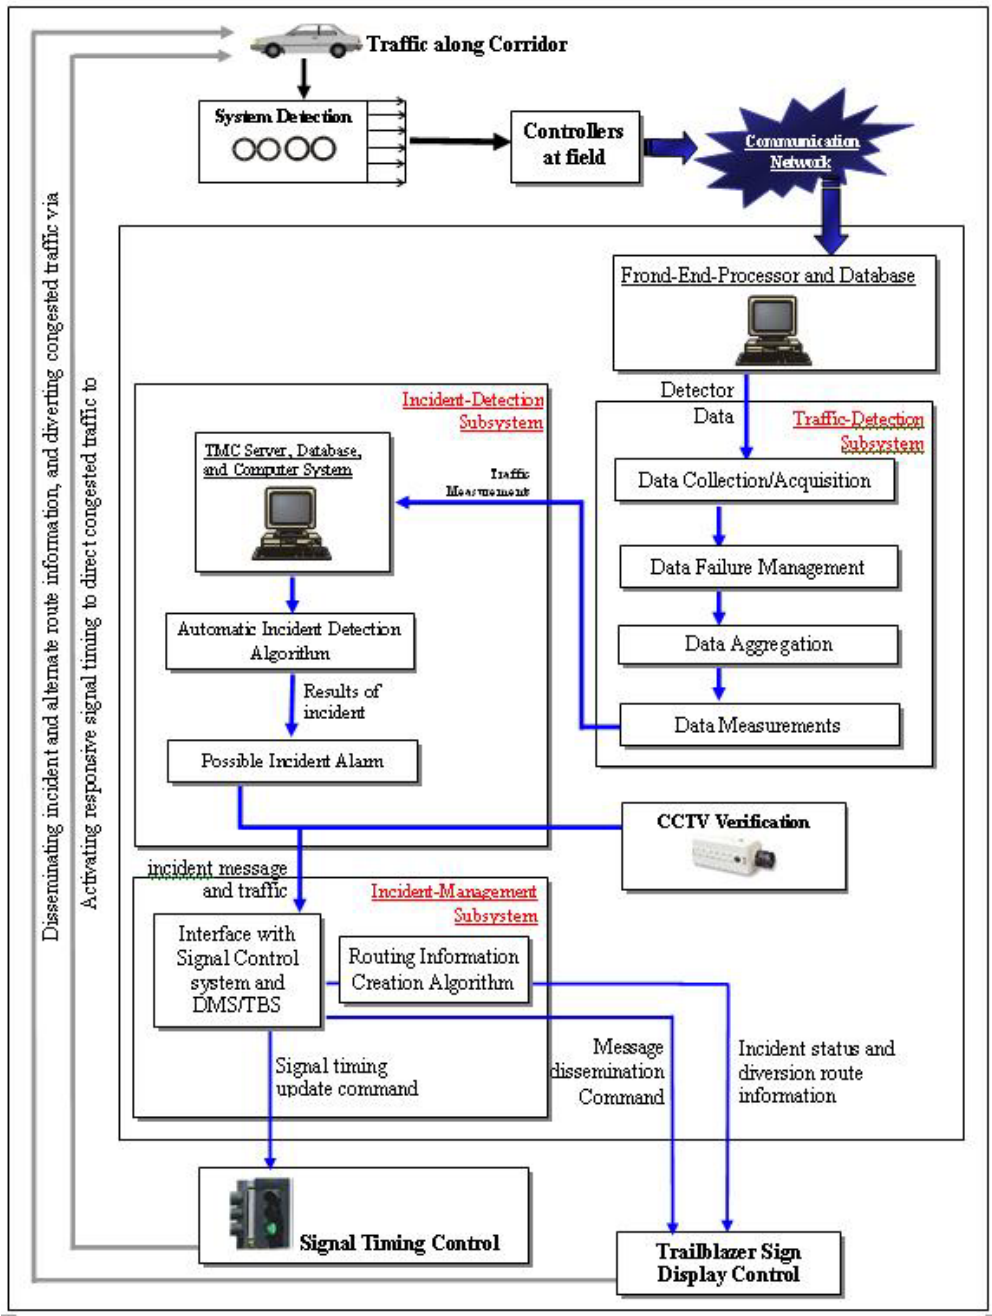

Figure 4. Concept of Operations for the Incident Management Scenario.

For example, as shown in **Figure 3**, the identified incident location is on the segment of Century Boulevard between Prairie Avenue and Crenshaw Boulevard. The videowall and/or workstations in TMC will display a message box with a flashing alarm incident message. In the meantime, the incident location is also highlighted or flashed onto the GIS-based map. The operator could then click on an incident icon on the map to display details about the traffic flow in the vicinity of the

incident. The operator then remotely controls the CCTV cameras at both Century/Crenshaw and Century/Prairie to verify the incident (**Figures 3** and **4**).

Divert Traffic via Route Guidance System and Signal Control Strategy: If an incident is verified, incident notification messages will be automatically sent to CMS and trailblazer signs (TBS) on the arterials in the vicinity of the incident location. The same alerts will also be displayed to traffic operators in the TMC. The messages displayed may guide drivers around the incident location to use other alternate routes.

The TBS and other roadside static directional signs will indicate the guidance information for detour, as shown in **Figure 4**. To make efficient use of the alternate routes and quickly disperse the accumulated traffic, signal control timing plans in the vicinity of the incident location will be adjusted on a real-time basis to accommodate the diverting traffic demand.

Similarly, traffic heading to LAX on I-105 could use an alternate route on a major or minor corridor to avoid incident related congestion occurring on that freeway. An example of this alternate routing from the freeway is shown in **Figure 4**. A TBS and a static directional sign will help guide the drivers the alternate route to LAX. A CCTV camera installed near the I-105 ramps along Crenshaw will allow the operators in TMC monitor traffic status near the I-105 and Crenshaw Boulevard.

DIAGRAMMATIC SIGNS FOR ALTERNATE ROUTE GUIDANCE

Trailblazer signs (TBS) and diagrammatic signs are recommended based on a number of studies on effectiveness of various roadside static signs (Zwahlen et al. 2003; Spencer et al. 2004). Diagrammatic signs have been proven very effective but quite costly, especially for multiple-lane streets connecting to freeway ramps, or exclusive turning lanes (Zwahlen et al. 2003). Zwahlen et al's study (2003) indicates that ground mounted diagrammatic signs on multi-lane arterials in advance of highway interchanges do provide useful navigational information, including the correct lane to enter the desired entrance ramp. Most evaluators felt that two right shoulder mounted diagrammatic signs, placed ½ mile (800 m) and ¼ mile (400 m) in advance of the interchange, are recommended. Hanscom (1971) reported, via a before-and-after study, successful applications of the diagrammatic signs on locations where "erratic maneuvers" frequently occur. Erratic maneuvers include weaving, hesitations, stop, and backup behaviors.

Several types of diagrammatic signs are recommended and introduced in the paper: freeway and arterial connector guidance, route information system (RIS) guidance, alternate route mileage information sign, and dynamic alternate route guidance signs. Typical examples of those diagrammatic signs are illustrated in **Table 2** and described below. Additionally, Carolina DOT's permanent static trailblazers (NCDOT 2001) of Hurricane Evaluation Route and incident alternate route on I-95 could be referred to a new design of traffic diversion alternate signs and location determination.

Route Information System Guidance (RIS) Sign: the development of the RIS stemmed from the need to show not only the usual information but also to give graphic representations of network-based route system (e.g., ring roads of a road network) (Vialis Traffic & Mobility 2004). The RIS indicates a tailback by means of

light points that may appear in a static or dynamic road sign. The example in **Table 2** shows a dynamic sign provides route direction information about the loop roads and shows congestion situation graphically. The system can inform through traffic of any congestion on the through route and also show any alternate routes. A detour route on this board can be shown if a severe congestion happens or a road is closed.

Table 2. Examples of Diagrammatic Signs for Alternate Route Guidance.

Route Information System Guidance Sign

Source: Vialis Traffic & Mobility 2004; FHWA 2003

Alternate Route Travel Time/Mileage Information Sign: this sign is typically used for a principle corridor to present travel time and/or mileage information to each egress that connects to other major routes or corridors. **Table 2** shows an example of real-time route information (Vialis Traffic & Mobility 2004).

Dynamic Alternate Route Guidance Sign: it is used to manage traffic for special planned or emergency events. It is essential that the diverted traffic encounter an equal or higher level of service on the alternate route compared with the mainline. Alternate route plan deployment typically requires significant law enforcement resources for alternate route traffic management and operations surveillance. Technology applications of dynamic alternate route guidance signs could reduce field personnel requirements. **Table 2** shows a dynamic trailblazer sign. During the program planning phase, stakeholders managing planned special events at permanent venues should evaluate the need for installing these devices along commonly used alternate routes serving the event venue (FHWA 2003).

CONCLUSIONS

The study presented in this paper discloses the functional and operational importance of a signing alternate route guidance system for traffic diversion strategies in a mixed roadway network. The most significant contribution of the study is the newly proposed concept of merging roadside signing route guidance systems into ATIS/ATMS planning and implementation in a mixed network. This paper presents a practical method to identify locations that are important to the network and to determine alternate routes to specific freeways and large traffic generators/attractors via an analysis of incident management scenario. The paper addresses signing route guidance system connecting non-crossed freeways in a mixed roadway network utilizing local streets. Finally, the authors attempt to summarize types of alternate route guidance signs with illustration of design examples. They are expected to provide necessary alternate route guidance infrastructures for enhancing ITS functionality. It is believed to be an important topic that has not been drawn intensive attention in past. Further research will focus on a system design of a specific alternate route guidance system for a typical freeway in an urban area, and conduct a microscopic simulation study to evaluate the operation and benefits of the alternate routes with ITS technology alternatives.

ABSTRACT

Driving fatigue is one of the main causes of traffic accidents. Many researchers believe that electroencephalography (EEG) is an accurate and promising method to detect driving fatigue. Based on the theories of biocybernetics, this article developed an EEG-based driving fatigue prediction indicator, and the process of calculating it was detailed. After indoor-experimental verification, it was found that the indicator has a good linear correlation with spirit response speed. The results have implications for predicting driving fatigue and are helpful for future development of driving fatigue countermeasures.

INTRODUCTION

Driving fatigue is no doubt harmful to traffic safety. While fatigue-related accidents are not a big part in all road traffic accidents, they are much more serious than the others. Therefore, it is necessary to take a series of countermeasures to avoid driving fatigue accidents.

At present, there are three main categories of countermeasures: behavioral countermeasures, technological countermeasures, and regulatory countermeasures. Behavioral countermeasures have little effect and few lasting restorative benefits; regulatory countermeasures are inflexible and their enforcement is costly and difficult; technological countermeasures' validity remains to be seen (Hartley 2004). In these three categories of countermeasures, research is focused on technological countermeasures, because they have some characteristics such as real-time and accuracy, which can make the countermeasures more effective to reduce fatigue-related accidents. In technological countermeasures, many researchers believe that electroencephalogram (EEG) can reflect the state changes of driving fatigue accurately and can be used as a predictor.

However, EEGs are only digital signals. These signals have no meaning themselves. They must be analyzed, and then quantitative indicators, which can represent the individual's mental state, can be determined. In past studies, researchers used EEGs as general engineering signals, and always extracted indicators based on signal spectral analysis. Compared with the indicators associated with slow-wave increase or slow-wave frequency increase used in conventional visual analysis of the EEG, these indicators are just a more precise expression form, and the effect does not exceed the effect of visual EEG analysis. Budi Thomas Jap investigated 8 EEG power spectrum indicators commonly researched in previous studies in a driving

simulator and found that the relationship between these indicators and the degree of driving fatigue are not entirely consistent with other research (Jap 2009). Therefore, these indicators are not precise predictors of driving fatigue, and their reliability has not been proven.

Since EEG signals are biomedical signals, in order to reflect the status of driving fatigue more accurately, more and more researchers are introducing the methods that are more suitable when analyzing biomedical signals. Peng (2007) introduced non-linear theory and believed that the correlation dimension indicator can reflect the characteristics of EEG when the driver is fatigued. Peng (2008) also proposed a new method to process EEG signals, which combined the Hilbert-Huang Transform method and approximate entropy method. He proved that the calculated values of that method can help distinguish the EEG between sitting quietly and driving between normal state and fatigue state. However, these indicators are rather cumbersome to calculate, so it is difficult to apply it in practice.

In order to get fatigue information from EEG signals, from the point of ergonomics, this paper introduces biocybernetic theories to process EEG by multiphase information analysis and develops a new driving fatigue indicator.

EXPERIMENTAL PROGRAMS

Experimental protocol

In the real world, it is dangerous for drivers to take part in driving fatigue experiments. In addition, the EEG recording system has poor anti-jamming ability, so the requirements on collecting environmental factors are higher, and it is difficult to control the factors in the real environment (Lal and Craig 2001). Therefore, as the basis for follow-up study, this article used simulation experiments. In the future, the effectiveness of the indicators can be verified using a driving simulator or in a real road environment.

Driving is a task composed of mental work and manual work. The volume of manual work is equal to the volume of general administrative work, while the volume of mental work is larger. Therefore, driving is a kind of sensory nerve task; driving fatigue is almost mental fatigue. Hence, mental fatigue research methods can be introduced into the study of driving fatigue. In the study of mental fatigue, the medical model of mental fatigue is very difficult to set up because there are many factors that may affect it. Therefore, sleep deprivation is commonly used to set up the medical model of mental fatigue. This is because: firstly, the negative effects of sleep deprivation on the human body are similar to the effects of mental fatigue, such as the level of operation is reduced and alertness is decreased; secondly, the controllability of sleep deprivation is larger, namely, the deprived time can be shorter or longer; thirdly, sleep deprivation is safe and does not harm human physiological and psychological functions. Consequently, although the negative statuses of human physiological and psychological functions affected by mental fatigue are not equal to which affected by sleep deprivation, the latter is accepted as a special case of the former (Xue et al. 2006).

Accordingly, this paper used the sleep deprivation method. The experiment started at 3:00 p.m. and at the beginning of the experiment all the participants had

been awake at least 19 hours. The fatigue arising from this situation is considered driving fatigue.

Independent indicators

The main purpose of this paper is to verify whether the developed EEG indicator can predict the degree of driving fatigue. Because fatigue cannot be directly measured, it is necessary to introduce some indicators as independent indicators to quantify the extent of driving fatigue. These factors are recognized in a large scope and easy to control. Through analyzing the relationship between these independent indicators and the developed EEG indicator, the effectiveness of the EEG indicator can be determined. However, many studies have overlooked the importance of independent indicators, and usually determine the extent of driving fatigue arbitrarily. In this way, their experimental results are unreliable. In this study, two independent indicators were used.

Subjective evaluation indicator

Most driving fatigue studies used the subjective evaluation method. This article asked the subjects to fill out self-reported fatigue level questionnaires (see Table 1) according to their own subjective feelings. Zhao (1992) had presented the questionnaire design principles and quantified methods. The quantified values were called subjective fatigue degree (SFD).

Table 1. Self-reported fatigue level questionnaire.

State / Level	Very alert	Alert	Not sure	Fatigue	Very fatigue
3 2 1					
-1 -2 -3					

Compared with other methods, subjective evaluation methods are simple to conduct and can save resources, but lacks objectivity. In order to ensure the reliability of scientific research, this kind of indicator should not be used alone, and some objective indicators need to be taken into account (Lal and Craig 2001).

PVT indicator

Psychomotor vigilance task (PVT) is a widely used standard test for the spirit response speed, which has better objectivity and reliability with mental fatigue (National Highway Traffic Safety Administration 1998). For driving fatigue measurement, PVT is suitable. Since the main requirement of driving task is response fast, and PVT is based on reaction time. Therefore, in the study of driving fatigue, it is appropriate to use the PVT result as an independent indicator.

According to the principle of PVT, the paper programmed the test using Stim2 software of Neuroscan. The task for the participants is to respond using a button when visual signals are shown in the middle of a black 17-inch LCD screen. The signal was yellow circle with a radius of 4 centimeters, and the emergence was random from 2 to 10 seconds. Participants were asked to use their right hand

(left-handed person left hand), and when the signal appears, press the mouse button as soon as possible. After the signal disappeared, the software will record the reaction time automatically. The task lasted 10 minutes. The length of the test and the data statistical method are various, but, once they are specified, PVT scores can be compared between different experiments.

The paper deleted the beginning three and the ending two data from every task result to remove the effect of adaptation. Then the average reaction time of the original 1 minute and the last 1 minute was calculated to present participants' mental status before and after PVT. As an independent indicator, it was named as vigilance reaction time (VRT).

EEG indicator

The NeuroScan 36 channel EEG recording system was used to record the EEG, whose Ag/AgCl electrode cap is easy to wear. Thirty-two EEG channels were recorded following the International 10-20 Montage system and referenced to right ears and sampled at 1000 Hz covering the major areas of the brain.

This article introduced biocybernetics theories to obtain fatigue information from EEG signals and developed a new indicator. The theoretical bases of the new indicator are as follows.

a. The human brain can be perceived as a control system, and EEG indicators are variables that change with time and space, which can describe its activities. Therefore, in the analysis of EEG, the laws and models that have been expounded in physical, mechanical, and other systems can be used. It will be helpful for understanding the nature of brain activities and patterns.
b. According to bio-medical theories, when the brain is fatigued, the power spectrum value of EEG alpha band will increase, while the information transmission and coordination between the two cerebral hemispheres will decrease (Feng 1986). In cybernetics theories, the amplitude-frequency and phase-frequency characteristics of the system transfer function, as well as the coherence function, can reflect the information transmission and coordination capability of the system.
c. During the process of driving, the entire brain takes part in the task. Because the temporal lobe is easily affected by outside sounds, such as human voice and car audio, the EEG signals from the frontal lobe, parietal lobe, and occipital lobe of the brain are taken into account.

Based on the theoretical analysis above, this article developed an indicator, named driving fatigue level (DFL), to measure the degree of driving fatigue. The calculation program is as follows.

a. Scan4.3 software was used to transfer the recording reference to linked ears and then remove the vertical ocular artifacts from original EEG data.
b. To the corresponding lobar, the signal from the left lead x_k is as input, and the signal from the right y_k is as output. Calculate the Fourier transform of x_k and y_k, recorded as X_f and Y_f.
c. Calculate the self-power spectrum of x_k, recorded as G_{xf}, and the cross-power spectrum of x_k and y_k, recorded as G_{xyf}.

Where, N is the number of signal sampling point, "*" indicates complex

conjugate.

d. Calculate amplitude-frequency and phase-frequency characteristic of transfer function between x_k and y_k.

if $X = \frac{G_{xyf}}{G_{xf}}$, then amplitude-frequency characteristic $|H_{xyf}| = |X|$, and

phase-frequency characteristic $\theta_{xyf} = \tan^{-1}\frac{\mathrm{Im}(X)}{\mathrm{Re}(X)}$

e. Calculate coherence function γ^2_{xyf} between x_k and y_k.

f. According to the self-power spectrum of the left lead signal from corresponding lobar, find alpha-wave dominant frequency (shown in Figure 1).

g. Obtain values at the point of alpha-wave dominant frequency, and calculate DFL.

$$G_{xf} = \frac{1}{N}|X_f|^2 = \frac{1}{N}X_f{}^* X_f \quad f = 0,1,\cdot\cdot,N-1 \qquad G_{xyf} = \frac{1}{N}X_f{}^* Y_f \quad f = 0,1,\cdot\cdot,N-1$$

$$\gamma^2_{xyf} = \frac{|G_{xyf}|^2}{G_{xf}G_{yf}} \quad f = 0,1,\cdot\cdot,N-1 \qquad DFL = \frac{1}{3}\sum_{lobar}\frac{\sqrt{G_{xf}}}{|H_{xyf}|\times\log_e|\theta_{xyf}|\times\gamma^2_{xyf}}$$

Experimental procedure

Nine young male participants who were licensed drivers were recruited in the study. The average age was 25. The participants first wore the EEG electrode cap, and then filled in the self-reported fatigue level questionnaire. Thirdly, they were asked to do a PVT test, and at the same time the EEG was recorded. After PVT, they were asked to fill in the self-reported fatigue level questionnaire again.

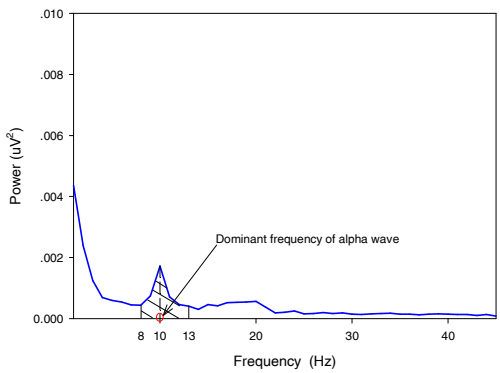

Figure 1. Alpha-wave dominant frequency calculation diagram.

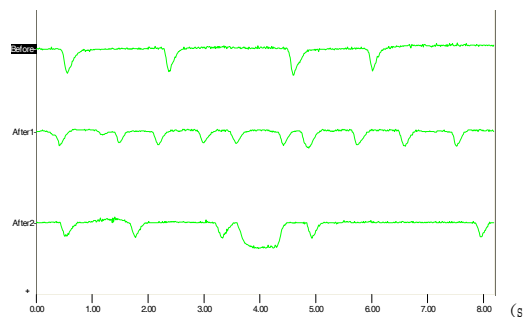

Figure 2. Example of vertical EOG before and after PVT test.

DATA ANALYSIS

Participants completed a PVT test under sleep deprivation. Their status was similar to the status under driving fatigue. Although the test time was only 10 minutes, it was enough to affect the mental state. This can be seen from the participants' vertical electrooculogram (EOG). As it was shown in Figure 2, there were three 8-second examples about the vertical EOG before and after the PVT. The EEG recording system collects EEG as well as EOG. EOG are electrical eye movement records from which we can see the movement of the eyelid. The movement of the

eyelid can reflect the level of fatigue to some extent (National Highway Traffic Safety Administration1998). As can be seen from Figure 2, at the beginning of PVT test, the blinks were fast, large-range, and independent. At the end of the test, the blinks became smaller in amplitude, faster in frequency, and continuous. Some participants' blinks became longer in time, as shown in Figure 2 After2.

Therefore, this article compared the EEG indicator with independent indicators before and after the PVT test (shown in Figure 3). It can be seen from the chart that:

a. all participants SFD were increased, which means that the PVT test can affect their mental state and make them feel fatigue;
b. except for the 2nd and the 3rd participants, VRT and DFL was also increased with SFD; and
c. VRT and DFL had same change trend.

The Pearson correlation test was made between the growth of SFD, VRT, and DFL. Table 2 shows the results.

As shown in Table 2, DFL growth and VRT growth had little correlation with SFD, which means that the estimation about fatigue made by their own are not accurate. Even the estimation can be quantified, but it is still difficult to meet the requirements of data analysis. From Table 2, the positive correlation between DFL growth and VRT growth was high. Then a linear regression analysis was made between them, as it was shown in Figure 4.

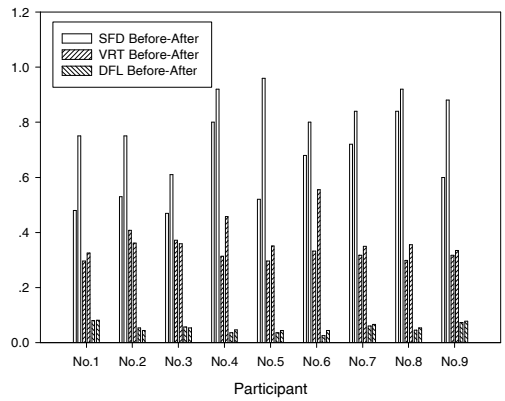

Figure 3. Changes of SPD, VRT, and DFL before and after every test.

Table 2. Pearson correlation matrix of SFD growth, VRT growth, and DFL growth.

	SFD growth	VRT growth	DFL growth
SFD growth	1.000		
VRT growth	-0.288	1.000	
DFL growth	-0.219	0.915	1.000

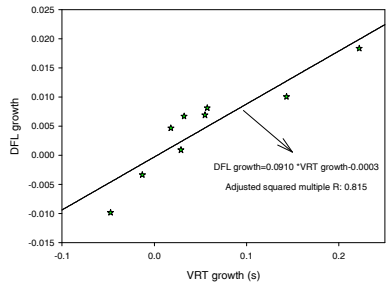

Figure 4. Linear regression results between DFL growth and VRT.

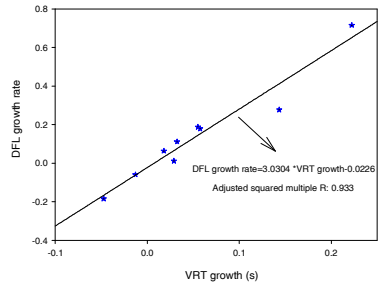

Figure 5. Linear regression results between DFL growth rate and VRT growth.

DFL growth was divided by the DFL before PVT test, and then the DFL growth rate was calculated. It removed individual impact on DFL. Figure 5 shows the results of linear regression between DFL growth rate and VRT growth.

CONCLUSION

PVT reaction time reflects the operational efficiency from eye to hand. Compared to the subjective methods or biochemical methods, it is more reliable and more acceptable to evaluate fatigue by operating performance (Zhu 2003). In this paper, there is a fine positive correlation between the growth rate of the EEG indicator and PVT growth, which means that the DFL growth rate can accurately reflect changes in operating performance. If this EEG indicator can be verified in the real driving environment, it could be used as a real-time driving fatigue monitoring instrument and applied to the field of fatigue countermeasures.

FUTURE WORK

This paper applied a sleep deprivation method to induce mental fatigue. After all, the mechanism of sleep is not the same as the driving fatigue mechanism, so, the findings of this paper required verification in the real world.

The purpose of driving fatigue research is to determine the threshold of fatigue and to judge a driver's fatigue level. If the driver was judged fatigue by the threshold, then he or she is not safe to drive. It is a feasible method to determine the threshold by the relationship between DFL growth rate and driver reaction time, and it is worth continued research.

ABSTRACT

The total braking torque(T) of a self-excited retarder is mainly made up of both the electromagnetic torque(T_g) of its power generation unit and the braking torque(T_e) of its eddy current brake. Calculation formulae for T_g and T_e were derived from the structure parameters respectively on the basic of the Magnetic Flux method and the Electromagnetic Theory. After verification by experiment, the total braking torque calculated theoretically was basically consistent with the experimental result for a 500Nm self-excited retarder. This would lay a theoretical foundation for further study on the relation between braking torque and structural parameters and optimizing the design for a self-excited retarder.

INTRODUCTION

Self-excited retarder is a kind of electromagnetic brake which integrates a power generation unit and an eddy current brake. When a vehicle brakes or decelerates, the power generation unit makes use of vehicle's movement inertia as initial power and transforms vehicle's kinetic energy into electrical energy which further powers the eddy current brake to achieve the purpose of brake or deceleration. So a self-excited retarder does not require vehicle batteries to provide excitation current and is free from the additional energy loss. At same time, it avoids bringing negative impact to other vehicle's electronic equipment. The total braking torque(T) of a self-excited retarder is mainly made up of both the electromagnetic torque(T_g) of its power generation unit and the braking torque(T_e) of its eddy current brake, i.e. $T=T_g+T_e$.

THE ELECTROMAGNETIC TORQUE(T_g)

The power generation unit, a rare-earth permanent magnet synchronous generator with radial structure, is usually divided into two parts: one is the stator (i.e. magnetic pole and armature winding) fixed on transmission body, another is the rotor(i.e. permanent magnet) connected to the vehicle's drive shaft by flange. Both the virtual displacement and the Maxwell tensor are two basic methods to caculate the electromagnetic torque(T_g) of a permanent magnetic machine. However, the former employs that one large number subtracts from another similar and this directly leads to reduction of T_g's effective bits. And the later is more sensitive to the density of finite element mesh and its accuracy depends on the selected integral path and the mesh quality[TANG Renyuan, 1997]. The Magnetic Flux method introduced in this paper is unsignificantly sensitive to the density of finite element mesh and is just determined by the magnetic flux within a pole space and less affected by the partial error.

The internal phasor diagram of a permanent magnet synchronous generator is shown in Figure1.

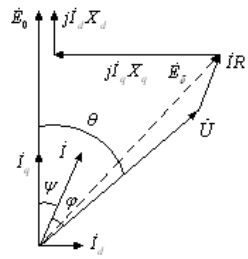

Figure 1: The internal phasor diagram of a permanent magnet synchronous generator.

The relation between variables described by Figure1 can be rewritten as the following equation(1):

$$\begin{cases} U\cos\theta = E_0 - I_d X_d - IR\cos(\theta-\varphi) \\ U\sin\theta = I_q X_q - IR\sin(\theta-\varphi)\psi \end{cases} \tag{1}$$

where, θ: power angle which is positive when $\dot{E}_0$ advances $\dot{U}$ in phase, φ: power factor angle which is positive when $\dot{I}$ advances $\dot{U}$ in phase, ψ: internal power factor angle which is positive when $\dot{E}_0$ advances $\dot{I}$ in phase, $\dot{E}_0$: no-load electromotive force, $\dot{U}$: armature terminal voltage, $\dot{I}$: armature winding current of each phase, R: armature winding resistance of each phase, X_d :direct-axis synchronous reactance, X_q: cross-axis synchronous reactance, I_d and I_q are the direct-axis armature current and the cross-axis armature current respectively, and $I_d = I\sin(\theta-\varphi)$, $I_q = I\cos(\theta-\varphi)$.

If disregarding the voltage of armature winding resistance, the inductive electromotive force $\dot{E}_\delta$ (i.e. air-gap EMF) of each phase approximately equals to armature terminal voltage $\dot{U}$. Thus, the equation(1) can be simplified as:

$$\begin{cases} E_\delta \cos\theta = E_0 - I_d X_d \\ E_\delta \sin\theta = I_q X_q \end{cases} \quad (2)$$

Projecting I_d and I_q onto $\dot{E}_\delta$, the electromagnetic power P_{em} of air-gap can be obtained:

$$P_{em} = mE_\delta I\cos\varphi \quad = mE_\delta(I_q\cos\theta + I_d\sin\theta) \quad (3)$$

where, m : phase-number of a permanent magnet generator. Air-gap EMF E_δ can be caculated by the following[TANG Renyuan, 1997; LIN Rongwen, 2004]:

$$E_\delta = \sqrt{2}\pi f \Phi_{1N} N_1 K_{dp} K_\Phi \quad (4)$$

where, $f = pn/60$: frequency of output voltage, p: the number of pair-poles, n: rotator speed, Φ_{1N}: fundamental air-gap flux when a permanent magnet generator is loaded, N_1 : number of series-wound armature winding for each phase, K_{dp}=$K_{d1}K_{p1}K_{sk1}$: winding factor. Thereinto, K_{d1} is armature winding distribution factor, K_{p1} is armature winding short-distance factor, K_{sk1} is flume factor.

According to the relation between torque and power, i.e. $P = wT$, the electromagnetic torque can be obtained.

$$T_g = \frac{P_{em}}{w} = \frac{mE_\delta}{w}(I_q\cos\theta + I_d\sin\theta) \quad (5)$$

where, $w = 2\pi n/60$ which is mechanical angular velocity of a permanent magnet generator. From the equations(4), (5):

$$T_g = \frac{mp}{\sqrt{2}}\Phi_{1N} N_1 K_{dp} K_\Phi (I_q\cos\theta + I_d\sin\theta) \quad (6)$$

If Φ_{1N} and θ can be caculated accurately, the electromagnetic torque(T_g) of the power generation unit can be obtained. Caculating Φ_{1N} and θ can be recured to magnetic vector potential A on the stator's inside surface and two-dimensional finite element analysis. First, node's magnetic vector potential A within a period, which is caculated by the finite element analysis, is sampled to be discrete sequence. Second, the discrete sequence is taken the Fourier Transform. Hence, the node's magnetic vector potential A can be described as[J.M Arinescu, 1988; LI Kaicheng, 2000; LIN Rongwen, 2004]:

$$A(x) = \frac{a_0}{2} + \sum_{k=1}^{\infty}[a_k\cos\frac{k\pi}{l} + b_k\sin(\frac{k\pi}{l})] \quad (7)$$

where, l: arc-length of half period(each pole).

In equation(7), a_1 is half of q-axis component of each-pole magnetic flux within armature unit-length, b_1 is half of d-axis component of each-pole magnetic flux within armature unit-length. Therefore, synthetic magnetic flux of each pole is:

$$\Phi_{1N} = 2L_{ef}\sqrt{a_1^2 + b_1^2} \tag{8}$$

where, L_{ef} : armature calculation-length.

Power angle can be expressed as:

$$\theta = arctg\frac{a_1}{b_1} \tag{9}$$

From equations(6), (8) and (9), the electromagnetic torque(T_g) can be caculated accurately.

THE BRAKING TORQUE(T_e)

The structure of an eddy current brake is usually divided into two parts: one is the rotor(i.e. rotary drum) connected with drive shaft by flange, another is the stator(i.e. pole and excitation coil) fixed on transmission body. The air-gap between the primary and the secondary is from 1mm to 1.5mm. Rotary drum is made of iron with good magnetoconductivity and low remanence ratio, such as electrical pure iron, low-carbon steel or alloy steel etc. Its outerside surface usually is founded with cooling fin so as to dissipate heat in time.

Magnetic field generated by excitation current forms a closed-loop in magnetic pole, air-gap and rotary drum, shown as Figure 2. Rotating drum cuts magnetic line and

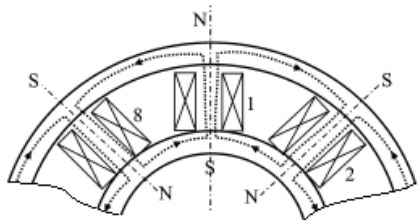

Figure 2: Distribution of magnetic pole and magnetic line.

produces eddy current in its inside surface. Because of skin-effect, eddy current mainly distributes within a thin layer of drum's inside surface and behaves as decaying exponential $e^{-\sqrt{w\mu\sigma z/2}}$ with the deepening of penetration depth. The equivalent penetration depth Δh is usually employed in engineering calculation and the amplitude of eddy current in the point of Δh reduces e times compared with that of inside surface[HE Ren, 2006], i.e. $e^{-\sqrt{w\mu\sigma\Delta h/2}} = e^{-1}$. Thus Δh can be obtained.

$$\Delta h = \sqrt{\frac{2}{w\mu\sigma}} = \sqrt{\frac{2\rho}{w\mu}} \tag{10}$$

where, σ : drum conductivity, ρ : drum resistivity and $\rho = 1/\sigma$, $\mu = \mu_r\mu_0$: drum magnetic permeability, μ_r : relative magnetic permeability, μ_0 : vacuum magnetic permeability, w: angular velocity of magnetic field and $w=2\pi N_p n/60$, N_p: the

number of pair-poles, n: the rotor speed.

In order to facilitate the analysis of braking power for the eddy current brake, the following assumptions are made: (1)The magnetic flux generated by excitation current just distributes within magnetic poles and disregards the flux leakage. (2)The relative magnetic permeability of magnetic material is a constant. (3)Ignore the mutual interaction between magnetic poles. (4)Magnetic line vertically penetrates the inside surface of drum. (5)Arc region, which is the area of drum's inside surface opposite the magnetic pole, is approximately regarded as a rectangle. This arc region can be equivalent to numerous linear conductors and all of them parallel drum-axes as shown as Figure 3.

When drum rotates, linear conductors vertically cut magnetic line with the speed $v=Dw$. According to the law of electromagnetic induction, electromotive force ε generated on linear conductor is

$$\varepsilon = Bvb = BDwb \tag{11}$$

where, D: inner radius of drum, b: length of magnetic pole along drum-axis, B: air-gap magnetic flux density.

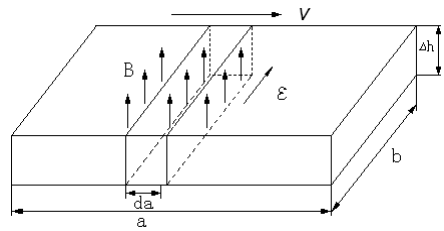

Figure 3: Schematic diagram of calculation model.

Resistance, current and power of linear conductor respectively is :

$$dR = \rho \frac{b}{\Delta h \cdot da} \tag{12}$$

$$di_e = \frac{\varepsilon}{dR} = \frac{BDw\Delta h}{\rho} da \tag{13}$$

$$dp = \frac{\varepsilon^2}{dR} = \frac{B^2 D^2 b w^2 \Delta h}{\rho} da \tag{14}$$

From equation(14), the braking power of each excitation coil can be obtained:

$$p = \int_0^a dp = \frac{B^2 D^2 w^2 S_{极}}{\rho} \Delta h \tag{15}$$

Hence, the total braking power of eddy current brake is:

$$P = \frac{2N_p B^2 D^2 w^2 S_{极}}{\rho} \Delta h \tag{16}$$

where, $S_{极} = a \times b$: pole area, a : the length of magnetic pole along rotor's circumference. Air-gap magnetic flux density B is the interactional result of the excitation current and the eddy current. Likewise, the magnetomotive force is also the interactional result of the excition curren and the eddy current. Therefore, the following equation holds[SUN Weimin, 2005]:

$$\Phi_m^{'} = \Phi_m - \Phi_e \tag{17}$$

where, Φ'_m : air-gap magnetomotive force, $\Phi_m = N_2 I$: magnetomotive force generated by excitation current, I: the excitation current, N_2 : the number of excitation coil, $\Phi_e = eI_e$: magnetomotive force generated by eddy curren, $e = \pi^2 \mu_0 \Delta h^2 / (3\rho^2)$: eddy current loss coefficient, I_e : the eddy current of the whole arc region[ZHAO Kaihua, 1985; SUN Weimin, 2005], and from equation(13)

$$I_e = \int_0^a di_e = \frac{BDaw\Delta h}{\rho} \tag{18}$$

Thus, magnetic flux of the arc region can be described as:

$$\theta = BS_{极} = \frac{\Phi_m - \Phi_e}{R_m} \tag{19}$$

The total reluctance R_m of magnetic circuit is[ZHAO Kaihua, 1985; SUN Weimin, 2005]:

$$R_m = 2R_{m0} + R_{m1} + 2R_{m2} + R_{m3} \approx R_{m0} = \frac{2L_0}{\mu_0 S_{极}} \tag{20}$$

where, R_{m0} : air-gap reluctance, R_{m1} : drum reluctance of a pole pitch, R_{m2} : magnetic yoke reluctance, R_{m3} : core reluctance L_0 : air-gap length.

From equation (19) and (20)

$$B = \frac{\mu_0 \rho N_2 I}{2\rho L_0 + \mu_0 Daew\Delta h} \tag{21}$$

Thus, from equation(16), (21) and $P = Tw$, the braking torque of the eddy current brake can be obtained:

$$T_e = \frac{2\mu_0^2 N_p N_2^{\ 2} D^2 w S_{极} \rho \Delta h I^2}{(2\rho L_0 + \mu_0 Daew\Delta h)^2} \tag{22}$$

THEORETICAL CACULATION AND EXPERIMENTAL RESULT

The power generation unit parameters of a 500Nm self-excited retarder are that

the number of pair-poles p=12, the number of armature winding for each phase N=8, the phase-number m=3, the rotor's outer diameter D_1=248mm, the stator's inner diameter D_2=249.5mm, the stator's outer diameter D_3=302mm, the length of air-gap δ=1.5mm. And the mechanical parameters of the eddy current brake are that the number of pair-poles N_p=6, the pole area $S = 36mm \times 48mm$, the drum inner diameter D_4=360mm, the drum outer diameter D_5=386mm, the length of air-gap L_0=1mm.

Theoretical curve of braking torque and that of experiment is shown as Fig.4. The total braking torque of theoretical calculation is basically consistent to the experimental result when drive shaft speed is lower than 1750r/min. But the difference between them tends to rise with the increase of drive shaft speed from 1750r/min. One of the main reasons for this phenomenon is that some factors which affect the braking torque, such as magnetic flux leakage, hysteresis loss and magnetic saturation etc, are not taken into account in order to simplify the derivation.

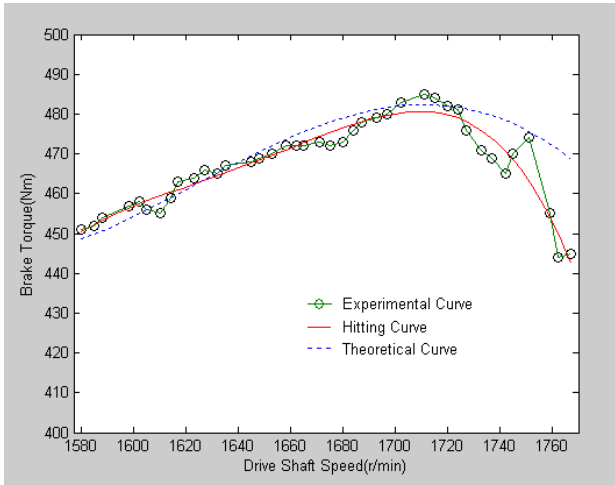

Figure 4: Braking torque curve.

CONCLUSION

The purpose of this study is to derive caculation formulae for the total braking torque from the structure parameters of a self-excited retarder. When the drive shaft speed is lower than 1750r/min, the relation between the total braking torque and the structure parameters can be precisely discribed by these formulae. So they can be taken as a reference in the design of the self-excited retarder. But further studies will be expected so as to perfect these formulae when the drive shaft speed is higher than 1750r/min.

ABSTRACT

Clutch engagement process of automatic mechanical transmission is investigated during the process of starting the vehicle. The kinetics of clutch engagement is analyzed and the dynamical equation was deduced. Clutch engagement speed is changed by body load and road condition. A method of correcting the driving intention is proposed to adopt quality of vehicle conversion coefficient. The more fuzzy input parameters arouse the more control rules and increase computational load of ECU; the method of double fuzzy controller is brought forward to control speed of clutch engagement. Simulation of the model is carried out in Matlab/Simulink. Results show that fuzzy control rules with quality of vehicle conversion coefficient can effectively improve clutch engagement process.

INTRODUCTION

In the development process of automatic mechanical transmission (AMT), the key issue is to control clutch engagement[Wang Yuncheng, 2000]. Automatic mechanical transmission removes the clutch pedal and controls clutch disengagement or engagement by ECU. The clutch control rules directly affect the vehicle starting and the service life of the clutch[Qi Zhanning, 2001]. During the process of starting a vehicle a basic requirement is that the process be smooth and without interference. A clutch engagement process is affected by the load, degree of slope, engine's rotation speed, gearshift and non-linear dynamic characteristics of the clutch, time-delay characteristics of the clutch engagement, external disturbance, and time-varying factors. It is difficult to control the clutch engagement for these very reasons. All across the world, scholars have conducted research and put forward various control methods[Lei Yulong, 2000]. However, these control methods involve complicated operations or their validity and robustness falls short of need. It is also difficult to guarantee real-time capability.

Road conditions and load differ each time a commercial vehicle starts up. In order to improve a vehicle's capacity to adapt to varied load and road conditions, clutch engagement speed is modified to use the parameters of vehicle load and degree of slope. At present, the throttle opening and the throttle opening rate of change are the input parameters of the controller, but the method that the vehicle load

and the varied road environment correct the clutch engagement has not been put forward. In this paper, the quality of vehicle conversion coefficient is a parameter to correct the driving intention to improve the clutch engagement. As more input parameters increase computational load, the double fuzzy controller is brought forward. This method of using the double fuzzy controller to control clutch engagement speed decreases the vehicle jerk and the friction..

QUALITY OF VEHICLE CONVERSION COEFFICIENT ζ

When the vehicle is started, incorrect clutch engagement speed arouses vehicle jerk or increases the friction work. Quality of vehicle conversion coefficient ζ is brought forward to correct the driving intention which is the output of the fuzzy controller.

Premising quality of vehicle without load is m. Road resistance reflects the road condition when the vehicle starts. Road resistance F_φ is:

$$F_\varphi = F_f + F_i = fmg\cos\alpha + mg\sin\alpha \qquad (1)$$

Where, F_f is rolling resistance. F_i is slope resistance. f is rolling resistance coefficient. α is an angle of slope.

When α is less, $\cos\alpha \approx 1$, $\sin\alpha \approx tg\alpha = i$.

Where, i is an angle of slope.

$$F_\varphi = mgf + mgi = mg(f + i) \qquad (2)$$

When the vehicle starts, vehicle speed is low thus air resistance is ignored.

Premising quality of vehicle with load is m_1, road resistance is:

$$F_\varphi = m_1gf + m_1gi = m_1g(f + i) \qquad (3)$$

Conversion quality of vehicle m' is the ratio of road resistance and rolling resistance with load. The formula is:

$$m'gf = m_1g(f + i)$$

$$m' = \frac{f + i}{f} m_1 \qquad (4)$$

Quality of vehicle conversion coefficient ζ is the ratio of conversion quality of vehicle m' and quality of vehicle without load m. The formula is:

$$\zeta = \frac{m'}{m} = \frac{f+i}{f} m_l \Big/ m \qquad (5)$$

DYNAMIC ANALYSIS OF THE CL UTCH

The role of the clutch is power transmission during the vehicle starting and the clutch engagement process is shown in Figure 1 [He Zhongbo, 2002; Liu Haiou, 2005].

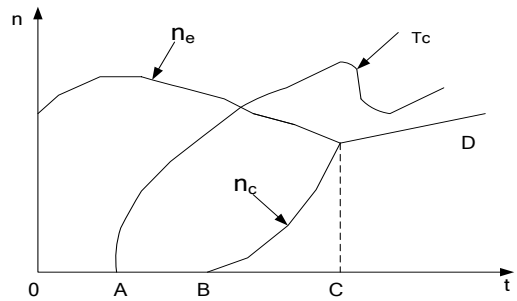

Figure 1. Clutch engagement Process.

From 0 to A, this stage eliminates the clutch idle stroke, so there is non-torque transmission. The clutch should engage as quickly as possible in this stage.

From A to B, friction is generated between the clutch master disc and the clutch slave disc. Transmission torque cannot overcome resistance torque, so the vehicle remains stationary. Considering the friction work, the clutch should engage as quickly as possible.

From B to C, the vehicle starts up because transmission torque from the clutch master disc to the clutch slaver disc can overcome resistance torque. The vehicle jerk is caused in this stage. In order to achieve smooth start-up of the vehicle, this stage should be a slowly bonding one.

Beyond C, clutch engagement speed has little effect on the friction work and the vehicle jerk because speed of the clutch slave disc has accorded with the speed of the clutch master disc. The clutch engagement should be completed quickly.

The clutch engagement dynamic model of the mathematical expression is[Luigi Glielmo, 2000; Zhao Yongsheng, 2006]:

$$J_e \dot{\omega}_e = T_e - c_e \omega_e - T_c \qquad (6)$$

$$J_v \dot{\omega}_v = T_c - c_v \omega_v - T_f \qquad (7)$$

Where the subscripts ‘e’ and ‘c’ are used for the engine and the clutch, respectively, ω_e is crankshaft angular speed (also called angular speeds of the engine)， J_e is the

moments of inertia for the engine, T_e is engine torque, c_e is damping coefficient at the engine, T_c is torque transmitted by the clutch, J_v is equivalent moment of vehicle inertia (it takes into account the presence of the clutch, the mainshaft, the powertrain and the vehicle), which will also depend on the gear ratio, ω_c is clutch disc angular speed, c_v is corresponding friction coefficient and T_f is equivalent load torque. Equation (6) models the rotation of the crankshaft, whereas (7) models the rotation of the so called clutch disk. The remaining part of the powertrain transmission system is simply modeled through the equivalent vehicle inertia J_v, and load torque T_f.

During the clutch engagement process, the dynamic characteristic of the diaphragm spring that the relationship between the load on the big end and the deformation on the small end is[Xi Gang, 2000]:

$$F_1 = \frac{\pi E\delta \ln(R/r)}{6(1-\upsilon^2)(R_1-r_1)^2}(\lambda_{11b} - k_{R1}\lambda_2)\times[(h - k_{r_1}\lambda_{11b} + k_1 k_{R_1}\lambda_2)\times (h - 0.5k_{r_1}\lambda_{11b} + 0.5k_1 k_{R_1}\lambda_2) + \delta^2] \quad (8)$$

Where R is outside radius of the diaphragm spring, r is inside radius of the diaphragm spring, E is elastic modulus, υ is poission ratio, h is inner cone higher, δ is plate thickness, R_1 is outer bearing radius, r_1 is inner bearing radius, λ_{11b} is the deformation of the big end, k_{R_1} is the ratio of the arm of force, $k_{R_1} = (R_1 - r_1)/(R_1 - r_F)$, r_F is deformation of the small end, k_{r_1} is the ratio of the arm of force, $k_{r_1} = (R - r)/(R_1 - r_1)$.

Generally the transmission torque of the dry clutch T_c is decided by the force, friction area and friction coefficient, which can be expressed as a function of the normal force applied to the clutch disk as follows:

$$T_c = z\mu F_1 R_{f,eq} \quad (9)$$

FUZZY C ONTROL OF THE CLUTCH ENGAGEMENT SPEED

Clutch engagement process is a nonlinear process. The open throttle and the road conditions embody the requirements for the vehicle start-up. The throttle opening and the throttle opening rate of change reflect the driving intention. In order to fully reflect the conditions of start-up, quality of vehicle conversion coefficient is a corrected factor to amend the driving intention which is the output of the fuzzy controller. The speciality of the fuzzy controller is the logic inference, and this simulates abstract thinking and results in a good convergence and robust capability.

With regard to the fuzzy controller, the throttle opening and the throttle opening rate of change are the subjective factors of the input parameters. The speed difference between the clutch master disc and the clutch slave disc and the speed of the clutch slave disc are objective factors of the input parameters. The speed of the clutch slave disc reflects the vehicle jerk. The speed difference between the clutch master disc and the clutch slave disc reflects the friction at work during the clutch engagement process. The fuzzy controller which possesses the two subjective factors entirely reflects the driving intention and controls the clutch engagement better. More input parameters in the single fuzzy controller cause more fuzzy rules and lead to more computational load of the single-chip. The input parameters of a single fuzzy controller have been disassembled to double fuzzy controllers. The method decreases the rules of each fuzzy controller and operator load of ECU and improves real-time capability.

It is shown that a large throttle opening leads to rapid start-up and a slower throttle opening to a slow run. The throttle opening and the opening rate of change are the input parameters of the first fuzzy controller. Controller's output reflects the driving intention.

Another fuzzy controller's input parameters have the driving intention which is been corrected by the quality of vehicle conversion coefficient, the speed of the clutch slave disc, and the speed difference between the clutch master disc and the clutch slave disc. The output is the clutch engagement speed. The clutch engagement speed has related with the vehicle jerk. In general[Qi Zhanning, 2001], the upper limit of the jerk is $10m/s^3$.

The linguistic sets of the throttle opening α are defined as[Wang Yuncheng, 2000]:

VS: Very Small, S: Small, M: Medium, B: Big, VB: Very Big.

The linguistic sets of the throttle opening rate of change $\dot{\alpha}$ are defined as:

NB: Negative Big, NM: Negative Medium, NS: Negative Small, ZO: Zero, PS: Positive Small, PM: Positive Medium, PB: Positive Big.

The linguistic sets of the driving intention I are defined as:

VS: Very Small, S: Small, M: Medium, MB: Medium Big, B: Big.

All of the speed of the clutch slave disc n_c, the speed difference between the

clutch master disc and the clutch slave disc Δn and the clutch engagement speed e have the same linguistic sets. These sets are defined as:

VS: Very Small, S: Small, LS: Little Small, M Medium, LB: Little Big, B: Big, VB: Very Big.

The normal Gauss function is adaptable to every variable membership function. The normal Gauss function reflects the change characteristic of the input parameters[Jiang Fachao, 2005]. A series of fuzzy rules are built according to the driving experience. The fuzzy inference rules of the driving intention are shown in Table 1.

Table 1 . The inference rules in t he driving intention fuzzy controller .

I	$\dot{\alpha}$						
	NB	NM	NS	ZO	PS	PM	PB
α VS	VS	VS	S	S	S	M	MB
S	VS	VS	S	S	M	MB	MB
M	VS	S	M	M	M	MB	B
MB	VS	S	M	M	MB	B	B
B	VS	S	M	MB	B	B	B

The correct value to the driving intention ω is that the quality of vehicle conversion coefficient ζ amends the value of driving intention from the first fuzzy controller. The formula is :

$$\omega = \lambda \cdot \mathrm{I} / \zeta \qquad (10)$$

Where, λ is coefficient.

Another fuzzy controller's input parameters are the correct value to the driving intention, the speed of the clutch slave disc and the speed difference between the clutch master disc and the clutch slave disc. The fuzzy rules are:

if ω=VS and n_c=VS and Δn=VS then e=VS

if ω=VS and n_c=VS and Δn=S then e=VS

⋮

The fuzzy algorithm of the clutch engagement adopts product way. The different input parameters operate the different output. The diagram of fuzzy control system is shown in Figure 2.

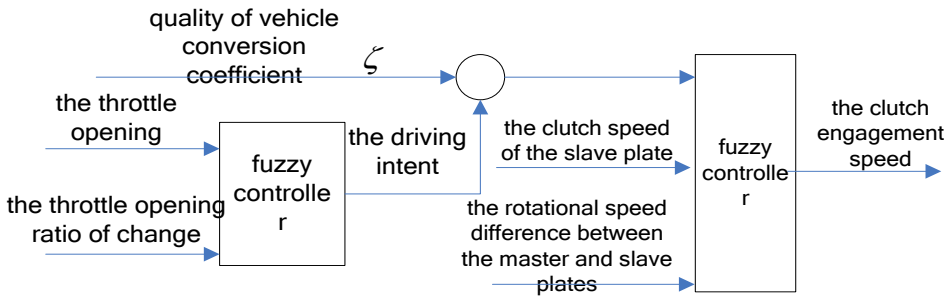

Figure 2. Diagram of fuzzy control system .

PID CONTROL OF THE CLUTCH ENGAGEM ENT PROCESS

Because the arithmetic power of ECU is limited and more fuzzy control rules increase operator load of ECU, the PID control method is adopted in this paper.

PID control method making use of proportion, integral, and differential calculates the system error to control the object. Proportional coefficient k_p rapidly takes response system change to output and effectively overcomes the effect of disturbance. The differential coefficient k_D reduces the steady-state error by correcting the accumulated error after the system stabilizes. The integral factor k_I reduces the overtop time and accelerates the system's response speed.. PID controller's equation is:

$$u_k = u_{k-1} + \Delta u_k \qquad (11)$$

$$\Delta u_k = k_p(e_k - e_{k-2}) + k_I e_k + k_D(e_k - 2e_{k-1} + e_{k-2}) \qquad (12)$$

where: $e_k = y_k - p_{k+1}$

RESULT OF SYSTEM SIMULATION

When the vehicle starts up on the upward slope, the system simulation based on all above control algorithms is conducted. The results of system simulation are shown in Figure 3. and Figure 4.

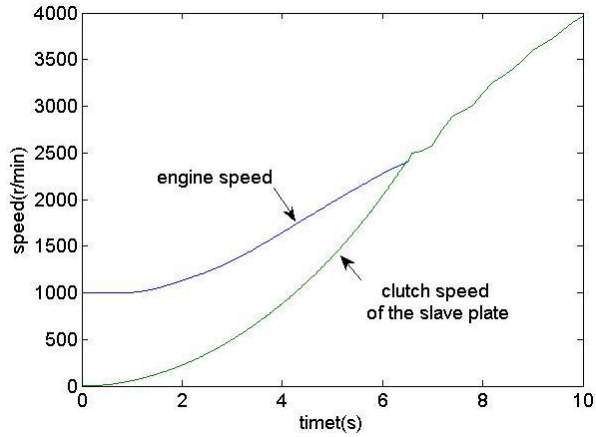

Figure 3. Clutch engagement without the vehicle mass conversion coefficient.

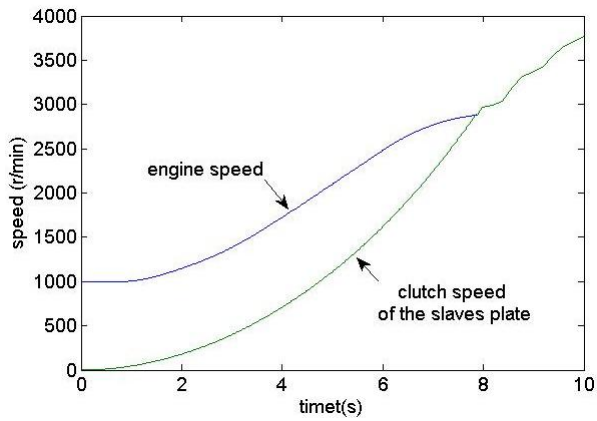

Figure 4. Clutc h engagement with the vehicle mass conversion coefficient .

Figure 3 shows the clutch engagement process without quality of vehicle conversion coefficient. The ECU does not correct the engagement speed in accordance with external condition changes and this causes a great jerk. Figure 4 shows the clutch engagement process with quality of vehicle conversion coefficient. The clutch engagement speed is confirmed by the subjective factors and the external condition. The driver's driving intention are thus fulfilled.

CONCLUSION

Quality of vehicle conversion coefficient reflects the load of the vehicle and the road conditions, which corrects the output parameter of the fuzzy controller. The fuzzy control method is adopted to control the clutch engagement speed. A larger number of input parameters in the single fuzzy controller cause the multiple number of fuzzy rules. The more rules lead to an increase in computation. The method used in this paper can decrease the number of fuzzy rules. The speed of the clutch slave disc is one of the input parameters of fuzzy controller. The result of simulation is good and meets the start-up demand of the vehicle and improves overall comfort.

ABSTRACT

This paper selects a suitable dispersant and emulsifier to prepare an oil base coal-oil-water slurry of Fuxin coal and Datong coal, studies a three-phase (oil, water, coal) ratio to the influence of rheological properties, and discussed combustion characteristics. The test result indicated: At 35% oil in the oil base coal-oil-water slurry belongs to Herschel-Bulkley fluid; at 30% oil belong to bulge plastic fluid. In other words the lower the oil content the higher the C/W proportion and viscosity. The coal-oil-water slurry caloric value drops along with the W/O proportion rise and W/C proportion drop. Under the identical shear rate, the apparent viscosity of Fuxin coal is bigger than the Datong coal. Under the same mass concentration, the combustion ash of Fuxin coal is lower than the Datong coal. Coal-oil-water slurry is thus found to have good combustibility and combustion efficiency and it is an industrial fuel prospect.

INTRODUCTION

The water-coal-slurry mixture which is composed of few chemical additives (approximately 0.5%-1%), 60%-70% powdered coal, and 30%-40% (Yu. et al. 2006) water is an ideal substitution fuel with low pollution, high efficiency, and is a strong fluid fuel. (YU et al.2003, ZOU et al.2006) The coal type, the chemical property, the grain shape and the grain-size distribution, the chemical additive composition, the pulping craft, the temperature and some factors which thick liquid density and affect the rheological properties..This article mainly studies 3 raw materials' (coal, oil, water) ratio to rheological properties and flammable influence by oil base water-coal-slurry (GU et al.1996, A TESO K G et al.2002, GUO et al.2005).

EXPERIMENT

Raw material and instrument

Fuxin coal（coal granularity <331μm is in proportion of 100%，coal granularity <31μm is in proportion of 53.88%，coal granularity <2μm is in proportion of 3.56%, M=5. 14，A=12. 20，V=29. 28，FC=53. 38). The ash is 5.09%; the calorific value is 31.48MJ/kg；Datong coal (coal granularity <331μm is in

proportion of 100%, coal granularity <31μm is in proportion of 59.78%, coal granularity <2μm is in proportion of 4.98%, M=2. 43, A=7. 13, V=34. 20, FC=56. 24). The ash is 10.2%, the calorific value is 33.28MJ/kg、0 diesel oil, chemical additive (alkyl phenyl polyethyleneoxide ether). 510 Fourier infrared spectroscopes, NXS-11 rotational viscosimeter, GR3500 oxygen bomb type calorimeter instrument.

Experimental Technique

The chemical additive is added to the diesel oil and take water to make oil base water. The Fuxin coal (Datong coal) is then placed under high speed agitation thus preparing the Fuxin coal (Datong coal) oil base water-coal-slurry.

1) According to proportion of coal: Water=1: 1, changes the oil content respectively is 30%, 35%, 40%, carries on the viscosity test to the Fuxin coal (the Datong coal) , make the rheological property curve.

2) Oil 40% invariable, the change internal phase coal and water proportion respectively is 3:2,2:3,1:4, carries on the viscosity test to them, make the rheological propertyless curve.

3) To prepares six kind of oil base water-coal-slurry by step 1 carry on the calorific value and combustion test,

4) To prepares six kind of oil base water-coal-slurry by step 2 carry on the calorific value and combustion test,

EXPERIMENTAL RESULTS

Influence three -phase ratio rheological property

Oil affects

The oil base water-coal-slurry of Fuxin coal (Datong coal) the viscosity and the shear rate relations see Figure 1 (Figure 2), From Figure 1, 2 we can see water-coal-slurry big change along with oil content change. the yield stress increases,along with the oil content reduction, the oil base water-coal-slurry transfers to pseudo-plastic fluid, when the oil content is 30%, two kind of oil base water-coal-slurry transforms into the bulge bingham fluid, then the yield stress increases rapidly, because COWS is the key of coal grain suitable stable three-dimensional structure. This kind of hydromass will certainly to have a high viscosity and static stability. The hydromass the rheological propertyless had along with the oil quality percentage drop, the hydromass present submits -pseudo-plastic, when the oil content drops more, causes the hydromass viscosity to increase and forms the bulge bingham fluid.

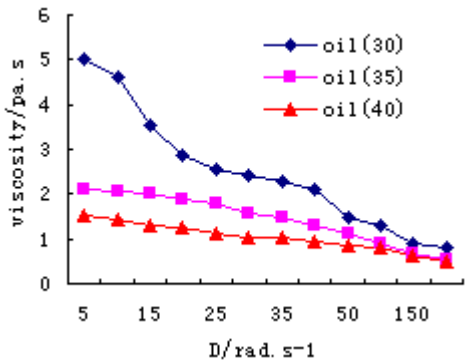

Figure 1. Viscosity curve at C_F /different oil .

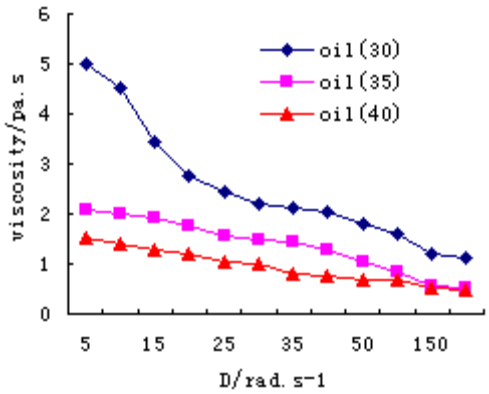

Figure 2. Viscosity curve at C_D /different oil .

Coal-water scale effect

From Figure 3, 4 we can know, the performance viscosity is increasing along with coal water proportion increase, the coal water proportion is higher, increases scope to be bigger. The water-oil -slurry is the typical pseudo-plastic fluid, the coal-oil -slurry is the typical bingham fluid, but oil- water-coal -slurry is pseudo-plastic fluid, the yield stress is reduces, then tends to be stable along with coal water proportion enlargement, the system deviates the plastic flow pattern to become submits - pseudo-plastic fluid.

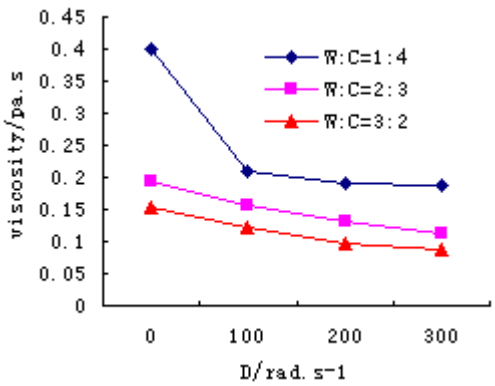

Figure 3. Viscosity curve at C_F/W

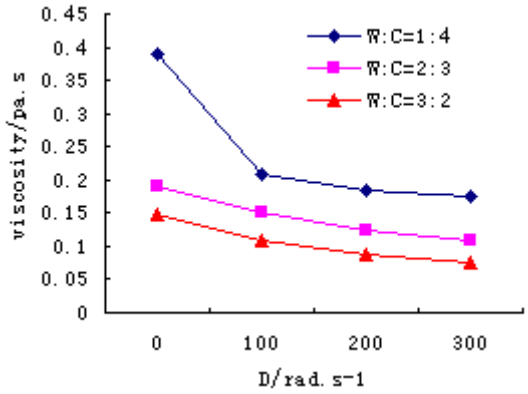

Figure 4. Viscosity curve at C_D/W

Influence flammable of three -phase ratio

Oil-water ratio effect

From Figure 5 we can see, when the coal content maintains is invariable, system calorific value reduces along with incompatible ratio increase, because the oil low heat value is bigger than water, the oil quality score influence system calorific value drops; But identical incompatible ratio, the Datong coal preparation calorific value is oil-water –slurry bigger than Fuxin coal preparation, because Datong coal low heat value is bigger than Fuxin coal.

Coal water scale effect

We can see from Figure 6 , when the oil content is invariable, system calorific value increases along with water coal ratio increase, because coal low heat value is bigger than water, the Datong coal-slurry calorific value is bigger than Fuxin coal-slurry. From Figure 5, 6 we know: the coal and the oil relative quantity were mainly the combustion calorific value, the water has not affected nearly to the system calorific value, two kind of anthrax calorific value were difference, the Datong coal calorific value is bigger than Fuxin coal under the identical condition, because the Datong coal low heat value is higher than Fuxin coal.

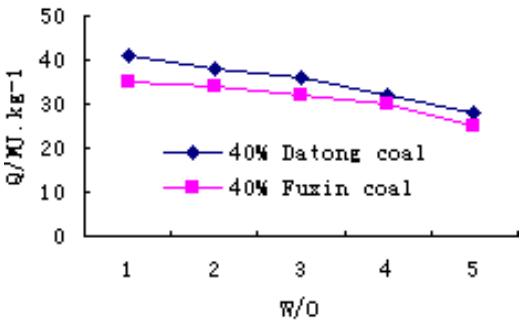

Figure 5. Heat curve at O/W

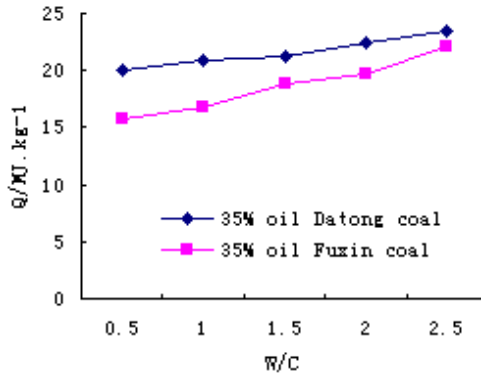

Figure 6. Heat curve at C/W

Coal ash affects

From Figure 7, 8 : Under on the same scale and quality fuel burning condition, the Datong coal ash is bigger than Fuxin coal, It is related with the preparation coal itself ash content ,It is not related with the temperature and the oil-water proportion .

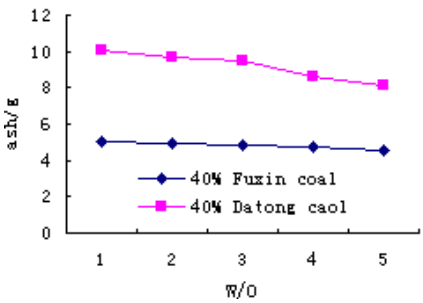

Figure 7. Gradation cur ve at O/W

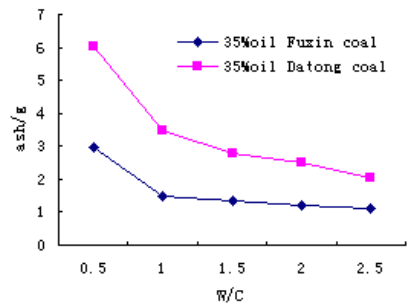

Figure 8. Gradation curve at C/W

CONCLUSIONS

1) The coal-oil-water slurry caloric value drops along with the W/O proportion rise and W/C proportion drop, the herschel-bulkley fluid change to bulge plastic fluid.

2) Under the identical shear rate, the apparent viscosity of Fuxin coal is bigger than the Datong coal; under the same mass concentration, the combustion ash of Fuxin coal is lower than the Datong coal.

ABSTRACT

A simulation model about the temperature controlling system of 25kW fuel cell power system(FCPS) which was analyzed by MATLAB/SIMULINK was built. This generates a control variable by the fuzzy control method to drive the radiator fan operating at different speeds in experiment, in order to make the FCPS work in optimal temperature state, and is stabilized at 63℃. This verifies the accuracy of the simulation analysis.

INTRODUCTION

As a green energy technology, the fuel cell technology is dominant in energy saving and environmental since it uses renewable energy-Hydrogen and realizes zero-emission. The proton exchange membrane fuel cell (PEMFC) is the most widely used of all existing fuel cell technologies. But the efficiency of fuel cell is about 50%, which means output power equals to heat dissipation. Thus the heat dissipation of PEMFC power system is very huge and is about 2-3 times that of an internal combustion engine exhaust heat. Due to the temperature sensitivity of the proton exchange membrane, the performance of fuel cell is badly affected by temperature. In low temperatures, the polarizations of fuel cells are increased and ohm impedance is bigger, which makes causes deterioration in performance. When the temperature rises, it will reduce ohm impedance, reduce polarization, and improve the speed of electrochemical reaction as well as the rate of proton transferrance in the membrane. This will result in better performance. When the

temperature is too high, the membrane activity reduces，and the performance level falls once again(Li Zhonghua 2007). At the same time, to make sure the temperature of fuel cell is well distributed, the temperature difference of the coolant's inlet and outlet should be no more than 10℃, the optimum being 5℃. Because of the low temperature of heat dissipation of fuel cell, the cooling system is in high demand (Hu Yunyu 200). Recently, there has been much research conducted in the area of fuel cell system models and control methods. For example, Geyer H K and Ahluwalia R K have invented a computer simulation tool, GC, which can be used for designing and analyzing the fuel cell system model. But there are only a few dynamic models of fuel cell system(Geyer H K 1998); Wohr M and Amphlett J C have researched on dynamic response of temperature (Wohr M 1998, Amphlett J C 1996); Pathapati P R has presented an integrated dynamic model of fuel cell system, whose model takes the transformation of fuel cell temperature, fluid influx of channel, and the influence of double-layer charge into account, and is realized in SIMULINK (Pathapati P R 2005). The control methods of fuel cell include traditional control, predictive control, fuzzy contro,l and neural network control .

25KW FCPS TEMPERATURE CONTROLLING MODEL

System structure model

The object of FCPS temperature control is the working temperature of the fuel cell stack. The executing mechanism includes water pump, radiator, fan, etc and water is the medium. The working principle is cooling water takes heat from fuel cell by cooling water pump, then transits through the water tank, and exchanges heat with air by fan in order to control the temperature of the stack. In this paper, owing to the huge dissipation heat of FCPS, two radiators are used, and each has its own fan. The cooling water pump is held working at a certain rotating speed keeping the water flux constant. The speed of the fan is adjusted to control the wind flux to finally control the temperature. The structure of FCPS temperature controlling system refers to **Figure 1**. The simulation model of FCPS temperature controlling system refers to **Figure 2**. It includes a fuel cell stack submodel, radiator submodel, water tank, and conduit submodel as well as a control unit submodel.

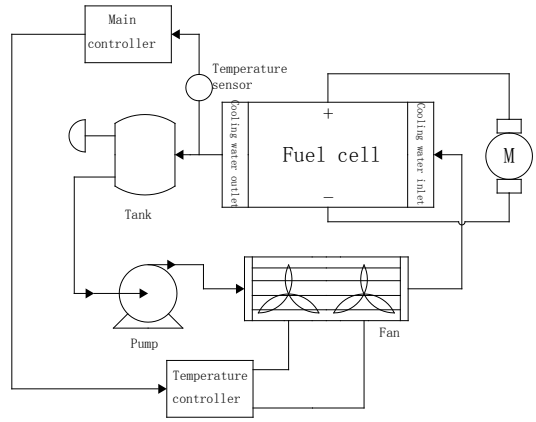

Figure 1. Structure of FCPS temperature controlling system.

The simulation model of FCPS temperature controlling system is based on the following parameters (see **Table 1**).

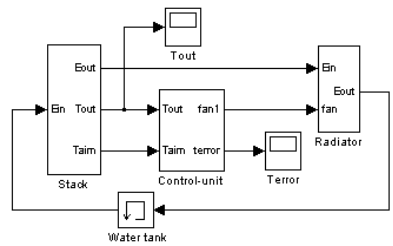

Figure 2. Simulation model of FCPS temperature controlling system.

Table 1. Parameters of PCPS temperature controlling system's simulation model.

Net output power of stack (kW)	Radiator length× width× thickness （mm×mm×mm）	Radiator pipe size length× width （mm×mm）	Cooling area of radiator （m^2）	Rated current of fan （A）
25	570×380×26	26×2	8.58	25
Rated voltage of fan （V）	Flux of water pump （L/min）	Ambient air temperature （℃）	Ambient water temperature （℃）	Total volume of cooling water (L)
12	170	25	20	25

Approaches of heat loss

The working principle of fuel cell stack is to convert the chemical energy of fuel (hydrogen) and oxidant (oxygen or air) to electricity directly by electrochemistry reaction, consume reactant, discharge outcome and release heat. The chemical reaction is:

$$H_2 + \frac{1}{2}O_2 \xrightarrow{Ele+Heat} H_2O$$

Fuel cell has three ways of discharging waste heat △Q: eradiation of fuel cell, water vaporization dissipation inside fuel cell, and discharging by circulating water. Reactant gas of fuel cell will bring in and take away some heat, but it can be ignored due to the slight difference between inlet and outlet temperature and the small heat capacity of gas. Analysis has shown that the waste heat of fuel cell is mainly taken away by water circulation $\triangle Q_{cool}$, occupying 90% of the gross. Eradiation and vaporization heat dissipation share little(Yan Fuwu 2005). To put the margin of heat dissipation in the design, the model could be simplified as: $\triangle Q=\triangle Q_{cool}$.

Stack model

According to the above analysis, we know that the heat dissipation and the electricity of stack export as 50% severally, the waste heat is taken away by circulation water only. So through a set of experiment data, we get a current (A) - power (W) curve of 25kW FCPS (see **Figure 3**). We then build a Look-up Table model in MATLAB/SIMULINK. After importing a time-current signal we can get a time-power signal, which is equivalent to time-heating power signal, namely an export E_{out} of the stack model. We can conclude the target working temperature based on the time-current data. Hold the rotating speed of water pump and the quality of cooling fluid at a constant. Control outlet temperature to 50℃ when current is under 110A, control outlet temperature to 58℃ when it is between 110-130A and control outlet temperature to 63℃ when it is over 130A. In this way it can reduce another export T_{aim} of the stack model. The stack model is shown in **Figure 4**.

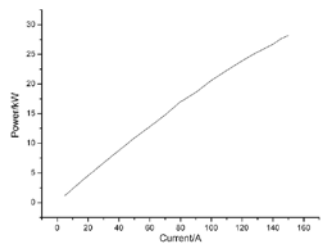

Figure 3. The Current-Power curve of 25kW FCPS.

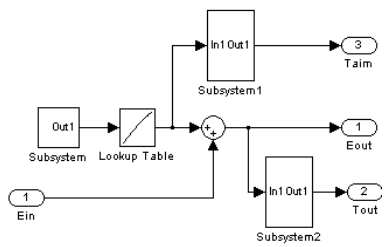

Figure 4. Stack model.

Radiator model

The heat taken away by the cooling system Q_{cool} is dissipated through the radiator, which means that $Q_{rad} = Q_{cool}$. Pump should have enough displacement and pressure in order to provide enough cooling water. At the same time, ensure enough air passes through the radiator to take the heat away when cooling water passes through the radiator. This can be computed as: $Q_{cool} = C_a \cdot \rho_a \cdot V_a \cdot \triangle t_a$.

Here C_a is specific heat of air, ρ_a is air density, V_a is flux of cooling air entering the radiator and equals the product of wind speed and positive area of radiator. In other words the fan should provide enough air. $\triangle t_a$ stands for the temperature difference between atmosphere and the one passed through the radiator, $\triangle t_a = T_{air,\ out} - T_{atm}$.

At the same time, heat dissipation of radiator is in direct proportion to air flux and temperature difference. That is: $Q_{rad} = K_{rad} A_{rad} (T_{rad} - T_{air})$.

Here K_{rad} is the heat transfer coefficient of the radiator; A_{rad} is the heat dissipation area of radiator; T_{rad} is the average temperature of cooling water in the radiator and is expressed by the arithmetic mean of inlet temperature $T_{rad,\ in}$ and outlet temperature $T_{rad,\ out}$. T_{air} is average temperature of cooling air and is expressed by arithmetic mean of ambient temperature T_{atm} and outlet temperature of cooling air $T_{air,\ out}$ (Yang Liansheng 1981). During the process of building the radiator model, we set the cooling water flux as fixed value. It means that the cooling water pump runs at a constant rotating speed. **Figure 5** shows the radiator model.

Tank and conduit model

Some heat is taken away by tank and conduits, so there is a certain temperature difference between the cooling water inlet and outlet. Cooling water flowing in the conduit also brings transmission delay. According to the law of thermodynamics we can build a simple tank and conduit model. But the heat taking away by the tank and conduit is limited, affects the whole model very little, so the model can be simplified (Gu Jing 2007). THeSpecific model is shown in **Figure 6**.

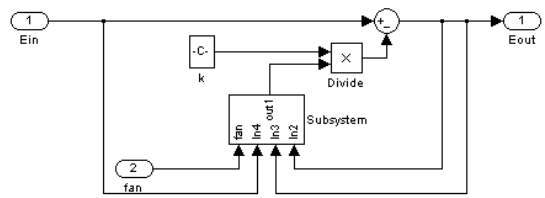

Figure 5. Radiator model.

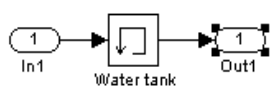

Figure 6. Tank and conduit model.

Control unit model

For the FCPS temperature control, the mathematical model and control parameters are not easy to determine accurately, but we can use fuzzy inference control. **Figure 7** shows the chart of control unit principle.

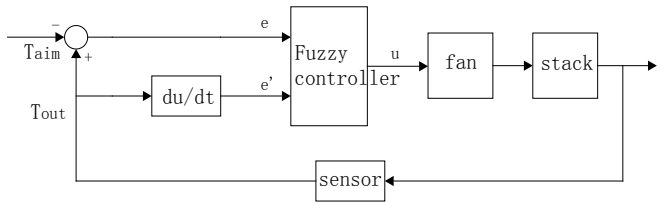

Figure 7. The chart of control unit principle.

In **Figure 7**, e expresses the difference between outlet temperature and target temperature. e' expresses the gradient change of outlet temperature.

The FCPS's temperature control is set according to experience. The experience -control method not only wastes resources but also cannot gain a high level of control. The FCPS fuzzy temperature control system built in this paper is based on multivariate fuzzy inference theory and FCPS experiment data. It can build wind speed (or fan rotating speed), basic rule, and control experience repository. We just need to modify the control algorithm of the module and verify the validity of the control algorithm by simulation. The model takes the target temperature and actual export temperature as input value. After dealing with input value, it produces an error signal and changes the rate of control objective separately. The model exports opening signal of cooling fan (in this simplified model, wind speed is exported) after fuzzy control calculation. Export signal Terror is the error of actual temperature and target temperature, just for observation. The control unit model refers to **Figure 8**.

SIMULATION ANALYSIS AND EXPERIMENTAL VERIFICATION

The paper gives a time-current signal as is shown in **Figure 9**. Dash dot line in **Figure 10** is target temperature controlled curve according to a Time-Current curve. Import a time-current signal to stack model, then simulate in SIMULINK and we get a simulation temperature curve shown as the solid line in **Figure 10**. Take the fan rotating speed which was gained in simulation model for reference to do experiment, and we can gain the experiment temperature curve. This is shown as the broken line in **Figure 10**.

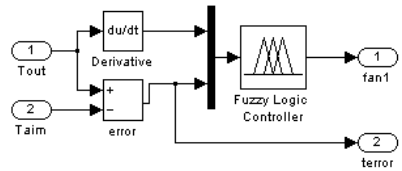

Figure 8. Control unit model.

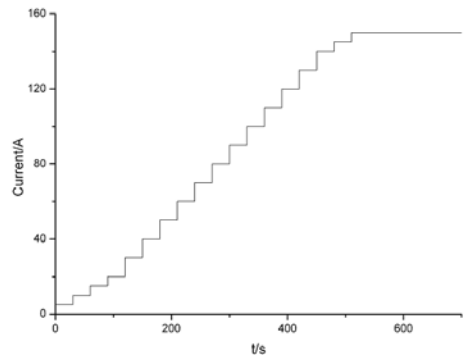

Figure 9. FCPS Time-Current signal.

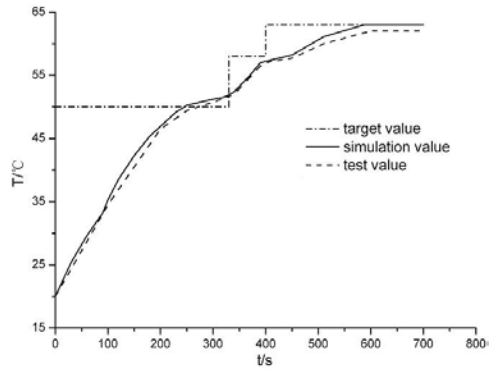

Figure 10. Target value, simulation value, test value's temperature curve.

From **Figure 10** we can see that, in simulation analysis, the temperature of the stack is low when the fuel cell starts working, so we do not control the fan. With the electrochemical reaction of fuel cell, temperature goes up. When the current works on 80A(270s), we start to control the fan and control stack temperature at 50℃. When the current is between 100~130A(330~450s) we control temperature at 58℃. When current has stopped transmitting 130A(450s), we keep the fan speed at maximum, and finally hold the temperature at a steady 63℃. In the experiment, the temperature is controlled and balanced at the three phases of target temperature and finally stabilized at 62℃. By comparing the temperature curve which was controlled by the experiment with that of simulation, we find that the model temperature is consistent on the whole with the experiment-controlled temperature curve. There are

some differences, the main reason being that temperature has a huge inertia and lag, and is greatly affected by ambient temperature.

CONCLUSION

The paper establishes simulation model of FCPS temperature controlling system. It includes fuel cell stack submodel, radiator submodel, water tank & conduit submodel as well as control unit submodel. It also simulates and analyzes 25kW FCPS's temperature controlled under the multivariate fuzzy inference theory by MATLAB/SIMULINK, and uses the results for experiment controlling. Finally we find that the experiment temperature curve is consistent with the simulation temperature curve on the general trend, and finally stabilizes at 62℃. It verified the validity of the control algorithm. The simulation analysis can provide reference for experiment research, reduce experiment task, and will play an important role in the design of FCPS.

ABSTRACT

As a key component of the Tertiary Sector, transportation consumes more and more energy and its consumption, which grows more rapidly as time goes by, takes up more than half of those consumed by the tertiary sector. Over half of which are being consumed by transportation by land, making it a giant consumer of energy. However, no dedicated research has been made so far on energy consumption by land cargo transportation as a primary problem and no specific data collection system on energy consumption by the sector has been worked out in the nation.

This paper builds a multivariable linear regression model, taking into consideration energy consumption by land cargo transportation and its underlying causes, and taking statistics by land cargo transportation enterprises as samples. Through analysis, the paper finds out what the most important causes are and to what extent the influence can be, discovering the key issue and most difficult part in energy saving and consumption reducing.

Transportation, as an essential contributor to rapid economic growth, is highly and closely related to economic development, and its output has been taking an increasingly larger share in the nation's gross national product, for it is a very important sector in our country's national economic system. (Energy Information Administration 2006) In addition, it is also essential to modern transportation system and logistics system, playing a major role in our nation's transportation system. Since road transportation vehicles are the largest energy consumers among motor vehicles, improving energy consumption efficiency and saving energy have great role to play in China's energy safety, environmental protection and the sustainable development of economy and society (Samaras et al.1999).

As energy is relatively scarce and non-renewable, energy saving and improving energy utilization efficiency becomes an important principle in energy consumption (Schipper et al.1993). According to the 11th Five-year Plan, China's energy consumption per unit GDP shall decrease by 20 percent at the end of the period, which makes studies on energy consumption a tough task in monitoring energy consumption (Environmental data compendium 1995). Since the methods and means that have been used to collect information concerning energy consumption in road transportation can not be applied to analyzing energy consumption by current land cargo transportation, reliable data can not be collected cost-efficiently, making it impossible for enterprise to collect information and control energy consumption in a scientific way. As a result, how to solve above-mentioned problem becomes the most

important and most difficult task in finding solutions to energy saving in China. This paper thinks analyzing and conducting research on energy consumption by land cargo transportation and establishing a scientific, simple and practicable data collecting model on energy consumption is essential to coming up with a solution to energy saving and consumption reduction for cargo transportation by land.

ESTABLISHMENT OF MODELS

Since there are few approaches by which people can get information on energy consumption by road transport industry or road transport enterprises, statistics collected are incomplete and it's also very difficult to obtain complete data. Thus relevant indicators are not available, including those on turnover and transport capacity by cargo vehicles and passenger vehicles using different fuels, making the analysis more difficult. This paper discusses road transport vehicle's energy consumption structure, influencing factors and its extents by establishing a regression model with statistics collected on 79 vehicles from a road cargo transport enterprise. This enterprise is a large-scale port logistics company in Shanghai, which has a strong representation in the field of container road transport in China.

RESEARCH APPROACHES

This paper adopts the approach of stepwise regression analysis with SPSS software. In statistics, stepwise regression includes regression models in which the choice of predictive variables is carried out by an automatic procedure. The specific approach is to introduce variables one by one until no significant variables can be selected or removed by the regression equation. The introduction of a variable or removed a variable from the regression equation is a step of stepwise regression. Every step must be tested to ensure that each time the regression equation contains only significant variables before the introduction of a new variable. Usually, this takes the form of a sequence of F-tests (He Xiaoqun 1998).

MODEL OF TOTAL OIL CONSUMPTION BY VEHICLES

With SPSS software, this paper makes a detailed stepwise regression analysis of total oil consumption (y_1) and its seven key influencing factors, including mileage (x_1), the number of goods carried (x_2), cargo weight (x_3), loaded one-way trip mileage (x_4), carrying rate (x_5), whole-trip kilometers utilization rate (x_6) and the age of vehicles. Through a series of tests and optimization, a multivariable linear regression model for total oil consumption and its seven key influencing factors can be found:

$$y_1 = -3.566 + 0.331x_1 + 0.807x_3 + 0.031x_4 - 0.513x_6 + u$$

MODEL OF OIL CONSUMPTION PER 50 KILOMETERS BY VEHICLES

With SPSS software, this paper also makes a detailed stepwise regression analysis of total oil consumption per 50 kilometers (y_2) and its seven key influencing factors, including mileage (x_1), the number of goods carried (x_2), cargo weight (x_3), loaded one-way trip mileage (x_4), carrying rate (x_5), whole-trip

kilometers utilization rate (x_6) and the age of vehicles. Through a series of tests and optimization, a multivariable linear regression model for total oil consumption per 50 kilometers and its seven key influencing factors can be written as follows:

$$y_2 = 34.452 + 0.115x_3 - 0.086x_5 + u$$

ANALYSIS OF INFLUENCING FACTORS

As we can see from the models, the most important factors that pose great influence on total oil consumption by road cargo transport vehicles are mileage, cargo weight, mileage of loaded one-way trip, and kilometers utilization rate. According to the parameters' signs in these models, we find that the coefficient signs for kilometers utilization rate are negative, indicating that the higher the kilometer utilization rate, the lower the oil consumption, thus the higher oil utilization rate. Likewise, the higher the kilometers utilization rate, the higher the loaded mileage in proportion to the whole trip, and the lower the deadhead mileage in proportion to the whole trip, the more efficiently the energy is utilized. Therefore, raising kilometers utilization rate is one of the most important methods to save energy and reduce fuel consumption for vehicles. Of course, there are many approaches by which to raise kilometers utilization rate. For example, the enterprises can cooperate to exchange information on cargos available and offer stowage service. Besides, it is advisable the government and agencies build logistics information systems or platforms, enhancing allocation of freight cars and information exchange between enterprises.

From the coefficient signs of three other independent variables, we can see that vehicle mileages, cargo weight and loaded one-way mileage are in proportional to vehicle's total energy consumptions. The longer the distance covered, the more energy the vehicle consumes; and more weight requires more power, thus requires more energy. In addition, the longer the loaded mileage, the more energy the vehicle consumes. Of course, there are many factors that have influences on vehicle's energy consumption. For example, when the vehicle ages, the vehicle's performance lowers and the engine's condition decreases because of friction. Surely, the vehicle's technological standard is also important. As a result, those vehicles that are out of date, low-efficient and consumes much energy should be replaced by vehicles that are highly efficient and energy-saving due to the use of high technology. Then by using vehicles that involve advanced energy-saving technologies, energy utilization rate can be increased, thus reducing energy consumption.

ANALYSIS OF THE EXTENT OF INFLUENCE

The Extent of Influence the Factors have on the Vehicle's Total Energy Consumption

To make an analysis of the extent of influence these influential factors have on vehicle's total energy consumption, we have to standardize the data and establish a regression model, acting on these standardized data. Thus a model can be obtained:

$$y_1' = (3.56E-013) + 0.976x_1' + 0.105x_3' + 0.048x_4' - 0.113x_6' + u$$

Here in this model, y_1'、x_1'、x_3'、x_4'、x_6' stand for the standardized indicators of total vehicle energy consumption (y_1), mileage (x_1), cargo weight

(x_3), loaded one-way trip mileage (x_4), and whole-trip kilometers utilization rate (x_6).

According to the structure of the regression model, we can see that, among the four influencing factors---mileage, cargo weight, loaded single-trip mileage, and kilometers utilization rate, kilometers utilization rate changes in the opposite direction as the vehicle's total oil consumption does, that is to say, it is inversely proportional to fuel consumption. Nevertheless, mileage, cargo weight and loaded single-trip mileage change in the same direction as the vehicle's fuel consumption does, that is to say, they are in proportional to fuel consumption.

If other variables remain unchanged, fuel consumption will decrease by 0.113 units when kilometers utilization rate increases by 1 unit. Likewise, fuel consumption will increase by 0.976 units when mileage increases by 1 unit, and fuel consumption will increase by 0.1105 units when cargo weight increases by 1 unit. When loaded single-trip mileage increases by 1 unit, fuel consumption will increase by 0.048 units. Therefore, it is the mileage that has most influence on fuel consumption, and kilometers utilization rate ranks only second. Influences that mileage, cargo weight, loaded single-trip mileage, and kilometers utilization rate have on vehicle's total energy consumption are illustrated in Figure 1.

Changes of the influentia l factors	Of mileage on total energy consumption	Of cargo weight on total energy consumption	Of loaded single-trip mileage on total energy consumption	Of kilometers utilization rate on total energy consumption
1.00	0.976	0.105	0.048	-0.113
2.00	1.952	0.21	0.096	-0.226
3.00	2.928	0.315	0.144	-0.339
4.00	3.904	0.42	0.192	-0.452
5.00	4.88	0.525	0.24	-0.565
6.00	5.856	0.63	0.288	-0.678
7.00	6.832	0.735	0.336	-0.791
8.00	7.808	0.84	0.384	-0.904
9.00	8.784	0.945	0.432	-1.017
10.00	9.76	1.05	0.48	-1.13
11.00	10.736	1.155	0.528	-1.243
12.00	11.712	1.26	0.576	-1.356
13.00	12.688	1.365	0.624	-1.469
14.00	13.664	1.47	0.672	-1.582
15.00	14.64	1.575	0.72	-1.695

Figure 1 . Influences all factors have on total energy consumption (in unit) .

As we can see, mileage has the greatest influence on energy consumption. So we should take routes that are in good condition to improve kilometers utilization rate when the transportation distance is long. Thus fuel utilization rate can be improved and energy consumption can be minimized.

The Extent of Influence Key Factors have on the Vehicle's Total Energy Consumptio n per 50 kilometer s

Making analysis of the effects on energy consumption, we can get another model:

$$y'_2 = (3.84E-011) + 0.280x'_3 - 0.353x'_5 + u$$

Here y'_2、x'_3、x'_5 are respective standardized indicators of total fuel consumption per 50 kilometers, cargo weight, and whole-trip vehicles kilometers utilization rate.

As we can see from the structure of the regression model, vehicle's kilometers utilization rate changes in the opposite direction as total fuel consumption per 50 kilometers does, that is to say, the rate is inversely proportional to the total fuel consumption. Besides, cargo weight changes in the same direction as the total fuel consumption does, i.e. it is proportional to the fuel consumption.

The rest of the variables remaining unchanged, if kilometers utilization rate increases by one unit, the total fuel consumption per 50 kilometers will decrease by 0.353 units. Likewise, if cargo weight increases by 1 unit, the total fuel consumption per 50 kilometers will increase by 0.280 units. So kilometers utilization rate has the greatest impact on fuel consumption per 50 kilometers. Influences that cargo weight and whole-trip kilometers utilization rate have on fuel consumption per 50 kilometers are as in Figure 2 .

Changes of influential factors	Of cargo weight on fuel consumption per 50 kilometers (in unit)	Of kilometers utilization rate on fuel consumption per 50 kilometers (in unit)
1.00	0.280	−0.353
2.00	0.56	−0.706
3.00	0.84	−1.059
4.00	1.12	−1.412
5.00	1.4	−1.765
6.00	1.68	−2.118
7.00	1.96	−2.471
8.00	2.24	−2.824
9.00	2.52	−3.177
10.00	2.8	−3.53
11.00	3.08	−3.883
12.00	3.36	−4.236
13.00	3.64	−4.589
14.00	3.92	−4.942
15.00	4.2	−5.295

Figure 2 . Extent of influence factors have on fuel consumption p er 50 kilometers (in unit) .

In order to conduct a more detailed analysis, we collected data on some

vehicles at random that are loaded on both trips. Analysis shows that a vehicle may consume some 30 liters of fuel per 50 kilometers if it is partly loaded on both trips (to and from), and some 37 liters of fuel if it is fully loaded. Analysis also shows that the longer the distance that the vehicle covers when fully loaded, the lower the fuel consumption per 50 kilometers, justifying the conclusion that the higher the kilometers utilization rate, the lower the energy consumption. Since the vehicle has to consume some 30 liters of oil when it is on the trip back unloaded, it may consume 57 liters of oil if it is fully loaded, much higher than what the vehicle consumes when it is fully loaded on its trip back. As a result, to increase fuel utilization rate, it is important to load the vehicle reasonably and improve its kilometers utilization rate.

Speaking of the influences cargo weight has on unit fuel consumption, we should make sure that the vehicles are fully loaded but not overloaded. Because of fierce competition, road transport enterprises often overload their vehicles to reduce cost, raising turnover. But actually, overloaded vehicles often consume more unit fuel, raising cost and decreasing the profit. So it is advisable that the vehicles be reasonably loaded not overloaded. Only in this way can we maximize fuel utilization rate.

CONCLUSIONS

With the analysis of models, it is safe to say that road cargo transport enterprises should take kilometers utilization rate, mileage, and cargo weight etc into consideration when taking measures to save energy. Of them, the first two factors are the ones that have the greatest influences, and kilometers utilization rate changes in the opposite direction as total fuel consumption and unit consumption do, that is to say, improving kilometers utilization rate can help save energy, reduce energy consumption and increase energy consumption rate. However, the last three factors change in the same direction as energy consumption does, that is to say, energy consumption can be decreased by lowering the three factors. It should be added that vehicle's technological level has great impact on the vehicle's fuel consumption level, and to improve the vehicle's technological level means to improve oil saving-related technologies and vehicle operation-related technologies. That is to say, new style high-tech vehicles should be used to replace high energy-consumption vehicles and the ones that are worn, and research on energy-saving technology shall be conducted to improve the vehicle's overall energy utilization rate. In addition, driver's experience is very useful to energy saving. However, the two problems exist in most cargo transport enterprises, making it necessary to take a comprehensive consideration. Experienced drivers can have obvious impact on energy saving if these vehicles are of high-tech and the operation is free of human interference.

ABSTRACT

Transportation is one of the areas where increasing levels of CO_2 emission have been the hardest to curb. The Chinese government has a clear policy for sustainable transportation development. However, the question of how to transfer policies into viable actions is very important. This paper discusses this issue from a business aspect. A sustainable policy is strategically important for business to survive and develop in China. Firstly, this paper gives an overview of the national sustainable transportation policy and its impact on business. Secondly, Shanghai IKEA is used as a case study and the transport characteristics of its customers are analyzed. CO_2 emissions for different modes are also calculated. Finally, based on the analysis, some reasonable suggestions are put forward keeping IKEA's business in mind.

BACKGROUND: SUSTAINABLE TRANSPORTATION POLICY , LOW-CARBON ECONOMY IN CHINA AND **IKEA 'S EFFORTS TO** REDUCE CO2 EMISSIONS

"China's Sustainable Development Strategy Report in 2009", which has just been published by the Chinese Academy of Sciences in March 2009, identified the strategic objective to develop a Low-carbon economy in China. The aim is to reduce CO_2 Emissions per GDP will be reduced by 50 percent before the year 2020. The report indicated that Energy-saving and CO_2 reduction could be important sources of competitive strength for companies. (Chinese Academy of Sciences, 2009)

Transportation is one of the areas where the trends of increased CO_2 emissions have been the hardest to curb. This is due to the existing policies for reductions accepted around the world (WWF, IKEA, 2008). In its sustainable transportation policy China specifies public transportation priority, transport demand management, and energy sustainability as required expectations. Also, sustainability is not just the responsibility of the government. All of the members of society should take responsibility. It concerns everybody and every enterprise could contribute for

it.

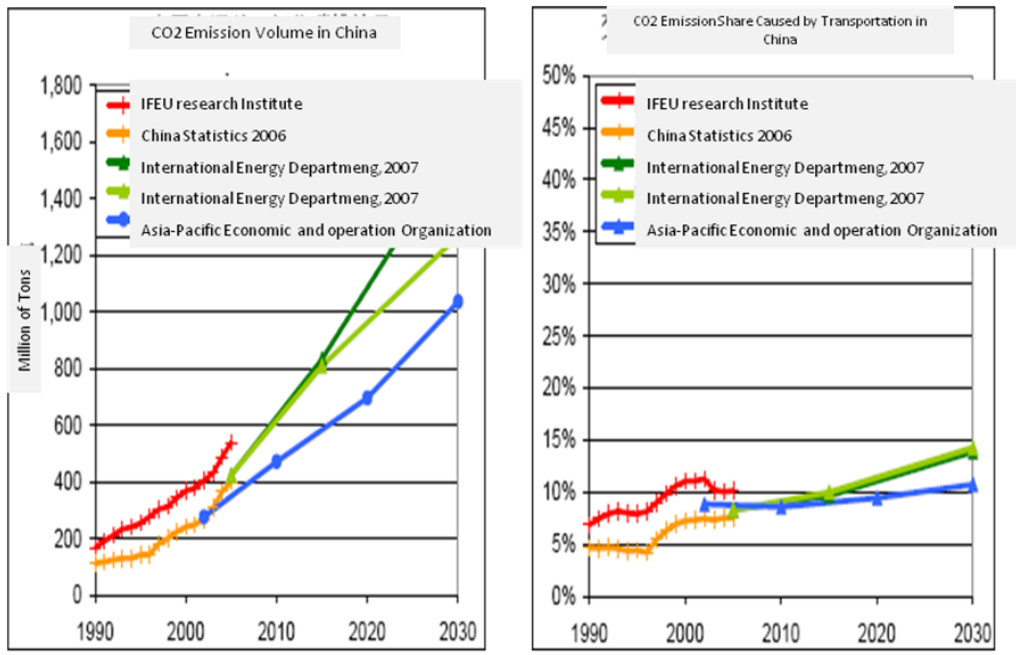

Figure1 . CO2 Volume and Transportation Share in China .

Two of the world's leading organizations are working closely to promote the responsible and sustainable use of natural resources. WWF, the global conservation organization, and IKEA, the home furnishings company, co-operate in the areas of responsible forestry, better cotton production, and climate change. The climate change projects explore ways in which joint efforts can contribute to reducing emissions of the greenhouse gas Carbon Dioxide (CO2). WWF and IKEA have decided to work together in the following areas:

- Energy efficiency and increased use of renewable energy at IKEA's suppliers leading to reduced energy use and reduced emissions of CO2 while simultaneously reducing the total supply cost.
- Sustainable transportation for customers which will result in reduced emissions of CO2.

The climate change projects have been propelled in China, Poland, Sweden and the UK.

CUSTOMERS SURVEY CONDUCTED IN SHANGHAI IKEA AND SHENZHEN IKEA AND DATA ANALYSIS

In order to gather information about CO2 emissions from customers who came to and from IKEA, an interview was conducted in early 2009. These interviews were conducted simultaneously on January 13, 16, 17, 18, and 19 in Shanghai and Shenzhen. The survey was planned and implemented by WWF, IKEA, and Tongji University. 375 effective samples in Shenzhen and 368 samples in Shanghai were

recorded.

CUSTOMER DISTRIBUTION IN THE CITY

In Shanghai, almost 50% customers came from Minhang District, Xuhui District, and Pudong District. We can see from Figure 2 that Shanghai IKEA is located at the very center of Shanghai City, which in turn is surrounded by buildings. It mostly attracts customers living near the store.

In Shenzhen, almost 74% customers hail from Nanshan and Futian Districts. We can see from Figure 3 that Shenzhen IKEA is located in Nanshan District. This store also attracts customers from surrounding areas.

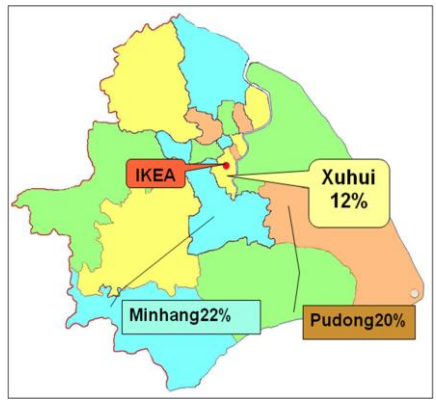

Figure 2. Shanghai IKEA and its high customer areas.

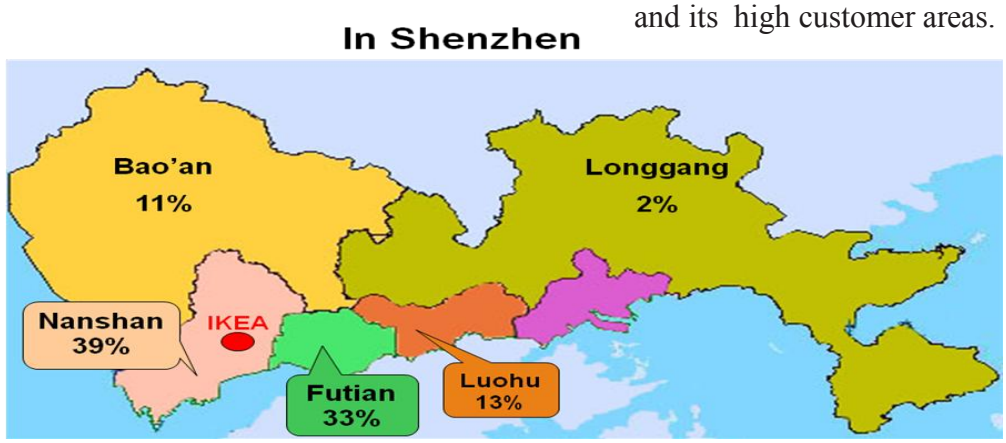

Figure 3. Shenzhen IKEA and its high customer areas .

MODE SPLIT OF CUSTOMER'S TRANSPORTATION

From the survey we get a clear information of mode share of bus, metro, private car, and taxi. Table 1 displays this information.

Table 1 . Mode Share of Ike Customers .

Mode share	Bus and metro	Private car	Taxi	Others
Shanghai	73%	12%	8%	7%
Shenzhen	50%	38%	8%	4%

Data shows a clear difference in level-of-service of transit in Shanghai and Shenzhen.

Figure 4. Location of Shenzhen IKEA Shanghai IKEA .

Shenzhen IKEA is surrounded by the freeway and is clearly convenient for car users. Shanghai IKEA is also located near Ring Road in Shanghai City. It is again easily accessible by car. There are also two metro lines which cross at this location. With the improvement in Shanghai's metro system, the metro is taking on a larger share of the transit pie. This is why we see an obvious difference between the modes of transit in Shanghai and Shenzhen.

ESTIMATING CO2 EMISSIONS BY CUSTOMERS

Usually we have two methods to calculate CO2 emission, fuel-based and distance-based. In the fuel-based methodology, fuel consumption is multiplied by the CO2 emission factor for each fuel type. This emission factor is relevant to the fuel's heat content, the fraction of carbon in the fuel that is oxidized, and the carbon content coefficient. In the distance-based method, CO2 emissions can be calculated by using distance based emission factors. In this method, the data we need may include vehicle mileage, freight ton-kilometers (or miles), passenger kilometers (or miles), etc.

For IKEA case study we used the distance-based method. Sampling data is amplified by the actual number on the survey day. We give a universal CO2 Emission factor for different transport modes.

Table 2 . CO2 Emission Factor based on Transport Mode (g/km) .

Mode	Bus	Metro	Motorcycle	Car	Bicycle	Taxi	Electronic bicycle
factor	19.74	61	220	506	0	168.67	0

Referred to 《Revised 1996 IPCC Guidelines for National Greenhouse Gas Inventories: Reference Manual》

Based on the above factors, we get the results of Customers CO2 emissions. Shanghai IKEA emitted 275T CO2 on the survey days with 73000 customers. Shenzhen IKEA emitted 230T CO2 with 41000 customers. Therefore the average CO2 per customer in Shanghai and Shenzhen IKEA is 3767g and 5610g.

FACTORS AFFECTING CUSTOMERS CO2 EMISSION

Clearly the transport mode structure and trip distance are two main factors that affect CO2 emission. It mostly depends on level-of-service of facility and location. (Jean-Pierre Nicolas, 2009)

The average transit share of the central city in Shanghai (inside Out Ring Road) is 33.1% This includes bus, metro, and taxi. (Shanghai Urban Comprehensive Transportation Planning institute, 2008). For IKEA Shanghai the number is 73%. Because IKEA is established in large cities in China, motorization transportation is a principal part of customers' transportation. We can therefore compare transit share in motorized transportation with IKEA. In Shanghai, the average number is 65%. It means IKEA Shanghai is promoting sustainable customer transportation. In Shenzhen, the average is 44.3%. For Shenzhen IKEA the average number is 50%. Here we can see that the mode share of IKEA customers is different from the whole mode structure in the city. See table 3.

Table 3 . Mode Structure Comparison .

share	Shanghai IKEA	Average[1] in Shanghai	Shenzhen IKEA	Average[1] in Shenzhen
Transit[2]	87%	65%	60%	55%
Car	13%	35%	40%	45%

[1] Average mode share in motorized transportation in the central city

[2] Including bus, metro and taxi

In conclusion it can be said that Shanghai IKEA is promoting a sustainable transportation structure. The Shenzhen IKEA, is still promoting a relatively average number.

The location of any particular Ikea also plays a big role. Today, it is difficult for IKEA to get a large piece of land in an urban center.. It is expensive and unavailable. Hence most of IKEA's new locations in China are situated outside the central city and are accessible by car.

In the survey, we also examined the tendency of customers to shift to public transport in the peak period and on weekends. 41% of car users in Shanghai would like to shift during such periods. 29% of car users in ShenZhen would like to make the same shift.. 68% of taxi users in Shanghai would like to change to bus or metro. 64% of taxi users in Shenzhen would like to change. The data also reveals that lifestyle habits will also affect the mode structure and in turn affect CO2 emissions.

MEANINGFUL LOCATION DECISION S FOR IKEA

If reducing CO2 emission per customer is the only objective in location

decisions for IKEA, achieving the objective will be relatively simple. IKEA is dedicated to environment protection but also hopes to attract more customers and increase volume of sales.

According to our analysis, IKEA is more attracted to nearby districts. First, it should not be isolated from the city and this will prevent the business from losing customers because of a longer commute. Second, the stores should be in or near compact commercial areas. Admittedly it is difficult to find core commercial areas, but sub-centers or new districts of cities are equally good choices.

High transit accessibility is thus a key factor for CO2 emission reduction. But car accessibility is also very important. IKEA's service area is identified as regional. It always takes metropolis or capital cities in China as location. These cities have a powerful economical influence on regional areas. Long distance trips will also depend on car transportation. Both car accessibility and transit accessibility must be considered while deciding on a location.

ABSTRACT

Based on dynamic simulation and finite element analysis, this paper studies the effect of electro-mechanical coupling on the dynamic characteristics of a crankshaft used in ISG HEV. First, a dynamic model of an electro-mechanical coupling shaft system including flexible crankshaft is built. Then a qualitative analysis of the dynamic property of crankshaft was performed, when the ISG motor worked at assistant pushing mode and power generating mode and when the ISG motor has not coupled to the crankshaft of the engine. It is found that there was no obvious difference on torsional vibration performance of the electromechanical coupling shaft system. But the bending stress of the crankshaft changed a lot, when the flywheel was superseded by the ISG rotor. The results are useful for designing the electromechanical coupling shaft system of a hybrid electric vehicle.

INTRODUCTION

Compared to traditional internal combustion engine vehicles, a hybrid electric vehicle has less fuel consumption and reduces greatly poisonous emissions. Considering the cost and the easy implementation of mass production, Integrated Starter/Generator Mild Hybrid Vehicle (ISG-MHV) has a growing market popularity (Chan, C.C., 2002, Yue, D.P., 2005, Zhou, L.B., 1999). In order to analyze some dynamic problems of the hybrid system electro-mechanical coupling shafting formed from the rigid connection between the ISG motor and the crankshaft, we employed the finite element analysis and multi-body dynamics combined method to analyze the change of stress distribution law and torsional vibration performance for the hybrid system shafting with ISG motor instead of flywheel. This is significant and instrumental for the transformation from conventional vehicles to hybrid electric vehicles.

1 TO BUILD THE FLEXIBLE MULTI-BODY DYNAMIC MODEL.

Finite element analysis not only offers the finite element model to the multi-body dynamic analysis, but also services the crankshaft stress analysis. At the same time, the flexible multi-body dynamic simulation can compute the stimulus for

the hybrid shafting during a cycle and provide the load for analyzing the stress concentration.

1.1 The finite element model for the crankshaft.

For an ISG hybrid electric vehicle, the crankshaft, main bearings, linkage mechanism, pistons and ISG motor make up the hybrid dynamic electro-mechanical coupling shafting. Since the crankshaft has a great influence on the shafting dynamic characteristics, the elastic deformation during running of the crankshaft has to be considered in the computation analysis. Therefore, a finite element model of the crankshaft has been built to generate a modal neutral file, including the crankshaft material, node, element and modal information through the modal comprehensive analysis.

1.2 The models for rigid parts.

Given the inertia force from the high-speed parts, such as the linkage mechanism and pistons, directly and greatly affecting the dynamic performance of the hybrid dynamic shafting, the mass and the design mass should be consistent. The centroid, mass and moment of inertia are required for the multi-body dynamic analysis (Hao, Z.Y., 2005). We thus accurately established 3-dimensional solid models for the pistons, linkage mechanism, belt wheel and simplified ISG rotor. With this, we obtain the corresponding dynamic parameters that were inputted into the simulation software to achieve the rigid model for the hybrid electro-mechanical coupling shafting.

1.3 To apply constraints and forces.

In multi-body dynamic analysis, the practical motion relationship between two parts is generally simplified to the idealized constraint. For example, the constraints between the piston and piston pin, piston and connecting rod small end, and connecting rod big end and crank pin are simplified as hinge constraints. The constraint between piston and cylinder wall is viewed as sliding. We ignored the elastic deformation of all the above mentioned parts and the temperature influence on the torsional-vibration-damper. The torsional-vibration-damper is used for controlling the torsional vibration of the crankshaft system and connecting the belt wheel and the crankshaft by computable stiffness and damping. The support to the crankshaft from main bearings is very important to the system dynamic analysis. The linear spring model, nonlinear spring model and hydrodynamic model are used to stimulate the main bearing's dynamic features (Zissimos, P. M.,2001). In this paper, the hydrodynamic model provided by ADAMS was selected (MSC). The multi-body dynamic model stimulus for the electro-mechanical coupling shafting consists of the cylinder pressure, the force moment on the crankshaft output end from ISG motor, and the power consumed by accessories. To analyze ISG motor's influence on the dangerous stress distribution of crankshaft, the assistance mode and the generation mode with the maximum torque for ISG motor at a constant speed were analyzed. This assumed as given the ISG hybrid electric vehicle control algorithm, while the

in-cylinder pressure curve was measured and the power consumed by accessories was computed and applied to the belt wheel. The multi-body dynamic analysis model of electro-mechanical coupling shafting used to analyze the system dynamic response under steady conditions is shown in Fig.1.

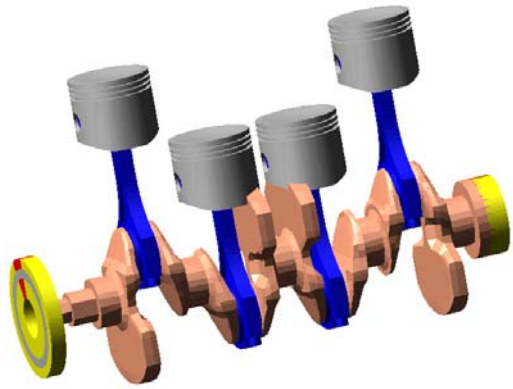

Figure 1. Dynamic analysis model of electro-mechanical coupling.

2 RESULTS AND ANALYSIS.

2.1 Dynamic analysis for the electro-mechanical coupling shafting.

Under the assistance mode and the generation mode with the maximum moment from ISG motor on a constant speed, the hybrid dynamic electro-mechanical coupling shafting was simulated through flexible multi-body dynamic analysis. The simulation result was in comparison with crankshaft-flywheel system, called flywheel mode before transformation to hybrid electric system. The results indicate that there is a similarity for the vertical stimulus on crank pins under the three above mentioned modes. Namely, the force on the crank pin at the second cylinder is minimum; the first near to the belt wheel and the third are larger; the fourth close to the ISG motor is maximum. Therefore, we merely analyzed the dangerous stress on the crank pin at the fourth cylinder. The comparison of the vertical force on the crank pin at cylinder four under the three modes during two cycles of engine is shown in Fig.2. The amplified one is Fig.3.

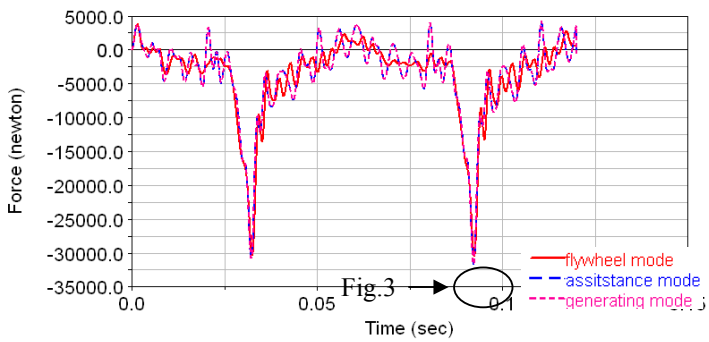

Figure 2. The comparison of the vertical force on the crank pin at the four the cylinder under the three modes.

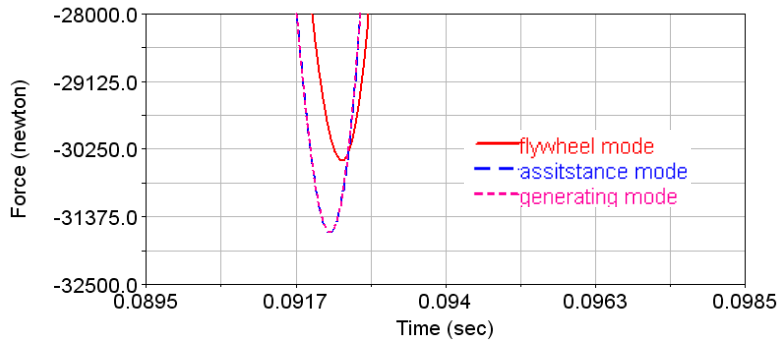

Figure 3. The amplification of Figure 2.

From Fig. 2, we can see that since the rotator mass and moment of inertia for ISG motor are smaller than the flywheel, the vertical force on the crank pin increases. As shown in Fig. 3, in generation mode the maximum force is 31640N, which is 1210N more than 30430N in the flywheel mode. The result illustrates that ISG motor has a great influence on the crankshaft in terms of the force condition. To more clearly explain the dangerous stress change of the crankshaft after connecting rigidly the ISG motor to the output end of the crankshaft, it is necessary to analyze the crankshaft's stress distribution.

2.2 Stress analysis for the crankshaft.

From this analysis, we see that the force on the crank pin at the fourth cylinder is maximum. We thus built a 1/4 model of a single crank to implement the stress analysis. Considering that the connecting rod big end applies force on the crank pin through the bearing, according to the empirical methods and the distribution law of the pressure of the finite-width oil film, we ignored the effect from the peak pressure mutation at the oil hole. We also assumed that the force boundary condition was that the load was distributed as a quadratic parabola along the connecting rod axial direction and as a cosine within 120-degree range of the circumferential direction. It is shown in Fig. 4 (Yin, J.M., 1997). The force was applied in the form of the function and assigned to all the valid nodes when computing.

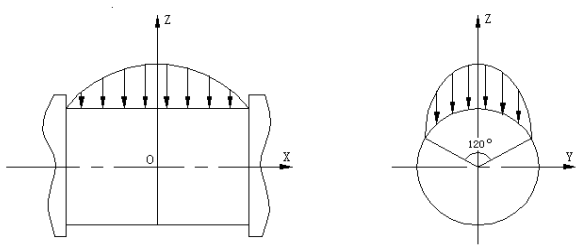

Figure 4. The pressure distribution of connecting rod journal.

Figs.5 and 6 are the stress distribution of the crank, when the vertical force on the crank pin is maximum under generation mode and flywheel mode respectively. From the stress nephogram, we clearly know that the forced dangerous points focus

on the lower part of the transition fillet between the main journal and the crank arm and on the topper part of the transition fillet between the connecting rod journal and the crank arm. The two crank stress distributions are basically similar, but the maximum stress value for the generation mode is 219.39MPa. This is much higher than that of the flywheel mode, 182.7MPa. According to the stress analysis, the fracture of the crankshaft is mainly due to the two transition fillets of the maximum dangerous stress, so the bending fatigue calculation at the transition fillets must ensure the satisfaction of the design requirement. Given the calculating formula of the fatigue safety coefficient provided by Yang (1980), we obtain a coefficient value of 1.09 after connecting rigidly ISG motor to the crankshaft output end. This exceeds the allowable range, 1.3-1.8. Therefore, the crankshaft could not meet the bending fatigue strength just with an electro-mechanical coupling transformation. The result shows that the connecting rigidly of the ISG motor rotator to the crankshaft output end without any transformation causes the change of the crankshaft structural strength. In order to meet the design requirement, the hybrid electro-mechanical coupling shafting should be redesigned and the materials should be reselected. In addition, the processing technology should be improved and the checking work should be implemented periodically to adapt to the different strength requirements between hybrid electric vehicles and conventional cars.

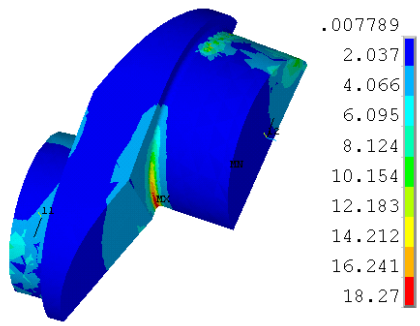

Figure 5. Stress nephogram when the vertical force on the crank pin is maximum in flywheel mode.

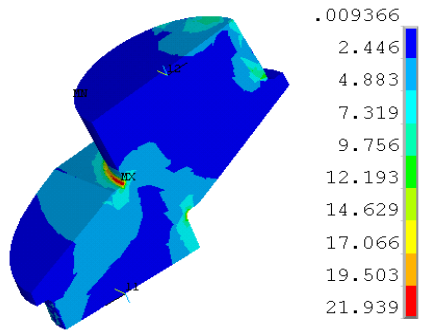

Figure 6. Stress nephogram when the vertical force on the crank pin is maximum in generation mode.

2.3 Torsional vibration analysis of the electro-mechanical coupling shafting.

A tangential force and a normal force whose size and direction are changing over time are imposed on each crank when running, so the torsional and the bending deformations of the crankshaft vary periodically. Connecting rigidly the ISG motor rotator to the crankshaft output end also has the same effect. As any elastic system with inertial mass, the electro-mechanical coupling shafting will form bending and torsional vibrations. In this paper, only the torsional vibration of the shafting is considered, because the bending rigidity is relatively large and the corresponding natural frequency is relatively high. This causes the possibility of bending resonance within the engine's working rotational speed range to be extremely small and negligible. To perform a torsional vibration analysis of a crankshaft based on the Hafner-Maass method, the inertia of each crankshaft throw about the crankshaft axis should be reduced to a physical equivalent torsional vibration train system. The natural frequencies for the conventional crankshaft system and the electro-mechanical coupling shafting after the hybrid dynamic transformation are shown in Table 1.

Table 1. The torsional vibration natural frequency of crankshaft system and electromechanical coupling shaft system.

Order(m)	Crankshaft System(Hz)	Electromechanical Coupling Shaft System(Hz)
1	703.91	1332.53
2	1917.69	2494.33
3	2877.50	3306.72
4	3439.51	6797.40
5	8397.52	8397.52
6	16285.17	16285.18

The speed range of the engine we researched is 800—3800r/m, that is to say the fundamental frequency is 13.3—63.3Hz. Our calculations shows that the harmonic orders of driving torque corresponding to the first order torsional vibration natural frequency of the two system are both above 11. The amplitude of driving torque declines with the rising of the harmonic order. The driving torque is always very small when the harmonic order is above 12 and will not induce obvious vibration (Liang, J., 1989). We know from Table1 that the torsional vibration natural frequency increased, when the rotor of ISG rigidly connected to the crankshaft. The corresponding harmonic order of driving torque is higher than 12 and avoids the resonance appearance at the working speed of engine. Therefore, the transformation of the crankshaft is safe and feasible on torsional vibration performance.

CONCLUSION

In this paper, the dangerous stress and torsional vibration characteristics of an electromechanical coupling shaft system used in ISG_HEV were analyzed, based on

multi-body dynamics and finite element method. The results show that because inertia and mass of rotor are lower than the flywheel, the contacting force between con rod and crank pin increased. For this reason, the rotor of ISG connected rigidly to the output terminal of crankshaft increased the dangerous stress of the crankshaft. On the selected engine, the crankshaft which was transformed to adapt to the HEV cannot meet the requirements of bending fatigue strength. Consequently we suggest that the crankshaft should be adjusted and checked again. Furthermore, the torsional vibration natural frequency of the crankshaft system changed after installing the ISG, but the resonance will not appear at the working speed of the engine. That is why the transformation of hybrid is safe and feasible in torsional vibration analysis. Generally, the transformation from IC engine automobile to HEV is easiest to realize, but the crankshaft system should be adjusted to meet the requirement of HEV.

ABSTRACT

Saving resources, protecting the environment and adopting sustainable development policy will be the objective requirements of highway transportation development in the future. The development of a long-term forecast the automobile population in a critical element to making long-term development plans for the China's highway transportation as well as the policies of environmental protection and energy conservation. Based on the analysis of China's economy, the forecast considers the factors of growth rates of economy, population, and automobile inventory and correlates the distributions of per capita GDP in different regions. The forecast uses methods of trends extrapolation, elasticity coefficient modeling, and inventory scenario comparison and calculates transportation future workload. From these analyses, the forecasted result is that by 2030, the automobile population is estimated to be 230-250 million, which is 1.7-1.9 times that of 2020, and 4.6 times that of 2010.

KEYWORDS: scenario analysis, automobile inventory, forecast

INTRODUCTION

Scientific and accurate forecasts of China's future automobile populations is an important basis for reasonable predicting of our nation's highway transportation and the long-term or short-term development plans of automobile industry in addition to the related policy concerning to environmental protection and energy resources (Chen, 2005).

Potential sources of uncertainty include numerous factors that could contribute to increase of automobile ownership. Although prior research has been conducted in predicting automobile populations have been conducted in China and worldwide, few the complexity of the transportation system and the diversity the related influential factors required by the transportation suggest multiple forecasting methods be used.

The metaphase and long-term forecast of the automobile population with consideration of scenario analysis tally more properly with the reality of China. The result of this study can be used as a guide for making reasonable projects of automobile production and highway transportation, adjusting production and demand and making decisions.

ANALYSIS ON FORCASTING METHODS OF AUTOMOBILE QUANTITY

The current forecasting methods of automobile populations can be generally divided into four categories: (1) time order, that is, the method of forecasting the future state with the previous materials; (2) is the regression forecasting method to find out the relationship between the forecasting variable and its related variables according to the historical materials at hand, so as to forecast the future state; (3) the judgment analysis method, which draws upon experiences and comprehensive analysis of similar states; (4) nerve network forecasting method, which employs of artificial intelligence technology with auto-organization and self-adoption features(Zhou et al., 2001).

Many variables influence the forecasting automobile populations, including, but not limited to, regional economic development, environmental quality, the increase of disposal income, policies, natural condition, highway conditions, the density of road nets and the changes in other industries related to the automobiles. All these factors constitute a quite complicated forecasting problem. So considering the above analysis, this paper describes a metaphase and long-term forecast of China's automobile population using the methods of trends extrapolation, elasticity coefficient, trend comparisons between domestic and worldwide populations, and calculation of transportation workload.

2 THE FORECAST OF AUTOMOBILE QUANTITY

2.1 Method of trends extrapolation

Using historical rates of increases in automobile population, trends were identified to to predict future tendencies of automobile quantity The increasing speed of future automobile quantity will be set up according to three schemes (Development Research Center of the State Council, 2004); the forecasting results of the 3 schemes are presented in Table 1.

Table 1. Automobile Forecast with Trend Extrapolation Method.

item	Period								
	2004-2010			2011-2020			2021-2030		
Volume growth rate (%)	11	12	13	9	10	11	6	6.5	7
Vehicle Population (10^4)	5039	5317	5609	11929	13792	15926	21363	25890	31328

2.2 The analysis method of elastic coefficient s

Since the increases of automobile populations is highly correlated stages of economic development, and possesses its own phase feature, the method of elasticity coefficients was used adopted to predict China's future automobile populations. The elastic coefficient targets in different historic stages are represented in Table 2(Ma et al., 2007).

Table 2. Elastic ity Coefficient of Automobile Development at Different Historical Periods .

Stage	Period	Growth Rate of GDP (%)	Growth rate of Maintain Volume (%)	Elastic Coefficient
five years	1980-1985	10.71	12.49	1.17

Growth rate of Maintain volume(%)	11.2	12	12.8	9.1	9.8	10.5	6.6	7.2	7.8
Maintain volume of automobile(10^4)	5094	5317	5549	12170	13543	15062	23059	27144	31920

2.3 The method of scenario analogy between domestic and abroad .

2.3.1 The analysis of foreign countries scene

The onset and rate of industrialization vary among countries and depend on varying economic conditions, including changes of interest rate. Consequently, the automobile populations of different countries per thousand capita GDP vary over time.. Using literature search, several countries were chosen that had similar economic development as China's reference system. The Table 4 shows the distribution on vehicles possessed by one thousand people and average GDP in

different countries.

Table 4 . Vehicle Ownership per T housand Capita GDP by Country .

Categories of per Capita GDP	Country	Per Capita GDP / (dollars)	Vehicle Ownership per Thousand (1000 Vehicle)
1000-3000 dollars	Malaysia	1170	51.90
	Brazil	2190	74.70
3000-5000 dollars	Brazil	3700	87.34
	Malaysia	3890	126.60
	Japan	4940	250.96
5000-10000 dollars	South Korea	5770	48.40
	South Korea	8910	292.4
Over 10000 dollars	South Korea	10240	133.50
	Japan	10440	323.39

2.3.2 Forecasting of the amount of automobile in different periods of China.

Using the previous forecasts (comparison with foreign automobile populations), China's future traffic policy, the current China vehicle population in various regions, (China Automotive Technology & Research Center, 2001-2004, National Bureau of Statistics of China, 2006), forecasts of future automobile populations were calculated for 2010, 2010, and 2030 and shown respectively in Tables 5 through 7.

Table 5. List of per capita GDP, population and automobile ownership in 2010 .

Income Distribution (dollars)	Population /10^4	per Capita GDP / Dollars	Vehicle Ownership per Thousand People / (veh/1000 pp)	Automobile Pop. forecast (veh)
＜1000 dollars	35164	746	5	1758200
1000-3000 dollars	72647	1676	30	21794100
3000-5000 dollars	16977	3850	70	11883900
5000-10000 dollars	8943	7090	180	16097400
≥10000 dollars	914	10479	200	1828000
Average	134645	2125	40	53858000

Table 6. List of per capita GDP, population and automobile ownership in 2020 .

Income Distribution (dollars)	Population /10^4	per Capita GDP / Dollars	Vehicle Ownership per Thousand People / (veh/1000 pp)	Automobile Pop. forecast (veh)
＜1000 dollars	2960	795	5	148000
1000-3000 dollars	80817	1974	50	40408500
3000-5000 dollars	29709	3769	80	23767200
5000-10000 dollars	23070	6883	200	46140000
≥10000 dollars	9531	13882	250	23827500
Average	146087	3867	100	146087000

Table 7. List of per capita GDP, population and automobile ownership in 2030 .

Income Distribution (dollars)	Population /10^4	per Capita GDP / Dollars	Vehicle Ownership per Thousand People / (veh/1000 pp)	Automobile Pop. forecast (veh)
1000-3000 dollars	39133	2262	50	19566500
3000-5000 dollars	49463	4037	100	49463000
5000-10000 dollars	38129	6786	180	68632200
≥10000 dollars	28366	16386	400	113464000
Average	155091	6524	180	279163800

The result of the international scene analogy predicts the prospect of China automobile market. China's automobile quantity increase from 53 million to 54 million cars in 2010; and from 130 to 150 - hundred million by 2020. By 2030, the vehicle population is predicted to be between 250 and 280 million.

2.4 The method of transportation workload calculation

The transportation load which the automobile transportation considers the composition of transportation system to calculate the automobile quantities. The average finished workload of highway passengers and goods transportation of China's whole society in 1980-2004 is shown in Figure 1. With the increased proportion increasing of the minibus, the average workload of the whole society's passenger buses tends to decrease. With the change of truck's structure and the increase of loaded Lorries, the workload of Lorries tends to rise. From this analysis, the rapid increase of cars is expected to continue into the future. With the constant increase of large size bus, mini cars and the decreasing proportion of medium cars, the transportation workload of each car will continuously increase. Predictable result of the whole society's automobile quantity in 2010, 2020, and 2030 is shown in Table 8.

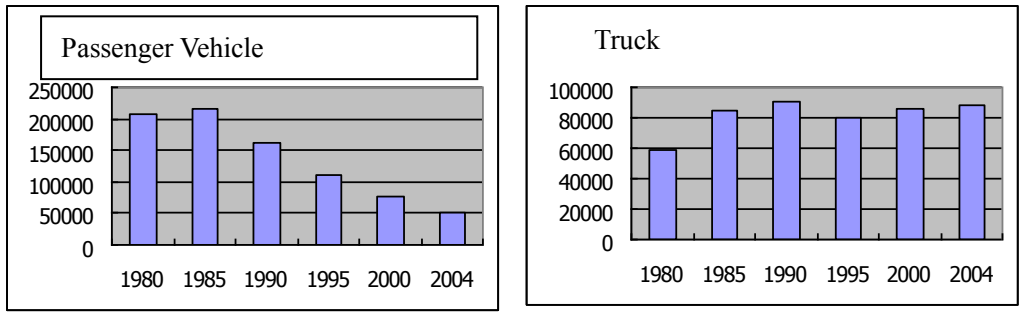

Figure 1. Workload Completed by Passenger vehicle and Truck s (1980-2004).

Table 8. Automobile Inventory in 2010, 2020 and 2030 .

Year	Passenger vehicle /[(10^8·passenger)·km]	Truck /[(10^8·t)·km]	Passenger Vehicle /[(passenger·km)·veh $^{-1}$]	Truck /[(t·km)·veh $^{-1}$]	'Automobile Population /10^4veh
2010	14300	11000	35000	80000	5461
			30000	70000	6338
2020	25000	16000	25000	90000	11778
			20000	80000	14500
2030	30000	22000	12000	100000	27200
			10000	90000	32444

According to transportation workload forecast China's automobile quantity in 2010, 2020, 2030 will separately up to 54 to 64 Million, 120 to 150 million, and 247 to 330 million, respectively.

3 THE ANALYSIS OF FORECASTING RESULT

The future China's automobile population depends on the rate of increase of of economic development and energy supply. The China's automobile population predictions for years 2010, 2020 and 2030 were developed through the use of the following methods: this forecasting result, the method of trends extrapolation, elastic coefficient, scenario analogy between domestic and international, and transporation workload conribution analysis.. Table 9 summaries the results of thes different forecasting methods.

Table 9. Automobile forecast results with different methods .

method	2010 /10^4 veh	2020 /10^8 veh	2030 /10^8 veh
trends extrapolation	5000-5600	1.2-1.6	2.1-3.1
elastic coefficient	5000-5600	1.2-1.5	2.3-3.2
scene analogy	5300-5400	1.3-1.5	2.5-2.8
transportation workload	5400-6400	1.2-1.5	2.7-3.3

CONCLUSION

In the coming 20 or 30 years, the China's automobile quantity will increase at a rapid rate. The forecasting result of automobile quantity shows that, by the year 2030, it will reach 230 million to 250 million, which is 1.7 times as much as the automobile quantity of 2020 and 4.6 times of 2010. The large extent of increase could provide additional pressures to the land and energy resources and the environmental quality.

The restriction of resources and the protection of the environmental are two subjects that must be considered in the development of China's highway transportation future. Such consideration would warrant the use of scientific development concepts in order to conserve resources, to protect environment, and to adopt sustainable development policy.

ABSTRACT

Electric vehicles require high reliability, relatively wide torque and speed ranges and a high-power volume ratio. At present, induction motors, permanent magnet synchronous motors and switched reluctance motors have been successfully applied to hybrid vehicles; but there are still many deficiencies. Permanent magnet synchronous motors are widely used in the drive of electric vehicles because of their efficiency, high power density and high-torque characteristics. In the paper a mathematical model for vector control algorithms, control methods, and control strategies for use by hybrid electric vehicle will be developed. Meanwhile, an analysis of control system mechanisms, design software, and hardware based on DSP-based control will also be undertaken. An application of vector-driven direct torque control will be examined. The experimental results proved that the system has good performance.

Keywords: permanent magnet synchronous motor, electric vehicle, energy feedback

1. ITRODUCTION

Hybrid electric vehicles (HEV) and fuel cell vehicles (FCEV) have become hot spots for R&D (Guo Wei et al. 1999). Permanent-magnet synchronous motors are widely used in electric vehicles because of their relatively high efficiency, high power density, high torque unit current, and wide-speed operation. Additionally their performance closely emulates the driving performance of traditional motor vehicles (Chu C.L et al. 2001). In this paper, based on mathematical modeling of permanent magnet synchronous motors, a vector control algorithm for permanent magnet synchronous motors to maximize torque/current control of permanent magnet synchronous motor used for hybrid electric vehicles will be presented. The goal is to maximize torque control per unit current output. This is a major current control strategy optimization for permanent magnet synchronous motors. When a permanent magnet synchronous motor operates with maximum torque/current control, it lets the motor accelerate with maximum electromagnetic torque (At this point the motor voltage and current

limits are reached), which makes the engine start quickly. In addition, starter/generator system's efficiency can improve because of the minimum of inverter output current.

2. BASIC MATHEMATICAL MODEL OF PERMANENT MAGNET SYNCHRONOUS MOTOR

Vector control is actually the control of current vector phase and amplitude of the motor's stator. When excitation flux of the permanent magnet and direct-axis and cross-axis inductance are determined, the motor torque is dependent on the stator's current space vector i_s, and the size and phase of i_s is dependent on i_d and i_q, that is to say, it can control the motor torque by controlling i_d and i_q. A certain degree of speed and torque correspond to a particular theoretical values of i_d and i_q, i_d^* and i_q^*. By controlling these two currents the actual values of i_d and i_q can be brought closer to the theoretical values i_d^* and i_q^*. The tighter vector control enables more precise control of the motor's torque and speed. (Kim Junha et al. 2002)

Because the actual feed current for the armature windings of the motor is three-phase AC current with values i_u, i_v and i_w there are three current control values, i^*_u, i^*_v and i^*_w, that the system can command. The theoretical values i_u^*, i^*_v and i^*_w are derived from the following conversion($e^{j\theta}$ transformation) and are based on i^*_d and i^*_q:

$$\begin{bmatrix} i_U^* \\ i_V^* \\ i_W^* \end{bmatrix} = \sqrt{\frac{2}{3}} \begin{bmatrix} \cos\theta & -\sin\theta \\ \cos\left(\theta - \frac{2\pi}{3}\right) & -\sin\left(\theta - \frac{2\pi}{3}\right) \\ \cos\left(\theta + \frac{2\pi}{3}\right) & -\sin\left(\theta + \frac{2\pi}{3}\right) \end{bmatrix} \begin{bmatrix} i_d^* \\ i_q^* \end{bmatrix} \tag{1}$$

Using the current control loop, the actual three-phase currents to the motor, i_U, i_V and i_W can be made consistent with the given theoretical values, thus realizing the control of motor's torque. (Cikanek et al. 2002)

3. THE CONTROL STRATEGY OF PERMANENT MAGNET SYNCHRONOUS MOTOR USED FOR ELECTRIC VEHICLE

Maximum torque/current control, also known as the maximum torque control of unit current output, is a major current control strategy used for permanent magnet synchronous motors. When permanent magnet synchronous motors adopt maximum torque/current control, the motors accelerate with the maximum electromagnetic torque deliverable within the motor voltage and current limits. This high torque makes the engine start quickly. In addition, starter/generator system efficiency can be improved because of the minimization of inverter output current. Next, we will do the specific analysis for the maximum torque/current control. (W. Xia et al. 1998)

When operating at the maximum torque/current control a motor's current vector should meet the following conditions:

$$\begin{cases} \dfrac{\partial (T_{em} / i_s)}{\partial i_d} = 0 \\ \dfrac{\partial (T_{em} / i_s)}{\partial i_q} = 0 \end{cases} \tag{2}$$

We can get the relationship between the electromagnetic torque, cross-axis, and direct-axis current components:

$$T_{em}^* = \sqrt{i_d^* (1 - i_d^*)^3} \tag{3}$$

$$T_{em}^* = \frac{i_d^*}{2}[1 + \sqrt{1 + 4i_q^{*2}}] \tag{4}$$

Stator's current component i_d^* and i_q^* can be expressed as:

$$\begin{cases} i_d^* = f_1(T_{em}^*) \\ i_q^* = f_2(T_{em}^*) \end{cases} \tag{5}$$

For any given torque, it can obtain the two weights of the smallest current which that can be used as current control command while achieving the maximum torque motor/current control. The current control curves found in Figure 1 are derived from Eq. (5).

The control operation of PMSM is closely related to the inverter system and the motor's performance is generally restricted by the inverter. The most obvious limitation is the extremum with the virtual value of phase voltage of the motor $U_{\lim}$, and the extremum of the virtual value of phase current $I_{\lim}$. Both are restricted by the inverter's DC side voltage and the maximum inverter output current. On the system's d-q axis the limit of voltage is $u_{\lim} = \sqrt{3}U_{\lim}$ and the limit of current is $i_{\lim} = \sqrt{3}I_{\lim}$.

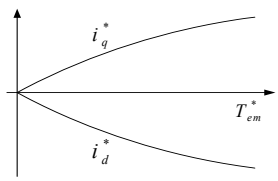

Fig.1 Curve of i_d^*、i_q^*

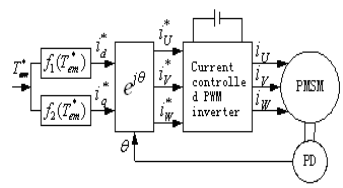

Fig.2 Control system of maximum rate of torque/current

Figure 2 is the system diagram of torque control link in the largest torque/current control. When the motor runs at high speed, the resistance is far less than the reactor, you can ignore the resistance of the voltage's drop, there is:

$$u = \sqrt{u_d^2 + u_q^2} = \sqrt{(X_q i_q)^2 + (X_d i_d + e_0)^2} \tag{6}$$

Where, X_d and X_q are the direct-axis reactance and cross-axis reactance of the motor, and e_0 is the no-load back-EMF. $e_0 = \omega\psi_f = \sqrt{3}E_0$
Using $u_{\lim}$ in place of u, Eq. 7 can be obtained:

$$(L_q i_q)^2 + (L_d I_d + \psi_f)^2 = (u_{\lim} / \omega)^2 \tag{7}$$

The equation above is the equation of a current limit circle. When the motor is running, the stator's current space vector can not only exceed the motor's voltage limit ellipse, but also the current limit circle. Motor's maximum torque/current track and the current limit circle intersect at point A, as shown in Figure 3:

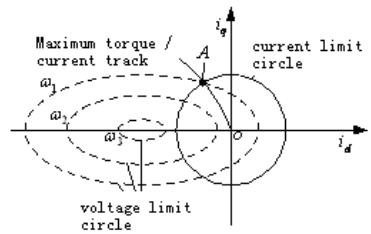

Fig.3 Vector graph of stator's current

The speed which corresponds to the voltage limit ellipse that goes through point A is ω_1. In OA paragraph of the maximum torque/current trajectory, the motor can run in the constant torque corresponding to the points of this trajectory, and the speed corresponds to the voltage limit circle which through this point is the turn-speed under this torque. Then, point A corresponds to the turning speed when the output torque of the motor is greatest. Turn-speed can be obtained through the following formula:

When $L_d \neq L_q$, (Salient-pole permanent magnet synchronous motor)

$$\Omega = \frac{u_{\lim}}{p\sqrt{(L_q i_{\lim})^2 + \psi_f^2 + \dfrac{(L_d + L_q)C^2 + 8\psi_f L_d C}{16(L_d - L_q)}}} \tag{8}$$

In the equation $C = -\psi_f + \sqrt{\psi_f^2 + 8(L_d - L_q)^2 i_{\lim}}$

When $L_d = L_q$, (Surface permanent magnet synchronous motor)

$$\Omega = \frac{u_{\lim}}{p\sqrt{(L_q i_{\lim})^2 + \psi_f^2}} \tag{9}$$

From Figure 3 we can see, when the motor runs at constant torque, the greater the torque value is, the lower the turn-speed is. Because voltage and current can not exceed their limits when the motor is running, so the torque corresponded to the point A is the maximum output torque of the motor. When maximum torque/current control is used and the current of the motor reaches its limit (corresponding to the maximum torque/current limit and current limit circle's node A), the cross-axis and direct-axis currents of the motor can be obtained from the following formula:

$$\begin{cases} i_d = \dfrac{-\psi_f + \sqrt{\psi_f^2 + 8(L_d - L_q)^2 i_{\lim}^2}}{4(L_d - L_q)} \\ i_q = \sqrt{i_{\lim}^2 - i_d^2} \end{cases} \tag{10}$$

While the electromagnetic torque is:

$$T_{em} = \frac{(4\psi_f + C)\sqrt{4\psi_f C + C^2}}{16(L_q - L_d)} \tag{11}$$

The current vector for the starter/generator at constant torque control can be found from Eq. (10). The starter/generator will provide acceleration with the maximum electromagnetic torque at a given speed when the current vector value follows along the maximum torque/current trajectory presented previously.

4. THE MANUFACTURE OF THE DRIVING SYSTEM OF PERMANENT MAGNET SYNCHRONOUS MOTOR

With a driving control system composed of DSP as the core a block diagram of the control circuit is shown in Figure 4. The motor's three-phase windings are controlled by a three-phase bridge circuit composed of IGBT modules made with EXB841integrated circuits.

DSP is composed of TI TMS320LF2407. Six way comparison units are used as the drive signals for the three-phase IGBT bridges. The signals will go to the EXB841 drive unit after they are processed; the capture unit 3 receive the pulse signal from the sensor which can control the phase; the mouth of analog-digital conversion unit 2, 3, 4 receive the signal from the current sensor of stator windings, the mouth 10 receives the sign from the current sensor of the axial coil.

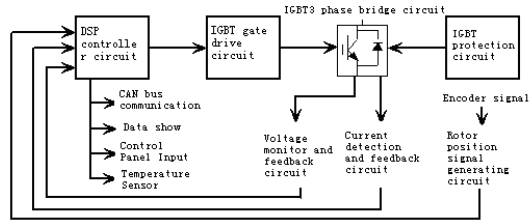

Fig.4 The controller's circuit diagram of permanent magnet synchronous motor

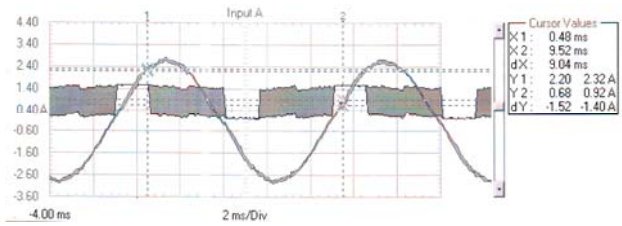

Fig.5 SPWM wave and phase's current wave of the PM synchronous motor driver

5. EXPERIMENT AND CONCLUSION

For the design of a motor control system, bench tests and functional tests can not only shorten the hybrid vehicle test cycle, reduce the risk and cost of R&D, but also guide further research for the system. This section researches the functional test of the permanent magnet synchronous motor system.

Figure 6 is the three-dimensional map of speed-torque-efficiency in electrical state; Figure 7 is the shadow map of peed-torque-efficiency in electrical state.

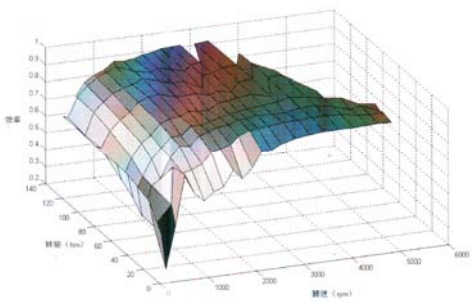

Fig.6 Three dimensional graphics of motor Speed - torque - efficiency in driving

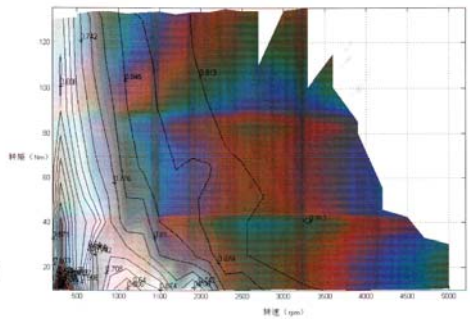

Fig.7 Dot band chart of motor speed - torque - efficiency in driving

From the comparison of experimental and theoretical efficiency, we can see that theoretical efficiency increases with the torque. In the calculation of theoretical efficiency additional wastage and mechanical wastage have been ignored as well as the effects that rising temperatures bring to electrical resistance of the motor. These simplifications will result in an increase in the value of theoretical efficiency at large torques. At low motor currents the measurements by the laboratory equipment will lead to higher relative error. Thus, the actual experimental efficiency at lower torques will be closer to theoretical efficiency and closer to experimental efficiency at higher torques.

ABSTRACT

This paper analyzes the mass-transfer and diathermancy of the three-way catalytic converter (TWCC). Applying mass-conservation and energy-conservation for gas and solid, the paper establishes a TWCC inner equation and makes the model dimensionless. The numerical models between the conversion efficiency and outlet-inlet gas temperature difference of TWCC working at a stable condition are derived. Lastly, the verified experiment is processed and the reasons for the errors are explained. The results show that the models are useful.

INTRODUCTION

Today every new gasoline car is equipped with a three-way catalytic converter (TWCC) in combination with a fuel control system to reduce the pollutant in the exhaust from the gasoline engine. On-board fault diagnosis (OBD) for TWCC is necessary under new emission legislation. The OBD system can monitor the catalyst performance and the engine operation. The monitoring methods and technologies for three-way catalyst converter (TWCC) efficiency are core techniques of the OBD system. The main methodologies currently assess catalyst performance indirectly by existing sensors.

Exhaust emission limits imposed on HC suggest that a catalyst assessment system based on a sensor monitoring this pollutant is more desirable, although a CO or NOx sensor is also a possibility. Presently, HC sensors are under development, but they are not yet commercially available. Therefore, until the necessary technological progress is made, a compromise technical solution must be found for the design of low-cost monitoring systems based on existing sensor technology.

Two alternative technologies are now under development (Botsaris and Sparis, 2000). The first approach, adopted by many auto manufacturers, uses existing oxygen sensors. With the oxygen sensor approach, an additional oxygen sensor is installed after the catalyst to evaluate the catalyst performance by comparing its signal with the normal oxygen sensor placed before the catalyst. Another approach using oxygen sensors for catalyst efficiency monitoring is temperature sensors known as thermocouples. The approach has not yet been introduced in car production. Because the reactions occurring in the catalytic converter are strongly exothermic,

the measurement of the exhaust gas temperature difference of the catalytic converter out-inlet offers valuable information regarding its efficiency. So the second approach is also called the exotherm method (Tsinoglou and Koltsakia, 2002).

Temperature sensor technology is quite advanced, so it is used widely in the avigation and automobile fields. Compared with the oxygen or HC sensor, the temperature sensor has the advantage of quick response, dependability and lower cost. Presently, the high temperature sensor can meet the demands of auto-exhaust emission measurement. So the exotherm method is one direction for study on OBD monitoring of TWCC.

However, OBD monitoring studies use temperature sensors mainly to centralize experimentation and to utilize some experiential or qualitative evaluation strategy. From the standpoint of hydrodynamics and multiphase catalytic exotherm, this paper probes the relation of the catalytic thermal quantitied index, i.e., catalytic outlet-inlet temperature difference, and TWCC efficiency, and establishes a quantitative control model.

ANALYSIS FOR TWCC TRANSFER -MASS AND TRANSFER -HEAT

Inside the TWCC, there are not only catalytic reactions in the gas phase and solid phase, but also complicated transfer-heat phenomena. The vehicle emission is produced in engine flow via the paths of a TWCC' carrier, where CO, HC and Nox react in the catalyst process. Simultaneously, the pollutants exchange the heat with the TWCC carrier, which includes the process of intricate chemical and physical reaction. The pollutants transfer heat and mass by convection. Heat is exchanged between the emission in the pathes and the carrier. The mass is transferred between the pollutants in the pathes and the exhaust emission is absorbed in the catalyst surface because of the concentration difference. The emission absorbed in the catalytic surface reacts differently than in phase catalysis, which would come into being in an exothermic reaction. The temperature grad in the TWCC brings transferring heat in solid phase, and the heat flows to the ambient through the shell of TWCC.

TRANSFER -HEAT AND TRANSFER -MASS MODELS FOR TWCC

Currently, most TWCCs used in vehicles are a type of beehive ceramic. So in this paper the object is this type TWCC. As the catalyst converter is beehive, the carrier of TWCC is folded with thin pathes. When the exhaust gas rushes into the carrier, in fact, the exhaust gas rushes into the pathes. Therefore, in order to establish the transfer-heat and transfer-mass models of TWCC, firstly, the models for the single path are set up.

TWCC Transfer -mass Models of Gas Phase and Solid Phase.

$$\varepsilon \frac{\partial C_{g,i}}{\partial t} + \frac{\rho_p v_p}{\rho_g} \frac{\partial C_{g,i}}{\partial x} = k_{f,i} \cdot S(C_{s,i} - C_{g,i}) \quad (1)$$

$$S_{cat} R_i(\overline{C}_s, T_s) = \frac{\rho_g}{M_g} k_{f,i} \cdot S(C_{g,i} - C_{s,i}) \quad (2)$$

Where ε is void of monolith; $C_{g,i}$ is gas state concentration of species "i", mole fraction; ρ is gas density, kg/m^3; v is gas velocity, m/s; $k_{f,i}$ is mass transfer coefficient of species "i", cm/s; S isgeometric surface area p.u.reactor volume, cm^2/cm^3; $R_i(\overline{C}_s, T_s)$ is specific reaction rate for species "i", mol/(Pt·cm^2·s); and T_S is wall temperature, K.

TWCC Transfer -heat Models of Gas Phase and Solid Phase.

The TWCC carrier transfer-heat model of the gas phase is the following equation:

$$\varepsilon \rho_g \frac{\partial T_g}{\partial t} + \rho_p v_p \frac{\partial T_g}{\partial x} = h_x \frac{S}{C_{p,g}} (T_s - T_g) \quad (3)$$

Where T_g is gas temperature, K; h_x is the heat transfer coefficient in the direction of x axle, J/(cm^2·s·K).

The TWCC carrier transfer-heat model of solid phase is established based on the single pathes model.

So The TWCC carrier transfer-heat model of solid phase is:

$$(1-\varepsilon)\rho_s C^M_{p,s} \frac{\partial T_s}{\partial t} = (1-\varepsilon)\left[\lambda_{s,x} \frac{\partial^2 T_s}{\partial x^2} + \lambda_{s,y} \frac{\partial^2 T_s}{\partial y^2} + \lambda_{s,z} \frac{\partial^2 T_s}{\partial z^2}\right] + h_x S(T_g - T_s) + S_{cat} \sum_{i=1}^{n} (-\Delta H)_i R_i(\overline{C}_s, T_s) \quad (4)$$

Where $C^M_{p,s}$ is the specific heat of the wall, J / (kg·K); λ_s is thermal conductivity of solid, J/(cm^2·s·K); $(-\Delta H)_i$ is the heat of combustion of species "i",J/mol.

DIMENSIONLESS TO TWCC TRANSFER -HEAT AND TRANSFER -MASS MODELS

Predigestion of the Models. Considering that the rate of chemical reaction is far faster than the rate of thermal response, the time to respond gas phase can be

ignored, i.e. $\frac{\partial T_g}{\partial t} = \frac{\partial C_{g,k}}{\partial t} = 0$.

Then the equation (1) and (3) can be predigested to the following two equations:

$$\frac{\rho_p v_p}{\rho_g}\frac{\partial C_{g,k}}{\partial x} = k_{f,k}\cdot S(C_{s,k} - C_{g,k}) \quad (5)$$

$$\rho_p v_p \frac{\partial T_g}{\partial x} = h_x \frac{S}{C_{p,g}}(T_s - T_g) \quad (6)$$

Because the TWCC's carrier is symmetrical along the axis, its coefficients of heat exchange in the direction of the y and z axes are the same. Then, $\lambda_{s,y} = \lambda_{s,z}$, the equation (4) can be predigested to:

$$(1-\varepsilon)\rho_s C_{p,s}^{M}\frac{\partial T_s}{\partial t} = (1-\varepsilon)\left[\lambda_{s,x}\frac{\partial^2 T_s}{\partial x^2} + 2\lambda_{s,y}\frac{\partial^2 T_s}{\partial y^2}\right] + h_x S(T_g - T_s) + S_{cat}\sum_{i=1}^{n}(-\Delta H)_i R_i(\overline{C}_s, T_s) \quad (7)$$

Dimensionless to TWCC Transfer -heat and Transfer -mass Models.

$$\overline{v}\cdot\frac{\partial \overline{C}_{g,k}}{\partial x} = \frac{Sh\overline{D}_k}{\overline{R}_h^2}(\overline{C}_{s,k} - \overline{C}_{g,k}) \quad (8)$$

$$\overline{S}_{cat}\overline{R}_k(\overline{C}_s, T_s) = \frac{Sh\overline{D}_k\varepsilon}{\overline{R}_h^2 D_a}C_{g,co}^{in}\overline{\rho}_g(\overline{C}_{g,k} - \overline{C}_{s,k}) \quad (9)$$

$$\frac{\partial \overline{T}_g}{\partial \overline{x}} = \frac{Nu\varepsilon}{Pr\,Re\,\overline{R}_h}\overline{T}_g^{0.832}(\overline{T}_s - \overline{T}_g) \quad (10)$$

$$\frac{1}{Pr\,Re}(\overline{\lambda}_{s,x}\overline{R}_h\frac{\partial^2 \overline{T}_s}{\partial \overline{x}^2} + 2\overline{\lambda}_{s,y}\frac{\partial^2 \overline{T}_s}{\partial \overline{y}^2}) + \frac{Nu\cdot\varepsilon\overline{T}_g^{0.832}(\overline{T}_g - \overline{T}_s)}{Pr\,Re\,\overline{R}_h(1-\varepsilon)} + \frac{\overline{S}_{cat}HeDa}{(1-\varepsilon)}\sum_{i=1}^{n}(-\Delta\overline{H})_i\overline{R}_i(\overline{C}_s, T_s) = 0 \quad (11)$$

TEMPERATURE MONITORING MODEL FOR CONVERSION EFFICIENCY OF TWCC

The average conversion efficiency of TWCC is defined as follows:

$$\eta = \frac{\sum_{i=1}^{n}(-\Delta H)_i C_{g,i}^{in}\eta_{i,\ ave}}{\sum_{i=1}^{n}(-\Delta H)_i C_{g,i}^{in}}\times 100\% \Rightarrow \sum_{i=1}^{n}(-\Delta H)_i C_{g,i}^{in}\eta_{i,\ ave} = \eta\cdot\sum_{i=1}^{n}(-\Delta H)_i C_{g,i}^{in} \quad (12)$$

The following model can be deduced with the above control models, which is the Temperature Monitoring Model for Conversion Efficiency of the TWCC:

$$\eta = \frac{\sum_{i=1}^{N} C_i M_i \cdot \sum_{i=1}^{N} C_i \rho_i c_{pi}}{\sum_{i=1}^{N} \rho_i C_i \cdot \sum_{i=1}^{n} (-\Delta H)_i C_{g,i}^{in}} \Delta T_{ave} \qquad (13)$$

The equation (13) indicates that the catalyst temperature difference is related to its efficiency, when the inlet-gas concentration is stable. So, in that case, catalyst efficiency or age can be evaluated by measuring catalytic outlet-inlet temperature difference.

VERIFYING EXPERIMENT FOR THE MODELS AND ERROR ANALYSIS

A TWCC in good condition is used in the verifying experiment on the engine bench, when the engine is in stable condition. The thermocouple sensors are used to measure temperatures in the TWCC inlet and outlet. At the same time, the concentrations of the inlet and outlet gas are gained from an AVL five-gas instrument. Combining with the different of the inlet-outlet exhaust temperature, this paper applies the above Temperature Monitoring Model to compute the conversion efficiency of the TWCC and, then, compares it with the measured result.

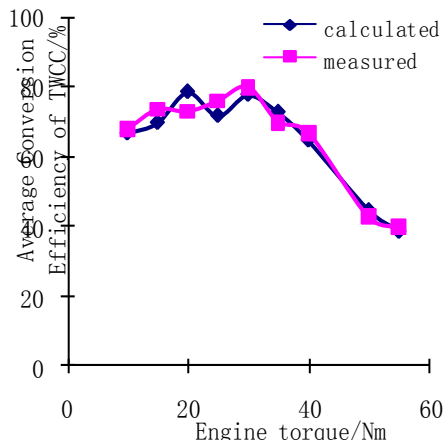

Figure 1. Comparison with average conversion efficiency of a TWCC at different engine torque .

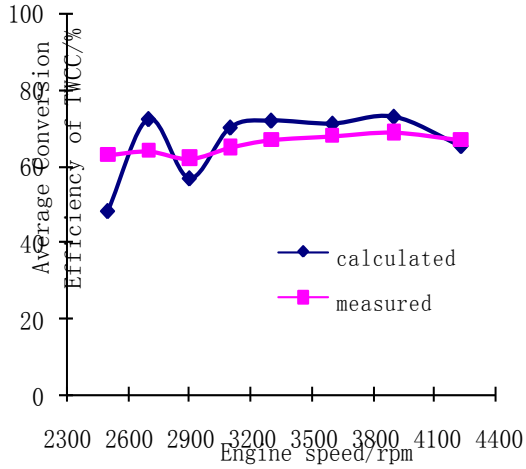

Figure 2. Comparison with average conversion efficiency of a TWCC at different engine speed .

It is shown in Figures 1 and 2 that the results of verifiying experiment and calculating with the model are consistent on the whole. The average error is 8.68%. Three reasons for the error were identified: First, the error is brought on by connatural error of the measuring devices. When measuring, the two devices cannot be absolutely synchronous. The temperature should be read at the same time when sampling, but it is difficult to finish. The temperature sensor's reliability and human error can be potential trouble. Second, the hypothesis of the model can be imperfect, which must make some error compared to the experiment result. Third, the selection of parameters in models can be problematic, because those parameters can vary from

the exhaust gas temperature and pressure.

CONCLUSION

The phenomena of transfer-mass and transfer-heat in theTWCC are discussed. From the standpoint of hydrodynamics transfer-heat and multiphase catalytic exotherm, according to gas phase and solid phase mass conservation and energy conservation within TWCC, the paper develops transfer-mass and transfer-heat conservation models for a monolithic catalytic converter and offers controlling equations to develop the monitoring model.

By making the equations dimensionless, the TWCC monolithic monitoring model is developed and the application of the monitoring models is analyzed. The analysis indicates that catalyst efficiency or age can be evaluated by measuring catalytic outlet-inlet temperature difference. Lastly, the verifying experiment is processed. It shows that the results of a verifiying experiment and calculating with the model are consistent on the whole. So, the model developed is useful for monitoring TWCC on board.

ABSTRACT

Progress in diesel engine and filtration materials have made it easier to apply a burner type diesel particulate filter (DPF) in emission control. A full-flow burner type regeneration system is developed to remove diesel particulate matter (PM) deposited in DPF. Auxiliary air from a turbocharger is used to assist the ignition of burner and complete the combustion. Seeking the optimal parameters in terms of spray angle, injection pressure and spray position, a computational fluid dynamics (CFD) model is constructed and validated. Simulation with this CFD model identifies the main impact factor. A bench experiment is used to investigate characteristic of this regeneration system. The results show that exhaust temperature can be enhanced to 300 ℃ in 100 s by the burner, when the engine works at 0 N·m. The exhaust can be heated up to 500 ℃ when the burner and DOC (diesel oxidation catalyst) work together. The burner system can regenerate DPF efficiently in a wide operating range combining with fuel additive.

INTRODUCTION

Diesel engines have been recognized as one of the most efficient power sources for transportation machinery, since the air pollution and energy problems have become increasingly severe. However, their particle emission is still a big problem, although much progress has been made in the past twenty years. For compliance with tightening emission regulations, diesel particulate filters (DPF) are widely acknowledged in particle emission control.

The great difficulty in DPF application is its regeneration, since the soot collected in a filter has to be burnt off periodically to prevent clogging of the filter and passive influence on the engine. Usually the required temperature-level of this combustion is above 500 ℃. Even this range may be lowered to 300℃. By means of catalyst, either coatings or fuel-borne, the regeneration can not be fulfilled in all operating conditions yet. So many active regeneration technologies, such as electrical heating, microwave heating and infrared heating, have been studied (He, et al, 2007; Tim, 2007; Tan, et al, 2005).

Compared with other technologies, regeneration by burner has higher energy

efficiency and is easier to control (Paul, et al, 2002; Zi, et al, 2008). There are two kinds of burner DPF systems: one is by-pass and the other is full-flow. In the by-pass system, the exhaust will not pass through the burner and DPF in the regeneration process. In this way, the combustion in the burner will not be affected by the exhaust. But the location of the burner in the exhaust system becomes a serious problem, because of its volume and cost. So full-flow burner is preferable in commercial applications. However, in a full-flow DPF system, the exhaust will pass through the burner in the regeneration process, which brings about the difficulty of combustion. In this paper, a full-flow burner using compressed air from a turbocharger is designed to reduce system cost and complexity. Compared with traditional design processes, the computational method is not limited by economic or technical constraints. So a CFD model is constructed in the full-flow burner design to determine the optimal parameters. According to the simulation results, a full-flow burner DPF after-treatment system is set up for experimental investigation of thermal response.

DPF REGENERATION SYSTEM

Figure 1 shows a schematic of the burner-type DPF regeneration system designed in this work. Engine exhaust gas passes through the wall-flow filter during the filtration period. A full-flow burner, DOC and DPF are arranged in turn in the exhaust tailpipe. Because the power of the burner mainly depends on the limited air supplied from a turbocharger, so a diesel fuel injector is located on upstream DOC aiming at enhancing exhaust temperature by HC's oxidation process. In addition, Fuel additive (Fe based fuel borne catalyst) is used to extend the regeneration area in the engine MAP and prolong regeneration intervals. In the regeneration process, the exhaust will be heated initially by the burner. When exhaust temperature at the DOC inlet reaches 300 ℃, diesel fuel is sprayed upstream DOC and the exhaust will be heated further to the regeneration temperature.

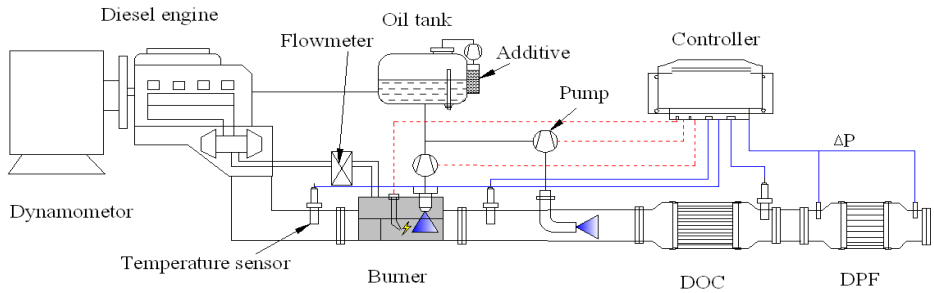

Figure 1. Schematic of DPF regeneration system .

BURNER CONFIGURATION AND OPTIMIZATION

Full-flow burn er configuration. A full-flow burner used in this paper is shown in Figure 2. The combustion chamber is "submersed" in the engine exhaust. This permits exhaust to circulate around the outside of the combustion chamber. In

this manner, the combusted fuel heat, as well as radiant heat emitted from the combustion chamber wall, is transferred to the exhaust. This limits heat loss during the combustion process.

The burner is fired with diesel. A schematic of the air distribution system in the burner is shown in Figure 3. The atomized fuel is provided by a swirl nozzle at the center of the first combustion chamber. Six small holes surrounding the nozzle let compressed primary air enter into the combustion chamber. A pair of electrodes operable to ignite fuel is located near the nozzle. The fuel is atomized and ignited in the first combustion chamber before entering the secondary combustion chamber. And it is completely burned in the secondary combustion chamber assisted by six swirl generator surrounding the expand chamber, through which the secondary air supply will flow to secure a homogeneous turbulent flow of the combustion air.

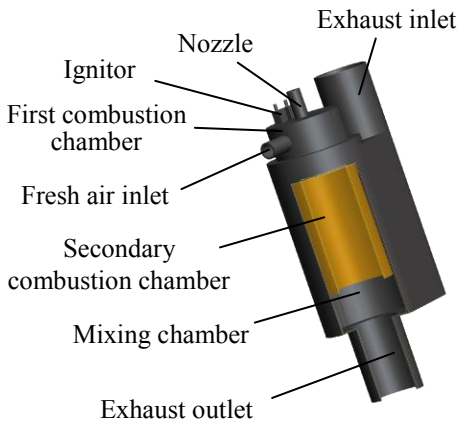

Figure 2. Layout of the burner .

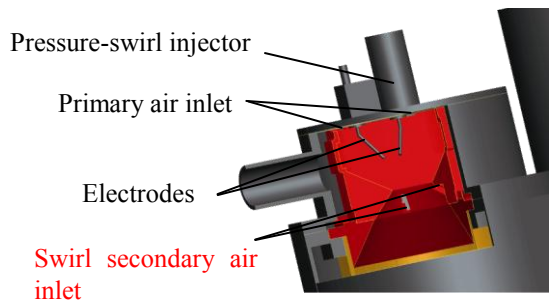

Figure 3. Schematic of air distribution system in burner .

CFD model and validation. Simplified assumptions introduced to the model are the following: First, the exhaust inlet and outlet are not modeled. Under this assumption, the mixture of engine exhaust and combustion air will not be considered. This leads to a lower number of mesh cells, better computational stability and minimization of computational time. Second, the combustion air inlet duct is not modeled. This simplification assumes that the combustion air flow will not be affected severely. Thus, only the combustion chamber is modeled. The surface of computational mesh is displayed in Figure 4. Tetrahedral mesh elements are applied. The proportion between primary and secondary air is 2:3. The length of the first combustion room is 40 mm, and its diameter is 72 mm. The length of the second combustion room is 195 mm, and its diameter is 94 mm. The entire mesh consists of about 71,953 cells. A pressure-swirl atomizer fuel spray model, probability density function (PDF) combustion model and RNG k-ε turbulent flow model are used in the simulation (Chiara, et al, 2007; Marek, et al, 2007).

Validation of the model is based on the mean temperature of the combustion chamber outlet. A SOFIM 8140.27S diesel engine was used in this project. The

details of the engine specification are listed in Table 3. Boundary conditions were set up as follows:

– inlet velocity for primary/secondary combustion air,

$v_1=v_2=15$ m/s, $T_{air}=300$ K

– outlet pressure at the combustion outlet,

$P_{out}=25$ kPa

– constant wall temperature of outer housing of combustion chamber,

$T_{wall}=500$ K

– constant mass flow for diesel fuel supply,

$Q_{fuel}=1$ kg/h, $T_{fuel}=300$ K

Figure 5 shows the results of the simulation and experiment. Experimental results are in good agreement with the CFD model.

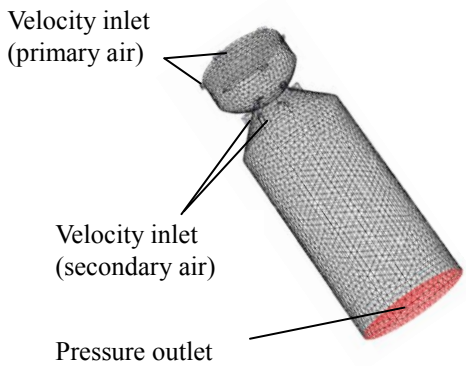

Figure 4. Computational mesh

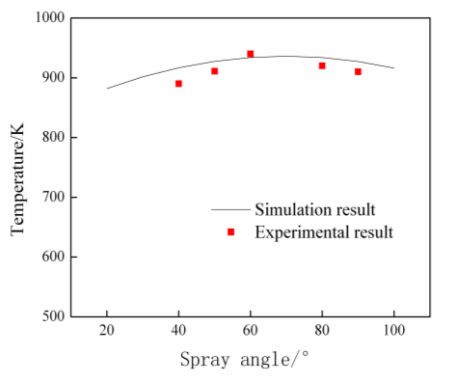

Figure 5. Comparison of experimental and simulati on results .

Configuration optimization . The main factors, which affect the combustion process, include spray position, spray angle and injection pressure. To determine the optimal parameters, an orthogonal experiment design is adapted. Due to the shape of the combustion chamber, interaction between the main factors must be considered. Table 1 shows the factors used in the experiment and Table 2 illustrates the simulation results. Injection position 1, 2 means the distance between the spray point and the center of the first combustion chamber is 0 mm, 10 mm.

R（Maximum difference）	1.75	54.75	31.75	12.25	16.25	1.25	

The performance of the burner mainly depends on air-fuel atomization and mixture formation. When the injection position moves toward the secondary combustion chamber, the decrease of primary air utilization will lead to lower mixture velocity of fuel and air. In the same way, the increase of the spray angle will bring about the better mixture of fuel and air. But a too large spray angle will enhance spray wall-impingement. The range analysis shows that the spray angle is the most important factor influencing combustion performance. The optimal scheme is $A_2B_2C_2$.

ANALYSIS OF REGENERATION SYSTEM CHARACTERISTICS

Experimental apparatus. As shown in Figure 1, three K-type thermocouples are arranged before burner DOC and DPF respectively. Pressure gage is located across DPF, which is made of Silicon Carbide and not catalyzed. The DPF is 178 mm in diameter and 152mm in length. The specifications of SOFIM 8140.27S diesel engine and other experimental apparatus can be seen in Tables 3 and 4.

Characteristic s of engine exhaust. In order to analyze the characteristics of the regeneration system, engine exhaust temperature and intake pressure are

investigated first. Figure 6 shows the change of exhaust temperature with engine speed and torque. From the graph it can be seen that most of the exhaust temperature is lower than 200 ℃ when the load of the engine is low. Figure 7 shows the change of intake pressure with engine speed and torque. It is clear that when the engine operates at low speed and load, the intake pressure is very low. This means little fresh air can be supplied by the turbocharger.

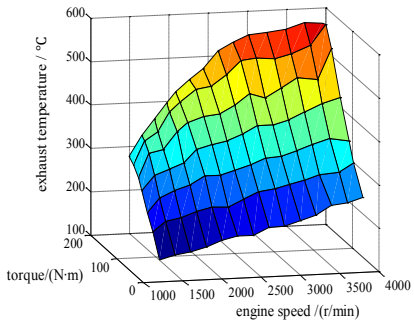

Figure 6. Change of exhaust temperature with engine speed and torque .

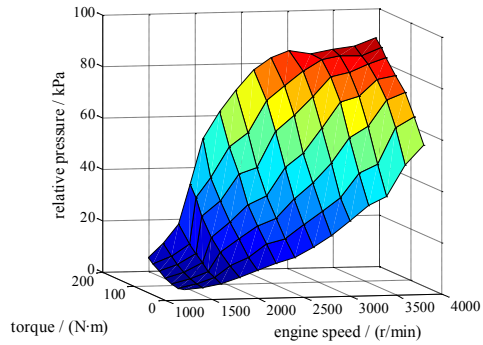

Figure 7. Change of intake pressure with engine speed and torque .

Figure 8 shows the change of exhaust temperature, backpressure and intake pressure with engine speed, when the engine works at 100% load. The DPF loading condition is 6g/L.

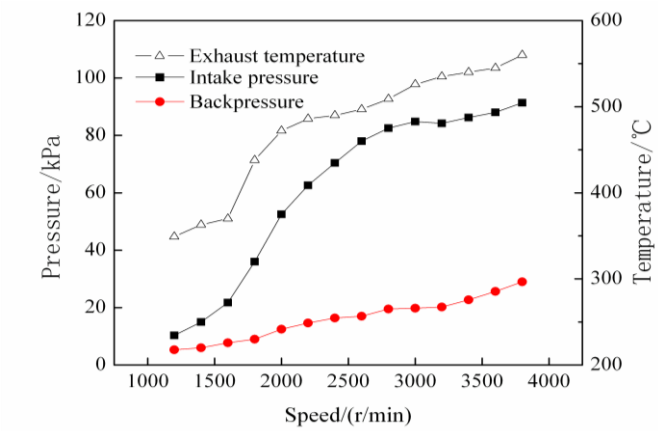

Figure 8. Effect of engine speed at 100% load on exhaust temperature, intake pressure and bac kpressure.

It is clear that exhaust temperature, backpressure and intake pressure increase with the engine speed. This is mainly caused by the increase of exhaust velocity. Although the backpressure and intake pressure both increase with the engine speed, the intake pressure increases more quickly because of the characteristic of turbocharger. The maximum difference between the backpressure and intake pressure reaches 65 kPa. Bigger pressure difference means more fresh air can be obtained

from the turbocharger. And when the engine works at high speed, exhaust temperature is high too. Both of these two conditions are helpful for DPF regeneration. But at low speed and low load operating condition of engine, regeneration is difficult due to the low exhaust temperature and low pressure difference between the turbocharger and exhaust pipe. So it is important to study the characteristic of the regeneration system as the engine operates at low speed and load.

Thermal response of the burner DPF system. The performance of burner DPF system at 0 N·m is shown in Figure 9. The fuel consumption of the burner and DOC is 1.0 kg/h, 1.5 kg/h respectively. It can be seen that performance of the burner at low engine speed is better and the temperature has been enhanced from 124 ℃ to 326 ℃ by the burner. Although temperature at the burner outlet increases with engine speed, the velocity of exhaust flow through the burner increases simultaneously. This means more exhaust will be heated up at the same time. So the difference of burner outlet temperature before and after burner working (△T) decreases as engine speed increases. The space velocity plays an important role in the application of DOC during the heating process. The geometry dimension of DOC used in Figure 9 is Φ120 mm×220 mm. Data in Figure 9 illustrate that DOC outlet temperature has been heated up from 178 ℃ to 500 ℃ at 2400 r/min. But when engine speed reaches 3200 r/min, temperature at DOC outlet is only enhanced to 413 ℃. The main explanation may be the higher space velocity. So a bigger DOC is applied in the experiment below.

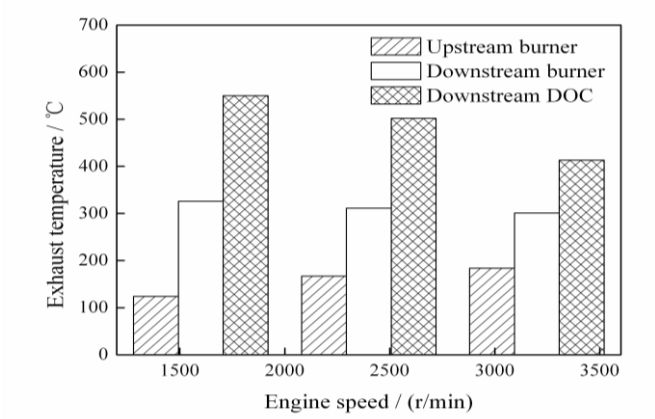

Figure 9. Performance of regeneration system at different speed .

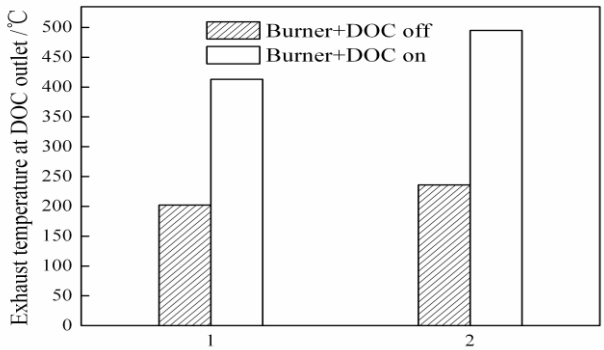
Figure 10 shows the comparison before and after the scheme was optimized at 3200 r/min, 0 N·m. Introducing bigger DOC is effective for heating up to a temperature of 500 ℃. The geometry dimension of DOC used in Figure 10 is Φ150 mm×220 mm.

Regeneration characteristics in engine condition of 2800 r/min, 40 N·m are shown in Figure 11. The exhaust has been heated up to 300 ℃ in 100 s by the

burner and heated up to 500 ℃ further by the after-treatment system in 300 s. In the prophase of the heating process, temperature downstream from the burner increases much faster. But when fuel is injected before DOC, the speed of temperature increase begins to slow down. This may be caused by the increase of backpressure due to higher exhaust temperature, which brings about an unfavorable influence on air supply from the turbocharger. With a fuel additive, when the exhaust temperature arrives at approximate 480 ℃, the backpressure begins to decrease and regeneration occurs.



1. Before optimized 2. After optimized

Figure 10. Comparison before and afte r optim ization.

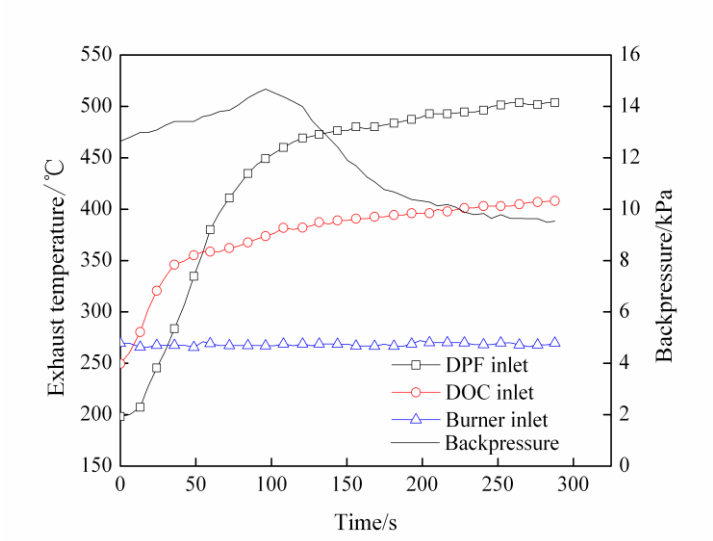


Figure 11. Regeneration characteristics in engine condition of 2800 r/min, 40 N·m.

CONCLUSION

A full-flow burner DPF system is designed to remove particulate matter from a diesel engine and the thermal response of this after-treatment has been investigated.

1) Result from the three dimensional simulation shows that: Spray angle is the most important factor which influences the burner performance after the main burner configuration is decided.

2) It is feasible to use compressed air from the turbocharger for DPF regeneration. The exhaust can be heated up to 300 ℃ at 0 N·m in 100 s when the full-flow burner works alone.

3) The burner DPF system, which can be divided into two steps in the heating process, can effectively enhance the exhaust temperature to 500 ℃ in a wide operation range.

4) The optimization of DOC space velocity and use of fuel additive are propitious for the application of the full-flow burner DPF system.

ABSTRACT

Asphalt permeable pavement (APP) is a passive structural low impact development material and component of green infrastructure for rainfall-runoff control. Multifunctional engineered APP can fulfill requirements as a load-transmitting surface while serving as a more environmentally conscious infrastructure material that functions to restore the in situ hydrology, reduce runoff, filter, and treat infiltrating runoff, reduce thermal pollution and temperature, also provide the load-carrying capacity of conventional pavement. Based on the determination of main value indices for runoff pollutants, the efficiency of controlling runoff pollutants has been studied from materials and structures of permeable pavement in this paper, then put forward to the keys of material and structure design for permeable pavement, which will provide techniques for designing ecotypic permeable pavement. All the results indicate high particle separation and the removal rate of chemistry oxygen demand can be achieved with APP. The effectiveness of APP for particle and COD removal also requires that these particle deposits are managed on a periodic basis through practices such as pavement cleaning.

INTRODUCTION

Conventional pavements are the most common examples of impervious surfaces in the urban environment and in part cause a significant modification of the local hydrologic cycle (Kuang 2007). Expansive impervious areas have a significant impact on reductions in groundwater recharge, the depletion of soil moisture, and the corresponding increase in runoff, also reduction evaporation and evapotranspiration, known as heat island effects (Sansalone et al. 2004). With respect to the problems caused by impervious pavements, asphalt permeable pavement functions as a passive

unit operation and process for storm water quality and quantity control through infiltration, evaporation, filtration, absorption and reaction mechanisms. Permeable pavement reduces runoff, flooding, and treatment requirements; act as a sorbent filter that reduces the pollutant loads of phosphorus and nutrients to the environment; and reduces pavement and water temperatures. It also increases infiltration back to the soil to provide groundwater recharge to enhance future water supplies (Sansalone et al., 2008). But there is little study on runoff pollutant control by asphalt permeable pavement, especially in China. So this study focuses on the efficiency of controlling runoff pollutant by materials and structures of asphalt permeable pavement which is very significant to purify underground water and make full use of rainfall.

METHOD

Indices of Runoff Pollutants

Studies indicated that runoff pollutants included suspended solids (SS), chemical oxygen demand (COD), phosphorus and nutrients, and the levels of Zn, Cu, Cd, Pb, Cr, Ni and so on (Park 2004; Li 2005), in which SS and COD are the main pollutants, which mainly come from tire abrasive granules, pavement material abrasive granules, leak of transportation goods and other granules relative to transportation. So the main runoff pollutant indices are determined as COD and SS.

Chemical Oxyge n Demand

Under the fixed condition, the consuming quantity of oxidant in dealing with water samples with strong oxidant is named by chemical oxygen demand, ab. COD (O_2，mg/L), which reflects the contaminated degree of reductive substances in the water sample.

Suspended Solid

Solid in the water can be divided into soluble solid and suspended solid, ab. SS(mg/L). The percentage of removal rate of SS indicates the degree of removal rate of solid granules in the water.

Water Sample

Water samples come from two kinds, one is highway runoff collected at the drainage in the rain; the other is prepared in the lab according to the components and quantities of runoff pollutants.

Compaction

In the paper, self-designed vibrating compaction method is adopted. Through test study on optimum vibrating techniques, vibration parameters are determined as follows: vibration frequency(30Hz), low swing (0.957mm), vibration force (7kn)、vibration time(2.5minutes). Specimen dimension: ϕ150mm×100mm. For cement permeable pavement materials, in order to avoid cement mortar staying on top or bottom during the compaction, the uniformity tests have been done under different vibrating times, then the optimum vibrating time is determined as 1min.

STRUCTURE OF PERMEAB LE PAVEMENT

Permeable pavements have been more and more widely applied in the USA, Europe, Australia and Japan in the last two decades. Especially in Japan, infiltration facilities including permeable pavements were introduced and progressively implemented during the 1980s. When rainfall infiltration was first implemented, its primary objective was to reduce runoff volume. With the enhanced recognition of water quality benefits, as well as the Japanese desire to maintain closeness with nature in an urban setting, however, permeable pavement philosophy has shifted more towards groundwater cultivation than runoff reduction since the 1990s. Until now typical permeable pavements have been formed in Japan. Permeable pavement has seldom been studied in China for its durability. But from the view of alleviating heat island effects, supplying groundwater, reducing runoff and so on, permeable pavements have more advantages, so this kind of permeable pavement should be designed at the roads of squares, resident sections, parking lots and some places in which load bearing is lower and traffic volume is smaller. The structure of permeable pavement in this paper is as follow Figure1.

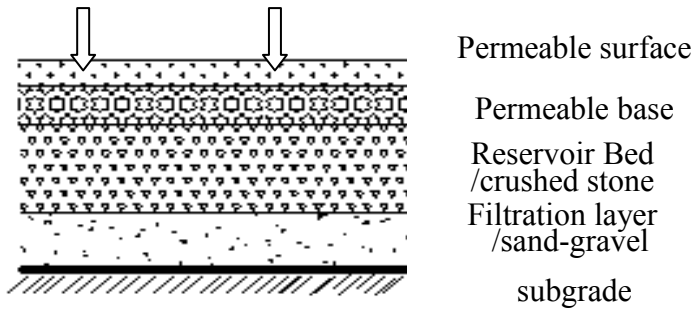

Figure1. Structure of permeable pavement.

TEST

Materials Composition

In order to distinguish the degree of removal rate of pollutants in different asphalt mixtures, continuous gradation and gap gradation of asphalt permeable mixture are adopted in the permeable pavement surface. While cement stabilized aggregate is adopted in the permeable base. Single seize as 13.2mm is applied to aggregate layer and 4.75mm is applied to sand-gravel bed course. The gradations are tabulated in Table1.

The optimum asphalt-aggregate ratio of permeable asphalt mixture is determined according to Marshall test，which is respectively as 2.8% for continuous gradation and 3.0% for gap gradation. The coarse skeleton of cement stabilized aggregates is shown in Table1, where air voids are filled by 15% of cement mortar, composed by w/c (0.36) and water reducer（0.6%）. Above materials are compacted

by vibrating techniques (seen as compaction).

Table1. Gradations of different layers .

gradation	Air void /%	seize/mm cumulative passing percentage/%											
		26.5	19.0	16.0	13.2	9.5	4.75	2.36	1.18	0.6	0.3	0.15	0075
continuous gradation of HMA	26.2	100	72	60.2	48.5	34.7	15.6	9.1	7.7	5.8	3.6	1.6	0
Gap gradation of HMA	20.2	100	100	100	50	50	25	25	13	13	5	5	5
Cement stabilized aggregate	21.8	100	89.7	80.8	61.7	29.3	0	0	0	0	0	0	0

Efficiency in Removal Pollutants of Structure Layer s

The values of COD and SS are measured for original water samples and through the structures' sample, accordingly, the removal rates of COD and SS are calculated, detail results are as follow Figure2.

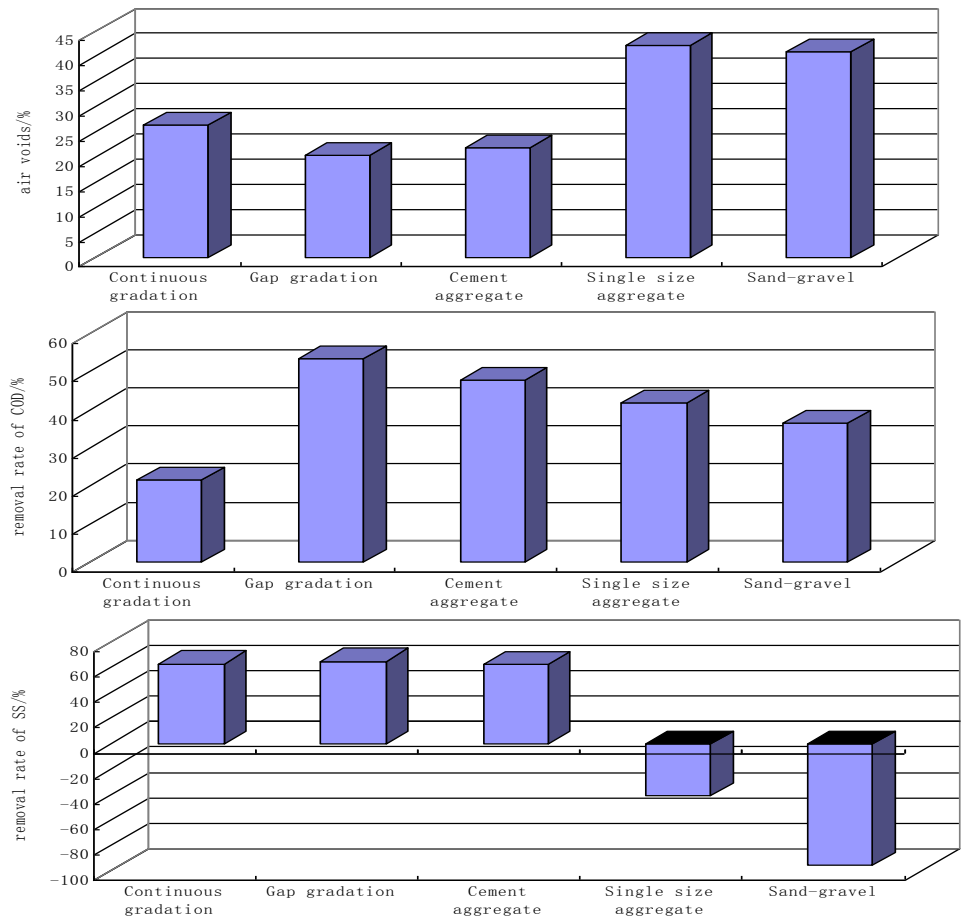

Figure2. Main technique value s of materials.

Some conclusion could be derived from Figure2,

① For permeable surface and base, the removal rates of COD are accreting from 21.74% to 47.83% with the decrease of voids from 26.2% to 21.8%, while the removal rates of SS are equal（62.82%~62.04%）, which mainly due to the COD depending on the filtration and absorption of porosity, so pore characteristics is critical to determine the functions of permeable pavement, which is less relation to the component material. Thus, pore characteristics are the key to design the permeable pavement.

② For loose reservoir bed and filtration layer, the air voids of crushed stone and sand-gravel are similar, so the removal rates of COD are equivalent, ranging from36%~42%. But value of SS is increasing evidently compared with water sample, that is, the removal rate of SS is negative. The reason is that materials of loose reservoir bed and filtration layer are dirty, including sand and mud and so on, which lead to sand and mud flowing with water sample when water pass through the structure layers.

③ Although the air voids of continuous and gap gradation are similar, the removal rates of COD are quite different. With the decrease of air voids, the removal rates of COD could improve to 2.47 times, from 21.74% to 53.62%, while the removal rates of SS are equivalent(62.82%~64.77%) and has similar trend with COD, little different is minor range. So the removal rate of COD is intimately relative to pore characteristics.

Efficiency in Removal Pollutants of Structure Combinations

There are two kinds of combination of structure layers, one is Permeable surface+ permeable base, the other is Reservoir bed+ Filtration layer. Calculating the removal rates of COD and SS, detail results are tabulated in Table2.

Table2. The removal rate of pollutant through diffe rent layers combination .

Structure layer	material	COD		SS	
		value（mg/L）	Removal rate /%	value（mg/L）	Removal rate /%
Permeable surface+ base	Continuous HMA+ Cement stabilized	101.7	43.48	2567.6	35.81
	Gap HMA+ Cement stabilized aggregate	79.9	55.62	2418.8	39.53
bed+ Filtration layer	Single size aggregate+sand-gravel	96.8	46.20	8328.4	-108.21
bed+ Filtration layer	Single size aggregate+sand-gravel+ fiber	63.5	64.72	1980.2	50.49

① From Table2, the removal rate of COD of structure combination is not the cumulated by the removal rate of individual structure layers. The removal effect of

structure combination is determined by the removal effect of individual structure and structure combining mode. The removal effect of COD mainly depends on the filtration, block and absorption of pore structure. While different layers may have similar pore characteristics, then the removal rates have similar values, so the removal rate of COD through structure combination is equivalent to the structure layer having higher removal rate of COD.

② Materials of different structure layers should be designed according to the functions of individual layers. That is, if the removal effect of COD is supposed on surface layer, the relationship between pore characteristics and the removal rate of asphalt mixtures should be studied further, then instructing the material design of permeable asphalt mixture according to pore structure.

③ The removal rate of SS for structure combination is lower than the removal rate of individual structure layers. The reason is that as the height of structure is increasing, the content of minor gravels is also increasing, while these gravels could flow with water sample, which makes the value of SS accreting. Also, fiber can make decisive function to retain the suspended solid.

CONCLUSION

- Although the materials of different Structure layers are quite different in the permeable pavement, they all have certain removal effects on COD, which indicates that the organic pollutants stayed in the pore structure of permeable pavement through filtration, absorption and block the function of purifying the water.
- Mixtures of permeable surface and base have been wrapped by binder and have better space network structure, which make suspended solids to stay in the inner pore structure, then exhibiting better removal rate of SS. While dirty aggregates exist in the loose reservoir bed and filtration layer，suspended solids increase when water sample flows through the structure layers, then the removal rate of SS is negative.
- The removal rate of COD of structure combination is not cumulated by the removal rate of individual structure layers, and is equivalent to the structure layer having higher removal rate of COD. The removal effect of structure combination is determined by the removal effect of individual structure and structure combining mode. While the removal rate of SS of structure combination is lower than the removal rate of individual structure layers.
- Permeable pavement structures have better removal effect of organic pollutants in the runoff, but increase the content of suspended solids. For the organic pollutants having heavier influence on water than suspended solids, it can be derived that permeable pavement has the efficiency on control runoff pollutants and fiber can be used in the subbed course to filtrate the suspended solids to purify the groundwater.

- It is just a beginning to study permeable pavement from control runoff pollutants. In order to apply the permeable pavements widely, the mechanism of pore structure controlling runoff pollutants should be researched deeply, which will benefit to carry out material and structure design definitely.

ABSTRACT

Currently, expressway toll stations in China generally use loading-based toll collection. Because vehicles spend long time either stationary or accelerating/decelerating in low gears, air quality is particularly susceptible to the accumulation of vehicle-emitted pollutants at toll plazas. In this work three-dimensional computational fluid dynamics (CFD) simulations were carried out to analyze the pollutant concentration distribution in the vicinity of tollbooths. Several influencing factors including wind velocity, wind direction and topography of toll plazas were considered. A simulation instance of the Wuzhuang toll plaza in Hefei-Nanjing expressway was performed. The simulation results show that the increase in wind speed facilitates the pollutant dispersion. There is higher concentration of pollutant as the angle between the direction of wind and traffic becomes larger. The existence of retaining walls impedes the pollutant dispersion. However, the slope of retaining walls has little influence on the variation of pollutant concentration.

INTRODUCTION

Automotive exhaust is the major source of air pollution at toll plazas. At the present time, expressway toll stations in China generally use loading-based toll collection. Vehicles spend a long time either stationary or accelerating/decelerating in low gears passing through the toll plaza, leading to relatively greater concentrations of pollutants in exhaust emissions than is the case at cruising speeds. The health of tollbooth workers is affected due to the proximity of the pollutant source. Therefore, it is significant to determine how these pollutants distribute at toll plazas and if, modifying some parameters, the pollution in the vicinity of tollbooths can be decreased.

Several field measurements of pollutant concentrations at toll plazas have been conducted in the past (Diab et al., 2005; Tsai et al., 2004). However, a limitation of direct field measurements is that all possible influencing factors are simultaneously operative and it is difficult to distinguish between those that are and are not significant. These factors include, among others, wind speed, wind direction, topology, traffic density, and they are all intertwined. Wind tunnel experiments and

numerical simulations provide an opportunity to examine the effects of various factors individually or in combination.

Recently, numerical simulations of pollutant dispersion without the need of complex experimental setups have been more frequent. Researchers have proposed two-dimensional and three-dimensional CFD models to simulate pollutant dispersion in street canyons. The results showed favorable agreement with the wind tunnel experimental results (Chang and Meroney, 2001; Sagrado et al., 2002; Chan et al., 2002). Compared to field measurements and wind tunnel experiments, numerical simulations are relatively inexpensive and more effective. Consequently, numerical simulation has become a powerful research tool. However, little is known about numerical simulations on pollutant dispersion at toll plazas. This paper presents three-dimensional numerical simulations on pollutant dispersion at toll plazas with the CFD code FLUENT 6.3. Flow and pollutant concentration are calculated based on the standard k-ε turbulence model. Effects of wind speed, wind direction and slope of retaining walls on pollutant dispersion near tollbooths are studied.

DESCRIPTION OF NUMERICAL SIMULATIONS

2.1 Toll plaza dimension .

As Fig. 1 shows, a simplified toll station with seven tollbooths was designed according to General Specification of Freeway Traffic Engineering and Roadside Facilities. In accordance with the toll station, three CFD models considering different influencing factors were built as shown in Fig. 2. The widths of outside traffic lanes, general traffic lanes and shoulders are 4.0 m, 3.2 m and 0.75 m respectively. The total width of the toll plaza is 44 m. The toll canopy is 6 m above the ground. The dimensions of toll islands and tollbooths are $60\times2.2\times0.2$ m^3 and $2.5\times1.5\times2.4$ m^3 respectively.

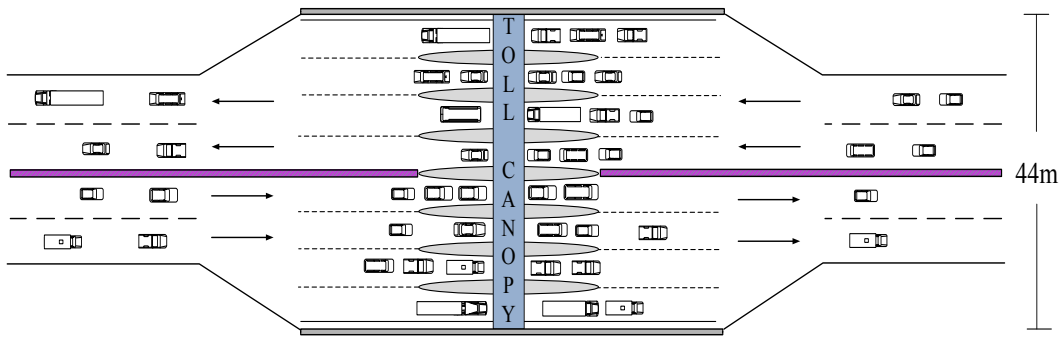

Figure 1. Schematic diagram of the toll station model.

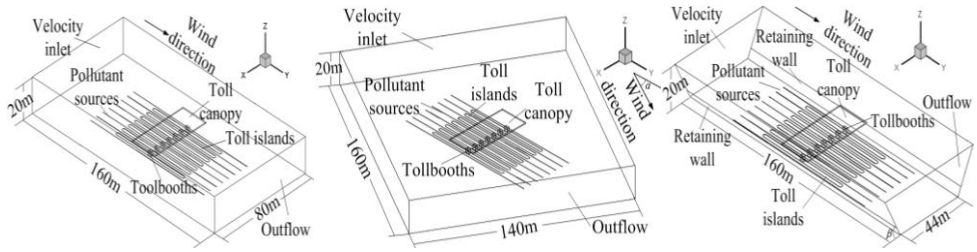

(a) (b) (c)

Figure 2. Illustrations of the computational domains considering the effects of (a) wind speed, (b) wind direction, and (c) slope of the retaining walls on pollutant dispersion.

From Fig. 2 we can see that the Y axis is parallel to the direction of traffic. α is the angle between the wind direction and the Y axis, as shown in Fig. 2(b). It should be noted that there are retaining walls on both sides of some toll stations due to topographic conditions and β means the slope of retaining walls, as shown in Fig. 2(c).

2.2 Simulation scheme .

In this study, we conducted three-dimensional CFD simulations to analyze the effects of wind speed, wind direction and slope of retaining walls on pollutant dispersion with FLUENT. This code has been widely used in simulations of pollutant dispersion in urban environments, especially in street canyons, with favorable results (Nazridoust and Ahmadi, 2006; Sabatino et al., 2007). In this paper, we designed a simulation scheme with nine cases to study the effects of different influencing factors on pollutant dispersion, as shown in Table 1. In case 1~3, wind speed is variable with the fixed wind direction and without retaining walls. In case 4~6, wind direction changes with the same wind speed and no retaining walls exist. As for case 7~9, wind speed and direction are both invariable with different slopes of the retaining walls.

Table 1. Simulation scheme with nine cases

	1	2	3	4	5	6	7	8	9
Wind speed at 20 m height/(m/s)	10	6	3	10	10	10	10	10	10
α/°	0	0	0	30	45	60	0	0	0
β/°	-	-	-	-	-	-	30	45	60

2.3 Boundary conditions .

In this paper, we chose CO as the representative pollutant to analyze the pollutant dispersion around tollbooths. The pollutant source was modeled as eight lines placed in the middle of each traffic lane with dimensions of 100×0.2 m^2 (Chan et al., 2002). We calculated the pollutant source strength, according to the investigation data of the Chayuan Toll Station (Chen et al. 2007), was 1.89×10^{-4} kg/s. The Chayuan Toll Station is located on the Chongqing-Guizhou highway with eight lanes and the

average traffic volume is 8000 vehicles per day. Velocity inlet boundary condition was used for the inlet wind flow. Thus, in all cases, incoming wind velocity had an atmospheric boundary layer profile $u = u_{z_0} \times (z / z_0)^{1/7}$. For the outlets at the end and lateral sides of the domain, an outflow boundary condition was assumed. All other solid surfaces of the domain (surfaces of tollbooths, toll canopy and retaining walls) were defined as walls with no slip velocity boundary condition. The line sources of CO were treated as mass flow inlets.

RESULTS AND DISCUSSIONS

Flow velocity and CO concentrations at the 1.5m height plane (tollbooth workers breathing height) were calculated. We also compared CO concentration on three observation lines: the center line of the computational domain perpendicular to the X axis (y=0 m) and the other two lines before (y=-5 m) and after (y=5 m) it. Because the flow velocity distribution is similar, only three representative contours of velocity magnitude are given in Fig. 3.

3.1 Effect of wind speed .

As shown in Fig. 3(a), wind speed approximately presents zonal distribution and decreases gradually along the positive direction of the Y axis. Wind speed decreases significantly in the areas behind the tollbooths which obstruct the airflow. The CO concentrations under different wind speeds were simulated, according to the case 1~3, and the results are shown in Table 2. Comparing the CO concentrations under three wind speed conditions, the maximum values all appear on the line behind the tollbooths (y=5 m). As wind speed increases, the maximum value of the CO concentration (68 mg/m^3, 50 mg/m^3 and 38 mg/m^3) reduces. This demonstrates that larger wind speed facilitates the pollutant dispersion and that pollutant accumulates behind the tollbooths. Chen et al. conducted field measurements of the CO concentration at Chayuan Toll Station in June and July, 2003. As shown in Table 3, the mean CO concentration outside the tollbooths is 10.865 mg/m^3. The results of measurements and simulations above are close. This demonstrates that the simulation results are reliable and further simulations can be carried out.

3.2 Effect of wind direction .

The CO concentrations under different wind directions were calculated according to case 4~6 and the results are summarized in Table 4. As shown in Table 4, when α increases, the range of the CO concentration extends. Additionally, the area of great CO concentration diverts from behind the tollbooths to the spaces among the tollbooths. This demonstrates that wind direction has a considerable influence on pollutant dispersion. Therefore, we can conclude that a smaller angle between the direction of wind and traffic better facilitates the pollutant dispersion in the vicinity of tollbooths.

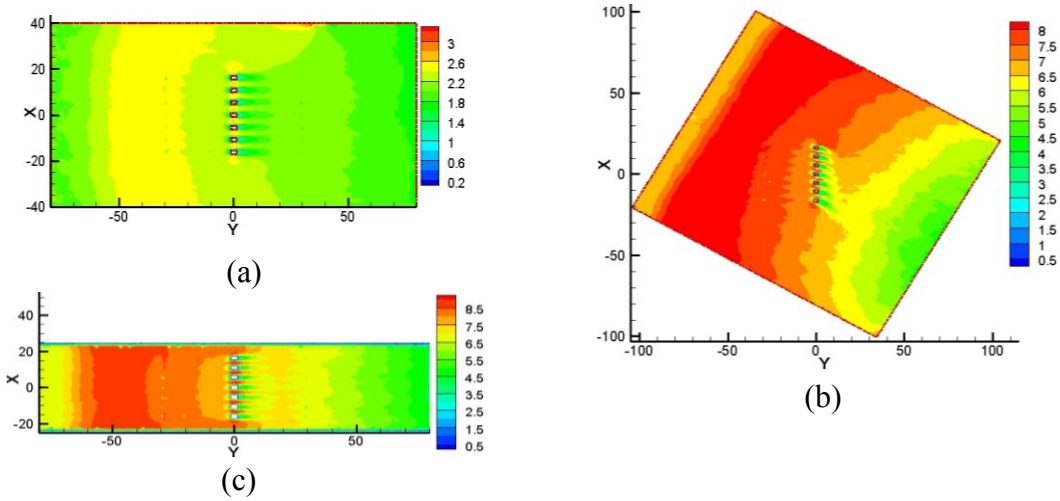

Figure 3. Flow velocity at the 1.5 height plane when (a) wind speeds of 3m/s, (b) α is 30° and (c) β is 30° , respectively.

Table 2. Range of CO concentrations under different wind speeds (mg/m ^{3})

Wind speed (m/s)	3	6	10
y=-5	0~28	0~18	0~14
y=0	0~22	0~15	0~12
y=5	0~68	0~50	0~38

Table 3. Statistics on the CO concentration (mg/m ^{3}).

Samp le number	mean concentration outside the tollbooths	standard deviation
12	10.865	3.305

3.3 Effect of the slope of retaining wall .

The CO dispersion of different slopes of retaining walls were simulated according to case 7~9. The results are also shown in Table 4. Table 4 shows that the ranges of the CO concentrations and the maximum values under three conditions are close. As a result, we can conclude that there is little influence on the pollutant dispersion when the slope of retaining walls changes.

Table 4 . Range of CO concentrations under different wind directions and slopes of retaining walls (mg/m ^{3}).

α/°	30	45	60	β/°	30	45	60
y=-5	0~30	0~160	0~600	y=-5	0~58	0~38	0~40
y=0	0~60	0~850	0~3800	y=0	0~158	0~106	0~110
y=5	0~325	0~525	0~750	y=5	0~140	0~102	0~155

A SIMULATION INSTANCE

The selected toll station is located on the Hefei-Nanjing expressway with 22 toll lanes, 48 km west from Nanjing. The retaining walls are 5 m high and their slope is 60° , because the ground is higher on both sides of the toll plaza. The distance between the retaining walls is about 120 m. The toll canopy is about 120 m long, 20 m

wide and 1m thick.

Two three-dimensional CFD models were established, according to the actual size of the Wuzhuang Toll Station, to study the effects of retaining walls on the pollutant dispersion. The computational domains have the approximate dimensions of 180 m × 160 m × 30 m. Based on the investigation data in September, 2006, the daily average traffic volume of the Wuzhuang Toll Station is 13860 vehicles per day. We again chose CO as the representative pollutant and the emission source strength is 3.21×10^{-4} kg/s. In this study, CO concentrations in the vicinity of tollbooths were calculated and the simulation results are shown in Table 5.

Table 5 . Range of CO concentrations with and without retaining walls (mg/m ^{3}).

with retaining walls	without retaining walls
0~24	0~12

As shown in Table 5, it is obvious that the average CO concentration is lower when no retaining walls exist. Therefore, the toll station should be located on flat and open land where pollutants dissipate easily.

CONCLUSIONS

Effects of wind speed, wind direction and slope of retaining walls on pollutant dispersion were studied using the CFD code FLUENT and some conclusions were obtained as follows.

Higher wind speed and smaller angle between the direction of wind and traffic better facilitates the pollutant dispersion in the vicinity of tollbooths. The existence of the retaining walls does not facilitate the pollutant dispersion. The slope of the retaining walls has little influence on the variation of the pollutant concentration. It is noted that there are some points where the concentration is much higher than others. This is because turbulence in the vicinity of the tollbooths leads to the accumulation of the pollutant.

Because of lack of the comprehensive field measured data, we paid more attention to the qualitative analysis of the simulation results. Future research can examine the effects of traffic density and toll collection mode on pollutant dispersion. In this paper, the simulation results of pollutant dispersion at the toll plaza with FLUENT are reasonable. As a result, the application of FLUENT to the CFD simulations on pollutant dispersion at toll plazas has good future prospects.

ABSTRACT

A large number of research documents and on-the-spot investigation of Dongting Lake in China show that urban action and water conservancy action of highway and separate-approach action of highway affecting migrant bird's habitat are the main actions of influence by highway on Dongting Lake ecosystem. The assessment index system of influence by highway on Dongting Lake ecosystem is set up. The index system consists of classification of highway, urban action of highway and water conservancy action of highway. Some factors of sensitive area on which urban action act by highway and election of the monitoring areas with 3S technology, and it's technique of assessment, the technique of area analysis on which water conservancy action act by highway are studied. Monitoring areas on which water conservancy action act by highway are divided out. The above items are the basis of monitor and assessment about influence by highway on Dongting Lake ecosystem with 3S Techniques.

Keywords: Dongting Lake ecosystem, 3S techniques, Assessment index, Urban action of highway, Water conservancy action of highway.

INSTRUCTION

It is shown that there is a great influence on the ecological environment about highway construction. The wetland is the most important to the ecological landscape and biodiversity on our planet, and one of the ecological environments on which human society develops (Daniel J. et al. 1998). Wetlands provide water resource and a mass of food and materials of our production. At the same time, wetlands play an important role in the following aspects: maintaining resources of biodiversity and rare species (Kevin J. et al. 2003), to keep from and delay flood, conservation storage fights drought, maintaining water and soil, reducing environment pollution, providing travel resources, and maintaining balance of ecology of the earth.

The Dongting Lake is one of the six wetlands in China. Since the 20th century, people had enclosed lakes and built up fields on a large scale. Hundreds of dykes formed, which are not of uniform size. The wetland of Dongting Lake is incoherent. Area of the lakes reduced seriously. Dongting Lake's flood regulating and storing, navigation, biodiversity, ecological environment were endangered seriously. Nowadays, water resource is being polluted by use of agriculture fertilizer; industry

and sanitary sewage, medicinal liquid for prevent infection of blood fluke. So it is necessary to protecting wetland resources in Dongting Lake.

There are 303 kinds of birds live in Dongting Lake area, its quantity reaches1.5 millions. There are 37 habitats that over ten thousand of birds gathered in each habitat. 119 kinds of fishes live in the lakes. Dongting Lake is the main producing area of black carp, grass carp, silver carp and bighead in China. This area is also the main habitat for Chinese sturgeon, white sturgeon, neomeris phocaenoides and white-flag dolphin. Dongting Lake wetlands is the most important habitat of migratory bird in midstream and downstream basin of the Changjiang River, its migratory birds has various in style, quantity heavy, intensive degree high characteristic. Now, the environment of these bird's habitats is endangered by change of ecology caused by change of water level, economic actions of people, killing the wild animal illegally by local people, the silt depositing and pollution, and the water level reducing by the famous Three Gorges Engineering.

As we all known, highway construction is the founder of economic development of Donting Lake area. But highway construction and operation will bring disadvantage to Dongting Lake ecosystem. For assessment of influence by highway on Dongting Lake ecosystem, we should take something into account: enclosing lakes and building up fields over a long time, industry and sanitary sewage, use of medicinal liquid to prevent from infection of blood fluke and unreasonable use of biodiversity resources of wetland. Based on that Dongting Lake ecosystem is protected very well, the highway construction in this area is good, which is the historical responsibility of the work for highway construction in Dongting Lake area.

For assessment of influence by highway on Dongting Lake ecosystem, we should answer the following questions firstly: 1. What are the main factors of highway that influences Dongting Lake ecosystem? 2. How to build the assessment index system of influence by highway on Dongting Lake ecosystem? 3. How to develop the technology and methods of assessment of influence by highway on Dongting Lake ecosystem based on 3S Techniques?

MAIN CAUSES IN INFLUENCE BY HIGHWAY ON DONGTING LAKE ECOSYSTEM

A large number of research documents and on-the-spot investigation of Dongting Lake tell us (Mao Wenyong 2003; Dai Mingxin 2004; Li Rendong et al.2004; Dong Xiaolin 2003): the long-term silt depositting, enclosing lakes and building up fields over a long time are the main factors which shrank the water area of Dongting Lake; enclosing lakes and building up fields, hunting excessively, industry and sanitary sewage, fertilizer and medicine liquid for prevent infection of schistosome are the main factors lead to threaten the biodiversity of Dongting Lake ecosystem; industry and sanitary sewage, fertilizer and medicinal liquid to prevent from infection of blood fluke are also main factors which lead to polluted the quality of Dongting Lakes water. So, when we assess the influence by highway on Dongting

Lake ecosystem, the factors described above should be taken into account.

A. Influence by highway urban action on Dongting Lake ecosystem

Under the influence of highway, urban areas will extent and rural area will become towns or urban, which is the highway urban action (Zhao Kang 2003).

Some scholars carried researches about change of land use in this area between 1979 and 1999 based on 3S technology (GPS, RS and GIS). According their result, construction area increased obviously in past twenty years, amount to 15467hm^2. From 1990 to 2000, there are 5520hm^2 farmlands changed to construction area, among which: 54.83% turned to urban; 32.18% turned to industry and communication area; 13% turned to residential area for farmers. From the situation described above, we can know how seriously the highway urban action influenced the ecosystem of Dongting Lake (Li Rendong et al. 2004).

According to the dot-axis pattern of the government's development plan of urban of Dongting Lake area, the emphases of construction and planning are East-belt, Middle-belt and Southwest-belt of this area. The axis of East-belt consists of part of Jingguang Railway, Jingzhu Expressway, G107 National Highway, Xiang River, and the east lakeshore of East Dongting Lake. The axis of Southwest-belt consists of part of Shichang railway, Changchang expressway, G319 National Highway, and the section Changde-Linli-Zhanggongmiao of G207 National Highway. The axis of Middle-belt consists of the four branches of Ouci River, the canal of Nanmao, the watercourse of Songli and Muping Lake, and the main highway connecting Yiyang city, Yuanjiang City, Maocaojie, Nan County, Huarong County and Shishou City in Hubei province. So, the long-term urban action in this area should be taken into account seriously when we do our research.

Because of urban action induced by highway, some indirect long-term disbennifit to the Dongting Lake ecosystem exists: wetlands were occupied by the construction of town; wetlands were polluted by garbage and sewage produced by the action of people in the town; wetlands were changed to use for other intent by people, which will lead to disbennifit to biodiversity.

B. Influence by highway water conservancy action on Dongting Lake ecosyste m

The area of Dongting Lake is the important comprehensive agricultural commodity production base of China. The agriculture economy is high developed. In this area, flood disaster often occurred. Since 1949, water conservancies have been built extensively. Highways in the area do great contribution to the water conservancy, fighting floods, and economic development. Highways and other constructions of communication should be worked together with water conservancies, which will do good to the conservation of Dongting Lake ecosystem. In general, the highway in this area should be constructed with good water conservancy action:

1) The integration of highways and dykes. The people, farmland and people's economic activity centralized in dykes, whose area amounted to 72.3% of all area of Dongting Lake area. The renovation of these dykes is the important work to the

water conservancy of the area of Dongting Lake. Nowadays, the total amount of dykes is 227. It is 226 that ten thousand mu of dykes of the above are counted. It has very great potentiality on integration of highways and dykes. The integration can provide the communication of each dyke, at the same time, can reduce area of wetlands and farmlands occupied by highway construction. When flood occurred, the highway based on the dyke will play an important role in fighting flood.

2) The coordination of highways with irrigation and water conservancy facilities. The renovation project of Dongting Lake, which has been carrying through, has adjusted the old layout of irrigation facilities seriously (Lu Xinhai et al. 2002). This change properly diminished the function of older bridges and culverts, which made older highway don't work together with water conservancies, even disuse these constructions. So the work of reconstruction and construction is very difficult. Besides provide communication functions, the coordination of highways with irrigation and water conservancy facilities can satisfy the needs of farmlands irrigation and fighting flood, and also benefit the conservation of Dongting Lake ecosystem.

The degree of integration of highways and dykes, the degree of coordination of highways with irrigation and water conservancy facilities, produce indirect long-term influence on the ecosystem of Dongting Lake area.

C. Influence by separate **-approach action of highway on migratory birds'** habitats in Dongting Lake wetlands

Highways break the wetland into pieces; the animals living in certain area can not court and get food in more wide area (Richard et al. 2000). Split up in kind will occur if long-term separation to one specie last, which is disadvantageous to the biodiversity. The construction of highways extends the area of people's activity, which endanger the nature and the conservation of some rare resources. The influence described above is the so-called separate-approach effect of highway.

In the area of Dongting Lake, people had enclosed lakes and built up fields over a long time, which produced many dykes. These dykes were not of uniform size. In term of the length and scope of the area, the influence by separate-approach action of dyke is more serious than that of highway. So the latter is less serious on the ecosystem of Dongting Lake wetlands. But, it is proved that the construction, car lights and noise of highway do have influences on the migratory birds' habitats (Rien Reijnen et al. 1995), which is different with the change of geographical environment. In general, the influence by construction and operation of highway on migratory birds' habitats should be researched seriously.

MAIN INDEXES IN ASSESSMENT OF INFLUENCE BY HIGHWAY CONSTRUCTION ON DONGTING WETLANDS ECOSYSTEM

The assessment indexes of influence by Highway on Dongting Lake ecosystem should be the quantization indexes, should reflect the region characteristic and change of ecosystem influnced by every influence factor. As far as the choice of

the indexes, we should take the main influence factors by highway on Dongting Lake ecosystem into account seriously. The indexes should be lay particular emphasis on to some extent.

A. Index of highway classification

According to the highway engineering technological standard (JTG B01-2003) published by department of communication of PR. China, and the reality of that there are a lot of rural highway in Dongting Lake area, the index of class of highways is classified as follows: expressway, 1st class highway, 2nd class highway, 3rd class highway, 4th class highway and rural highway.

B. Index of highway urban action

The index of highway urban action consists of land-use index and society-economy index.

1) Land-use index

Land-use index consists of agriculture-land index, construction-land index and unused-land index.

Agriculture-land index includes such indexes as farmland, garden plot, woodland, grassland and other.

Construction-land index includes such indexes as urban, town, rural residential area, communication, water conservancy, self-existent industry and land for special use

Unused-land index includes such indexes as unused land that it is unused and other than land for agriculture and construction, other land that is water area other than water area for agriculture and construction. Unused land index includes such indexes as desolate land, marsh, sandlot and naked-land; other land includes index includes such indexes as river, reedy area and shoal.

We use the change value of these indexes and the rate of change of these indexes to reflect the influence degree of highway urban action directly:

If $A_j^{t_1}$, $A_j^{t_2}$ represent the area of land of kind j in class i at time t_1 and t_2, so we can get $\Delta A_{ij}^{t_1-t_2}$,the corresponding area changed of land of kind j in class i (a class includes some kinds) , and $\alpha_{ij}^{t_1-t_2}$,the corresponding rate of change:

$$\Delta A_{ij}^{t_1-t_2} = A_{ij}^{t_2} - A_{ij}^{t_1} \qquad \alpha_{ij}^{t_1-t_2} = \Delta A_{ij}^{t_1-t_2} / A_{ij}^{t_1}$$

So as for class i: $\sum_{j=1}^{n} A_{ij}^{t_1}$, $\sum_{j=1}^{n} A_{ij}^{t_2}$ are the area of time t_1 and t_2, then $\Delta A_{ij}^{t_1-t_2}$, the corresponding area changed, and $\alpha_{ij}^{t_1-t_2}$, the corresponding rate of change, could be calculated:

$$\Delta A_i^{t_1-t_2} = \sum_{j=1}^{n} A_{ij}^{t_2} - \sum_{j=1}^{n} A_{ij}^{t_1} \qquad \alpha_i^{t_1-t_2} = \Delta A_i^{t_1-t_2} / \sum_{j=1}^{n} A_{ij}^{t_1}$$

2) Society-economy index

Society-economy index consists of agriculture population in town,

non-agriculture population in town, general production value of agriculture, general production value of industry and production value of foodstuff.

We use the change value of these indexes and the rate of change of these indexes to reflect the influence degree of highway urbanization indirectly.

So, as for the society-economy index of class j in the period between t_1 and t_2, we have:

$$\Delta B_j^{t_1-t_2} = B_j^{t_2} - B_j^{t_1} \qquad \beta_j^{t_1-t_2} = \frac{\Delta B_j^{t_1-t_2}}{B_j^{t_1}}$$

In the formula: $B_j^{t_2}$, $B_j^{t_1}$ are society-economy index of class j at t_1 and t_2; $\Delta B_j^{t_1-t_2}$ is the value changed of the index; $\beta_j^{t_1-t_2}$ is the change rate of the index.

C. Index of highway water conservancy action

1) Index of integration of highways and dykes

This index is the quotient of two number of one certain highway: length of integration of highway and dykes and the general length of this highway:

$$\phi = (\sum_{j=1}^{n} l_{ij}) / L_i$$

where ϕ represents the index of integration of highways and dykes; l_{ij} is the length of integration of highway--i and dyke—j; L_i is the general length of highway—i.

2) Index of coordination of highway bridges and culverts

This index is the quotient of two number of one certain highway: one number is the number of coordination of highway bridges and culverts with irrigation and water conservancy facilities n_i ; another number is the general number of highway bridges and culverts N_i, $K_i=n_i/N_i$, in which K_i is the index of coordination of highway bridges and culverts.

THE AREA MONITORED WITH 3S TECHNOLOGY FOR INFLUENCE OF URBAN ACTION OF HIGHWAY, AND THE METHODS OF MONITORING AND ASSESSMENT

A. Analysis of sensitive area influenced by urban action of highway in Dongting Lake

There are 208 towns and cities in the area of Dongting Lake, about 140 towns and cities, among which 69.3%, are along the classified highway in this area. These towns and cities are the start, end or important station of highway, they are also important points of economic development, and of course they are sensitive areas influenced seriously by urban action of highway.

To expressway, the area easily influenced by urban action of highway is the one in which there are junctions of interchange, or entrance to way and way out.

To other class highway, because of their character of open and intersection at grade, sensitive areas can be easily influenced by urban action of highway distribute widely.

Development of industry promotes the urbanization in Dongting Lake area.

Highway construction is the founder of industry and urbanization, and after the construction of highways, the area along these highways would be industrialized and urbanized rapidly.

The determination of sensitive area is not only decided by the actuality of influence by urban action of highway in Dongting Lake wetlands ecosystem, but also the future of influence, so the long-term plan of town and city construction in Dongting Lake area should be taken into account.

In addition, the degree of influence of highway urban action on Dongting Lake wetlands ecosystem is in correlation to the highway location relative to Dongting Lake wetlands.

After establish of PR. China in 1949, 15 farms owned by the government had been built. These farms are located in center area of Dongting Lake area and the area between north Dongting Lake and Jing River, which are wetland easily destroyed. And each farm was connected by various class highways and roads, so these farms have become various scale towns and cities. The influence by these towns and cities on Dongting Lake wetland ecosystem should be taken into account seriously, and these areas should be classified as sensitive area influenced by highway urban action.

The influence of urban action of rural roads is little relatively, but it is widely and largely in amount. Along the roads, there are a lot of farmer's houses and some other constructions distributed widely, for which we can not set up city infrastructures. So the influence of road's urban action should be considered as a whole.

B. The choice of area to be monitored for influence of urban action on Dongting Lake wetlan ds ecosystem

To technology, the indexes of influence by highway urban action on Dongting Lake wetlands ecosystem have some statistical characters. So some sample areas, part of all sensitive areas influenced by urban action of highway, could be monitored, and after statistical computing, from the data of these samples we can get the index of influence by urban action of highway statistically.

To economy, because of high price of high resolving power satellite images, and high expense of on-the-spot investigation, we choose some proper sample areas equably to represent all sensitive areas influenced by urban action of highway, which is depend on amount of the funds of research. And in these sample areas, the areas of urbanization really occurred is selected for monitoring area based on 3S technology.

After thinking of causes described above, we select Lixian County, Jingshi Town, Anxiang County, Nanxiang County, Huarong County, Qianlianghu farm, Baoheti Town, Hanshou County, Haozigang Town, Xihu farm, Maocaojie Town, Yuanjiang City, Fengnan Town, Xiangying County, Quyuan farm, Lujiao Town, Datong farm and Junshan District, Yueyang City, all 18 sensitive areas influenced by urban action of highway, as the monitoring areas (see Figure 1).

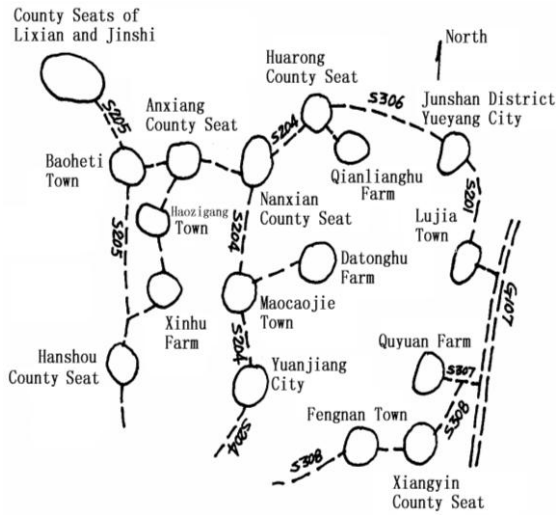

Figure 1. Areas monitored based on 3S technology for highway water conservancy action

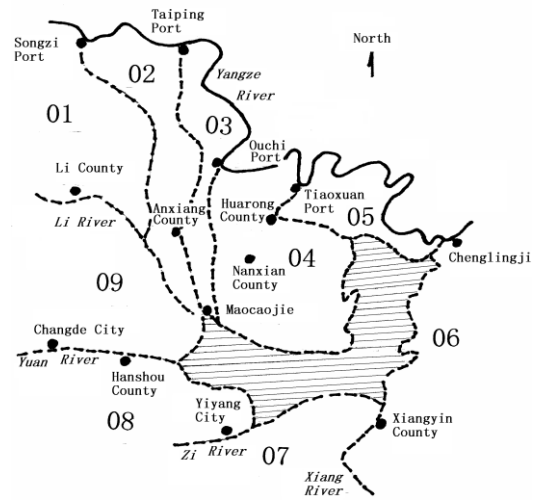

Figure 2. Areas monitored based on 3S technology for highway urban action

C. Methods of monit oring and assessment of influence of urban action of highway on Dongting Lake ecosystem

The monitoring and assessment may be based on multi time interval and multi-band TM satellite images and ERDAS processing. Detail methods and technologies include: technology of urban area classify based on remote image; grading of urban area and fixing on right for each grade; analysis of spatial-temporal character of urban land-use change; analysis of correlation between spatial-temporal character of urban land-use change and each index of society-economy; research on policies and technologies for control the influence of urban action of highway, which is for the conservation of wetlands; analysis and computing for mathematical statistic model of influence by urban action of highway on Dongting Lake wetlands ecosystem.

THE AREA MONITORED BASED ON 3S TECHNOLOGY FOR INFLUENCE BY WATER CONSERVANCY ACTION OF HIGHWAY, AND THE METHODS OF MONITORING AND ASSESSMENT

A. Separation of monitoring wetlands area influenced by water co nservancy action of highway in Dongting Lake area

The water conservancy construction is focused on the flood protection and drain waterlogged farmlands and farms irrigation in dyke. There are close relationships between Integration of highways and dykes and coordination of highways with water conservancy facilities. The analysis on water conservancy action of highway should take wider spatial area and two indexes of water conservancy action into account, which will benefit to macro-hold integration of highways and dykes and coordination of highways with water conservancy facilities under the highway-line running rationally.

Along the center lines of watercourses of rivers mentioned above, the whole monitoring area is separated into nine parts, each part is the basic unit in monitoring and analysis of influence by water conservancy action of highway on Dongting Lake ecosystem. In analysis, intra-unit and between-unit, the present situation and the trend of degree of integration of highways and dykes and coordination of highways with water conservancy facilities will be analyzed (see Figure 2).

B. Methods of area analysis on influence by water conservancy action of highway in Dongting Lake area

The methods of area analysis on influence by water conservancy action of highway in Dongting Lake area are based on 3S technology. The location of highways, dykes and water conservancies facilities is relatively stable, the area analysis on influence by water conservancy facilities of highway should use GIS as the platform. Up-to-date digital topography map reflecting the actuality of water conservancy action of highway and the data from on-the-spot investigation or remote images should be collected, the former is principal and the latter is secondary, as the data source of expert system for area analysis on influence by water conservancy action of highway on Dongting Lakes wetlands ecosystem. Aided by the expert's analytical system, in large area we can analyze and assess the integration of highways and dykes and the coordination of highways with irrigation and water conservancy facilities, we can also do spatial analysis on some correlative problem, which can support technologically the future highway's planning and reconstruction of existing highways. The aim of analysis is to take full advantage of highway's communication function, as well as to protect the Dongting Lake wetlands ecosystem.

CONCLUSION S

This paper focused on several problems of assessment on influence by highway on Dongting Lake ecosystem:

1) The main factors of influence by highway construction on Dongting Lake wetland ectope are: urban action of highway, water conservancy action of highway and highway's separate-approach action on migratory birds' habitats ecosystem.

2) The index system for assessment on influence by highway. The choice of index should emphasize on some certain causes.

3) According the analysis of monitoring area of urban action of highway, and to take the technology and economy into account, 18 areas of town or city are selected as monitoring area for assessment of influence by urban action of highway on Dongting Lake ecosystem. The main technology of monitoring and assessment will be based on 3S technology.

4) Based on multi time interval and multi-band TM satellite images and procession of ERDAS, the monitoring, analysis and assessment of influence by urban action of highway may be carried on.

5) Along center line of Yangtze River's four watercourses, Xiang River, Zi

River, Yuan River and Li River, the whole monitoring area for assessment on influence by water conservancy action of highway is separated into nine parts; each part is the basic unit of monitoring and analysis.

6) Area analysis on influence by water conservancy action of highway should be based on 3S technology, and ArcGIS could be the platform of integration of data source. The analysis area should be a large area, and then the integration of highways and dykes and the coordination of highways with irrigation and water conservancy facilities should be spatial analyzed with relational geography.

ABSTRACT

This research uses a Gongnong square intersection as a research object and TSIS for vehicle emission simulation. We obtain the input parameters, including road structure and traffic flows, through a field survey of Gongnong square,. Then taking emission as the main indicator and traffic delay as a second indicator, we use CORSIM modules of TSIS to simulate traffic operation. Two modified interchange projects are presented to judge whether reducing the vehicle emission and improving the traffic flow can be achieved simultaneously. This research offers a foundation for further road network analysis and research on emission reduction.

1. PREFACE

Signalized road intersections always are the crucial points with traffic-related pollutant concentrations, because levels often prove to be very high (Horowitz,1982). Interchanges are increasingly used to replace a variety of types of intersections and, thus, to improve traffic flow management and safety level. Transportation officials may also consider improvements in air quality and reductions in emissions, as they attempt to maximize interchange benefits (Witkowski,1988).

A model appears to be an important forecasting tool to reproduce traffic behavior along each link connected to the intersection. The application of TSIS is needed for this study (Wang, 2008). Once data, such as topographic and geometrical features of the road, vehicular flows, and lights intersection settings, have been provided; parameters such as the queue maximum length, the number of vehicles stopped, and the mean delay can be evaluated. Thus, different driving kinematics (acceleration, cruise, deceleration, idle) affecting vehicles approaching to or departing from the intersection are computed. In turn, these are the basic inputs for the emission model to estimate pollutant modal emissions along each link. Based on these data, we can project delay time and emission in different situations.

2. MODEL INTRODUCTION AND APPLICATION

TSIS-CORSIM is a microscopic traffic simulation software package for signal systems, freeway systems, or combined signal and freeway systems (Mctrans, 2007). The model, based on a simplified box model applied to the intersection area,

results from a comparison with respect to two of the most currently used intersection models. Starting from the queue and modal emissions algorithms both are implemented in the TSIS model.

2.1. Simulation procedure

The intersection model has been developed according to the scheme described in Figure 1. Vehicle queue parameters and emissions estimation finally result from a model built in a cascade fashion by a queue algorithm and a modal emission model. If the data including traffic light settings, traffic flows, intersection geometry and morphlogy, and car fleet composition are input, all the other models can be used to estimate a vehicle queue and total emissions at the intersection.

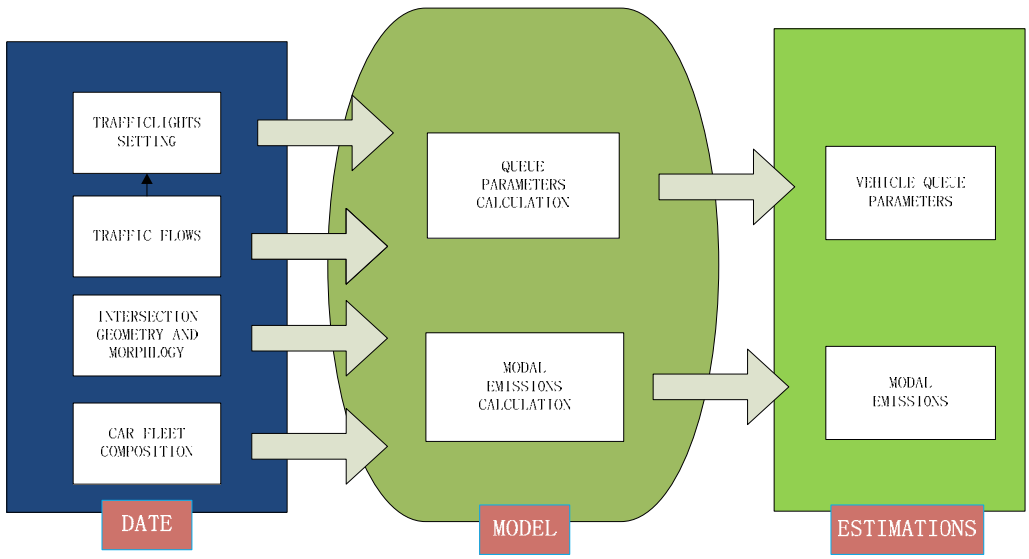

Figure 1. Simulation procedure of the intersection modeling for the estimation of delay time and emissions.

2.2. Queue and emission models

As showed in Figure 1, the first step is aimed at the investigation of traffic light settings, traffic flows, intersection geometry and morphlogy, and car fleet composition. The second step is to simulate queue parameters and emissions for estimating the delay time and emissions.

Once data such as vehicle flows, traffic lights setting and intersection geometry and morphology have been input, parameters such as the queue maximum length, the number of vehicles stopped and the mean delay per vehicle during an entire signal cycle can be calculated.

Emissions during the acceleration, cruise, deceleration and idle modes are estimated by means of the corsim module. Once car fleet compositon has been provided, the instantaneous emission rate of each car can be seen in the simulation and the total emissions of a district can be calculated.

3. SITE DESCRIPTION AND TRAFFIC SURVEY

Analysis of the intersections in Changchun city indicates that more serious traffic jams appear in Gongnong square, Xinmin square, Zhanqian square, Renmin square and other road intersections. However, only the Gongnong square intersection is a five-way plane intersection. This can be regarded as a T-shaped intersection and a cross intersection in this analytical process. As one of the most important intersections in Changchun city, both traffic and emissions have been locally collected by the intersection area.

First, we gathered field data on traffic light settings, intersection geometry and morphlogy, and then surveyed the vehicle flows, car fleet composition and turn ratios.

3.1. Site description

Gongnong square is a five-way plane intersection, and vehicle flow is heavy. It can be driven south on Renmin street, east on Nanhu road, west on Nanhu road and on Gongnong street in four directions from Renmin street. It can be driven north on Renmin street, west on Nanhu road, south on Renmin street and Gongnong street four directions from the east on Nanhu road.

At the same time, the left-turn vehicle flow from the north on Renmin street and the left-turn vehicle flow from the east and west from Nanhu road both need to drive through the flow. This creates transportation confusion at peak periods throughout the intersection, when vehicles are packed in like sardines. The vehicles from the north on Renmin street and the east from Nanhu road always need to wait for two or more signal cycles when driving through the intersection. This condition has a serious impact on the smooth operation of the entire intersection. Figure 2 is an overview of Gongnong square intersection.

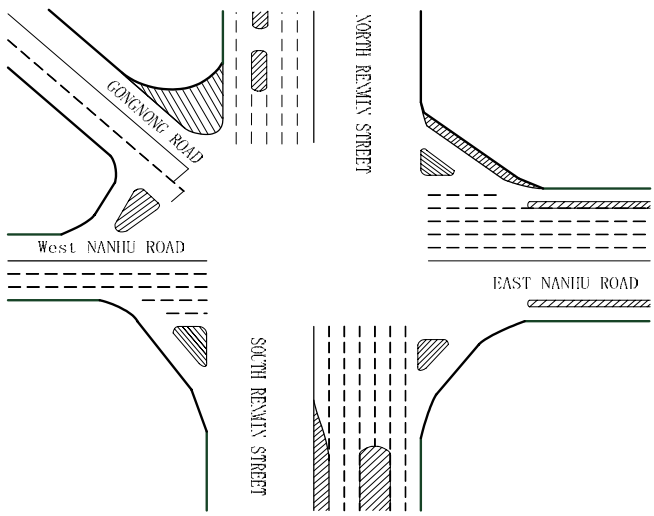

Figure 2. Overview of Gongnong square intersection.

3.2 Traffic survey

In order to simulate the situation of the Gongnong square intersection, beside inputting the geometry and morphology, we also need to investigate the vehicle flow, car fleet composition, and turn ratios of each inlet. Considering that the periods of time will have great influence on vehicle flow and emissions, we select the weekday morning and evening pea. Survey results can be used for simulating the discharge conditions and delay time in peak hour. The traffic survey result is shown in Tables 2 and 3.

Table 2. Gongnong square intersection's vehicle flows and car fleet composition in morning and evening peak period.

Inlet Name	Total vehicle flows（veh/h）	Bus（veh/h）	Truck percent (Barring bus)
North Renmin Road	1828	146	1%
North Renmin Road	1937	116	2%
East Nanhu Road	1572	66	1%
West Nanhu Road	720	48	1%
Gongnong Road	662	22	1%

Table 3. Gongnong square intersection's turn ratios of each inlet in workday's morning and evening peak period.

Inlet Name	Turn Ratio (%)				
	North Renmin Road	Sourth Renmin Road	East Nanhu Road	West Nanhu Road	Gongnong Road
North Renmin Road		65.75	25.82	7.77	0.66
North Renmin Road	55.66		20.75	0.98	22.61
East Nanhu Road	22.14	16.79		29.90	31.17
West Nanhu Road	31.95	10.83	54.72		2.5
Gongnong Road	⊗	92.75	⊗	7.25	

4. ANALYZING MODELLING RESULTS

The aim of this paper is to optimize emissions. At the same time, since delay time is a complementary indicator, we want to verify whether improvements also achieve optimization in delay time. Finally, we examine the effect of different projects on vehicle emissions by comparing data simulation before and after the project was implemented.

Interchanges can be a feasible alternative to reduce vehicular emissions and make intersections more environment-friendly. We select incomplete interchange and cloverleaf interchange as two hypothetical cases. In order to simplify the introduction, using project A represents an incomplete interchange and project B represents a cloverleaf interchange. Project A changes the north-south direction of Renmin Street to an incomplete interchange. Project B is a modified cloverleaf interchange. For better channelization, we took Gongnong road into the entire project. After simulating three projects, we compared the delay time and emissions.

4.1. Comparision of delay time

Table 4 indicates that project B accounts for the least queuing delay compared to the original project. Absence of traffic signal control and of traffic in different directions through a loop ramp simultaneously reduces the queuing delay and control delay time by as much as 99.39%. Project A also has a very good improvement compared with the original project. The north-south direction of vehicles on Renmin street, separated from the other three roads and lacking a traffic signal, eliminates traffic flow interference and also reduces queuing delay.. At the same time, control delay of project A shows a great improvement.

Table 4. Comparision of delay time in the three projects.

Delay categories		Control delay （sec/veh）	Queuing delay （sec/veh）
Original project		1837.1	1943.8
Project A	Incomplete interchange	1245	1277.1
	Reduction percent	－32.23%	－34.30%
Project B	Cloverleaf interchange	18.4	11.8
	Reduction percent	－99.00%	－99.39%

4.2 Comparison of emission

As shown in Table 5, there are significant reductions from the change from intersection to interchange. Project A had 18.01% reductions in total exhaust compared with 24.51% reduction in project B. For the three emissions, project B performs better than project A by 3%-13%. For aggregate emissions, project B is

lower than project A by 6%.

These findings indicate that project B is the better option for achieving significant reductions in emissions and corresponding reductions in delay time. They demonstrate that changing the intersection can reduce total emissions and make traffic run more smoothly.

Table 5. Comparision of vehicle emissions in the three projects.

Project	CO(g/h)	NOx(g/h)	HC(g/h)	Aggregate(g/h)
Original project	3568.766	405.202	223.343	4197.311
Project A	2910.422	360.0255	171.0645	3441.512
	－18.45%	－11.15%	－23.41%	－18.01%
Project B	2654.730	372.381	141.375	3168.486
	－25.61%	－08.10%	－36.70%	－24.51%

5.CONCLUSION

A hypothetical case study has offered a method for evaluating the user benefits from highway improvements. Our research compared two interchange projects and an intersection in terms of the delay and vehicle emissions for a workday's morning and evening peak periods. The results indicate that the interchange generates delay and total vehicle emissions reductions.

The model presented in this paper has been implemented into a geographic information system focused on the Gongnong square intersection, with the aim of managing atmospheric pollution due to urban traffic. It was found that the cloverleaf interchange performed better than the existing intersection control in reducing vehicular emissions. The project's positive environmental impacts include:

(1) Travel time benefits, including control delay and queuing delay from the interchange and highway as well as improved crossing capacity at th Gongnong square intersection.

(2) Improved air quality due to a reduction of idling and stop-and-go traffic situations.

The Method of Determining Traffic Impact Range of Developing Project Based on Threshold Value

ZHOU Chao[1], WANG Xiaoning[2] and DENG Shuanglong[2]

[1]China Highway Engineering Consulting Group Company Ltd, P.C. 100000, PH 13091711424, email: nn2k@163.com

ABSTRACT

It is important to determine the scope of the traffic impact on the traffic impact analysis scientifically and rationally. This paper studies the method of determining threshold value of traffic impact range. It is reasonable that the decreasing of service level of signal intersection surrounding projects by one grade is regarded as the threshold value. The method of application is introduced by taking the example of Harbin International Exhibition and Sports Center developmental project. The result shows the method of determining the threshold value of traffic impact range is rational, simple and effective.

CLOUD MODEL

Deduced from the theory of cooperative, this method considers approximately the traffic impacts to the surrounding road sections which are induced by project practice as the poison gas discharged into air, which is composed of many subsystems (Soumya et al. 1993; Wang et al. 2001). In this kind of open and steady-going system, all subsystems are distributed in the whole impact range as circles, which diffuse under the impact of project practice in a turbulence field of turbulence distributing equably in all directions. The impact of project practice is associated with its type and intensity and is positively related to the intensity (e.g. the larger-scale commercial projects possess a much heavier traffic impact to the surrounding road networks than the projects of researching and developing of new science and tech). The impact received by the road sections and intersections in the impact range is equal to the impact induced by the local subsystem. The impact reaching the distance of x off the project entity can be computed in the following equation, in which the average value $\overline{C}$, of the impact degree C, can explain the impact induced by the project entity at some distance.

$$C(x) = \frac{\xi Q}{4\sqrt{\pi x^2}} \quad (1)$$

In the equation above, ξ represents the outer-oriented diffusion ratio of the traffic impact, the value of which is related to the type and intensity of the project,

$\xi \in$（0，1）. Q represents the unit impact to the surrounding road network. By supposing C_d as the ultimate impact and $\overline{C} = C_d = \xi Q / 4\sqrt{\pi} x_d^2$, we can acquire the maximum distance that the project impact can reach under the condition of ultimate impact as follows:

$$x_d = \beta \sqrt[3]{\frac{\xi P a}{4\sqrt{\pi} C_d}} \tag{2}$$

By utilizing the equation above, we can determine the maximum range of the different impacts induced by the project practice. In this equation, β can be adjusted to 1, 0.3, 0.05, and so on. The C_d can be determined by trial balance. Also, with some available software of transportation planning, such as TRIPS, we can determine C_d by analyzing the difference of traffic state in the surrounding road network before and after the project practice simply by choosing the apt traffic volume and the level of service. The determination of constant a in the equation is also related to the type and intensity of the project, $a \in (0.15，1)$.

This method can be applicable for every project of different type, scale and intensity, and for TIA of long term and short term. However, because the C_d in the equation is different in different projects, the results may have some errors. Also, the model is too complicated to adopt in real tasks.

EXPERIENTIAL METHOD

Each of the following items should be considered in a TIA once it happens:

①The traffic volume of the surrounding roads has effects on the in and out traffic volume of the project.

②At the planned entrances, the surrounding roads do not have left-turn lanes.

③At the entrances and exits, the stadium does not meet demand.

④The entrance lanes in the drawing plan are too close to the other entrances or intersections.

⑤The project is for special use or restricted by some conditions in detailed planning.

For the developing and utilizing of some local lands, the impact range of some districts is composed of all roads and intersections, where the induced traffic volume exceeds the capacity during peak hours by 5%, and places where the characteristics of traffic vary.

As the methods above mostly refer to the American experience, further research has not been carried out to see whether they can be adopted well in our

country or not. The impact range is mostly determined by the location, features and type of the project.

THE DETERMINATION OF THE THRESHOLD VALUE

The Concept of Threshold

The threshold value is introduced here to explain when we should take the surrounding roads or intersections into consideration for the traffic impact range, according to how much they are affected by the project practice.

The Basic Principles of Determining the Threshold Value

①The combination of qualitative analysis and quantitative analysis. Because the types and scales of projects vary greatly, in addition to the different locations and different states of the surrounding road networks, it is easy to make the problem much more complicated when simply the quantitative analysis is done. This requests us to use qualitative analysis for some special problems, to which quantitative analysis is not applicable (Huang et al. 1999).

②The combination of universality and particularity. In the determination process of the threshold value, the more complicated and more special parts which surround the project entity should be isolated to be determined by qualitative analysis; while in ordinary situations, the determination should be made by the following methods.

The Classification of the Proposed Projects

According to the practical state of our country, projects are classified into three kinds (Zhang et al. 2001):

①projects with a particularly sensitive location

②special projects

③common projects

Because the first two belong to special cases, the determination of the impact range for them should be considered from the state of the project location and the self characteristics of the project; while the third one belongs to common cases. This paper focuses mainly on the third case.

Methods of Determining the Threshold Value

In practical cases, the threshold value is used to determine whether the surrounding parts of the project entity should be considered in the traffic impact range under some specific traffic impact. However, theoretically, the essence of threshold value is the new traffic demand resulted from the project practice, while the new induced traffic demand may lower the service level of the surrounding traffic establishment, or even the service level of the whole road network. The impact to the surrounding roads resulting from the induced traffic volume can be concluded into three kinds: the surrounding signalized intersections, entrance and exit of the project entity and the surrounding road sections. When determining the

impact range, it is unreasonable to simply lay the impact resulting from the project on the entrance and exit. As we know, the intersections play a more important role in traffic improvements, simply because they are the bottle-necks of the whole road networks. So, this paper takes the surrounding signalized intersections as research objects. We find that it is reasonable to take the service level decreasing by one grade as the threshold value.

THE DETERMINATION OF THE IMPACT RANGE

According to the former discussion, the threshold value is determined by the service level of signalized intersections decreasing by one grade. So, the parts which achieve the threshold value will be included in the impact range. That is to say, we should compute the service levels of the surrounding signalized intersections before and after the project practice first, and then determine the impact range by linking the intersections at which the service level decreases by one grade as the boundary of the impact range.

Classification of Service Level

Service level is defined as a kind of quality criteria to measure the condition of traffic flow and the feeling of drivers and passengers. The mean stop delay of each vehicle in the standard analysis period of 15 minutes is used to represent the service level of signalized intersections. The criteria of service level are listed in Table 1.

Calculation of Delay of Intersections

This paper uses the method from the American Road Capacity Manuscript to calculate the delay of intersections. In every group of lanes, average delay of each vehicle is computed by formula (3), while the average delay of the induction section and the whole intersection can be computed by formula (4) and (5) respectively.

$$d = 0.38C\frac{(1-g/C)^2}{[1-(g/C)(X)]} + 173X^2\left[(X-1)+\sqrt{(X-1)^2+16X/c}\right] \tag{3}$$

In this formula, d represents the average delay of each vehicle in each group of lanes, *s/veh*; C represents the cycle time of the signal, *s*; g/C represents the ratio of each group of lanes; X represents the saturation of each group of lanes. C represents the capacity of each group.

$$d_A = \sum_i d_i v_i / \sum_i v_i \tag{4}$$

d_A - delay of induction section A, s/veh; d_i - delay of group i in induction section A, s/veh;

v_i - Correction flow of group i.

Furthermore, average the delay of each induction section; we can achieve the average delay of the whole intersection:

$$d_J = \sum_A d_A v_A / \sum_A v_A \quad (5)$$

d_J – average delay of each vehicle in this intersection, s/veh;

v_A - Correction flow of induction section A, veh/h.

The level of service for the intersection can be determined by referring to Table 1 according to the average delay of the intersection acquired above.

Table 1. Level of Service Standard of Signal Intersection

Level of Service	Average Delay (s)	Level of Service	Average Delay (s)
A	≤5.0	D	25.1～40.0
B	5.1～15.0	E	40.1～60.0
C	15.1～25.0	F	>60.0

NUMERICAL STUDIES

Taking the TIA of the Harbin International Exhibition and Sports Center (IESC) as an example, we use the methods introduced above to determine the impact range. In order to determine the level of service for the intersections, we assume:

①In the completion year of the project, the signal timing of intersections does not vary. Data is from the investigation (Harbin Transportation Planning and Research Agency et al. 2002) in 2002.11.17-2002.11.20 by authors.

②In the completion year of the project, the asymmetry coefficient of the two directions of roads is 0.5. At each intersection, the ratios of left-turn, right-turn and straight-proceed are the same as the data of investigation in 2002.

③In the completion year of the project, the function of each lane is the same in 2002.

According to Formula (3), (4) and (5), the average delay at the intersections near the IESC before and after its completion is calculated. Also, we listed the level of service in Table 2.

Table 2. Vehicle Average Delay and Level of Intersection Service of Intersection of Project Build Former and After

No.	Name of Intersections	Former Average Delay	Later Average Delay	Former Level of Service	Later level of Service
1	Hongqi Street—Huaihe Road	19.3	25.2	C	D
2	Nanzhi Road—Huaihe Road	9.7	11.5	B	B

3 Huanghe Road—Huashan Road	6.3	13.7	B	B
4 Huanghe Road—Songshan Road	9.8	16.3	B	C
5 Changjiang Road—Huashan Road	15.6	26.4	C	D
6 Changjiang Road—Songshan Road	17.0	24.8	C	C
7 Songshan Road—Minjiang Road	6.9	15.7	B	C
8 Hongqi Street—Minjiang Road	20.0	24.6	C	C
9 Hanshui Road—Huashan Road	7.9	13.2	B	B
10 HanshuiRoad—Songshan Road	13.0	23.1	B	C
11 Hongqi Street—Hanshui Road	14.9	25.0	B	C

Table 2 shows that the levels of service of Intersections 1, 5, 10, 11 decrease by one grade, so, according to the former discussion, these intersections should be included in the impact range; and by linking these intersections along the roads they belong to, we can determine the impact range, which is encircled by the linking of HuaiHe Road、HuaShan Road、HanShui Road and NanZhi Road.

CONCLUSION

Based on the review and analysis of the traditional methodologies to determine the traffic impact range, this study develops the concept of the threshold value for determining impact range and the way to calculate the threshold value. The threshold value presented in this paper is defined as one lower degree of level of service for intersections which surround the proposed project. Then, the traffic impact range is determined by connecting the intersections which meet the demand of the threshold value. In order to illustrate this methodology, a case study based on Harbin International Exhibition and Sport Center project is introduced. The main conclusion of this study is the fact that this new method based on the threshold value is reasonable, and it is more convenient and less complicated than traditional ones. Also, it is a practical method that can be widely used in China.

ABSTRACT

In order to study the calculation method of interchange noise pollution, the traffic noise is connected with the length of the ramp according to the feature of traveling with variable speed on the ramp. The thesis chooses the equivalent sonic level as the assessment index, defines the concept and discusses the calculation method of relative equivalent sonic energy according to the definition of equivalent sonic level; it also establishes the functional relationship between relative equivalent energy and the length of the ramps. The calculation formula of interchange equivalent sound level is deduced through the integral operation of the ramp length. Take Heda interchange in Heilongjiang province for example. The result shows that this method can calculate the noise pollution in the variable motion sections on the ramp as well as the noise pollution according to the interchange geometric alignment design conditions.

INTRODUCTION

As important nodes of highway and urban road network, interchanges have particularly serious noise pollution problems (Wang 2005; Wang 2005; Zhang 2005; Zhang 2005). Because of the various forms and complex structures, the geometric design condition will affect the driving noise intensity directly. The key point of interchange's noise calculation, compared with noise calculation of road sections, is the calculation method on variable motion sections (American Association of State Highway and Transportation Officials et al. 2001). According to the principle of vehicle radiation noise accumulated gradually with travel distance, this paper defines notion of relative equivalent sonic energy at first, secondly on the basis of summarizing and generalizing the research of the relationship between noise level and speed home and abroad, provides the fitting relationship between relative equivalent sonic energy and vehicle speed, and then establishes the conic relationship between relative equivalent sonic energy and the length of ramps according to the functional relationship between vehicle speed

and the length of ramps. Finally through the integral operation, the relative equivalent sonic energy per vehicle when accelerated traveling on the ramp is given and the calculation method of interchange noise is proposed based on the definition of equivalent sound level and noise superposition formula (Wang 2007).

CONCEPT AND CALCULATIO N METHOD OF RELATIVELY EQUIVALENT SONIC ENERGY

According to the definition of sound level, the value at point *j'* is:

$$L_{P\,j'} = 20\lg\frac{P_{j'}}{P_0} = 10\lg\frac{P_{j'}^2}{P_0^2} \qquad (1)$$

Where $L_{Pj'}$ is the sound level of point j', dB;

$P_{j'}$ is the sound pressure of point j', Pa;

P_0 is the standard sound pressure, taking the hearing threshold sound pressure （2×10^{-5}Pa）.

According to formula (1), it gets:

$$10^{0.1L_{Pj'}} = \frac{P_{j'}^2}{P_0^2} \qquad (2)$$

This paper chooses the equivalent sound level to calculate noise pollution, which is defined as follows:

$$L_{eq} = 10\lg\frac{1}{T}\int_0^T 10^{0.1L_{P\,j'}}\,dt \qquad (3)$$

Where T——The noise measurement time;

$L_{Pj'}$—— The sound level of point j',dB.

According to formula (2) and (3), it defines u as relative equivalent sonic energy at point *j'*. So U representes the total of that between [0，T]. According to formula (4), the relative equivalent sonic energy at point *j'* can be obtained if its sound level is known.

$$u = \frac{P_{j'}^2}{P_0^2} = 10^{0.1L_{Pj'}} \qquad (4)$$

THE FITTING RELATIONSHIP BETWEEN RELATIVE EQUIVALENT SONIC ENERGY AND VEHICLE SPEED

This paper divides vehicles into five types, namely motorcycle, light-duty vehicle, medium-duty, heavy-duty and oversize vehicle. Based on some researches, this paper calculates sound level at the situation of V=10、20、30、40、50、60、70、80、90 and 100km/h. Then through analyzing the mean value of sound level at the same speed, this paper gets the sound level at that point and the relationship between sound level and vehicle speed by fitting (see Table 1).

Table 1. The Relationship Between Noise Level and Vehicle Speed

Vehicle Type	The Relationship Between Sound Level and Vehicle Speed
Light-Duty Vehicle	$L_1 = 8.93L_n(V) + 35.35$
Medium-Duty Vehicle	$L_2 = 12.89L(V) + 26.52$
Heavy-Duty Vehicle	$L_3 = 9.33L_n(V) + 42.03$
Oversize Vehicle	$L_4 = 6.54L_n(V) + 60.09$
Motorcycle	$L_5 = 7.09L_n(V) + 49.41$

According to formula (4), the relative equivalent sonic energy u, when the vehicle is at a certain speed, can be calculated. And Table 2 is the result of fitting u and V by quadratic polynomial.

Table 2 The Relationship Between Relative Equivalent Sonic Energy and Vehicle Speed

Vehicle Type	The Relationship Between Relative Equivalent Sonic Energy and Vehicle Speed
Light-Duty Vehicle	$u_1 = 7589.6V^2 - 273184V + 4E+06$
Medium-Duty Vehicle	$u_2 = 100746V^2 - 6E+06V + 8E+07$
Heavy-Duty Vehicle	$u_3 = 46174V^2 - 1E+06V + 2E+07$
Oversize Vehicle	$u_4 = 288873V^2 - 1E+07V + 2E+08$
Motorcycle	$u_5 = 43587V^2 - 2E+06V + 4E+07$

THE FUNCTIONAL RELATIONSHIP BETWEEN SPEED AND RAMP LENGTH OF VARIABLE MOTION SECTION

When driving on interchange ramps, the changes in speed are very complex, because both uniform motion and variable motion exist. Generally, the speed changing process on the ramp can be divided into four situations, namely the process with one deceleration and one acceleration, the process with one deceleration only, the process with one acceleration only and the process with more than one deceleration and acceleration. According to the above situations, this paper establishes the function between vehicle speed and the length of the ramp in variable motion sections. Researches show that though the ramps' alignment composition is different, the vehicle speeds the ramps can support are different, the expressions of relationship between speed and ramp length are different, the forms are the same, which can be expressed by formula (5):

$$V = el^2 + fl + g \qquad (5)$$

Where V is vehicle speed driving on the ramp, km/h;

L is the ramp length of driving, m;

e、f、g is coefficients.

The calibration of coefficients e、f、g in formula (5) refers to reference (El-Aassar et al. 2006).

THE RELATIVE EQUIVALENT SONIC ENERGY OF VARIABLE MOTION SECTION

From Table 2, the relationship between relative equivalent sonic energy per vehicle of type i and speed can be represented by formula (6).

$$u_i = \alpha V^2 + \beta V + \chi \quad (6)$$

When taking formula (5) into formula (6), it gets:

$$u_i = M_1 l^4 + M_2 l^3 + M_3 l^2 + M_4 l + C_2 \quad (7)$$

The coefficients of M1、M2、M3、M4 and C2 in formula (7) refer to reference.

When driving on ramps, the relative equivalent sonic energy is accumulated gradually with the driving length on ramps. So using the knowledge of advanced mathematics, the total relative equivalent sonic energy per vehicle when driving from point a to point b on a ramp is:

$$U = \int_a^b f_l(l)\,dl \quad (8)$$

Taking formula (7) into formula (8) and making definite integral, it gets the relative equivalent sonic energy of variable motion section:

$$U = \left[\frac{M_1}{5} l^5 + \frac{M_2}{4} l^4 + \frac{M_3}{3} l^3 + \frac{M_4}{2} l^2 + C_2 l \right]_a^b \quad (9)$$

THE RELATIVE EQUIVALENT SONIC ENERGY OF UNIFORM MOTION SECTION

According to the velocity V of uniform motion, the corresponding sound level can be obtained based on Table 1. Also the relative equivalent sonic energy u of uniform motion section can be deduced based on formula (4). Furthermore, the total relative equivalent sonic energy *U'* accumulated in the uniform motion section will be deduced by multiplying the driving ramp length by u.

THE EQUIVALENT SOUND LEVEL OF RAMP S

The relative equivalent sonic energy accumulated at the left-turn ramp is equal to the sum of the relative equivalent sonic energy accumulated in the variable motion section U and the uniform motion section *U'*. Take the left-turn ramp for example, hypothesize that there are n_1 left-turn ramps at a intersection, and the traffic volume of No.k_1 ramp with No.i vehicle is A_{zdk1i}, so the equivalent sound level of left-turn ramp is 10 times the logarithm of all relative equivalent sonic energy.

$$L_{zz} = 10 \lg \sum_{k_1=1}^{n_1} \sum_{i=1}^{5} A_{zdk_1 i} [U + U'] \quad (10)$$

Where L_{zz} is the total equivalent sound level of all left-turn ramp, dB;

k_1 is the number of left-turn ramp;

n_1 is the total number of left-turn ramp;

A_{zdk1i} is the traffic volume of no.k_1 ramp with no.i vehicle, pcu/h

U is the relative equivalent sonic energy of variable motion section;

U' is the relative equivalent sonic energy of uniform motion section.

NUMERICAL STUDI ES

Take Heda interchange located at the crossing of Yibao highway and Heda highway for example. According to the method in segment 3, the fitting relationship between velocity and length at the variable motion section of every ramp is shown as follows (see Table 3).

Table 3 The Fitting Relationship Between Velocity and Length at Variable Motion Section of Heda Interchange Ramp

Title	The Stake Number	The Fitting Relationship
Ramp A	k0+000~k0+731.19	$V=2E\text{-}04l^2\text{-}0.1547l+84.929$
Ramp F	k1+80~ k1+331.114	$V=\text{-}3E\text{-}05l^2+0.1403l\text{-}48.37$
Ramp G	k0+000~ k0+290	$V=\text{-}2E\text{-}05l^2\text{-}0.047l+84.99$
	k0+510~k0+650	$V=\text{-}3E\text{-}05l^2+0.0932l+29.257$
Ramp B	k0+000~ k0+260	$V=\text{-}0.0024l^2+0.0572l+67.241$
	k0+460~k0+786.11	$V=0.0007l^2\text{-}0.7879l+272.36$
Ramp C	k0+380~ k0+450	$V=\text{-}0.0001l^2\text{-}0.037l+117.46$
	k0+740~k0+820	$V=\text{-}3E\text{-}05l^2+0.1018l+13.468$
Ramp D	k0+353.39~k0+563.39	$V=\text{-}4E\text{-}05l^2+0.1197l+31.348$
Ramp E	k0+550~k0+760	$V=\text{-}4E\text{-}05l^2+0.1368l+5.6962$
Ramp H	k0+600~k0+811.817	$V=\text{-}4E\text{-}05l^2+0.1411l\text{-}1.2509$

According to the designed traffic flow of Heda interchange and the data in Table2 and Table 3, the equivalent sound level of every ramp about Heda interchange in scheme 1 can be calculated (see Table 4).

CONCLUSION

According to the features of ramp variable motion sections, the thesis defines notion of relative equivalent sonic energy, derives the relationship between the relative equivalent sonic energy and the length of ramp by fitting, then deduces the calculation formula of interchange equivalent sound level through the integral operation of ramp length, and finally purposes the noise calculation methods of the left-turn ramp as well as the right-turn ramp. The Numerical Studies show that this method can evaluate the influence of interchange geometric alignment to the ramp noise. If the geometric design condition of a interchange and its traffic value are known, the noise pollution can be calculated.

The Study on Design Method of Vehicle Intake Silencer Based on Three-Dimension/One-Dimension Models Coupling

J. Li[1] and Q. Guan[2]

[1]Traffic College, Northeast Forestry University, He Xing Road 26#, Harbin City, 150040. PH: 13624614575; email:lijk_01@tom.com.
[2]Traffic College, Northeast Forestry University; Harbin City, 150040.

ABSTRACT

Stricter noise legislation makes it increasingly important to utilize the intake silencer on automobiles. Analysis of research on automobile intake silencers identifies its main problems for domestic engines. This research applies a reliable test platform and theories, as well as acoustics analysis software and hydrodynamics,,to propose a new method of designing an intake silencer. The purpose is to control air intake noises effectively and to reduce overall vehicle noise. A 1-Dimension (1-D) model for a certain gasoline engine and 3-Dimension(3-D) model for a Helmholtz intake resonator were set up with GT-POWER and STAR-CD software respectively, to form a combined model for both engine and silencer. A 1-D/3-D coupling model was developed. It reduced overall engine noise by 4.2dB. Simulation results compared favorably with test results, verifying the rationale for the design of the silencer.

INTRODUCTION

Engine intake noises have become an important automobile noise source. To improve NHV quality, it is most effective to use a properly structured intake muffler. It should reduce vehicle noises while leaving the interior engine structure and automotive power performance basically unchanged.

Domestic automobile manufacturers have not yet achieved a design that satisfactorily reduces intake noises and adapts to newer regulatory demands. Relevant research methods are somewhat backward. Therefore, improving the standards of intake muffler design is very significant (Pang, 2006).

USING SOUND INTENSITY FOR NOISE MEASUREMENT AND NOISE SOURCE IDENTIFICATION

To measure sound intensity, two microphones must be placed at an appropriate distance. They are often assembled into a microphone sound intensity probe. The use frequency of a sound intensity probe is closely related to the small interval distance, so there is no need to consider the phase difference problem between the sound and vibration velocity signal (Mo, 2002).

Through testing and analysis of the sound intensity spectrum, we found the

noise:

(1) of an internal combustion engine increase with its speed.

(2) near the engine inlet are larger than others and the intake noise frequency mainly focuses on 100 ~ 1231Hz.

SETTING UP THE MODEL OF INTAKE RESONATOR

Identification for intake system noises frequency

Acoustic radiation on the engine surface can be measured by an automotive chassis dynamometer. Through frequency analysis, the time-domain signal of the intake noises measured are transferred by Fast Fourier Transform(FFT), as shown in Figure 1.

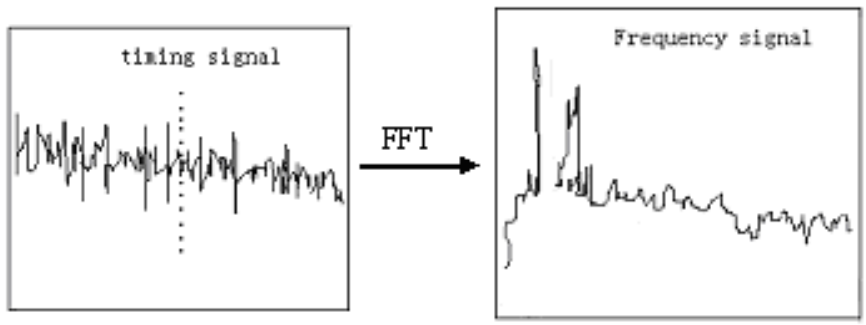

Figure 1. Signal for time-domain , frequency-domain in intake system noise.

The study found that the noise spectrum at low frequencies had three obvious peaks in the engine intake manifold. The center frequency is respectively 120,210 and 270Hz, via formulas (1) and (2). We can see that certain frequency noises can be reduced in the intake process by designing a reasonable resonant. The above three peaks of low-frequency band noises can be mainly eliminated through the muffler.

Considering the installation location and anechoic frequency of the resonator in the engine, the resonator structure size was derived, as shown in Table 1.

Table 1. Resonator size.

number	1	2	3
V/L	2.45	0.87	0.41
S/mm^2	298	317	308
L/mm	21	16	19

Setting up the intake resonator model grid

To verify whether the designed resonator can meet the noise reduction expectation without affecting vehicle performance, a 1-D/3-D coupled simulation between resonator and engine was set up and installed between the air filter and inlet pipe.

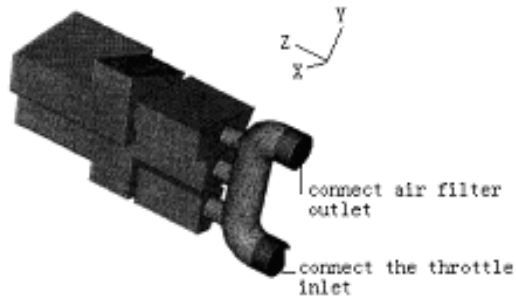

Figure 2. Three dimensional computational grid of resonator.

The calculation border region of the selected resonator 3-D model is as follows: The inlet air side is at the outlet of the filter. The outlet air side is at the inlet of the throttle valve. We take a 3-D resonator CAD model to the grid generator to divide the computational grid. A total 66008 units and 86900 nodes were generated. From Figure 2, the model can better reflect the actual geometric structure of the resonator.

Calculation model

The mathematical model of the resonator internal flow field is mainly composed of the mass conservation equation, momentum and energy conservation equations, state equation and thermodynamic relation, and formula k-ω equation as follows:

(1) Turbulent kinetic energy k

$$\frac{\partial}{\partial t}(\rho k)+\frac{\partial}{\partial x}\{\rho\mu_j k-[\mu+\frac{\mu t}{\sigma k}]\frac{\partial k}{\partial x_j}=\mu(P+P_B)-\rho\varepsilon-\frac{2}{3}[\mu_t\frac{\partial \mu i}{\partial xi}+\rho k]\frac{\partial \mu i}{\partial xi}+\mu_t P_{NL}\ (1)$$

σ_k for the turbulent Prandtl number, P_{NL} for the nonlinear term.

(2) Turbulent and kinetic energy dissipation rate ε

$$\frac{\partial}{\partial t}(\rho\varepsilon)+\frac{\partial}{\partial xj}\{\rho\mu_j\varepsilon-[\mu+\frac{\mu_t}{\sigma_\varepsilon}]\frac{\partial}{\partial x_j}\}=C_{\varepsilon 1}\frac{\varepsilon}{k}\{\mu_t P-\frac{2}{3}[\mu_t\frac{\partial \mu i}{\partial xi}+\rho k]\frac{\partial ui}{\partial xi}+$$

$$C_{\varepsilon 3}\frac{\varepsilon}{k}\mu_t P_B-C_{\varepsilon 2}\rho\frac{\varepsilon^2}{k}+C_{\varepsilon 4}\rho\varepsilon\frac{\partial ui}{\partial xi}+C_{\varepsilon 1}\frac{\varepsilon}{k}\mu_t P_{NL}\qquad(2)$$

$C_{\varepsilon 1}$、$C_{\varepsilon 2}$、$C_{\varepsilon 3}$、$C_{\varepsilon 4}$ for constants of the model, shown in Table 2 and the turbulent viscosity $\mu_t=\rho C_\mu\frac{k^2}{\varepsilon}, C_\mu$ for experience constant $C_u = 0.09$.

Table 2. The standard turbulence model constants.

σ_k	σ_ε	σ_h	σ_m	$C_{\varepsilon 1}$
1.0	1.22	0.9	0.9	1.44

Algorithm and boundary conditions

Using pressure implicit with splitting of the operators (PISO) algorithm, resonator boundary conditions are as follows: import and export are both setting the speed import. The initial value is zero, when calculating. STAR-CD will automatically read the GT-POWER's calculation results and then obtain the flow rate value of imports. Turbulent density is 0.02 and the length is 0.003m. Take the gas as ideal gas, and the wall temperature for a fixed temperature which can meet the ideal gas state equation.

GASOLINE ENGINE AND EXHAUST MUFFLER MODELING

Gasoline engine model

We set up a gasoline engine model and selected a reasonable combustion model. Based on the first law of thermodynamics, its mathematical description is:

$$\frac{d(m_c \mu')}{d\alpha} = -p_c \frac{dV}{d\alpha} + \frac{dQ_F}{d\alpha} - \Sigma \frac{dQ_W}{d\alpha} - h_{BB} \frac{d_{mBB}}{d\alpha} \tag{3}$$

m_c for gas quality in cylinder,p_c for gas pressure , u' for internal gas energy, α for the crank angle,$-p_c \frac{dV}{d\alpha}$ for the work by cylinder, $\frac{dQ_F}{d\alpha}$ for fuel generation heat quantum, $\Sigma \frac{dQ_W}{d\alpha}$ for piston wall loss heat, $h_{BB} \frac{d_{mBB}}{d\alpha}$ for the enthalpy value.

Using the engine combustion model provided by GT-POWER, the combustion room is divided into two regions, according to the combustion exothermic rule Weber function:

$$\frac{dx}{d\alpha} = \frac{\alpha}{\Delta\alpha_c}(m+1) y^m e^{-ay(m+1)} \tag{4}$$

Where $dx = dQ/Q, y = (a - a_0)/\Delta a_c$,Q for the total heat released by combustion, a_c for the start angle, m for the shape factor, and $\Delta\alpha_c$ for the combustion duration. A friction model is set up following Chen-Flynn. At resonator module, setting the resonator CFD control model, the volume V=3.5L, fluid convergence diffrence sets to zero, the engine pre-cycle number for 5. After the model is completed, we loadedthe required noise sensors, set the frequency octave with a

range of 100 ~ 4 000Hz.

Exhaust muffler model

Using the muffler module inner GT-POWER, an exhaust muffler model was set up (Song, 2005).The pipe length of import and export is 0.1m, the diameter set atr 0.0486m, the expansion cavity length for 0.2823m, perforated pipe aperture at 4mm, perforation rate 20%, the perforated plate is partition, and hole diameter is 5mm. Then, using GT-POWER and STAR-CD coupling technology, the gasoline engine model, resonator, and exhaust muffler were organically combined. This constitutes the resonator-gasoline engine simulation platform, as shown in Figure 3.

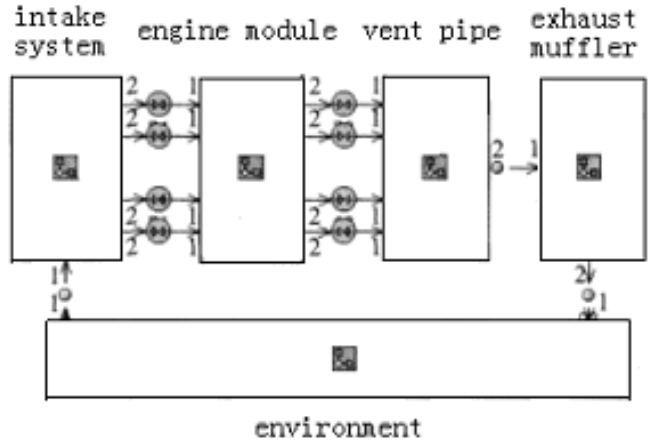

Figure 3. Resonator-gasoline engine simulation platform.

ANALYSIS OF RESULTS

Performance analysis of resonator

When the acoustic frequency f = 120Hz and the acoustic wave incident frequency is equal to the structure frequency of resonant, a strong resonance occurred in the cavity. Then, we used insertion loss to evaluate the dispersed voice performance of the resonator.

Figure 4 shows the calculation results of insertion loss to the engine intake manifold, when installing a resonator at the different stable conditions.

As can be seen, the noise of the intake system has been significantly inhibited at the resonant frequency point. Because only three resonator cavities are in the resonator, the frequency of noise production is concentrated at about 120, 210, and 270Hz. The max value of insertion loss can reach 10dB. Where resonant cavity characteristics occurred, the reduction noise effect is clear in the narrow band. The others are almost not. The increase of insertion loss means that the radiation noise becomes small.

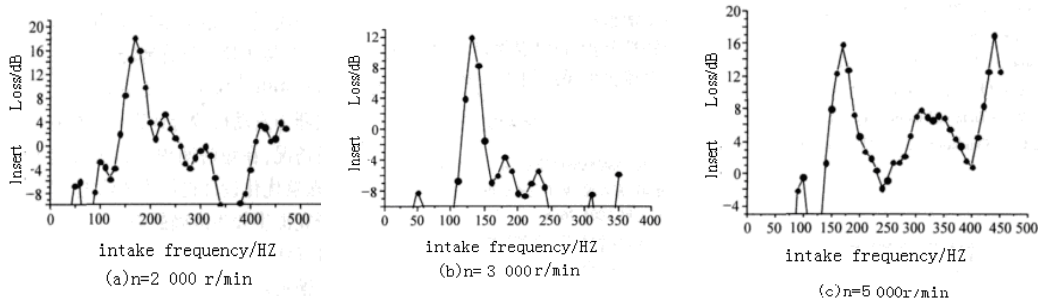

Figure 4. The insertion loss of resonator at different rotating speeds.

The impact of the resonator on engine performance

Against the experimental data of engine out-characteristics, the model sets the engine operating parameters and the initial boundary value conditions for nine work conditions. They respectively correspond to the full load conditions under the rev 1500 rpm, 2000 rpm, 2500 rpm, 3000 rpm, 4000 rpm, 4500 rpm, 5000 rpm and 5500 rpm. This allows for evaluation of the accuracy of the cycle model set up by the whole engine.

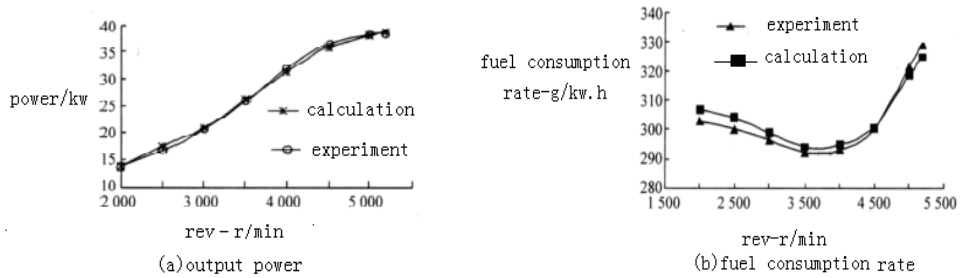

Figure 5. Data comparison between the calculated value & experimental value.

Figure 5 shows that engine output power has significant decline under rev 4000~4500 rpm, while others decreased slightly. The overall output power changed little (Zhang, 2004).

EXPERIMENTAL STUDY

Model validation

To verify the validity, Figures 5(a) and 5(b) respectively express the comparison results between calculated value and experimental measurement data on engine output power and fuel consumption rate. The results have a minor deviation at some condition point, but the deviation is not more than 4% in the majority of conditions. Therefore, the results are deemed to be acceptable (Heinrich, 2005).

The out-vehicle noise experiments

In accordance with the requirements of the noise regulations, an out-vehicle noise experiments were carried out. The results are expressed in Table 3. The experiment field was in highway maintenance center in the open air.

Table. 3. Experimental results of the out-vehicle acceleration noises Unit: dB(A).

Structure	The out-vehicle acceleration noise measurement				Average
Original vehicle	Left side	78.5	77.8	77.9	78.0
	Right side	74.9	75.1	74.8	74.9
Bettement vehicle	Left side	73.6	73.8	74.2	73.8
	Right side	71.3	72.4	73.6	72.6

The results show that the vehicle acceleration noise has been reduced from 78dB (A) to 73.8 dB(A) after the installation of the resonator.

CONCLUSION

The study has shown that an intake resonator can effectively reduce engine intake noises and at some frequencies can reduce them significantly. The full vehicle noise decline can be as large as 4.2dB(A) without distinct changes in engine power. Through the coupling calculation between the resonator and engine, the 3-D flow fields can be simulated within the resonator, thereby obtaining much accurate air flow data in a short time. This provides an important basis for optimal design of the resonator and more accurate ways for the general simulation study of gasoline. This creates the conditions for further study of airflow regeneration noises.

ABSTRACT

Because of the analysis of interchange traffic noise pollution is not systematic and deep enough in transport project environmental impact appraising, this paper analyzes large-scaly interchange's characteristics from perspective of occupation, capacity, driving speeds, the turning radius of ramps and vehicle operation conditions, and analyzes the impact factors of large-scaly interchange traffic noise from perspective of vehicle density, velocity, vehicle types, driving cycles, pavement material, slopes, distances and obstacles. At last this paper presents that large-scaly interchange has the characteristics of different traffic noise influence due to different location and the scale of interchanges, relative slight single vehicle noise, needing consideration of acceleration and deceleration noise and complexities of noise source, etc.

INTRODUCTION

The large-scaly interchange, the significant nodes of highway and urban road network, plays an important part in improving intersections' capacity, solving the problem of traffic congestion and guaranteeing traffic unimpeded (Qiao et al. 2001). While at the same time, the large-scaly interchange noise is one of the main source of environmental pollution, and its evaluation and management is one of the main tasks in the transport project environmental impact appraising. However at practical operation, because of the not systematic and deep enough analysis of the interchange noise features, the quality of environmental impact appraising is influenced (Duan 2000). So in order to provide reference for interchange noise impact appraising, this paper analyzes interchange properties, noise influence factures and its characteristics systematically on the basis of summarizing and generalizing the relative researches.

THE DEFINITION OF LARGE -SCALY INTERCHANGE

The large-scaly interchange in this paper has large area occupation and serious environmental pollution, and it is the crossing by too or more road at different plane, and connected by ramps (Wu et al. 2002). Interchanges can be classed into highway interchanges and

urban road interchanges, the functions, main components and design methods of which are basically the same. But because they are affected by topography, ground objects and toll mode, the two types of interchange are different at the land using, design indexes and environmental pollution characteristics.

THE PROPERTIES OF LARGE -SCALY INTERCHANGE

1 Large Area Occupation

The interchange scale needs to be determined at feasibility research stage and preliminary design stage. Generally speaking, the area occupied by interchange usually is large (see Table 1).

Table 1 Land Occupation of Domestic Interchanges Constructed in Recent Years

Title of Interchange	Occupation (m^2)	Region	Built-Up Year
Gonghexinlu Interchange	200,000	Shanghai	2005
Daxinglu Interchange	50,000	Xi'an	2006
Tingjiao Interchange	70,000	Nansha	2006
Shuangqiaomen Interchange	345,000	Nanjing	2004

2 Great Capacity

According to traffic survey data statistics, a straight lane capacity in plane intersection is 1800~2000 pcuh/h, a turning lane is 1700 pcu/h, and roundabout intersection is over 3000pcu/h. The total capacity of an interchange is 10000~15000pcu/h, which is 6~8 times greater than that of a plane intersection.

3 High Driving Velocity

Because of signal control and other interferences when passing a plane intersection, the delay time is so long and the vehicle velocity is slow. The interchange not only realizes every traffic flows' spatial separation, but also eliminates some interferences including signal control, so its vehicle velocity is improved and the delay time is reduced. The traffic investigation shows that the vehicle velocity is 16~20km/h on the road with plane intersection while the straight velocity is 60~70km/h and turning velocity is 30~50km/h on the road with interchange.

4 Small Turning Radium of Ramps

Ramp is the connection road which is connected by two intersect roads and turning vehicles can driving on it. Because of the limitations of the connected road and using land, the ramp radius is smaller than that of the main line and connected road (see Table 2 and Table 3).

Table 2 The Minimum Circular Curve Radius of Ramps

Vehicle Velocity of Ramp(km/h)		80	60	50	40	35	30
The minimum circular curve radius(m)	General Value	280	150	100	60	40	30
	Limit Value	230	120	80	45	35	25

Table 3 The Main Line Design Velocity of Intersection

The Main Line Design Velocity(km/h)		120	100	80	60	40
The Minimum Horizontal Curve Radius(m)	General Value	2000	1500	1100	500	250
	Limit Value	1500	1000	700	350	150

5 The Complex Driving Conditions

On a free interchange, the velocity of turning vehicles on ramp, which come from main line I to main line II, is slower than that on the main line. So the process of driving from main line I to a ramp and then to main line II is a variable motion, which can be divided into five stages: distributary's driving, reduction's driving, uniform (or variable) driving, acceleration's driving and confluence's driving. On toll collection interchanges all the turning vehicles will stop at the toll station. So there is reduction's driving stage when arriving the toll station and acceleration's driving stage when leaving it.

6 The Serious Traffic Noise Pollution

The large-scaly interchange has serious traffic noise due to its great capacity, high velocity and complex driving conditions, etc. Zhang Anting monitored and evaluated the noise pollution of Yayuan interchange in Shenzhen (see Table 4) (Zhang et al. 2005). According to "Standard of environmental noise of urban area" (GB3096-93), which specified the standard of 70 dB in the day and 55dB at night, the noise pollution of Yayuan interchange is serious, especially at night.

Table 4 The Vertical 24 Hour Equivalent Sound Level of Yayuan Interchange

Monitoring Point	The Vertical Dimension From Bridge Surface /m	The Horizontal Distance From Bridge Surface /m	L_d/Db	L_n/dB
Floor 5 of Yayuan Hotel	3	18	70.8	66.6
Floor 6 of Police Bureau	9	15	69.9	64.8
Floor 10 of Police Bureau	21	15	69.7	64.6
Floor 16 of Police Bureau	39	15	70.5	65.9

THE INFLUENCE FACTURES OF LARGE -SCALY INTERCHANGE NOISE

The large-scaly interchange noise is produced mainly by vehicle's driving system and the friction between tire and road surface.

And the noise produced by vibration of structures is also an important component. The main factors that affect the interchange noise are:

(1) Traffic Flow Density

According to some researches the noise level will increase about 3dB when traffic flow density increases 1 time. So the traffic flow density is the key factor and interchange capacity is the direct acting factor.

(2) Velocity

The regression formula of the mean radiation noise level per vehicle type L_{wi} and velocity is shown as follows based on "Specifications for Environmental Impact Assessment of Highways" (Chang 2001).

Heavy-duty Vehicles: $L_{w,L} = 77.2 + 0.18v_L$ (1)

Medium-duty Vehicles: $L_{w,m} = 62.6 + 0.32v_m$ (2)

Light-duty Vehicles: $L_{w,s} = 59.3 + 0.23v_s$ (3)

Where i is the type of vehicle.

(3) Vehicle Type and Driving Cycle

The vehicle noise of uniform motion is related to engine noise, driving transmission system noise and vehicle structure. The noise approximate scope when the velocity is 30km/h refers to "Specifications for Environmental Impact Assessment of Highways". In general condition, the noise of variable motion is much serious than that of uniform motion.

(4) Pavement Material

The noise of tire is related to pavement material and pavement texture. Its correction value is shown as follows (see Table 5).

Table 5 Correction Value of the Pavement

The Pavement	$\Delta L_{pavement}$ (dB)
Asphalt Concrete Pavement	0
Cement Concrete Pavement	1~2

The experimental result shows that the pavement material affects tire noise much of light-duty vehicles. On the rigid pavement, its strength is proportional to velocity, and when the velocity is over 80km/h, the tire noise plays a dominant role.

(5) Longitudinal Slope

When driving on a slope, dynamic noise is proportional to longitudinal slope. The correction value is shown as follows.

Heavy-duty Vehicles: $\Delta L_{ls} = 98\beta$ (dB) (4)

Medium-duty Vehicles: $\Delta L_{ls} = 73\beta$ (dB) (5)

Light-duty Vehicles: $\Delta L_{ls} = 50\beta$ (dB) (6)

Where β is road longitudinal slope, %.

(6) Distance

Distance has significant attenuation of noise. Researches show that the sound level reduces 3 dB when distance increases 1 time (Chang, 2001)

(7) Obstacle

The obstacle's noise attenuation is an important factor. The most typical obstacle is noise barrier, which is usually installed near buildings where influents to people's life and study. In addition, houses and greenbelts also have additional attenuation to propagation of noise. The general rural houses are much dispersive and its additional attenuation value refers to the relevant references. The forest belts' noise attenuation is much difference due to its wood breed, planting method, density and seasonal variation. Usually its value is estimated as follows.

$$\Delta L = k \cdot b \tag{7}$$

Where k is the mean attenuation coefficient of forest belt, taking 0.12 ~ 0.18 Db;

b is the width of forest belt passing by noise, m.

THE NOISE PROPERTIES OF LARGE -SCALY INTERCHANGE

1 The Different Noise Influence with Different Location

The interchange's location affects its pollution directly. When the highway interchange is far from urban area with low building density, the noise influence is little. While the urban interchange is at high density place, so the traffic noise affects people's life and study directly (Wang 2007).

2 The Different Noise Influence with Different Scale

Generally speaking, because of large-scaly interchange's many connecting sections, ramps, lanes and great capacity, its noise is more severe and the influence range is extensive.

3 Relative Slight Noise of Single Vehicle

Because of the spatial division of conflict flows in interchange, the traffic flow is continuous which has the characteristics of great capacity, little energy consumption, less tire and mechanical wear and so on. So the noise of single vehicle is relative slight.

4 The Noise of Acceleration Motion and Reduction Motion Needs To Be Considered

When driving from the main line, vehicles decelerates into a ramp. And after a uniform motion, the vehicle accelerate leaves the ramp and into a connection road. The condition is opposite when driving into ramps. So acceleration reduction motion noise is important in interchange.

5 The Complex Noise Source

The trunk road noise source can be considered as a limited

discontinuous line-source, and the noise maximum value is at the point of 10～15m from road surface. However, the interchange noise source is not linear. When monitoring at nearby location, the noise source can be considered as a discontinuous line-source composed by every point-source. When the monitoring point is higher, the noise of other roads (including interchange branches) will be greater until the interchange can be considered as an area-source.

6 The Prominent Noise of Connecting Section

The design velocity of interchange main line and ramp are different. If the difference is great, the noise of braking at the connecting section will be greater. And the vibration of bumping at bridge-head as well as ear-piercing noise is also the part of influence.

CONCLUSION

On the basis of summarizing and generalizing the relative interchange traffic noise, this paper definite the interchange from the angle of transport project environmental impact appraising, and analyzes the properties of interchange as well as the main factors that affect traffic noise. At last this paper presents the noise characteristics of large-scaly interchange from the perspective of different traffic noise influence due to different location and the scale of interchanges, relative slight single vehicle noise, needing consideration of acceleration and deceleration noise and complexities of noise source, etc.

ABSTRACT

There are very few research achievements about the effect of aggregate density variation on the properties of asphalt mixture. In this paper, it was studied by testing in the laboratory at the same gradation and the same asphalt aggregate ratio. The results showed that, as aggregate gradation, water absorption, asphalt aggregate ratio remain unchanged, the coarse aggregate density increases, percentage of voids decrease accordingly. When the density increases by 0.2 g/cm^3, percentage of voids reduces by 1%, and the voids in mineral aggregate of the mixture changes little, and the mixture's capacity to prevent deformation at the high temperature decreases accordingly, but the density variation changes very little about the water stability and anti-cracking at low temperature. Considering the percentage of voids changing range of the asphalt mixture, it is suggested that during the production process, the density of the same batch of the coarse aggregate can only float within the range of ± 0.1kg/cm^3.The result of this research can be taken as a useful reference as modifying and revising the related technical specifications of the asphalt pavement.

FOREWORDS

Asphalt mixture gradation variation, temperature variation, compaction variability have been very much concerned by both domestic and oversea scholars, and have drawn attention of numerous professional road technicians. But there are very few researches about the mixture properties by the density variation of aggregate. In Asphalt Pavement Construction Technical Specification (JTG F40-2004), the requirements about aggregate density on the highway with asphalt surface are as follows the min of the relative density of the surface layer is 2.60, the min of the relative density of the fine aggregate is 2.50; the min of the relative density of the other layers of coarse, fine aggregate is 2.50. However, there isn't any specification requirement about the density variation range of the same batch. During the usual construction, in the same stone processing plant, the relative density of the limestone floats from 2.60 to 2.80.

This paper intends to focus on the research of the impact on the volume index and the pavement properties of the mixture caused by the density variation of the coarse aggregate, which was tested in the laboratory at the same gradation and the same asphalt aggregate ratio.

TESTING MATERIALS

Asphalt. Using the SBS modified asphalt, Table 1 shows its technical indicators.

Table 1. Specifications of Asphalt.

Test item		Test results
Penetration 25℃,100g , 5s，0.1mm		56.3
Penetration Index PI		0.33
Ductility 5℃,5cm/min ,cm		35.6
Softening point $T_{R\&B}$（℃）		88.6
Flashing point（℃）		294
Solubility（%）		99.8
Storage stability: 163℃，48hrs，Minus of penetration℃		0.3
Elastic recovery 25℃，%		95.0
Dynamic viscosity (Pa·s)	135℃	2.05
	165℃	0.52
Rotating thin film heating test (RTFOT) Residues (163℃,85min)	Change of Quality (%)	-0.09
	Ductility 5℃,5cm/min,cm	30.5
	Penetration ratio (%)	84.0

Aggregate. During the construction process of the middle layer AC-20C of the highway, 4 kinds of coarse aggregate with the 4 different densities from the mixing plant were chosen. Table 2 shows the test results of the key technical index of these 4 kinds of materials. Table 3 and table 4 show the test results of the technical index of the fine aggregate and slag.

Table 2. Specifications of Coarse Aggregate.

Test item	Coarse Aggregate 1	Coarse Aggregate 2	Coarse Aggregate 3	Coarse Aggregate 4

VOLUME INDEX OF THE MIXTURE

4 kinds of mixture with the same kind of asphalt of SBS modified asphalt, the same gradation of AC-20C, the same asphalt aggregate ratio of 4.4% were created, but four different kinds of limestone with the different density. The test results about their volume index from table 6 show that,

a) As the aggregate gradation, water absorption, and asphalt aggregate ratio remain the same, the density of coarse aggregate increases, and percentage of voids decreases accordingly; density increases by 0.2 g/cm^3, percentage of voids reduces by 1%;

b) Because the aggregate gradation is the same, the voids in mineral aggregate (VMA) Changes little;

c) The stability of the mixture decreases with the increasing of the density, the flow value increases accordingly, and the capability to prevent deformation becomes weaker and weaker.

Table 6. Mixture Volume Index.

Coarse aggregate type	Apparent relative density /g/cm^3	Bulk relative density /g/cm^3	Water absorption /%	Percentage of voids /%	VMA /%	Stability /kN	Flow value /0.1mm
Aggregate 1	2.623	2.588	0.52	4.2	13.1	14.30	15.40
Aggregate 2	2.688	2.653	0.49	3.9	13.1	12.28	18.70
Aggregate 3	2.748	2.713	0.47	3.6	13.0	11.10	29.50
Aggregate 4	2.823	2.784	0.50	3.2	12.9	9.53	35.10

PROPERTIES OF THE MIXTURE

First of all, those four kinds of mixture in table 6 were tested through high-temperature rutting test about the high temperature performance. Table 7 gives out the related result. Table 7 shows that at the same asphalt aggregate ratio, same gradation, anti-deformation became weaker and weaker at the high temperature while the density increases.

Table 7. Mixture Rutting Test Results.

Coarse Aggregate Type	Rutting Test Dynamic Stability /（times/mm）			Average /（times/mm）
	1	2	3	
Aggregate 1	6425	6387	6345	6386
Aggregate 2	6130	6209	6108	6149
Aggregate 3	5812	5789	5634	5745
Aggregate 4	5138	4987	5156	5094

Secondly, those four kinds of mixture in table 6 were tested through the Marshall immersion test about their water stability. Table 8 gives out the test results. From the table, the difference of the residue stability of these four mixtures is very small. All are more than 90%.

Table 8. Mixture Marshall Immersion Test Results.

Coarse Aggregate Type	Asphalt aggregate ratio /%	Percentage of voids /%	60℃,1h Stability /kN	60℃,48h Stability /kN	Residual stability /%
Aggregate 1	4.4	4.2	14.30	12.90	90.2
Aggregate 2	4.4	3.9	12.28	11.19	91.1
Aggregate 3	4.4	3.6	11.10	10.08	90.8
Aggregate 4	4.4	3.2	9.53	8.70	91.3

Finally, those four kinds of mixture in table 6 were tested through the

low-temperature -10℃ bending test about their anti-cracking at the low-temperature. Table 9 gives out the test results. From the table, the flexural strength, flexural modulus and tensile strain changed very little, which means the anti-cracking of the mixture at the low temperature is equivalent.

Table 9. Mixture at Low Temperature Bending Test Results.

Coarse Aggregate Type	Asphalt aggregate ratio /%	Porosity /%	Flexural strength /MPa	Modulus /MPa	Tensile strain /uε
Aggregate 1	4.4	4.2	7.76	2896	2678
Aggregate 2	4.4	3.9	7.27	2197	3308
Aggregate 3	4.4	3.6	7.84	2530	3098
Aggregate 4	4.4	3.2	8.08	2851	2835

CONCLUSION

The effect on the volume index and the pavement properties of the mixture caused by the density variation of the coarse aggregate was studied, which was tested in the laboratory at the same gradation and the same asphalt aggregate ratio. The results show, as mineral aggregate gradation, water absorption, asphalt aggregate ratio remain unchanged, the coarse aggregate density increases, percentage of voids decrease accordingly. When density increases by 0.2 g/cm^3, percentage of voids reduces by 1%, and the voids in mineral aggregate of the mixture changes little. Mixture's capacity to prevent deformation at the high temperature decreases accordingly, but the density variation changes very little about the water stability and anti-cracking at low temperature. Considering the percentage of voids changing range of the asphalt mixture, it is suggested that during the production process, the density of the same batch of the coarse aggregate can only float within the range of ± 0.1kg/cm^3.

ABSTRACT

Gradation is one of the key factors affecting various performances of asphalt pavement. Current gradation testing methods, extracting-sieving method and burning-sieving method, have many disadvantages since some important properties of the aggregate particles may not be obtained due to the lack of an objective way of quantifying critical aggregate properties. This paper uses the digital image processing techniques to carry out a series of image processing operations to the side images of the asphalt mixture specimen girder, and calculates the passing rates of aggregate particles with different sizes according to the geometrical characteristics of each aggregate particle after segmentation of the aggregate particles. Furthermore, it draws the gradation curve according to the passing rates. The paper also carries out an error analysis to the measured data. The result shows that the method based on image processing is worth being promoted in practice.

KEYWORDS: asphalt mixture, gradation, aggregate, digital image, boundary rectangle, fitting ellipse

INTRODUCTION

Asphalt pavement is the main type of highway pavements in China (Zhang 2003). How to assure the quality of the building material of the asphalt pavement is important. Gradation is the mineral composition of the asphalt mixture. The traditional asphalt mixture gradation testing methods, extracting-sieving method and burning-sieving method, have weaknesses such as complicated operation, time consuming, and low data accuracy. Also, the experimental data seriously depends on the operator.

The main properties of aggregate particles studied using digital image processing techniques are size, shape (Maerz 2004, Pan and Tutumluer 2005), and angularity (Shu et al 2006). Besides, someone gives 3D description of the aggregate particles based on the image processing techniques (Corriveau et al 2005, Barrot et al 2006). Some of the studies use the Fourier analysis method (Wettimuny and

Penumadu 2004), and the others use the wavelet analysis method (Shin and Hryciw 2004). The properties of asphalt mixture are mainly gradation (Abdullah and Obaidat 1998), air voids (Arambula et al 2007), and the automatic test system (Sun et al 2005).

The data precision obtained from the recent study is not high enough and the study of the gradation of aggregate particles in the asphalt mixture using digital image processing techniques is still limited. This paper uses the image acquisition device at relatively low expense to obtain the images and applies the digital image processing techniques to achieve the automatic measurement of the aggregate gradation in the asphalt mixture to obtain the better data precision.

ASPHALT MIXTURE DIGITAL IMAGE ACQUISITION

The asphalt mixture specimen is cut into girders and the side images are acquired by using a fixed line scan camera. The image acquisition hardware is sketched in Figure 1.

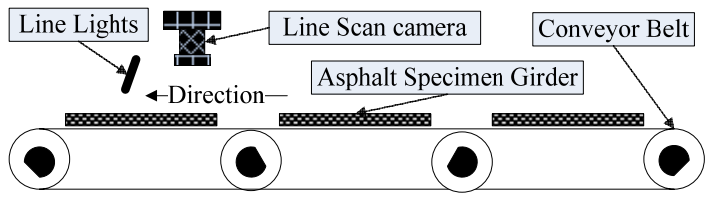

Figure 1. Sketch map of image acquisition hardware

The physical length of the acquired image is 10cm, which is equal to 2048 in pixel. One of the gray-scale images acquired and its histogram are shown in Figure2.

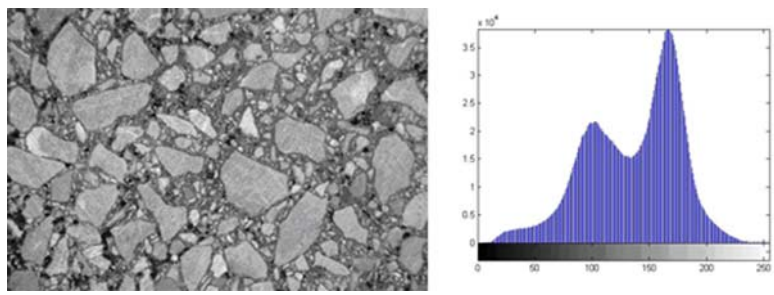

Figure 2. Gray-scale image and its histogram

DIGITAL IMAGE PROCESSING TECHNIQUES OF ASPHALT MIXTURE

The paper adopts the digital image processing techniques to carry out a series of processing and analysis to the acquired asphalt mixture image, and gets the area and volumetric percentage of the aggregate particles with different particle sizes.

Asphalt Mixture Image Preprocessing Techniques

One of the most common problems encountered during image is poor contrast resulted from the illuminating environment. It can often be improved by amplitude rescaling of each pixel. This method modifies the gray-scale value of each pixel dot by dot to modify the dynamic scope of gray-scale in the image. It can expand or compress the gray-scale scope, or compress in some dynamic area whereas expand in another area. The gray-scale image after contrast manipulation and its histogram are shown in Figure 3.

This paper uses median filtering processing to the asphalt mixture images to clean the salt and pepper noises (Gonzalez, 2002). In median filtering, the neighbors must be set, and the output value of the pixel in question equals to the median of the neighbors. The shape of the neighbors determines the geometric space and the size of the neighbors determines the number of values that the median comes from. This paper selects 3*3 neighbors to carry out median filtering operation because the 2*2 neighbors can not clean the noise well whereas the 5*5 neighbors can result in blur of the particle edge. The image after median filtering processing is shown in Figure 4.

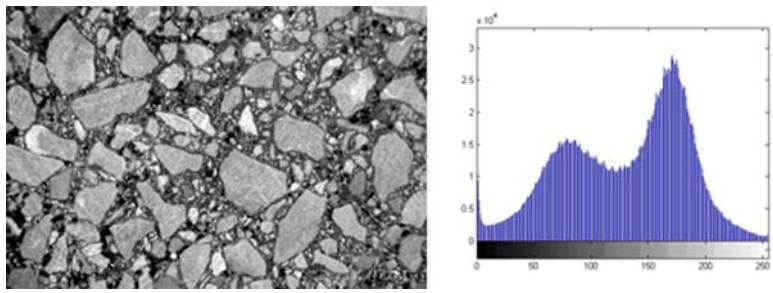

Figure 3. Gray-scale image after contrast manipulation and its histogram

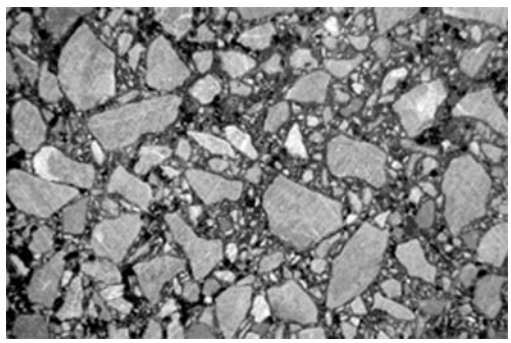

Figure 4. Median filter image (3*3 neighbors)

Binary asphalt mixture image processing

There are many methods to obtain binary image from gray-scale image among

which the gray-scale based method is usually used. This paper uses an adaptive threshold method to obtain the binary image. The binary images obtained are shown in Figure 5. There are some conglutinations of the particles, thus, morphological operations (Gonzalez, 2002) need to be carried out after getting the binary image of the asphalt mixture. First, the erosion operation is carried out to separate the particles. Then, the close operation to fill the holes which are caused by the noise points in the particles, and then uses the dilation operation to restore the particle size. The binary image after the morphological operations is shown in Figure 6.

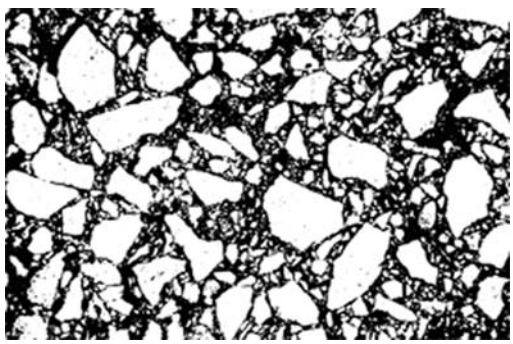

Figure 5. Binary image

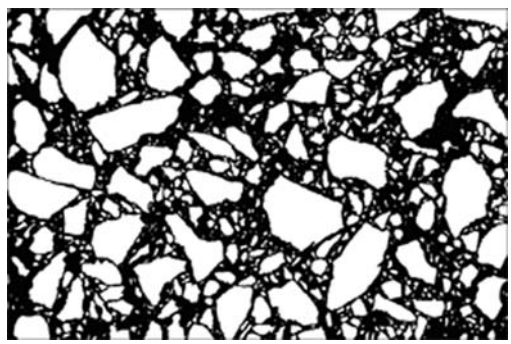

Figure 6. After morphological operations

Asphalt mixture image segmentation

There are many kinds of image segmentation methods. It can be generally divided into region based, edge based and the combination of the two. After getting the binary images of the asphalt mixture, there are at least two methods to obtain the edge images. One is through the image calculating, the other is the edge tracing method. Image calculating method needs to carry on the erosion operation and then subtract from the original binary image, which is more complicated. This paper carries on edge tracing on the binary image directly and obtains the edge image.

Particle analysis

The particle analysis can be carried on by both the binary image and the edge image. This paper carries on particle analysis based on the binary image and draws the label of each particle in the asphalt mixture image (Figure 7). It extracts characteristics such as area, boundary rectangle, fitting ellipse of each particle and save the data into a Microsoft Excel file.

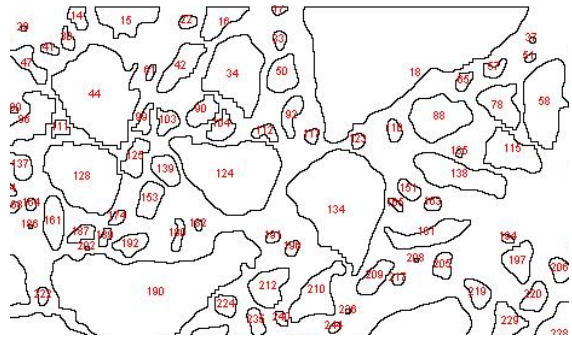

Figure 7. Part of the labeled image

DATA ANALYSIS AND ERROR ANALYSIS

In order to simulate the sieving process accurately, this paper extracts characteristics such as the area and minimum edge rectangle of each aggregate particle, and then calculates the area of the particles, the volume of the restored ball according to the sieve size and the short edge of the boundary rectangle separately to get the passing rate of the aggregate particles with different particle sizes, and further draws the gradation curve.

Data analysis

This paper calculates the passing rate with two different methods. AC-13-area presents the passing rate calculated by area of the aggregate particles; AC-13-volume presents the passing rate calculated by volume of the restored ball and the volume is calculated by using: $v = 4\pi (A/\pi)^{3/2}/3$, where v is the volume of the restored ball and A is the area of the particle.

25 images of the AC-13 gradation asphalt mixture are processed in this paper and the average passing rate of each control sieve (Table1) is obtained. From Figure 8, it can be seen that the measured data is smaller than the designed values.

Table 1. Average passing rate of AC-13 gradation asphalt mixture

Sieve size (mm)	Passing rate (%)		
	AC-13-design	AC-13-area	AC-13-volume
0.075	4	0	0
0.15	9	0.0463877	0.0010796
0.3	15	0.4330286	0.0194674
0.6	24	2.3584637	0.20614
1.18	38	8.926129	1.237419
2.36	55	21.2791	4.7327562

4.75	77	42.469925	18.38467
9.5	93.5	68.684775	52.520292
13.2	95	95.714447	87.732932
16	100	100	100

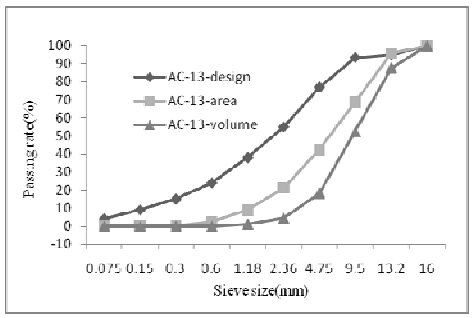

Figure 8. Comparison of gradation curve of AC-13 gradation asphalt mixture

Further, this paper calculates the coarse aggregate and fine aggregate separately to find the factor affecting the measured result. According to the highway criterion, the aggregate particles are divided into coarse aggregate and fine aggregate. The coarse aggregate includes aggregates with particle size larger than 2.36mm, and the others are fine aggregate. The gradation curve for the fine aggregate drawn according to the passing rates is shown in Figure 9. The gradation curve for the coarse aggregate drawn according to the coarse aggregate passing rates is shown in Figure 10.

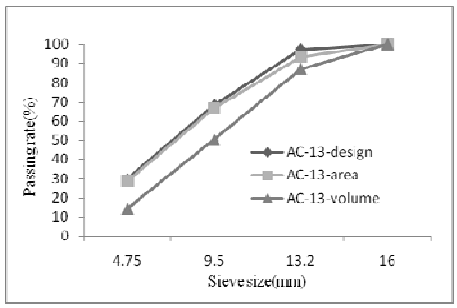

Figure 9. Comparison of gradation curve of coarse aggregate

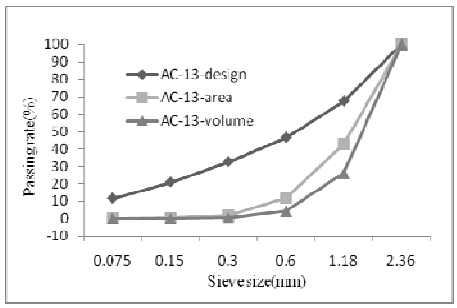

Figure 10. Comparison of gradation curve of fine aggregate

Error analysis

For the measurement of the coarse aggregate whose particle size is greater than 2.36mm in the AC-13 gradation asphalt mixture, the passing rate calculated according to the particle area is not significantly different than the design gradation and its gradation curve is almost the same as the design gradation curve (Figure 9).

The gradation of the fine aggregate in the AC-13 asphalt mixture is smaller than the design value (Figure 10) because of the cohesion of the small particles and the excessive erosion operations during the binary image morphological processing. Beside, the image resolution and the illuminating environment where the images were acquired are also the factors affecting the recognizing and extraction of the fine aggregate particles.

The result calculated according to the volume of restored ball is smaller than the design value since the images being processed are 2D images of the asphalt mixture and only one section plane of the asphalt mixture girder is processed.

CONCLUSION

There are many test methods for the size and shape properties of single aggregate particles and the gradation of mineral aggregate mixture using the image processing techniques. However, the study of the gradation of the aggregate particles in the asphalt mixture has not been well studied. This paper uses the digital image processing techniques and obtains relatively good results.

There are difference between the designed the gradation and the measured gradation, this paper considers the coarse aggregate and fine aggregate separately and gets the results that the fine aggregate particles can not reflect the true condition of the asphalt mixture and result in errors.

However, the image-based aggregate gradation measurement of asphalt mixture could greatly improve the measuring speed and data accuracy after error compensation, thus can be taken as an effective substitution of present test methods. In the future work, image resolution will be increased and new image processing techniques will be employed to improve the measurement precision of the fine aggregate particles.

ABSTRACT

The thermal stress response in asphalt overlay under different cooling conditions was analyzed considering thermal-viscoelasticity of asphalt mixture. The influence of cooling speed, initial temperature, cooling range, pavement thickness and base modulus on temperature stress were represented. The results indicate that, the cumulated thermal stress in asphalt overlay is small at high temperature; initial temperature and cooling speed distinctly affect thermal stress in asphalt overlay; reflective cracks occur in thinner asphalt overlay more easily, while top-down cracks happen in thicker asphalt overlay more easily; and too large base modulus is unsuitable to controlling thermal crack in asphalt overlay.

KEY WORDS

road engineering; asphalt overlay; thermal-viscoelasticity; thermal stress

INTRODUCTION

Thermal cracks seriously shorten service period of asphalt pavements in seasonal frost regions and permafrost regions. Wang (Wang and Zhu, 2004) studied thermal stress condition of asphalt concrete under low temperature. On the basis of the theory of thermal elastic mechanics, the accumulated thermal stress of an one -dimension asphalt concrete bar was computed in consideration of asphalt mixture's modulus changing with decreasing temperature; Li (Li et al., 2006) analyzed thermal cracks based on the fracture mechanic theory; Yang (Yang and Liu, 2006) did thermal-structural analysis of asphalt pavements. The influence of temperature-dependent material properties, such as asphalt mixture stiffness, has been taken into account. Zheng (Zheng, 2001) and Tian (Tian et al., 2002) carried out the thermal stress test of asphalt concrete beam by the thermal stress restrained sample tester (TSRST). Qian (Qian et al., 2003) studied thermal stress in asphalt overlay based on thermal-viscoelasticity theory by using the finite element method,

but the effects of cooling condition and pavement structure parameters were not analyzed, thus their conclusion could not be applied directly to asphalt pavement design. This paper simulated thermal stress response in asphalt overlay under various cooling conditions based on thermal-viscoelasticity theory by using the commercial finite element software ANSYS. A parametric study is also done to isolate the effect of various factors on thermal stress response, aiming at the understanding of the mechanism of thermal cracking in asphalt pavements.

THERMAL-VISCOELASTICITY

Asphalt mixture is thermal-viscoelastic under normal environmental temperature. The relaxation is usually defined by the Generalized Maxwell model (Zheng et al., 2003; Zheng et al., 2004; Qian et al., 2006). For the Generalized Maxwell consisting of of N sets of Maxwell models, the relaxation modulus E is defined by Eq. 1 below:

$$E(t) = \sum_{1}^{N} E_i e^{-t/\tau_i} \tag{1}$$

Where, $\tau_i = \eta_i / E_i$ is the relaxation time of the ith Maxwell element.

Actually, the relaxation modulus and creep compliance both vary with time and temperature, independently. Usually, high temperature would accelerate its creeping or relaxing process. The relaxation occurred during a long time under a lower temperature could take place in a shorter time under a higher temperature. This is called the correspondence principle. And correspondence principle could be described as (Zheng, 2001):

$$E(T,t) = E(T_0, t/\alpha_T), \tag{2}$$

Where, T_0 is the reference temperature, α_T is the shift factor.

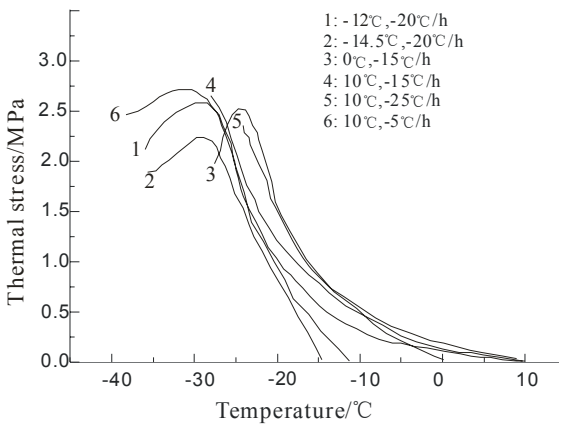

Fig. 1 Test results of TSRST

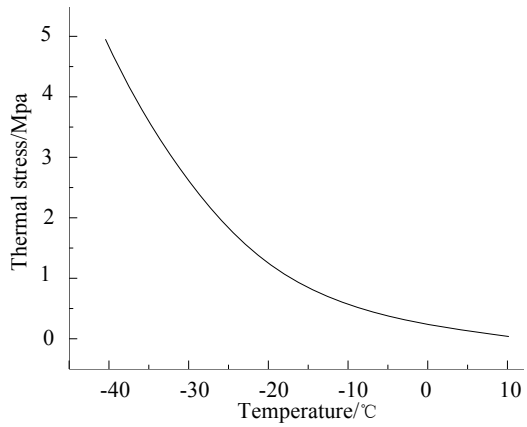

Fig. 2 FEM numerical result of TSTST

VALIDATION OF THE SIMULATION BASED ON THERMAL-VISCOELASTICITY

Zheng (Zheng et al., 2004) chose seven initial temperatures for the thermal stress restrained sample test which are spaced 5 ºC apart, and the lowest initial temperature is -20 ºC. The cooling rate is -5 ºC/h, -10 ºC/h, -15 ºC/h and -20 ºC/h, respectively. The results are shown as Fig. 1.

The numerical simulation of the TSRST was carried out to validate the application of thermal-viscoelastic theory for calculating thermal stress in asphalt mixture. The TSRST sample was discretized in Solid185 which is a type of element in ANSYS. The parameters of the asphalt mixute are shown in Tab. 1 and Tab. 2.

Tab.1 Parameters of the Maxwell model

E_1/MPa	659.9	τ_1/s	4 315 000	E_4/MPa	432	τ_4/s	145 100
E_2/MPa	10 410	τ_2/s	32.12	E_5/MPa	4 148	τ_5/s	191.6
E_3/MPa	2 535	τ_3/s	986.4	E_6/MPa	1 613	τ_6/s	7 570

Tab.2 Values of α_T at different temperatures

Temperature/℃	-20	-15	-10	-5	0	5	10	15
α_T	0.0117	0.0546	0.2402	1	3.953	14.87	53.36	183.3

One case of the test of TSRST was chosen to be simulated. Its initial temperature is 10 ºC, and the cooling rate is -5 ºC/h. In the simulation, the thermal shrinkage coefficient is approximately considered as constant during the cooling process . And the numerical result is shown as Fig. 2.

Fig. 2 shows that the numerical result is almost consistent with the test results (shown in Fig. 1) before temperature falling to -30 ºC. The thermal-viscoelasticity numerical model could reveal the stress relaxation of asphalt concrete accurately.

NUMERICAL MODEL FOR THE ANALYSIS OF THERMAL STRESS IN ASPHALT PAVEMENTS

Basic assumptions

Some assumptions of material characteristics and asphalt pavement structures are made as below:

a) The asphalt overlay is thermal-viscoelastic, the materials of other layers are all homogeneously isotropic and elastic;

b) The gravity of asphalt pavements is ignored;

c) The lateral sides of the pavements are horizontally restrained, and the top surface of overlay is free in all degrees, and the subgrade bottom is fixed.

Parameters of simulated asphalt pavements

Since different pavement structures lead to different thermal stress responses, it's necessary to analyze the effect of various structures. For the simulations below, the parameters are the same as those listed in Tab. 3, except for additional

explanations.

Tab.3 Numerical parameters of asphalt pavement

Layer No.	Layer name	Thickness (mm)	Young's modulus(MPa)	Poisson's ratio	Thermal shrinkage coefficient
1	Asphalt overlay	70	—	0.3	2E-5
2	Base	150	1500	0.25	1E-5
3	Sub-base	150	600	0.35	1.5E-5
4	Subgrade	1000	40	0.35	50E-5

Temperature field of asphalt pavements

The one-dimensional model was chosen to represent the temperature field in asphalt pavements under cooling conditions, which is listed as Eq. 3:

$$T(t,z) = T_0 + \Delta T_m \frac{t}{t_m} \exp(-z / z_0), \tag{3}$$

Where, z is the depth of asphalt pavement, ΔT_m is temperature cooling range, t_m is cooling time, and z_0 is the depth constant which usually varies from 0.2 m to 0.3 m.

THE ANALYSIS OF THERMAL STRESS IN ASPHALT OVERLAY

Asphalt mixture is typically a thermal-viscoelastic material in service environment. Thus, the thermal stress in asphalt overlay must be influenced by temperature load which could be characterized by initial temperature, cooling rate and cooling range. Furthermore, the performance of asphalt pavements is essentially related to the overlay's and base's thicknesses and moduli. It's necessary to analyze thermal stress response of various structures under different temperature loads.

The effect of base state on thermal stress response was studied. Two models were created: the base is intact in model 1, but cracked in model 2. The initial temperature was 5 ºC, the cooling range was 30 ºC, and the cooling rate was 10 ºC/h. The results are shown as Tab. 4.

Tab.4 Thermal stress of the two different models

Model No.	Thermal stress at overlay bottom(MPa)	Thermal stress at overlay surface(MPa)
1	4.77	8.39
2	9.168 822	9.087 229

It is shown in Tab. 4 that tensile thermal stresses at both bottom and surface of asphalt overlay of model 2 are more disadvantageous than that of model 1. So

model 2 was chosen to accomplish the parametric study below.

Influence of initial temperatures

In this simulation work, the initial temperatures were -5 ºC, 0 ºC, 5 ºC, 10 ºC, respectively. The cooling range was 40 ºC, and the cooling rate was -10 ºC/h. The results are shown in Fig. 3 and Fig. 4.

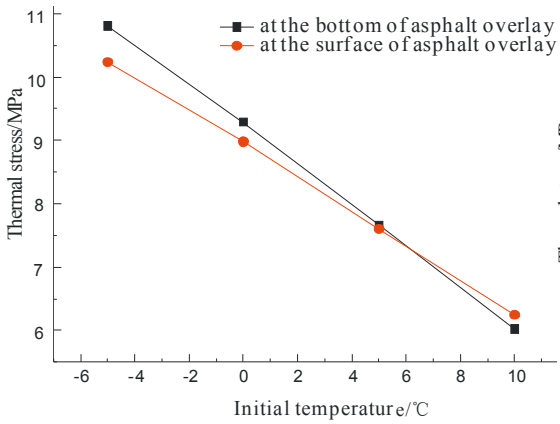

Fig. 3 Influence of initial temperature

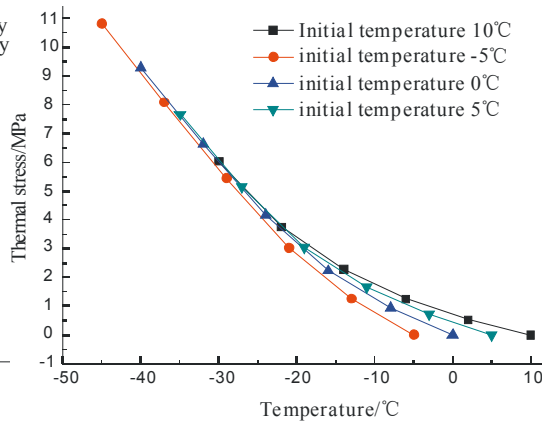

Fig. 4 Thermal stress-temperature curve of various initial temperatures

It can be seen from Fig. 3 that the thermal stress increases with the falling of initial temperature. This is to say, to the same cooling range and cooling rate, the lower initial temperature, the greater the thermal stress. Furthermore, for high initial temperature, after cooling, the thermal stress at asphalt overlay surface is smaller than that at overlay bottom. For low initial temperature, the thermal stress at overlay surface is greater than that at overlay bottom. Thermal stress at bottom is more susceptive to initial temperature.

Fig. 4 presents thermal stress-temperature curves of various initial temperatures. The lower initial temperature is, the steeper the curve. This is to say, though cooling range is small, thermal stress could still be great, if initial temperature is low enough. At low temperature section of Fig. 6 (≤-20 ºC), the curves are almost the same, which indicates that it behaves more like elasticity than like viscoelasticity when temperature is lower than -20 ºC for asphalt concrete.

Influence of cooling range

In this simulation, the initial temperature was -5 ºC, the cooling rate was -10 ºC/h, and the cooling range varied from 10 ºC to 40 ºC at the interval of 10 ºC. The numerical results are shown in Fig. 5.

Fig. 5 shows that the greater cooling range is, the higher thermal stress at overlay surface and bottom. The increase of thermal stress is not linear but accelerative to cooling range, which was caused by the viscoelastic characteristic.

Influence of cooling rate

To study the influence of cooling rate on thermal stress in asphalt overlay, the parametric study of cooling rate was done. The cooling range was 30 ºC, and the initial temperature was 5 ºC. The cooling rate was -5 ºC/h, -10 ºC/h, -15 ºC/h and -20 ºC/h, respectively. The results are shown in Fig. 6 and Fig. 7.

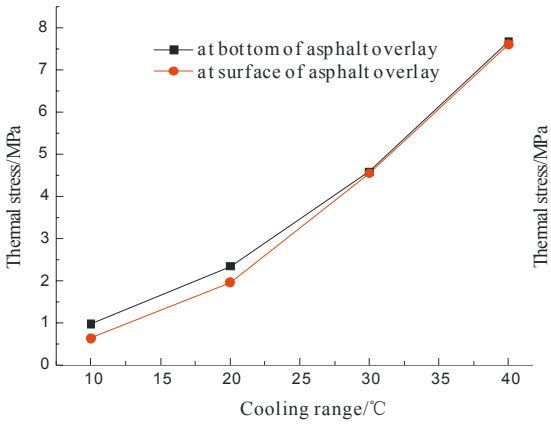

Fig. 5 Influence of cooling range

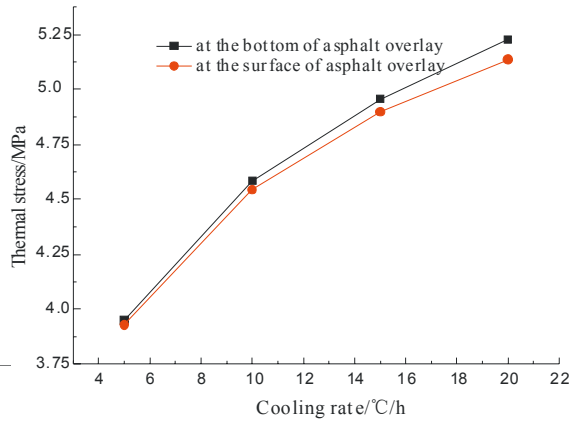

Fig.6 Influence of cooling rate

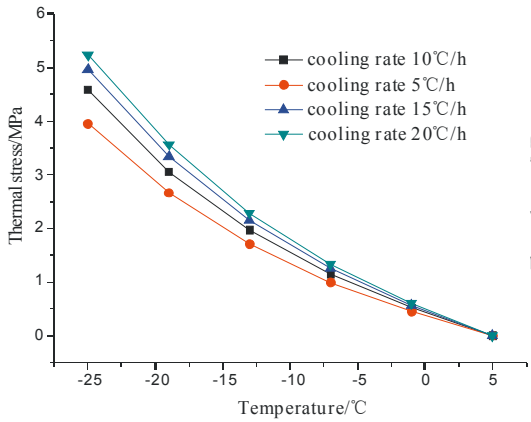

Fig. 7 Thermal stress-temperature curve of different cooling rates

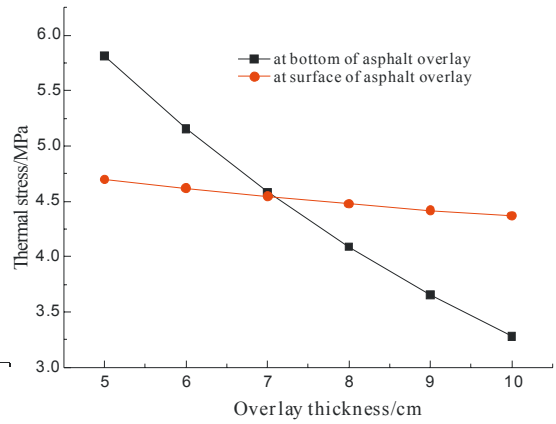

Fig. 8 Influence of asphalt overlay thickness

It can be seen from Fig. 6 that thermal stress increases as cooling rate increases . Furthermore, the stress at the bottom of asphalt overlay increases more quickly than that at the surface, which indicates that thermal stress at the bottom of asphalt overlay is more susceptive.

Fig. 7 is temperature-thermal stress curves of various cooling rates. It shows that the greater cooling rate, the steeper curve is. In ultra disadvantageous cooling load, for example, the raid of cold snap, great thermal tensile stress would occur in asphalt overlay.

Influence of overlay thickness

Aimed at secondary road, such pavement structures whose overlay thickness varies form 5 cm to 10 cm at the interval of 1 cm were simulated. In the numerical

analysis, the cooling range was 30 ºC, the cooling rate was -5 ºC/h, and the initial temperature was 5 ºC. The results are shown in Fig. 8.

Fig. 8 shows that thermal stresses both at surface and bottom of asphalt overlay fall with the increase of overlay thickness. This is to say, greater thickness of asphalt overlay leads to smaller thermal stress under the same temperature loads. But, with the increasing of overlay thickness, the thermal stress at overlay surface falls slowly, while that at bottom falls rapidly. This indicates that the stress at the bottom is dominant for cracking when overlay thickness is greater than 7 cm, since in this situation the stress at bottom is higher than that at surface. When overlay thickness is smaller than 7cm, the stress at surface controls the cracking of asphalt overlay. Therefore, reflective cracks appear easily in thinner asphalt overlay , while cracks tend to start from the surface for thicker asphalt overlay.

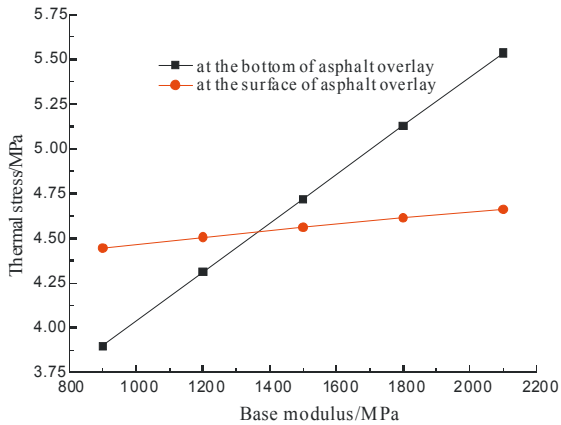

Fig. 9 Influence of base modulus

Influence of base modulus

Base modulus is a key index of pavement design, so the parametric study about base modulus was done. The cooling range was 30 ºC, the cooling rate was -5 ºC/h, and the initial temperature was 5 ºC. Base modulus was 900 MPa, 1200 MPa, 1500 MPa, 1800 MPa and 2100 MPa, respectively. The results are shown in Fig. 9.

It is shown in Fig. 9 that thermal stress increases with the increase of base modulus, especially that at overlay bottom. Bases whose modulus is not very stiff may limit thermal stresses, leading to better control of thermal crack in asphalt pavements. The modulus between 1200 MPa to 1500 MPa is recommended, taken the bearing ability of wheel loads into account.

CONCLUSIONS

A three-dimension finite element model of asphalt pavements was created based on thermal-viscoelasticity theory. The thermal stress in asphalt overlay was analyzed, and the parametric studies were done to isolate the influence of different factors, such as cooling rate, cooling range, initial temperature, base modulus and overlay thickness. Some conclusions were draw from the numerical work.

a) The thermal stress accumulated in asphalt concrete is not considerable until the temperature is lower than -5 ºC;

b) Initial temperature and cooling rate affect thermal stress in asphalt overlay. The lower initial temperature is, the greater thermal stress. The slower cooling rate is, the smaller thermal stress;

c) Reflective cracks occur more easily in thinner asphalt overlay , while top-down cracks occur more easily in thicker asphalt overlay;

d) Bases whose modulus is not very stiff may limit thermal stress induced in asphalt overlay, leading to better control of thermal cracking in asphalt pavements.

Abstract: Ductility is an important property of evaporated residue of modified emulsion asphalt. Ductility of the modified asphalt will change after treated by emulsification. In order to analyze the influence of different factors on the ductility of the evaporated residue of modified emulsion asphalt, ductility values of the residue are measured with different emulsifiers, solution PH values and stabilizers. Furthermore, mechanism of the coefficients that may lead to behavior changes of the ductility is analyzed. The test results show that the ductility of the evaporated residue of modified emulsion asphalt is sensitive to different emulsifiers, solution PH values and stabilizers. Ductility of the modified asphalt will have great loss after treated by emulsification. Ductility of the evaporated residue will present different behavior with different emulsifiers and modified asphalt; it will increase as the solution PH value increased; ductility loss of the residue caused by the organic stabilizer is larger than the inorganic salt stabilizer; behavior changes of the ductility loss are different from the content change of the two kinds of stabilizers.

Key word: *pavement engineering; modified emulsion asphalt; evaporated residue; ductility; effect factors*

1 Introduction

Modified emulsion asphalt has many advantages, such as normal temperature construction, low cost and low pollution. It is widely used in road construction and maintenance (Chenhui et al. 2007). The modified emulsion asphalt is mainly composed by the modified asphalt and water. While the oil-water mixed system is unstable systems, its storage is not easily. In engineering, modifications are often made to improve its stability, such as adding the emulsifier and stabilizer, or changing the solution PH value (Mingjian et al. 2008; Yu 2007).

The ductility is an important index of evaporated residue of modified emulsion asphalt. It will directly affect the pavement performance of the modified emulsion asphalt. Ductility of the evaporate residue will change by the admixture added. In order to analyze the ductility change law of the evaporated residue of the modified emulsion asphalt, the effect of the emulsifier, stabilizer and the solution PH value are analyzed in this research, and some suggestions on the processing modified emulsion

asphalt are provided.

2 Materials and Methods

2.1 Performance indexes of modified asphalt

Three types of modified asphalt are used in test and their basic performance indexes are shown in the Table.1.

Table.1 Basic indexes of the three type modified asphalts

Serial name	Type of the asphalt	Ductility(5℃)	Penetration(25℃)	Softening point
A1	SBS modified SHELL asphalt	53.7	71.8	63.4
A2	SBS modified SK asphalt	71	94.1	65.7
A3	SBR modified SK asphalt	147	103.3	47.2

2.2 Preparation of evaporated residue of modified emulsion asphalt

Firstly, the admixtures, such as the emulsifier and stabilizer, are added into the water to form emulsion. Then the emulsion is heated up to about 75～80℃ until the emulsion becomes transparent. Meanwhile, the modified asphalt is heated up to 175～180℃. Subsequently, the hot modified asphalt is slowly added into the transparent emulsion and the high speed shearer is used to stir for 45 minutes, then the emulsion asphalt is formed when the emulsion is cooled and the foam disappeared. In the end, the evaporated residue of modified emulsion asphalt would be made through heating the modified emulsion asphalt directly.

3 Effect of emulsifier

3.1 Emulsion mechanism

Water repels oil, so the emulsion composed of asphalt and water will present layer phenomenon. The emulsifier as a surfactant can make the asphalt particles homogeneous dispersion in solution. The emulsion mechanism is as follow.

(1) For the emulsifier molecular has a hydrophilic (water-attracting) group and a hydrophobic (oil-attracting) group, the emulsifier has adsorbability. This structure not only can decrease the interfacial tension between the asphalt and water but also has the function to connect the asphalt and the water.

(2)When the emulsifier is added, the molecules of the emulsifier will be soon absorbed on the surface of asphalt particles and the hydrophobic group will insert the asphalt particle to form interfacial film which can make the asphalt particles keep discrete state in the collision.

(3)The interface film between the asphalt particle and water can form a double electric layers structure, in which the inner layer is arranged densely and very solidity, but the outer layer will exists a sliding film between the water and the colloidal particle. Sliding surface exist the potential difference which will keep the asphalt particles separation in repulsion, so the stability of the emulsion is improved.

In brief, the emulsifier can improve emulsion stability through decreasing interface tension, stabilizing interface film and increasing the mutual exclusion force of the interface charges.

3.2 Results and Analysis

In this test, two type emulsifiers (cationic emulsifier E1 and E2) are used. One cationic emulsifier, E1, is added to the modified asphalt A1 and A2； another cationic emulsifier E2 is added to the modified asphalt A2 and A3. Various kinds of emulsifier is analyzed, including 0.6%，0.8%，1.0%，1.2%，1.4% and 1.6%. The oil-water ratio is 50:50. Results of ductility of the evaporated residue with different emulsifier contents are shown in Figure.1.

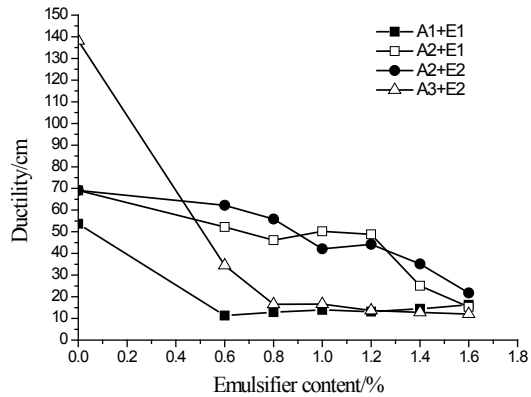

Figure.1 Ductility change curve of asphalt with different emulsifier

Analytical results showed as follows.

(1) When the emulsifier E1 is added, ductility of the evaporated residue of modified emulsion asphalt A1 and A2 will reduce in different degree. When content range of the emulsifier E1 is 0.6%～1.4%, the ductility of the modified asphalt A1 will slowly increase with the growth of the emulsifier E1 content, but the ductility of the modified asphalt A2 will decrease at first, then increase and arrive a certain peak, last decrease rapidly.

(2) When the emulsifier E2 is added, ductility of the evaporated residue of modified emulsion asphalt A2 and A3 will also decreased. When content range of the emulsifier E2 is 0.6%～1.4%, ductility of the modified A2 and A3 will slowly decreased with the growth of the emulsifier E2 content. For different emulsifiers, such as the emulsifier E1 and E2, evaporated residue of the modified asphalt A2 has different change laws of the ductility.

(3)When the different modified asphalts and emulsifiers are mixed, ductility of the evaporated residue will present different behaviors as the emulsifier content changed, some will always keep reducing and some will present ductility recovery. However, for the particular modified asphalt and emulsifier, the behavior of the ductility is fixed.

(4) The cause for ductility loss of the modified asphalt is that asphalt particles are encapsulated by interface film of the emulsifier. The different emulsifiers have different volatile performance. When emulsion loses water, the asphalt particles combine again. Some interface film of the emulsifier still exists in the asphalt, like a wall to separate the asphalt particles to combine indeed, so ductility properties will reduce when the emulsifier is added.

4 Effect of the stabilizer

4.1 Stabilization mechanism

(1)When inorganic salt stabilizer is added into emulsion, the ions of the inorganic salt stabilizer can not only improve the thickness of the double electric layers around the asphalt particles but also enhance the potential difference and repulsive force among the asphalt particles. So, inorganic salt stabilizer can improve the stability of the emulsion.

(2)According to Stokes theory, when organic stabilizer is added into the emulsion, viscosity of the continuous phase is increased, density difference between water and colloidal particle is reduced. At the same time, the thickness of interfacial film is increased. Thus, organic can improve the stability of the emulsion.

4.2 Results and Analysis

In engineering, the calcium chloride (CaCl2) is often used as the inorganic salt stabilizer and the polyvinyl alcohol (PVA) is often used as the organic stabilizer (Jinjing et al. 2008). In this test, the modified asphalt A2 and the water are mixed to form the emulsion, in which the oil-water ratio is 20:80. Emulsifier E1 is added with a fixed content of 0.8%, the different contents of the calcium chloride and PVA is added in emulsion to analyze the effect of the stabilizer on ductility of evaporated residue. Several different contents of the stabilizer is analyzed, including 0.1%, 0.2%, 0.4%, 0.6%, 0.8% and 1.0%. The curves of the ductility of evaporated residue with different stabilizer contents is shown in Figure.2

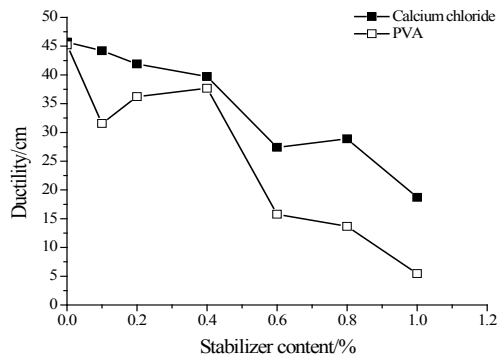

Figure.2 Ductility change curve of evaporated residue by different stabilizer

The results are shown as follows.

(1)When the stabilizer content range is 0.0%～1.0%, the ductility loss of evaporated residue will increase based on the growth of stabilizer content, but the behaviors of the evaporated reside of the modified emulsion asphalt A2 are different for the two stabilizers. Final ductility loss caused by organic stabilizer is larger than inorganic stabilizer.

(2)For inorganic salt stabilizer, ionic charge can enhance the interface film thickness and make it even firmer. When emulsion loses water, the buffer function of interface film in the modified asphalt will increase with increasing the content of the inorganic salt stabilizer, so ductility of the evaporated residue will always present downward trend with the inorganic salt stabilizer content improved.

(3) For organic stabilizer, as content of the organic stabilizer is enhanced, ductility of the evaporated residue will decrease at first, then increase and arrive at a certain peak, finally, decrease sharply. When emulsion loses water, PVA particles are dispersed in the modified asphalt; when PVA particles play a role of buffer function, ductility of the evaporated residue will decrease; when the PVA particles play an

interconnect action, the ductility will increase.

5 Effect of solution PH value

5.1 Effect mechanism of PH value

A suitable PH value of the solution may not only enhance the activity of emulsifier but improve the emulsion stability, because the PH value can affect the ionization state of the emulsifier and improve the potential difference as well (Jingyi et al. 2007). In summary, acid or neutral solution is fit for the cationic emulsifier; alkaline solution is fit for the anionic emulsifier. Now, people in engineering mainly take the cationic emulsifier.

5.2 Results and Analysis

In this test, cationic emulsifier E1 and E2 are separately added into modified A2; emulsifier contents both are 0.8%; water-oil ratio both is 80:20. In order to analyze the influence of PH value taken on ductility, the hydrochloric acid solution with 35% concentration is added into the emulsion to regulate the solution PH value. Ductility of the evaporated residue with different PH value is measured. The test results are shown in the Figure.3

The test results show that the solution PH value has great influence on the ductility of the evaporated residue. The ductility of the evaporated residue will increase as the solution PH value enhanced. Recent research demonstrates that the stability of emulsion asphalt will decrease with the growth of solution PH value. As solution is improved, interface film around the asphalt particles will become thinner and its buffer function will become thinner, so ductility of the evaporated residue will become larger as the growth of the PH value.

6 Conclusions

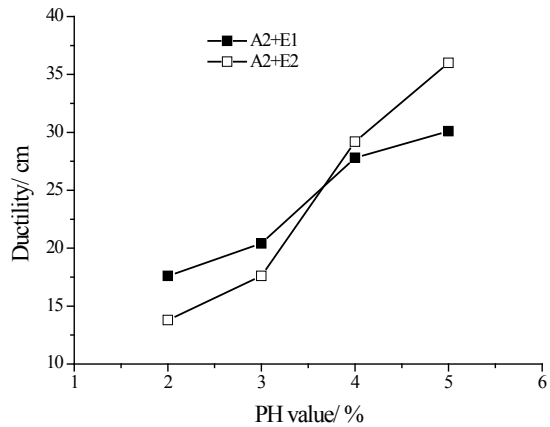

Figure.3 Ductility change curve of the evaporated by different PH values

(1) The emulsifier will decrease the ductility of the evaporated residue of modified emulsion asphalt. For the same modified asphalt, different emulsifiers can lead to different ductility loss. In engineering, various emulsifiers need contrast test to measure the emulsion stability and the ductility loss of the evaporated residue. Then, suitable emulsifier is determined through tradeoff between ductility and stability.

(2) Both of inorganic salt stabilizer and organic stabilizer can lead the ductility loss of the evaporated residue. Organic stabilizer can lead more ductility loss than inorganic salt stabilizer. In practical engineering, we need to strictly select stabilizer and control addition quantity of stabilizer.

ABSTRACT

Based on the assumption of Kirchhoff thin plate, we derive the constitutive equations and the boundary conditions on all four edges for variable Winkler foundations to solve the problem of Cement Concrete Pavement (CCP) supported by a non-uniform foundation. The constitutive equation is a fourth-order differential equation with variable coefficients that has no known analytical solution. A Weighted-Residual Method (WRM) is developed to solve the problem approximately. In our WRM numerical tests, a mixed-type trial function, i.e., the biharmonic function, and a weight function based on the least-square method are selected to eliminate residual errors. Results show that, compared to the finite element method, the WRM computational method produces a relative error of only 3.2%, which satisfies the error requirement of general engineering applications. The novel WRM developed in this paper appears to be a good approximation method in solving the problem of CCP supported by non-uniform foundations.

INTRODUCTION

The theory of CCP design assumes a uniform distribution of foundation under the pavement. It is therefore difficult to apply the theory directly to deal with local differential settlements which occur commonly in the highway construction practices. Taking the mountainous expressway that crosses many cut-to-fill locations in south China as an example, it developed 7.9 percents broken slab ratio in 11km pavements after opening to traffics in the early two years (Luo Zhu, 2003). This paper focuses on the mechanical model of non-uniform foundation by establishing a new calculation method.

THE GOVRENING EQUATION AND BOUNDARY CONDITIONS

Like all elastic plates, the design of slab on non-uniform support is special case of the problem of solving the governing differential equation with certain boundary conditions. In the case of non-uniform support, the assumption of Kirchhoff thin plate first published in 1850 still holds (Timoshenko 1959).

Based on this assumption, the geometric equations, physical equations,

deformation compatibility equations (Qu et al. 2000), and the governing differential equation on non-uniform foundation can be derived as follows:

$$D\nabla^2\nabla^2 w(x,y) + k(x,y)w(x,y) = q(x,y) \qquad (1)$$

where ∇^2 is Laplacian Operator, $\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$; $W(x,y)$ is deflection function; $q(x,y)$ is external loads distributing function; $k(x,y)$ is foundation distributing function; D is bending rigidity of plate, $D = \frac{Eh^3}{12(1-\mu^2)}$, which E, μ, h refers to Elastic Modulus, Poisson's Ratio and slab thickness respectively.

The four free-edge boundary conditions of plates are given as follow:

(1) The moments on edges of the plate are equal to zero, that is M_x=0, M_y=0.

(2) The total transverse shearing force is also equal to zero, that is $Q_x + \frac{\partial M_{xy}}{\partial y} = 0$, $Q_y + \frac{\partial M_{xy}}{\partial x} = 0$.

THE BASIC PRINCIPLE OF WRM

For the differential equation derived from non-uniform support is a Variable Coefficient Fourth-order Differential Equation, it is hard to find an analytical solution method. The WRM, an effective method in solving differential equation approximately, is introduced herein to tackle this difficult problem in this paper.

The basic idea of this method is presented below (Qiu 1991). For example, the governing differential equation for a certain problem is

$$P_m(u) = f_0 \qquad \text{in domain } \Omega \qquad (2)$$

The boundary equation is

$$Q_t(u) = f_t \qquad \text{at boundary } \Gamma_t \ (t = 1,2,\cdots, m) \qquad (3)$$

where P_m is m orders partial differential operator, Q_t is $t-1$ orders boundary normal differential operator, ft（t=0, 1,…, m）is coordinate functions, the boundary of Ω domain is given as

$$\Gamma = \bigcup_{t=1}^{m} \Gamma_t \qquad (4)$$

First, let the trial function $\bar{u}$ as

$$\bar{u} = \sum_{i=1}^{n} c_i \phi_i \qquad (5)$$

where $\{\phi_i\}$ is the base of trial function, c_i is parameter to be determined.

Substituting the trial function in equation (5) into the governing equation (2) and boundary equation (3), the domain residual error and boundary residual error can be computed with equations (6) and (7) respectively.

$$R_I(\tilde{u}) = P_m(\tilde{u}) - f_0 \qquad (6)$$

$$R_t(\tilde{u}) = Q_t(\tilde{u}) - f_t \qquad (t=1,2,\ldots,m) \qquad (7)$$

Various methods can be used to eliminate the residual error. We multiply the domain weight function with the domain residual error and the boundary weight function with the boundary residual error. Then, the unified equation for eliminating the residual error becomes:

$$\int_\Omega R_I(\tilde{u}) W_{Ij} d\Omega + \sum_{t=1}^{m} \int_{\Gamma_t} R_t(\tilde{u}) W_{tj} d\Gamma = 0 \qquad (j = 1,2,\cdots, n) \qquad (8)$$

This unified equation includes a series of equations, which has n unknown parameters. We can solve this system of equations and substitute the c_i solutions back into the trial function equation (5). This gives the approximate solution to the original problem.

THE SELECTION OF TRIAL FUNCITON

It is important to select a trial function which has significant influence on the precision in lower-order calculation. There is no universal technique in the selection of a good trial function. Engineering judgment and familiarity with particular problem domains are often relied upon for such selection process.

The more information we know about the problem, the more easily we are able to select a good trial function. If the selected trial function is close to the true analytical solution, the WRM can benefit from fast convergence and computational efficiency. If the selected trial function contains all the characters of the true analytical solution, the WRM may even produce the exact solution.

There are three types of trial functions. If the assumed that the trial function is just a solution to the boundary equations that is called a “boundary-type” trial function compared to the “domain-type” trial function. If the assumed trial function is neither a solution to the governing equation nor one to the boundary equation, it is usually called as a “mixed-type” trial function.

The principle for selecting a trial function is that the linear combination of the function base should approach the true exact solution. It means that the function base

must be a perfect sequence and linearly independent to each other.

THE SELECTION OF WEIGHT FUNCITON

Various kinds of weight functions, based on different methods including Least Square Method, Collocation Method, Sub-domain Method, Galerkin Method, and Moment Method can be used to eliminate the residual error. Theoretically, different types of weight functions can be chosen that can result in different levels of solution precision and computational complexity (Miltiades Elliotis et al. 2007). In this paper, we select the Least Square Method and its basic principle is discussed below. In order to minimize the integral of the squared domain residual error, we apply the extreme condition of functional theory:

$$I(C_j) = \int_v R^2 dv \qquad (9)$$

$$\frac{\partial I}{\partial C_j} = 0 \qquad (10)$$

Then, the equation for eliminating the residual error is obtained:

$$\int_v R \frac{\partial R}{\partial C_j} dv = 0 \qquad (j = 1,2,\cdots,n) \qquad (11)$$

Equation (11) is then used to determine the parameters $C_j (j = 1,2,\cdots,n)$.

ANALYSIS OF A NUMERICAL EXAMPLE

As shown in Figure 1, a square cement concrete slab with four free edges is arranged at the cut-to-fill location of a road section. The side length of the slab is 4m and the thickness is 0.25m. The Elastic Modulus and Poisson's Ratio of the concrete is 3.5×10^4MPa and 0.15 respectively.

The shadowed areas of the figure represent vehicle footprints which are rectangular for convenient comparison with the finite element method. The individual footprint area is 400cm^2 with the pressure of q_0=0.625MPa (Deng et al. 2001). The distribution of Winkler foundation is exponential along the X-axis as shown in formula (12).

$$k = 97.98\exp(0.1014x) \qquad (12)$$

where k is foundation reaction modulus (MPa/m), and x is abscissa.

It is difficult to find a trial function that meets the requirement of both the governing equation and boundary equation. So a mixed-type trial function is chosen. Since the biharmonic function is effective in solving plastic slab problem (Xu et al. 1980), the following biharmonic trial function is used in calculation

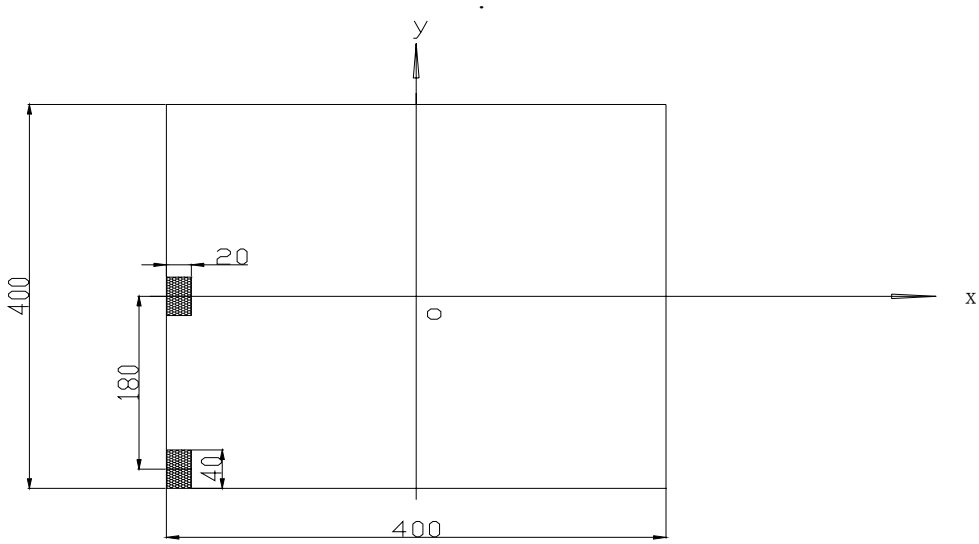

Figure 1. The layout of a plate (unit: cm)

$$\overline{w}=\sum_{i=1}^{\infty}\begin{bmatrix}\sin\alpha_{i1}x(c_{i1}e^{\alpha_{i1}y}+c_{i2}e^{-\alpha_{i1}y}+c_{i3}ye^{\alpha_{i1}y}+c_{i4}ye^{-\alpha_{i1}y})+\\ \cos\alpha_{i1}x(c_{i5}e^{\alpha_{i1}y}+c_{i6}e^{-\alpha_{i1}y}+c_{i7}ye^{\alpha_{i1}y}+c_{i8}ye^{-\alpha_{i1}y})+\\ \sin\alpha_{i2}y(c_{i9}e^{\alpha_{i2}x}+c_{i10}e^{-\alpha_{i2}x}+c_{i11}xe^{\alpha_{i2}x}+c_{i12}xe^{-\alpha_{i2}x})+\\ \cos\alpha_{i2}y(c_{i13}e^{\alpha_{i2}x}+c_{i14}e^{-\alpha_{i2}x}+c_{i15}xe^{\alpha_{i2}x}+c_{i16}xe^{-\alpha_{i2}x})\end{bmatrix} \quad (13)$$

where, $\alpha_{i1}=i\pi/l_x$, $\alpha_{i2}=i\pi/l_y$, l_x and l_y refer to slab length and width.

The trial function (13) fits the biharmonic equation $\nabla^4\varphi=0$, so it can effectively reduce the domain residual error and computational complexity (He 2006). For easier explanation, we used only the first order of the trial function to illustrate the numerical example.

A weight function based on the Least Square Method is selected (Xu et al.1997). Let i=1 in formula (13) and then put it into formula (8), the unified equation for eliminating the residual error can be derived as

$$AC=b \quad (14)$$

where A is a matrix of 16×16, C is the coefficient vector to be determined, b is the load vector.

Solving equation (14), we find the values *C:*

$$\mathrm{C}=\frac{q_0\times10^{-4}}{D}[4,21,-3,-4,2,40,-10,0,25,55,-7,-1,-8,-65,0,-2]^{\mathrm{T}} \quad (15)$$

where q_0 is the footprint pressure, D is the bending rigidity of the slab.

Substituting all parameters into equation (13), we obtained the approximate deflection function.

Extreme value analysis indicates that the maximum deflection is 0.6314 *mm*, and the maximum deflection calculated by finite element method is 0.6521 *mm*. The relative error is only 3.2% which satisfies the error requirement in engineering applications. The numerical example above demonstrates that the WRM has a necessary accuracy in solving the problem of CCP supported by non-uniform foundations.

CONCULSIONS

Based on the assumption of Kirchhoff thin plate, we derived the constitutive equations and the boundary conditions on all four edges using variable Winkler foundation model to solve the problem of CCP supported by non-uniform foundations. The governing constitutive equation is a fourth-order differential equation with variable coefficients, which has no known analytical solution. The WRM is selected to solve the equations owning to its straightforward underlying principles, convenient implementation, efficient calculation, and great precision. A numerical example shows that the relative error is only 3.2%, when WRM is compared with finite element calculation, which satisfies engineering requirement. WRM is therefore demonstrated to be a novel computational approximation method.

ABSTRACT

This paper presents a new method to predict the plastic radius of compaction pile with hole expanded by blasting or tamping techniques. The new formulae are obtained based on Yu's unified strength theory. The strength difference in tension and compression and intermediate principal stress effect on the material strength are considered, and, hence, the obtained formulae can be used for a wide range of materials. The plastic zone of soil during hole-forming by blasting and tamping techniques can be predicted based on the derived formulae in this study. The effects of the blasting and tamping process on the adjacent piles can be reasonably assessed, and the weight of hammer and tamping times can then be determined. Previous results obtained based on Tresca, Mises, and Mohr-coulomb criterion are all special cases of the results derived in this paper.

Keywords: Highway engineering, Unified strength theory, foundation, compaction pile, hole-forming, tamping techniques

INTRODUCTION

Compaction pile is one of the most effective techniques for roadbed foundation in Loess Plateau of North China. As well known, dry loess has better capacities and can sustain nearly vertical slopes, being perennially under-saturated. However, when locally saturated, it disaggregates instantaneously and loses its capacity. The consequence of this process will result in foundation collapse. The technique of compaction can eliminate the collapsibility of roadbed and improve its bearing capacity. There are basically two steps in the construction of compaction pile. (1) Make a hole with pressing in steel sleeve, vibrating sunken tube, or explosive

expansion to evacuate the soil. (2) Fill in and tamp the soil or lime-soil repeatedly until the hole is filled.

Original soil layer above pile top is a minimum of 1 meter in the process of hole-forming of compaction pile (GB50007, 1990). According to the Chinese codes, the pile spacing can be determined by the average compaction coefficient of soil among piles and the pile diameter. Usually the compaction coefficient should not be less than 0.93, and the spacing is estimated in the range of 2.0-2.5 times of pile diameter. However, the provisions from Chinese codes (GB50202, 2002 and JGJ79, 2003) are only associated with the physics nature of soil density, while regardless of the mechanics feature of that. The previously obtained formulae for estimating the plastic zone and deformation are mainly based on the Mohr-Coulomb strength criteria. The effect of intermediate principal stress on the material strength cannot be included in the model and, therefore, usually cannot accurately predict the plastic zone and deformation.

In this paper, plastic analysis of compaction pile with hole-forming by explosive expansion or tamping technique is investigated, and the formulae to predict the plastic zone obtained in this paper is based on the unified strength theory. The strength difference in tension and compression and intermediate principal stress effect on the material strength are considered, and, hence, the obtained formulae can be used for a wide range of materials. The effects of blasting and tamping process on the adjacent piles can thus be reasonably assessed, and the weight of hammer and tamping times can then be determined. Previous results obtained based on Tresca, Mises, and Mohr-coulomb criterion are all special cases of the results derived in this paper.

UNIFIED STRENGTH THEORY

Based on twin shear strength theory, Yu M.H. (Yu M.H., 1994, 1998, 2004) developed the unified strength theory. The theory takes the effect of σ_2 into consideration and uses a unified mechanical model to describe the features of different materials. Its mathematical expression is simple and given as follows:

$$F = \sigma_1 - \frac{\alpha}{1+b}(b\sigma_2 + \sigma_3) = \sigma_t \qquad \sigma_2 \le \frac{\sigma_1 + \alpha\sigma_3}{1+\alpha} \tag{1a}$$

$$F = \frac{1}{1+b}(\sigma_1 + b\sigma_2) - \alpha\sigma_3 = \sigma_t \qquad \sigma_2 \ge \frac{\sigma_1 + \alpha\sigma_3}{1+\alpha} \tag{1b}$$

$$\alpha = \sigma_t / \sigma_c \quad , b = \frac{(1+\alpha)\tau_s - \sigma_s}{\sigma_s - \tau_s} = \frac{(1+\alpha) - B}{B-1}, \qquad B = \frac{\sigma_S}{\tau_S}$$

where α is tension-compression resistance ratio, i.e., σ_s versus σ_c, and generally less than 0.5 for rock and soil, and b is parameter for the influence of intermediate principal shear stress.

In Geotechnical Engineering, the former equations are generally expressed by cohesion force (shear strength) c_0 and internal fractional angle φ. The parameters in formulae (1a, 1b) can be substituted by the parameters of c_0, φ as follows:

$$\alpha = \frac{(1-\sin\varphi)}{(1+\sin\varphi)}, \sigma_t = \frac{2c_0\cos\varphi}{1+\sin\varphi}, \tau_s = c_0, B = \frac{2\cos\varphi}{1+\sin\varphi}, \quad b = \frac{2(1-\cos\varphi)}{2\cos\varphi-(1+\sin\varphi)}$$

PLASTIC ZONE OF SOIL MEDIA AROUND A PILE WITH HOLE FORMED BY EXPLOSION TECHNIQUE

Analysis of soil media around a pile with hole expanded by blasting technique. The following assumptions are made in this study:

(1) It is coupled charge mode. The cross-section of blast-hole spaces is circular. Considering the dynamic compressive response time of soil is much longer than that of explosion, linear blasting cartridge along its axis line is assumed to detonate at the same time, neglecting the influence of variation of soil lateral pressure along the pile on the effect of blasting compression.

(2) The problem is treated as plain strain problem according to the characteristics of the problem. In the process of piling construction in which holes are formed by explosion technique, soil layer with a 1- to 2-m thickness is required above the soil media. The layer is generally evacuated until explosion expanded piling is tamped. Soil is compacted latterly through explosion expanded action among piling, which is settled at appropriate pile spacing. Therefore, this paper assumes that the soil media around a hole is a problem of plain strain in the process of pore-forming by explosion expansion technique. Polar coordinate is taken and the positive direction directs outward along radial (see Figure 1). Soil media around a hole is assumed as a cylinder with a thick wall. At a point far away from the center, both radial stress and tangential stress are equal to original soil stress.

When

$$r \to \infty$$

Static earth pressure is given by:

$$p_2 = k_0 \gamma z$$

The pressure p_2 is assumed as linear distribution along the depth direction *h*; r_0 is the radius of the borehole; r_a is the radius of the expanded hole by explosion; and r_b is the radius of plastic zone induced by the explosion process.

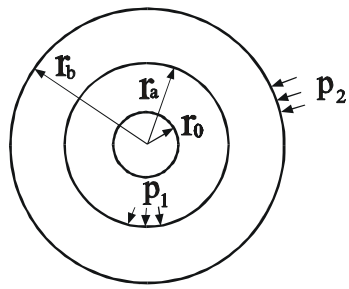

Figure 1. Schematic diagram of a hole formed by blasting technique.

A formula is obtained from literature (Lin, Hu W., and Peng G., 2003) as follows:

$$r_a^2 = r_b^2 - \left(r_b^2 - r_0^2\right)\left(\frac{4p_1 r_0^{1.5}}{\rho_m D^2 r_b^{1.5}} + 1\right)^{-0.25} \tag{2}$$

where ρ_m is the initial compaction density of soil, and p_1 is the initial stress on the wall of blast hole.

Given by:

$$R_a = \frac{r_a}{r_0}, R_b = \frac{r_b}{r_0}$$

Formula (2) can be expressed as:

$$R_a^2 = R_b^2 - \left(R_b^2 - 1\right)\left(\frac{4p_1}{\rho_m D^2 R_b^{1.5}} + 1\right)^{-0.25} \tag{3}$$

The formula reflects the expansion rule of blast hole, when soil medium is subjected to the action of blast. Formulae (2, 3) indicate that the radius of expansion of an expanded hole is related to the radius of plastic region, initial stress of explosion, radius of blast hole, medium density, and longitudinal wave speed.

Radius of plastic region. When explosive is fully coupled, initial pressure of the wall of blast hole can be predicted as:

$$p_1 = \frac{\rho_0 D \rho_e D_e^2}{2\left(\rho_0 D + \rho_e D_e\right)} \tag{4}$$

where ρ_e is explosive density, D_e is the blast speed, ρ_0 is the initial density of soil medium, and D is the longitudinal wave speed.

When $r = r_b$ (see Figure 2), the radial stress component in elastic region for circular hole is:

$$\sigma_{rb} = -p_1 R_b^{-1.5} \tag{5}$$

According to the theory of elastic mechanics, the stresses in soil media around a pile can be obtained as:

$$\sigma_r = -\frac{r_a^2\left(p_1 - p_2\right)}{r^2} - p_2, \quad \sigma_\theta = \frac{r_a^2\left(p_1 - p_2\right)}{r^2} - p_2, \quad \sigma_z = \nu\left(\sigma_r + \sigma_\theta\right)$$

In plastic region, due to $\nu \to 0.5$, the following relationship can be obtained:

$$\sigma_z = \frac{\left(\sigma_r + \sigma_\theta\right)}{2}$$

Owing to $\sigma_1 \geq \sigma_2 \geq \sigma_3$, the relationship among stresses are given as follows (Zhao, Zhang, and Liao, et al., 2000):

$$\sigma_1 = \sigma_\theta = \frac{r_a^2(p_1 - p_2)}{r^2} - p_2 \tag{6}$$

$$\sigma_2 = \sigma_z = \frac{(\sigma_r + \sigma_\theta)}{2} \tag{7}$$

$$\sigma_3 = \sigma_r = -\frac{r_a^2(p_1 - p_2)}{r^2} - p_2 \tag{8}$$

The equilibrium equation is obtained from plastic mechanics and given as follows (Wang, Xiong, and Huang, 1982):

$$\frac{d\sigma_r}{dr} - \frac{\sigma_r - \sigma_\theta}{r} = 0 \tag{9}$$

Substitute formulae (6, 7, and 8) into formula (1) of unified strength theory, and the following formulae are obtained:

$$\sigma_\theta = \frac{2(1+b)\sigma_t}{2(1+b)-b\alpha} + \frac{\alpha(2+b)\sigma_r}{2(1+b)-b\alpha}$$

$$\sigma_r - \sigma_\theta = \frac{2(1+b)(1-a)\sigma_r}{2+2b-b\alpha} - \frac{2(1+b)\sigma_t}{2+2b-b\alpha} \tag{10}$$

Substitute formula (10) into (7), considering boundary conditions:

$$r = r_a, \sigma_r = -p_1$$

Integrate formula (9), and the radial stress can be obtained:

$$\sigma_r = -\left(p_1 + \frac{\sigma_t}{1-\alpha}\right)\left(\frac{r}{r_a}\right)^{\frac{2(1+b)(\alpha-1)}{2(1+b)-b\alpha}} + \left(\frac{\sigma_t}{1-\alpha}\right) \tag{11}$$

When $r = r_b$, the radial stress of outer boundary in plastic region is equal to that of inner boundary in elastic region.

Using:

$$\nabla = \frac{2(1+b)(\alpha-1)}{2(1+b)-b\alpha}, \quad \zeta = \frac{\sigma_t}{1-\alpha}, \quad R = \frac{r}{r_a}$$

According to formula (10), the following formula can be obtained:

$$\sigma_{rb} = -(p_1 + \zeta)(R_b)^\nabla + \zeta \tag{12}$$

Substitute formula (12) into formula (5), and the following equation is obtained:

$$-p_1 R_b^{-1.5} = -(p_1 + \zeta)(R_b)^\nabla + \zeta$$

The above formula, which is the unified solution of plastic radius of soil media, can be expressed as follows:

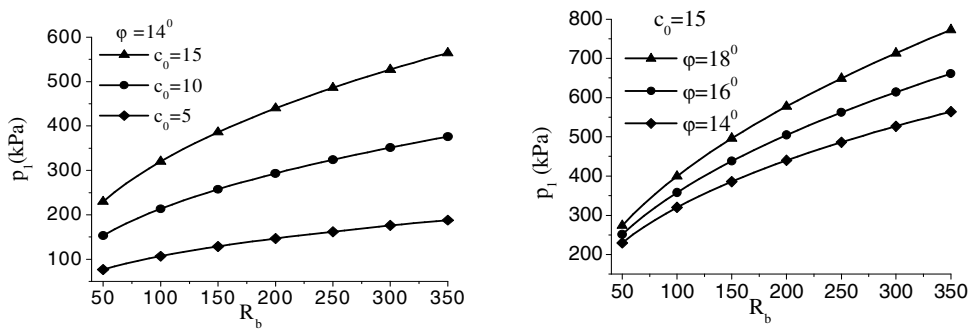
$$-p_1 R_b^{-1.5} + (p_1 + \zeta)(R_b)^{\nabla} - \zeta = 0$$

Expression ∇, ζ based on c_0, φ, and leading to:

$$\nabla = \frac{-2}{1+\cot\varphi}, \quad \nabla + 2 = \frac{2}{1+\tan\varphi}, \quad \zeta = c_0 \cot\varphi \tag{13}$$

$$-p_1 R_b^{-1.5} + (p_1 + c_0 \cot\varphi)(R_b)^{\frac{-2}{1+\cot\varphi}} - c_0 \cot\varphi = 0 \tag{14}$$

where p_1 is determined by formula (4). The plastic boundary scale radius of soil media among piles with holes expanded by blasting technique, R_b, is obtained by substituting p_1 into formula (14). Substitute R_b into formula (3), and post-expansion scale radius of soil media R_a is determined. The relationship between initial stresses of pre-blasting and plastic scale radius is predicted by formula (14) using a varying internal cohesion force and fractional angle. The relationships between p_1 and R_b are plotted in Figure 2 (a) and (b), respectively. It can be found that the required initial blast stress p_1 increases with the increasing cohesion force and fraction angle if the radius R_b is the same.



(a) **(b)**

Figure 2. Relationship between p_1 and R_b.

STRESS ANALYSIS OF SOIL MEDIA AROUND PILE SUBJECTED TO TAMPING

Plastic analysis of soil media around pile subjected to tamping. It is proven from engineering practice that the initial hole diameter has generally no change through the process of filling and tamping. Here we assume that the deformation of soil media around a pile is very small, and the soil media can be treated as homogeneous materials and a semi-infinite body.

Thus, the geostatic stresses in perpendicular directions are the same as that in horizontal plane. Polar coordinate is used for stresses analysis (see Figure 3). Soil media around a hole is assumed as a cylinder with a thick wall. At an infinite point,

both radial stress and tangential stress are equal to original soil stress. When $r \to \infty$,

equations (6)-(8) can be obtained based on the theory of elasticity.

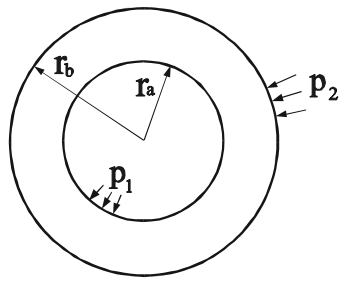


Figure 3. Schematic diagram of tamping

When $r = r_b$, solve formulae (8, 11), leading to:

$$-\left(\frac{r_a}{r_b}\right)^2 (p_1 - p_2) = -\left(p_1 + \frac{\sigma_t}{1-\alpha}\right)\left(\frac{r_b}{r_a}\right)^{\frac{2(1+b)(\alpha-1)}{2(1+b)-b\alpha}} + \frac{\sigma_t}{1-\alpha} + p_2 \quad (14)$$

According to formula (13), the above formula can be expressed as follows:

$$(p_2 + \zeta)R_b{}^2 - (p_1 + \zeta)R_b{}^{\nabla+2} + (p_1 - p_2) = 0 \quad (15)$$

$$p_2\left(R_b{}^2 - 1\right) + p_1\left(1 - R_b{}^{\nabla+2}\right) + \zeta\left(R_b{}^2 - R_b{}^{\nabla+2}\right) = 0 \quad (16)$$

When formulae (15, 16) are expressed by notation φ, c_0, formula for plastic radius of soil media around a pile forming by tamping is given as follows:

$$(p_2 + c_0\cot\varphi)R_b{}^2 - (p_1 + c_0\cot\varphi)R_b{}^{\frac{2}{1+\tan\varphi}} + (p_1 - p_2) = 0$$

$$p_2\left(R_b{}^2 - 1\right) + p_1\left(1 - R_b{}^{\frac{2}{1+\tan\varphi}}\right) + c_0\cot\varphi\left(R_b{}^2 - R_b{}^{\frac{2}{1+\tan\varphi}}\right) = 0 \quad (17)$$

Application of the formula for plastic radius of soil media around a pile forming by tamping.

(1) When $\alpha = 0, \sigma_t = 0$, formula (14) can be expressed as follows, which is suitable for granular soil (Han, and Huang, 1999):

$$p_2 R_b^2 - p_1 R_b + p_1 - p_2 = 0 \quad (18)$$

Solve the former formula, and lead to:

$$R_b = 1, \quad \text{or} \quad R_b{}' = \frac{p_1 - p_2}{p_2}$$

(2) When $\alpha = 0$, formula (24) can be rewritten as follows, which is applicable for ideal elasto-plastic model (Han, and Huang,1999).

$$(p_2 + \sigma_t)R_b^2 - (p_1 + \sigma_t)R_b + p_1 - p_2 = 0 \quad (19)$$

Solve the former formula, and lead to:

$$R_b = 1, \text{or} \quad R_b' = \frac{p_1 - p_2}{p_2 + \sigma_t}$$

CONCLUSIONS

In this paper, a newly developed unified strength theory is used to carry out the plastic analysis of compaction pile. The unified strength theory includes the strength difference in tension and compression and intermediate principal stress effect on the material strength. Hence, the obtained formula to predict the plastic zone and deformation can be applicable for a wide range of soil material. Previous results obtained based on Tresca and Mohr-Coulomb criterion are all special cases of the results derived in this study. The obtained formula can be applicable to estimate the influences on the adjacent pile in the process of forming a new hole with the blasting or tamping method. The weight of hammer and tamping times can then be reasonably determined based on the results.

ABSTRACT

This paper presents the bridge damage identification from the dynamic response induced by the vehicle moving on a simply supported bridge deck modeled as a finite element model based on the sensitivity analysis. The moving vehicle is modeled as a two-degree-of-freedom system comprising of five parameters. The damage indices are defined by the bend stiffness reduction of the bridge element. Starting with the zero damage indices vector, the identification can be realized based on the least-squares method and the regularization technique from measured bridge responses measurement. Measurement noise and road surface roughness are considered in the numerical simulations. Simulation studies indicate that the identified results are acceptable and the proposed method is feasible.

INTRODUCTION

Damage detection of the structural system has been a research-active topic in the last several decades. Specially integrated with structural health monitoring technique, damage identification online is becoming more and more important and practical for large projects in civil engineering. Li and Haldar (2004) proposed a novel system identification procedure for nondestructive damage evaluation of structures from dynamic responses. It is a finite-element-based time domain linear system identification technique and capable of identifying structural properties at the elemental level. Majumder and Manohar (2003) presented the time domain approach for damage detection with vibration data as well. In addition, Banan and Hjelmstad (1994) proposed two algorithms for estimating member constitutive properties of a finite-element model with known geometry and topology from measured displacements under a static loading. Yang et al. (2004) extracted the fundamental bridge frequency from the dynamic response time history of a vehicle passing over

the bridge.

This paper presents the bridge damage identification from the dynamic responses of a simply supported bridge modeled as a finite element model based on the sensitivity analysis. The moving vehicle is modeled as a two-degree-of-freedom system comprising of five parameters. The damage indices are defined by the bend stiffness reduction of the bridge element. Starting with the intact bridge system, the identification can be realized based on the least-squares method and the regularization technique from the measured bridge responses. Effects from different response types, locations, noise levels, and road surface roughness are included in the study.

THEORY ON BRIDGE PARAMETERS IDENTIFICATION

Five-parameter vehicle model. The five-parameter vehicle model of the two-degrees-of-freedom system shown in Figure 1 comprises of five components: an upper mass (m_{v1}) of the bogie, a lower mass (m_{v2}) of the axle connected to a damper (c_v), a spring (k_{v1}), and another spring (k_{v2}) to represent the stiffness of the tire. The equations of motion of the masses m_{v1} and m_{v2} are respectively:

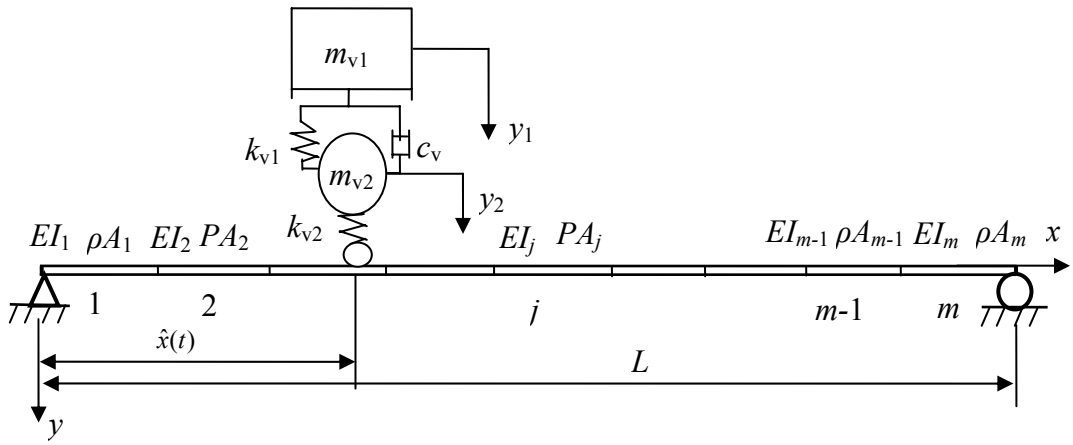

Figure 1. Vehicle-bridge system.

$$m_{v1}\ddot{y}_1 + c_v(\dot{y}_1 - \dot{y}_w) + k_{v1}(y_1 - y_2) = 0 \quad (1)$$

$$m_{v2}\ddot{y}_w - c_v(\dot{y}_1 - \dot{y}_2) - k_{v1}(y_1 - y_2) + k_{v2}\left[y_w - (w(\hat{x}(t)) + r(\hat{x}(t))\right] = 0 \quad (2)$$

and the interaction force (P_{int}) between the vehicle and the bridge can be expressed as:

$$P_{\text{int}} = (m_{v1} + m_{v2})g + k_{v2}[y_2 - (w(x(t) + r(\hat{x}(t))] \quad (3)$$

where $r(\hat{x}(t))$ (Honda et al., 1982) is the roughness of the surface at the interaction point between the vehicle and the bridge.

Equation of Motion for the Vehicle-Bridge System. The elemental mass

and stiffness matrices are obtained using the Hermitian cubic interpolation shape functions. The simply supported beam structure is discretized into *m* Euler beam elements. The equation of motion for the bridge can be written as:

$$M_{\mathrm{b}}\ddot{R} + C_{\mathrm{b}}\dot{R} + K_{\mathrm{b}}R = H_{\mathrm{c}}P_{\mathrm{int}} \tag{4}$$

where $M_{\mathrm{b}}, C_{\mathrm{b}}$ and K_{b} are the mass, damping, and stiffness matrices of the bridge respectively. $\ddot{R}, \dot{R}$ and R are the nodal acceleration, velocity, and displacement vectors of the bridge respectively, and $H_{\mathrm{c}}P_{\mathrm{int}}$ is the equivalent nodal load vector from the bridge-vehicle interaction force. H_{c} is a $N \times 1$ matrix with zero entries except at the DOFs (degrees-of-freedom) corresponding to the nodal displacements of the beam elements on which the load is acting, and N is the number of DOFs of the bridge after considering the boundary condition.

The Rayleigh damping is used to model the structural damping here. The damping matrix can be presented as a linear combination of the mass and stiffness matrices, such as:

$$C_{\mathrm{b}} = \alpha_1 M_{\mathrm{b}} + \alpha_2 K_{\mathrm{b}} \tag{5}$$

in which α_1 and α_2 are two Rayley damping coefficients, determined generally by two adjacent modal damping ratios and its corresponding natural frequencies in radian.

Based on Equation (3), combining Equations (1) ,(2) and (4), we have:

$$\begin{bmatrix} M_b & H_c^T m_{v1} & H_c^T m_{v2} \\ 0 & m_{v1} & 0 \\ 0 & 0 & m_{v2} \end{bmatrix} \begin{Bmatrix} \ddot{R} \\ \ddot{y}_1 \\ \ddot{y}_2 \end{Bmatrix} + \begin{bmatrix} C_b & 0 & 0 \\ 0 & c_v & -c_v \\ 0 & -c_v & c_v \end{bmatrix} \begin{Bmatrix} \dot{R} \\ \dot{y}_1 \\ \dot{y}_2 \end{Bmatrix} + \begin{bmatrix} K_b & 0 & 0 \\ 0 & k_{v1} & -k_{v1} \\ -k_{v2}H_c & -k_{v1} & k_{v1}+k_{v2} \end{bmatrix} \begin{Bmatrix} R \\ y_1 \\ y_2 \end{Bmatrix} = \begin{Bmatrix} H_c^T(m_{v1}+m_{v2})g \\ 0 \\ k_{v2}r(\hat{x}(t)) \end{Bmatrix} \tag{6}$$

To find the time response of the beam and the vehicle from Equation (6), a step-by-step solution can be obtained using the Newmark method.

Once the nodal responses of the bridge are obtained, the vertical deflection, velocity, acceleration, and strain responses of the bridge at position *x* and time *t* can then be expressed as the following :

$$w(x,t) = H(x)\,R(t), \quad \dot{w}(x,t) = H(x)\,\dot{R}(t), \quad \ddot{w}(x,t) = H(x)\,\ddot{R}(t) \tag{7}$$

$$\varepsilon(x,t) = -z\frac{\partial^2 w(x,t)}{\partial x^2} = -z\frac{\partial^2 H(x)\,R(t)}{\partial x^2} \tag{8}$$

where $H(x)$ is a $1 \times N$ vector with zero entries except at the degrees-of-freedom

corresponding to the nodal displacements of the *j*-th beam element on which the point *x* is located.

Sensitivity analysis of bridge responses respect to damage indices. The damage indices (α_s^j) is defined to represent the reduction of the elemental bend stiffness of the bridge. The physical parameters become:

$$(EI)_d^j = (EI)_0^j(1+\alpha_s^j) \qquad (-1 \le \alpha_s^j \le 0,\ j = 1, 2, \cdots, m) \tag{9}$$

where $(EI)_0^j$ are the parameters of the intact bridge, and $(EI)_d^j$ are the parameters of the damaged bridge. The *j*-th elemental bend stiffness can be found in Figure 1.

Taking the first derivative of Equation (6) with respect to the damage indices (α_s^j) of the bridge, $j = 1, 2, \cdots, m$, we have:

$$\overline{M}\ddot{S}_{(\alpha_s^j)} + \overline{C}\dot{S}_{(\alpha_s^j)} + \overline{K}S_{(\alpha_s^j)} = \overline{P}_{(\alpha_s^j)} \tag{10}$$

where:

$$\overline{M} = \begin{bmatrix} M_{\mathrm{b}} & H_{\mathrm{c}}^T m_{\mathrm{v1}} & H_{\mathrm{c}}^T m_{\mathrm{v2}} \\ 0 & m_{\mathrm{v1}} & 0 \\ 0 & 0 & m_{\mathrm{v2}} \end{bmatrix}, \overline{C} = \begin{bmatrix} C_{\mathrm{b}} & 0 & 0 \\ 0 & c_{\mathrm{v}} & -c_{\mathrm{v}} \\ 0 & -c_{\mathrm{v}} & c_{\mathrm{v}} \end{bmatrix}, \overline{K} = \begin{bmatrix} K_{\mathrm{b}} & 0 & 0 \\ 0 & k_{\mathrm{v1}} & -k_{\mathrm{v1}} \\ -k_{\mathrm{v2}}H_{\mathrm{c}} & -k_{\mathrm{v1}} & k_{\mathrm{v1}}+k_{\mathrm{v2}} \end{bmatrix},$$

$$\ddot{S}_{(\alpha_s^j)} = \begin{bmatrix} \frac{\partial \ddot{R}_1}{\partial(\alpha_s^j)} & \frac{\partial \ddot{R}_2}{\partial(\alpha_s^j)} & \cdots & \frac{\partial \ddot{R}_N}{\partial(\alpha_s^j)} & \frac{\partial \ddot{y}_1}{\partial(\alpha_s^j)} & \frac{\partial \ddot{y}_2}{\partial(\alpha_s^j)} \end{bmatrix}^{\mathrm{T}},\ \dot{S}_{(\alpha_s^j)} \text{ and } S_{(\alpha_s^j)} \text{ are similar}$$

with $\ddot{S}_{(\alpha_s^j)}$, and $\overline{P}_{(\alpha_s^j)} = \begin{bmatrix} -\frac{\partial K_b}{\partial(\alpha_s^j)}R - \alpha_2 \frac{\partial K_b}{\partial(\alpha_s^j)} & 0 & 0 \end{bmatrix}^{\mathrm{T}}$.

The mass, damping, and stiffness matrices in the above equations are time varying. The sensitivity matrices in Equation (10) can be obtained by Newmark method similarly.

The sensitivity time history vertical deflection, velocity, acceleration, and strain responses of the bridge at position *x* and time *t* can then be obtained based on the bridge nodal response sensitivity derived from Equation (10).

IDENTIFICATION OF BRIDGE PARAMETERS

Formulation. The case when a vehicle moves across the bridge deck from left to right at a constant speed is studied. The measured bridge response in time domain will be used to identify the bridge element damage indices. Below we try to make use of *v* and *S* to express bridge response (deflection, velocity, acceleration, or strain) measurement and its sensitivity with respect to the bridge damage indices.

v_m denotes the measured bridge response.

Assuming initial zero values to the damage indices vector to be $p_0 = \{\alpha_s^1, \alpha_s^2, \cdots, \alpha_s^m\}^{\mathrm{T}} = \mathbf{0}$, the corresponding response (v_0) and sensitivity matrix ($\overline{S}_0$) can be solved from Equations (5) and (10). The difference between the measured and calculated bridge responses can be obtained by the following formulation.

$$\Delta v_r = v_m - v_r, \; r=0, 1, 2,\ldots \tag{11}$$

The difference vector Δp_r can be solved from the following equation.

$$\overline{S}_r \Delta p_r = \Delta v_r, \; r=0, 1, 2,\ldots \tag{12}$$

where $\overline{S}_r$ is a $N_{\mathrm{t}} \times m$ matrix. N_{t} is the number of sampled data points and r is the number of iterations.

The bridge responses sensitivity matrix with respect to the bridge damage indices for a one-degree-of-freedom system and a two-degrees-of-freedom system, respectively, can be formulated same form as:

$$\overline{S}_r = \begin{bmatrix} \dfrac{\partial v_r(1)}{\partial(\alpha_s^1)_r} & \dfrac{\partial v_r(1)}{\partial(\alpha_s^2)_r} & \cdots & \dfrac{\partial v_r(1)}{\partial(\alpha_s^m)_r} \\ \dfrac{\partial v_r(2)}{\partial(\alpha_s^1)_r} & \dfrac{\partial v_r(2)}{\partial(\alpha_s^2)_r} & \cdots & \dfrac{\partial v_r(2)}{\partial p(\alpha_s^m)_r} \\ \vdots & \vdots & \cdots & \vdots \\ \dfrac{\partial v_r(N_t)}{\partial(\alpha_s^1)_r} & \dfrac{\partial v_r(N_t)}{\partial(\alpha_s^2)_r} & \cdots & \dfrac{\partial v_r(N_t)}{\partial(\alpha_s^m)_r} \end{bmatrix} \tag{13}$$

where $\ddot{y}_r$ are the acceleration responses of the bridge vehicle in r-th iteration step, and $(\alpha_s^j)_r$ is the j-th bridge element damage indices corresponding r-th iteration step.

With the updated damage indices vector $p_{r+1} = p_r + \Delta p_r$ (r=0, 1, 2,…) in the next iteration, the response (v_{r+1}) and sensitivity ($\overline{S}_{r+1}$) can be calculated again. The above process is repeated until the identified damage indices increment of the successive iterations is smaller than a pre-defined tolerance level, namely defined as

following form:

$$\left\|\Delta p_r\right\| < Tolerance \tag{14}$$

where ||•|| is the norm of the matrix, and the tolerance is taken equal to 1.0×10^{-6} in the following numerical simulations.

The absolute error in the identified results is calculated as $AE = \sum_{j=1}^{m} \left\| \left(\alpha_S^j\right)_{true} - \left(\alpha_S^j\right)_{identified} \right\|$, where ||•|| is the norm of the vector. The formulation for identification from measured velocity or displacement responses of the bridge can be similarly derived.

Regularization. The set of damage indices difference Δp_r obtained from Equation (12) using a straight-forward least-squares solution would be unbound. A regularization technique (Law et al., 2001) can be used to solve the ill-posed problem in the form of minimizing the function.

$$J(\Delta p_r, \lambda) = \left\|\overline{S}_r \Delta p_r - \Delta v_r\right\|^2 + \lambda\left\|\Delta p_r\right\|^2 \tag{15}$$

where λ is the non-negative regularization parameter corresponding to the optimal results. The *L*-curve method (Hansen, 1992) is employed to determine the optimal regularization parameter. Optimizing Equation (11) is equivalent to the solution with the following damped least-squares method.

$$\Delta p_r = (\overline{S}_r^{\,T}\overline{S}_r + \lambda I)^{-1}\overline{S}_r^{\,T}\Delta v_r \tag{16}$$

where I is the identity matrix. Singular value decomposition is used in the pseudo-inverse calculation in this paper.

SIMULATION STUDY

In the numerical simulation studies, the parameters of the vehicle-bridge system are defined as following. Parameters of the simply supported bridge: for the single-span bridge: L=30m, EI=2.5×10^{10} Nm^2, ρA=6.0×10^3 kg/m and ξ=0.02 for all modes; Parameters of vehicle: for the five-parameter vehicle: m_{v1}=3.6×10^3 kg, c_v=1.0×10^3 Ns/m, k_{v1}=6.0×10^5 N/m, m_{v2}=0.4×10^3 kg, k_{v2}=8.5×10^5 N/m.

The simply supported bridge is discretized into ten Euler Bernoulli beam elements. The speed of the vehicle is 20 m/s and the sampling frequency is 200 Hz, the number of sampled data points N_t is 300. Road surface roughness of class A to D according reference is included in the following numerical simulations.

White noise is added to the calculated acceleration responses of the system to simulate the polluted measurements.

$$v_m = v_{\text{calculated}} + E_P \times N_{\text{oise}} \times \sigma(v_{\text{calculated}}) \tag{17}$$

where v_m is simulated measured acceleration responses, $v_{\text{calculated}}$ is calculated acceleration responses, E_P is noise level, N_{oise} is the standard normal distribution vector with zero mean value and unit standard deviation, and $\sigma(v_{\text{calculated}})$ is the standard deviation of the calculated acceleration responses.

Effect of Different Road Class. Here we make use of noise-free strain responses at *L*/3 of the bridge span to identify bridge damage indices for different road classes (from A to D). The 4th bridge element is assumed to be damaged, $\alpha_s^7 = 10\%$, and the other elements are intact. The identified results are listed in Table 1.

Table1. Identified damage indices (%) with different road surface roughness.

Element No.	Road surface roughness of the bridge			
	Class *A*	Class *B*	Class *C*	Class *D*
1	0.00	0.08	0.16	0.17
2	0.00	-0.06	-0.08	-0.10
3	0.00	0.04	0.07	0.08
4	-10.00	-9.95	-9.92	-9.91
5	0.00	0.04	0.08	0.09
6	0.00	-0.04	-0.08	-0.09
7	0.00	-0.01	-0.07	-0.08
8	0.00	-0.07	0.10	-0.10
9	0.00	0.07	0.11	0.11
10	0.00	0.13	-0.19	-0.21
AE (%)	0.00	0.55	1.01	1.11
Iteration times	36	40	38	38

From Table 1, we can obtain following observations. All the identified results are accepted, the identified accuracy decrease with Road class, and the road surface roughness may affect the vehicle-bridge system similar to random noise. The worst results correspond with the Road class D; its absolute error (*AE*) is 1.11%. However, the iteration times are almost not affected by road surface roughness. This indicates that the proposed method is practical and efficient. Because the surface of the bridge is relatively good in general, so the road surface roughness is taken as class C below.

Effect of measured station and different types responses. In this case, we assume $\alpha_s^2 = \alpha_s^9 = 5\%$, $\alpha_s^4 = 10\%$ and the other elements damage indices are zeros. The noise-free vertical displacement, velocity, acceleration, and strain responses at

L/4, *L*/2 and *L3*/4 of the bridge span identify bridge damage indices, respectively. Table 2 gives the identified results.

Table 2. Identified damage indices (%) from different response measurements.

Element No.	Vertical displacement			Vertical acceleration			Strain		
	L/4	*L*/2	3*L*/4	*L*/4	*L*/2	3*L*/4	*L*/4	*L*/2	3*L*/4
1	0.07	0.00	-0.08	-0.03	0.00	0.00	0.07	0.00	-0.08
2	-4.96	-5.00	-4.99	-4.99	-5.00	-5.00	-4.96	-5.00	-4.99
3	-0.08	0.00	0.01	0.02	0.00	0.00	-0.08	0.00	0.01
4	-0.05	0.00	-0.02	-0.01	0.00	0.00	-0.05	0.00	-0.02
5	-9.97	10.00	-9.98	-9.99	-10.00	-10.00	-9.97	10.00	-9.98
6	-0.05	0.00	-0.01	-0.01	0.00	0.00	-0.05	0.00	-0.01
7	0.02	0.00	-0.01	0.00	0.00	0.00	0.02	0.00	-0.01
8	-0.07	0.00	-0.03	-0.07	0.00	0.00	-0.07	0.00	-0.03
9	-4.97	-5.00	-4.98	-4.98	-5.00	-5.00	-4.97	-5.00	-4.98
10	0.10	0.00	-0.07	0.14	0.00	0.00	0.10	0.00	-0.07
AE (%)	0.54	0.00	0.28	0.32	0.00	0.00	0.54	0.00	0.28
Iteration times	26	48	35	52	47	54	24	51	34

We can infer from Table 2 that the measured station locations clearly affected identified results, the middle span responses give better results, and response types cause different effects on the identified results. When the measured station is not in the middle span, vertical acceleration responses give the best results, vertical velocity responses give the worst results, and the results from vertical displacement and strain responses are same. The acceleration and strain responses are easily obtained accurately in actual testing, this point proves that this method can be used to solve practice problems.

Table 3. Identified damage indices (%) with different noise level.

Element No.	Noise level（%）					
	0		5		10	
	Strain	Acceleration	Strain	Acceleration	Strain	Acceleration
1	-5.00	-5.00	-5.11	-4.90	-5.33	4.76
2	0.00	0.00	-0.16	-0.15	-0.35	0.29
3	0.00	0.00	-0.08	0.09	-0.13	-0.15
4	-10.00	-10.00	-10.30	-10.19	-10.63	-10.48

6	-15.00	-15.00	-15.45	-14.62	-15.85	-15.68
7	-10.00	-10.00	-10.20	-10.19	-10.50	-9.56
8	0.00	0.00	-0.11	-0.08	-0.13	0.12
9	0.00	0.00	-0.16	0.12	-0.35	-0.29
10	-5.00	-5.00	-5.13	-5.08	-5.38	-5.30
AE (%)	0.00	0.00	2.05	1.66	4.25	3.60

Iteration times	50	45	51	45	53	46

Effect of different noise level. We assume six elements to be damaged, $\alpha_s^1 = \alpha_s^{10} = 5\%, \alpha_s^4 = \alpha_s^7 = 10\%, \alpha_s^5 = \alpha_s^6 = 15\%$ and the other elements to not be damaged. The identified results in Table 3 are obtained from vertical acceleration and strain responses at the middle span with noise level 0, 5% and 10%.

We can see clearly from Table 3 that the identified absolute errors increases with noise level, iteration times slightly vary with noise level, and the vertical acceleration responses give better results than strain responses.

CONCLUSIONS

From the simulation studies we can conclude the following:

(1) The identification is not very sensitive to the measured noise and the road surface roughness affect the identified results similarly with random noise.

(2) The identified damage indices results from different types of responses of the bridge at different measured stations all are accepted. The measured locations and response types all affect the identified results. We suggest that vertical acceleration and strain responses at middle span should be adopted in the practice.

ABSTRACT

Crumb rubber modified asphalt (CRMA) mixture is a typical viscoelastic material. The pavement made from CRMA mixture has anti-skid surfaces and the pavement is good in reducing the traffic noise. Moreover, building the road with CRMA mixture is important in controlling the pollution cased by a large amount of discarded tires. In order to study the rheological characteristics of CRMA mixture, a series static creep testes for the material has been performed at -15℃、0℃、15℃、30℃ and 45℃ respectively. The experimental results indicate that the Burgers model is good in simulating the viscoelastic characteristics of CRMA mixtures. Viscoelastic parameters and time dependence of creep stiffness modulus can be obtained from the simulation of the experimental data. The result shows that creep stiffness modulus decreases rapidly at the initial stage of loading, then the rate of change decreases, and finally creep stiffness modulus approaches to a stable value at the end of loading.

Keywords: crumb rubber modified asphalt mixture; viscoelasticity; creep; creep stiffness modulus；Burgers model

1. Introduction

CRMA is prepared by adding crumb rubber powder into asphalt. The application of crumb rubber particles can improve the mechanical properties of asphalt at low temperatures and improve the durability of the pavement. Moreover, consuming discarded tires in making CRMA benefits the effect of controlling the pollution caused by the large number of discarded tires and has reduced the cost of building roads (Palit, 2004).

As a typical viscoelastic material, an asphalt mixture has creep and

relaxation properties (Judith, 2006; Jincheng, 2007; Naisheng, 2007). The uniaxial static compression creep tests of Open-Graded Friction Courses (OGFC) CRMA mixture of 20% porosity were carried out on a UTM-25 material testing machine. The rheological and viscoelastic characteristics of CRMA were obtained from the results of the tests.

2. Creep test of crumb rubber modified asphalt mixture

OGFC-13 was adopted in the tests. CRMA material was obtained from Tianjin, and the aggregate was basalt. The specimens of 20% porosity were used in the following experiments. The specimens were prepared by a rolling compaction machine. Both diameter and height of the test specimens were 100 mm. In order to observe the viscoelastic behavior of CRMA mixture in a large range of temperatures, the experiments were carried out at -15℃、0℃、15℃、30℃ and 45℃ respectively. Because of the temperature sensitive deformation of the material, different stresses were selected as 0.5 Mpa at -15℃ and 0℃; and 0.1 Mpa at 15℃、30℃、and 45℃. Control testes were performed at each temperature. In order to reach the uniform temperature, the specimens were conditioned for four hours in the environment chamber before each test. The specimens were first preloaded with 1% of testing load for three minutes. Then loading and unloading were carried out during specified time periods. The sample deformation was measured by strain transducer (as shown fig.1). The experimental data was collected at every twenty seconds. The creep test curve is shown in fig.2. The time period of each creep test was 60 min.

3. Analysis of the experimental results

(1) The viscoelastic constitutive model of CRMA mixture

Fig.1 Loading in creep test

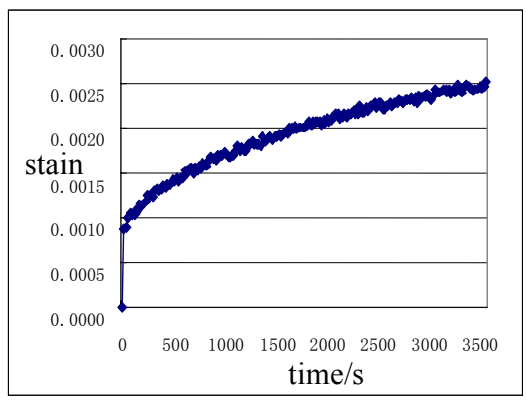

Fig.2 curve of creep test

Based on the experimental data, the Burgers model has been demonstrated appropriate in representing viscoelastic characteristics of CRMA mixture. The total deformations defined by this model are elastic deformation、viscoelastic reheology deformation and viscoelastic deformation. The constitutive equation is shown as follow:

$$\sigma + p_1\sigma + p_1\ddot{\sigma} = q_1\dot{\varepsilon} + q_2\ddot{\varepsilon}$$

Where $$p_1 = (\eta_1 E_1 + \eta_1 E_2 + \eta_2 E_1)/E_1 E_2$$

$$p_2 = \eta_1\eta_2 / E_1 E_2$$

$$q_1 = \eta_1$$

$$q_2 = \eta_1\eta_2 / E_2$$

The constitutive equation of Burgers model is expressed by viscoelastic parameters

$$E_1E_2\sigma + (\eta_1E_1 + \eta_1E_2 + \eta_2E_1)\dot{\sigma} + \eta_1\eta_2\ddot{\sigma} = E_1E_2\eta_1\dot{\varepsilon} + E_1\eta_1\eta_2\ddot{\varepsilon}$$

Substitute $\sigma = \nabla(t)\sigma_0$ in the constitutive equation and perform Laplace transform, we have

$$\sigma_0/s + p_1\sigma_0 + p_2 s\sigma_0 = q_1 s\bar{\varepsilon}(s) + q_2 s^2\bar{\varepsilon}(s)$$

Solve the above equation, we have

$$\bar{\varepsilon}(t) = \sigma_0\left[\frac{1}{s^2(q_1 + q_2 s)} + \frac{p_1}{s(q_1 + q_2 s)} + \frac{p_2}{q_1 + q_2 s}\right] \quad (1)$$

Replace the creep strain by reversion of Laplace transform, we have

$$\varepsilon(t) = \sigma_0\left[\frac{p_1q_1 - q_2}{q_1^2} + \frac{t}{q_1} + (\frac{p_2}{q_2} - \frac{p_1q_1 - q_2}{q_1^2})e^{-\lambda t}\right] \quad (2)$$

where $\lambda = q_1/q_2$.

If equation (2) is expressed in viscoelastic parameters

$$\varepsilon(t) = \sigma_0\left[\frac{E_1 + E_2}{E_1E_2} + \frac{t}{\eta_1} + \frac{1}{E_2}e^{-\lambda t}\right]$$

where $\lambda = E_2/\eta_2$.

(2) Parametric fitting of rheological data

Fitting of creep test results was carried out in determining coefficients in the Burgers model (Reibo, 2004; Xuejun, 2004). The instantaneous elastic strain ε_0

can be obtained from the recorded data. So the elastic modulus of spring is

$$E_1 = \sigma_0 / \varepsilon_0$$

Eliminate the instantaneous elastic strain from the model, the remaining strain is

$$\varepsilon(t) = \sigma_0 \left\{ \frac{1}{E_1} + \frac{t}{\eta_1} + \frac{1}{E_2}\left[1 - e^{-E_2 t/\eta_2}\right] \right\}$$

$$\delta(t) = \varepsilon(t) - \varepsilon_0 = \sigma_0 \left\{ \frac{t}{\eta_1} + \frac{1}{E_2}\left[1 - e^{-E_2 t/\eta_2}\right] \right\}$$

When time approaches infinite, the equation becomes

$$\delta(t)_{t\to\infty} = \sigma_0 \left\{ \frac{t}{\eta_1} + \frac{1}{E_2} \right\}$$

So we can get viscosity coefficient η_1 by measuring the slope of the last section in the strain / time curve

$$\eta_1 = \sigma_0 / \tan\theta$$

Set $t = 0$ in equation (1) and $\delta(t)_{t\to\infty} = \sigma_0 / E_2$, the elastic modulus of spring in delay element becomes

$$E_2 = \sigma_0 / \delta(t)_{t\to\infty 2}$$

In order to get the viscosity coefficient of dashpot in **the** delay element, convert equation (1) into

$$-\delta(t) + \frac{\sigma_0}{E_2} + \frac{\sigma_0 t}{\eta_1} = \frac{e^{-E_2 t/\eta_2} \cdot \sigma_0}{E_2}$$

Take logarithm at both sides

$$\log\left\{ -\delta(t) + \frac{\sigma_0}{E_2} + \frac{\sigma_0 t}{\eta_1} \right\} = \log\frac{\sigma_0}{E_2} - \frac{E_2 t}{\eta_2}\log e$$

and denote the slope of the function above as γ， we have

$$\tan\gamma = -\frac{E_2}{\eta_2}\log e$$

Therefore

$$\frac{\eta_2}{E_1} = -\log e / \tan\gamma \qquad \eta_2 = -\frac{0.4343}{\tan\gamma} E_2$$

All viscoelastic parameters of the Burgers model are represented in Table 1

Table.1 Fitting parameters of the viscoelastic model

E1	η1	E2	η2
1200	2388231	1100	211075

Experimental data can be fitted by the viscoelastic parameters in table 1 (Fig.3). Good agreement between the Burgers fitting curve and the experimental data has been observed.

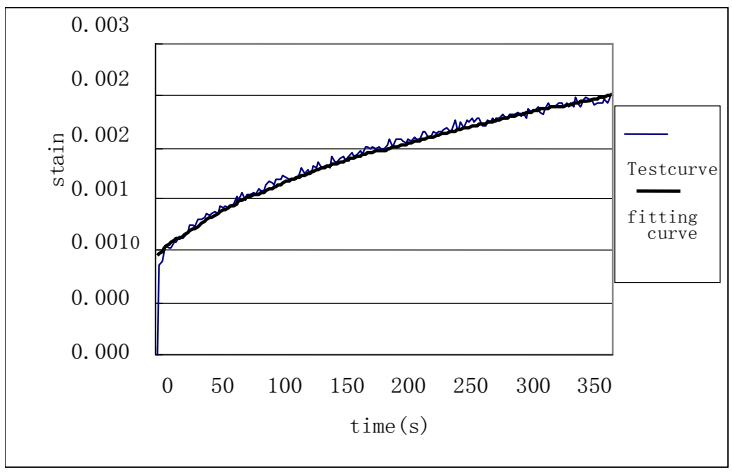

Fig.3 Fitting curve of creep test date

(3) Creep stiffness modulus

The time dependence of creep stiffness modulus of CRMA mixture has been observed at different temperatures in the creep tests (Fig 4). It is noticed that time

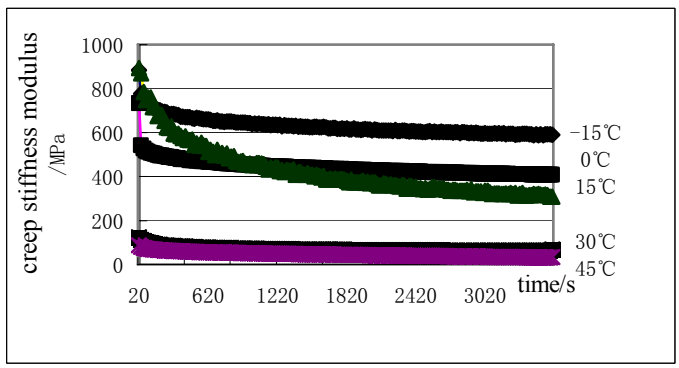

Fig.4 Time dependence of creep stiffness modulus of crumb rubber modified asphalt mixture

dependence of creep stiffness modulus is similar at different temperatures. Creep stiffness modulus decays rapidly at the initial phase of loading, then the decay rate

slows down and finally the creep stiffness modulus approaches to a stable value at a preset temperature. The final stable value of creep stiffness modulus is lower at higher temperatures.

4. Conclusion

(1) The creep behavior of CRMA mixture has been studied by static compression creep test. A good agreement between the simulation curve of the Burgers model and the experimental curve has been observed. Burgers model therefore has been proven adequate to describe the viscoelastic characteristics of CRMA mixture.

(2) The creep stiffness modulus decays rapidly at the early stage of loading, then the decay rate slows down and finally the creep stiffness modulus of CRMA approaches to a stable value at different temperatures. The smaller creep stiffness moduli are observed at high temperatures.

(3) The viscoelastic parameters of CRMA mixture from the static creep test provide good working references for the design of crumb rubber modified asphalt pavement.

ABSTRACT

This study illustrates a regularized method in the viscoelastic analysis of asphalt pavement based on time-domain creep tests. The method is capable of overcoming the ill-posedness of interconversion between creep compliance and relaxation modulus by solving a Volterra integral equation of second kind with regularization. The discrete data of relaxation modulus is calculated by the regularized method and fitted to the generalized Maxwell model. After the viscoelastic parameters of asphalt mixtures are obtained, the nonlinear finite element model of pavement is developed and the computed results indicate that the viscoelastic mechanical responses of pavement are greatly affected by temperature and loading time. The results of this study are expected to be utilized to predict and validate the distress of asphalt pavement in the design and maintenance periods.

Keywords: Asphalt mixtures; Viscoelasticity; Creep tests; Regularization methods; Finite element method.

INTRODUCTION

Asphalt mixtures are typical composite materials which are composed of graded aggregates, asphalt binders, and air voids. The mechanical behavior of asphalt mixtures is complex, and exhibits nonlinearity with correlation to time, frequency and temperature. However, many design methods still employ linear elastic theories to calculate the pavement responses. In order to analyze the responses of pavement structure more realistically, the nonlinear constitutive law of asphalt mixtures is usually expressed by viscoelastic models (Huang 1993, Sun and Luo 2008).

To formulate the characteristic functions of viscoelastic materials, creep compliance and relaxation modulus are usually employed. The two functions which are usually obtained by corresponding tests are related by a convolution (Tschoegl 1989). Once the source function (the function from which one converts) is given, the target function (the function to which one converts) can be predicted by an interconversion method. In generally, it is difficult to implement a constant-strain

relaxation test on stiff asphalt mixtures, while a constant-stress creep test is much easier. Therefore in order to obtain the viscoelastic parameters of asphalt mixtures, it is necessary to firstly carry out creep tests and then to convert creep compliance to relaxation modulus.

The objective of this paper are (1) to present a regularized method for solving the ill-posed problem of interconversion between creep compliance and relaxation modulus; (2) to fit the calculated relaxation modulus to a generalized Maxwell model; (3) to illustrate the viscoelastic mechanical response of asphalt pavement with respect to different temperatures and loading time by finite element method.

NUMERICAL CALCULATION OF THE RELAXATION MODULUS

There are various methods for acquiring discrete relaxation modulus from creep data. Because of the relationship between creep compliance and relaxation modulus, the direct methods must require the solution of a Volterra integral equation of first kind, which is an ill-posed problem (Hopkins and Hamming 1957). In this section, we convert the Volterra integral equation to a second kind by the mathematical differential and discrete relaxation modulus is determined by solving the Volterra integral equation of second kind with regularization.

In the time domain, the general constitutive equation of linear viscoelasticity can be stated by the Boltzmann superposition integrals

$$\sigma(t) = \int_0^t E(t-\tau)\dot{\varepsilon}(\tau)d\tau\,, \tag{1}$$

$$\varepsilon(t) = \int_0^t D(t-\tau)\dot{\sigma}(\tau)d\tau\,, \tag{2}$$

where $\sigma(t)$ and $\varepsilon(t)$ are stress and strain functions, respectively; $E(t)$ and $D(t)$ are relaxation modulus and creep compliance, respectively; t is time. *Eqs.* (1) and (2) indicate that the stress (or strain) at the present time t under an arbitrary strain (or stress) history follows a linear superposition of all strains (or stress) applied at previous time τ.

Applying the Laplace transform and the inversion of Laplace transform to *Eqs*. (1) and (2), we obtain

$$t = \int_0^t E(t-\tau)D(\tau)d\tau\,, \tag{3}$$

$$t = \int_0^t D(t-\tau)E(\tau)d\tau\,, \tag{4}$$

Eqs. (3) and (4) are the Volterra integral equation of first kind.

Differentiating *Eqs.* (3) and (4) with time t, we find

$$1 = E(0)D(t) + \int_0^t \frac{\partial E(t-\tau)}{\partial t} D(\tau)d\tau\,, \tag{5}$$

$$1 = D(0)E(t) + \int_0^t \frac{\partial D(t-\tau)}{\partial t} E(\tau)d\tau\,. \tag{6}$$

Eqs. (5) and (6) are Volterra integral equations of the second kind which are well-posed. For the given discrete creep data $D(t)$, we can use *Eq*. (6) to compute discrete values of $E(t)$. It can be seen from *Eq*. (6) that the derivative of $D(t)$ should first be given. As we known, it is still an ill-posed problem to determine the derivative of $D(t)$. In this paper, we use a method to compute the numerical differentiation of $D(t)$ to overcome the ill-posedness, which is under the frame of Tikhonov regularization.

Discrete values of $D(t)$ obtained from experiment, are given at a discrete set of points $0 = t_1 < t_2 < \cdots < t_n$. We can approximate $D(t)$ by a cubic spline function $D_*(t)$ defined as follows (Wang et al. 2002):

(1) $D_*(t_i+) = D_*(t_i-)$, $D_*'(t_i+) = D_*'(t_i-)$, $D_*''(t_i+) = D_*''(t_i-)$;

where $D_*(t_i \pm)$ denotes the right and left limit of $D_*(t)$ at point t_i, $i = 2,3,\cdots,n-1$.

(2) $D_*''(t_1) = D_*''(t_n) = 0$;

(3) at point t_i, $i = 2,3,\cdots,n-1$, the third order derivative of $D_*(t)$ satisfies

$$D_*'''(t_i+) - D_*'''(t_i-) = \frac{1}{\alpha}\frac{t_{i+1} - t_{i-1}}{2}(D(t_i) - D_*(t_i)), \tag{7}$$

where α is the regularization parameter.

The above method is effective and well-posed in the numerical differential of general function, especially discontinuous function. For keeping the numerical integral method simple and stable, the compound trapezoidal formula of Newton-Cotes methods for integration *Eq*. (6) is used in this paper, namely

$$1 = D(0)E(t_i) + \frac{1}{2}(t_2 - t_1)\frac{\partial D(t_i - t_1)}{\partial t}E(t_1) + \frac{1}{2}\sum_{j=2}^{i-1}(t_{j+1} - t_{j-1})\frac{\partial D(t_i - t_j)}{\partial t}E(t_j) + \frac{1}{2}(t_i - t_{i-1})\frac{\partial D(t_i - t_i)}{\partial t}E(t_i). \tag{8}$$

LABORTORY CREEP TESTS AND RELAXATION MODULUS OF ASPHALT MIXTURES

Static creep is the simplest response of viscoelstic behavior and it is easy to be carried out in the laboratory. Static compressive creep tests are conducted to obtain material parameters of a linear viscoelastic constitutive model. The tests are generally implemented under static loading and isothermal conditions, and creep deflection is measured by linear variable differential transformer (LVDT).

The asphalt mixtures used in this study are a 13*mm* AC surface mixture. The coarse aggregates of mixtures were crushed limestone and the SBS polymer-modified asphalt cement was used as the asphalt binder. The stress level was 0.1 MPa, and three test temperatures were used: 0℃, 20℃ and 30℃. The data of creep compliance and calculated relaxation modulus at 20℃ are shown in Figure 1. As quasi-elastic method is usually used to provide an approximation for the

characteristic of asphalt mixtures, the result of $E(t)$ compared with $1/D(t)$ is shown in Figure 2. It is found that the quasi-elastic method cannot exactly describe the entire time-history behavior of asphalt mixtures, especially for long times.

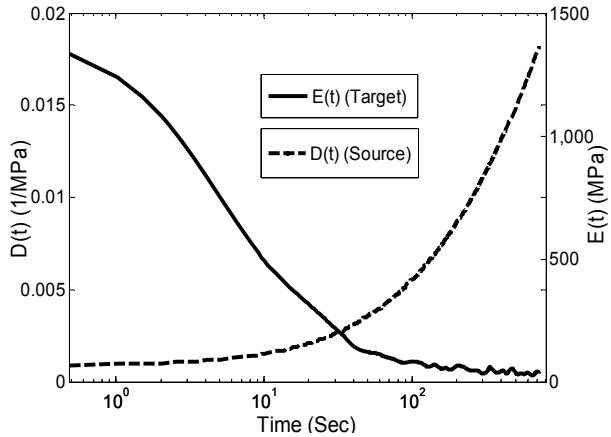

Figure 1. Creep Compliance *D(t)* and Calculated *E(t)*

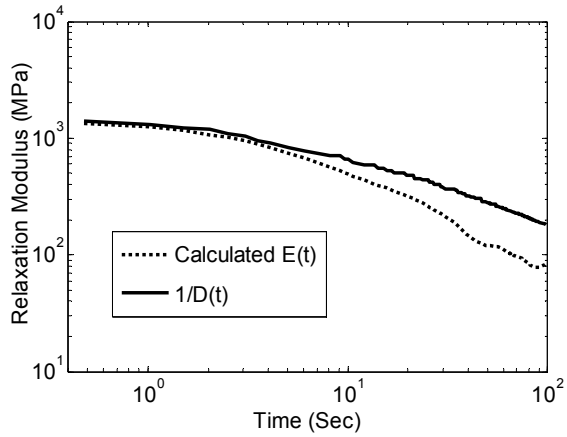

Figure 2. Calculated *E(t)* Compared With Reciprocal of *D(t)*

To formulate the physical model of relaxation modulus, the generalized Maxwell model is widely employed to express the viscoelastic characteristics of asphalt concrete. The model consists of n Maxwell elements connected in parallel and the relaxation modulus is given by a Prony series,

$$E(t) = E_n + \sum_{i=1}^{n-1} E_i e^{-E_i t/\eta_i} \qquad \text{and} \qquad \rho_i = \frac{\eta_i}{E_i} \tag{9}$$

where E_n, E_i, η_i and ρ_i are equilibrium modulus, spring modulus, dashpot viscosity and relaxation time, respectively.

The parameters of Prony series can be determined by solving a system of linear algebraic equation, such as collocation and linear least-squares methods (Park and Scharpery 1999). However, the relaxation times and sampling points are selected arbitrarily, the spring modulus may generate negative results which have no physical meaning. The other method for determining the parameters is the solution of

constrained nonlinear least squares (Mun et al. 2007). In this study, the second method is chosen and implemented by using MATLAB software. The discrete relaxation modulus is fitted to Prony-series as shown in Figure 3.

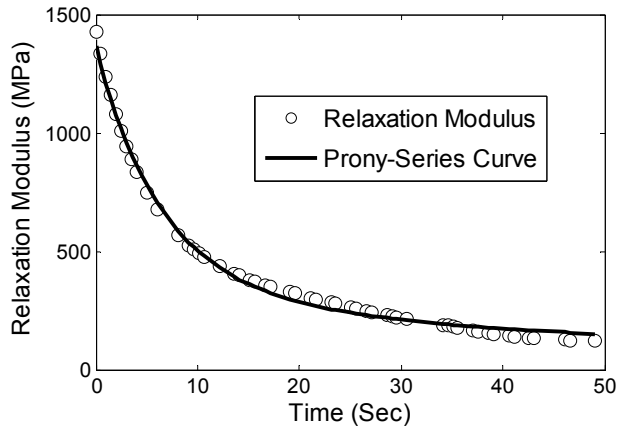

Figure 3. Prony-Series Fit to the Calculated Relaxation Spectra

VISCOELASTIC ANALYSIS OF PAVEMENT STRUCTURE

The finite-element method is well-suited for pavement analyses, especially for complex situation, such as different types of load, pressure, material nonlinearity and dynamic analysis. In this study, 3-D pavement model of dual tire is developed. To indicate the configuration of tire and pavement surface contact, the dual circular area is replaced by a rectangular area (Huang 1993), and the 3-D finite-element model is a quarter of geometric dimension by symmetrical principle.

The viscoelastic model of asphalt concrete is introduced into the finite element analysis of pavement structure. The base layer, subbase layer and subgrade layer are assumed linear elastic, the viscoelastic parameters of AC layer are given by the above sections. The nonlinear results of the analyses are summarized in Figure 4. In the figure, four different parameters are compared, namely, deflection of pavement surface, pressure strain of top subgrade, stress at bottom AC layer and tension stress at bottom base layer. It is observed that the deflection of surface pavement and pressure strain of top subgrade increase with time and temperature. Stress at bottom AC layer and tension stress at bottom base layer decrease with time, while they increase with temperature.

Figure 4. Viscoelastic Responses of Asphalt Pavement

CONCLUSION

Nonlinear analysis based on viscoelastic model for calculating mechanical response of asphalt pavement is presented in this paper. The method of acquiring relaxation spectra is effective to overcome the ill-posed nature of integral equation by equation transformation and a regularized method. The viscoelastic response of pavement suggested that all mechanical parameters were greatly sensitive to the temperature and loading time. The calculated results can be utilized to predict and validate the distress of asphalt pavement in the design and maintenance periods.

Abstract: In order to study material performance of modified unsaturated polyester Fiberglass Reinforced Plastic (FRP) pavement plate and its application in rapid crater repairing on airfield pavement, experiments were conducted to test its flexural and direct tension strengths; and the loading-vehicle was used to simulate one type of airplane to run on the repaired pavement with the FRP plate hundreds of times. It was discovered that the optimal mesh size of fiberglass in FRP plate was 120; the flexural tension strength of the plate could reach 240MPa; the direct tension strength of that could reach 200MPa; and the direct tension elastic modulus of that is larger than 15GPa. These data indicated that the toughness and the performance to resist flexural tension damage of the reinforced material were better. The results indicate that the damage to FRP plate was mainly induced at joints between the plate and subgrade. The flexural deflection not more than 5cm could be served as a standard to judge whether the repaired pavement could be used continuously.

Introduction

Assembly pavement plate, originated from World War II, was often made of armor plate with hole, aluminum plate and Fiberglass Reinforced Plastic (FRP) plate. It was often put to use as the assembly material in rapid crater repair after one airfield was attacked. It has the merit of light weight, being convenient of storage, being convenient to put together, and being able to be used directly after completion of construction. The Engineering Research & Development Center (ERDC) of USA has successfully studied the folded FRP pavement plate for practical application. This study aimed at one kind of pavement plate reinforced with modified unsaturated polyester fiberglass reinforced plastic. The experiments on material performance and simulated loading were carried out to analyze its characteristics and use demand.

1 Experiment on Material Performance

The tested pavement plate with a height of 1cm was pressed with fiberglass

having different fineness and modified unsaturated polyester.

The results of related study indicate that the carrying capacity of repaired pavement structure (Fig.1) depends on the height of backfill subgrade, compaction ratio and elastic modulus of the materials. The vertical cumulative plastic deformation of pavement structure will be induced by repeated loading of airplanes, which will cause out of joint between pavement and understructure and the flexural deformation of pavement plate. If the toughness and the tension resisting capacity of pavement are not sufficient, the fracture from below to top will happen.

According to the deformation characteristics induced by loading of assembly pavement plate, flexural modulus, flexural strength, tension modulus, tension strength and Poisson's ratio of four kinds of FRP plate with fiberglass having different fineness were tested.

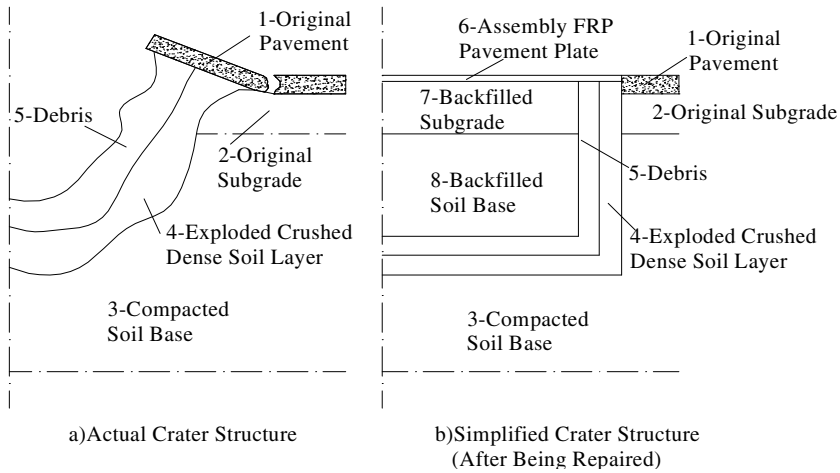

Fig.1 Airfield pavement structure before and after crater being repaired

1.1 Specimen Molding

According to Specification of Testing Method about Flexural Property of Fiber reinforced material (GB3356-1999), flexural tension specimens were fabricated with the length of 150mm, width of 12.5mm, and height of 10mm; direct tension specimens were fabricated with the length of 230mm, width of 25mm, and height of 10mm. To avoid stress concentration in the holding part for direct tension specimens, the hard aluminum sheet having the length of 50mm and width of 25mm was used as tension strengthening sheep. The hard aluminum sheet was then stuck in the two terminals with omnipotent glue as the tension strengthening sheet before experiments.

1.2 Experiment Method

1.2.1 Flexural Tension Property Experiment

The flexural loading experiment was executed in the trisection point with the testing machine of MTS-810. The initial loading is 10N; loading speed is 2mm per minute. Data was collected automatically by computer to draw loading versus deflection (*P* versus *f*) curve (Fig.2).

The flexural elastic modulus E_f is:

$$E_f = \frac{\Delta P \cdot L^3}{4b \cdot h^3 \cdot \Delta f} = K_f \cdot \frac{L^3}{4b \cdot h^3} \tag{1}$$

Where, P is the loading increment in the initial straight line part of P versus f curve; f is the deflection of the midpoint in the specimen; L is the space between fulcrums on the specimen, whose value was taken as 136mm; b is the width of specimen; h is the height of specimen; K_f is the gradient in the initial straight line part of P versus f curve.

The flexural elastic strength σ_f is:

$$\sigma_f = \frac{3P_f \cdot L}{2b \cdot h^2} \tag{2}$$

Where, P_f is the maximum loading when the specimen was broken in the flexural tension experiment.

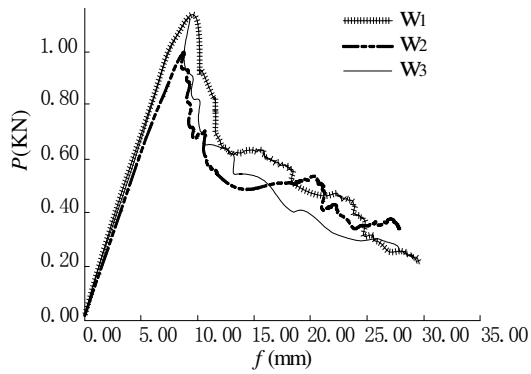

Fig.2 *P-f* curve (120 order fiberglass)

1.2.2. Direct Tension Property Experiment

To accurately obtain the values of direct tension modulus E_t and Poison's ratio μ, two strain gages were separately stuck in the middle of the specimen along the axial direction and transverse direction. The strains in these directions were ε_{z1} and ε_{h1}. To eliminate eccentricity influence, two other strain gages were also stuck on the reverse side of the specimens. The two strains were ε_{z2} and ε_{h2}. The specimen was clipped by a clamp of the tension testing machine in the experiment. The loading is 0.5KN per level. The strain reading was recorded to draw the curve of σ versus ε_z, and ε_h versus ε_z curves (such as Fig.3 and Fig.4).

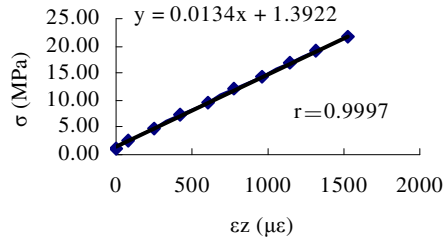

Fig.3 σ-ε_z curve (120 order fiberglass)

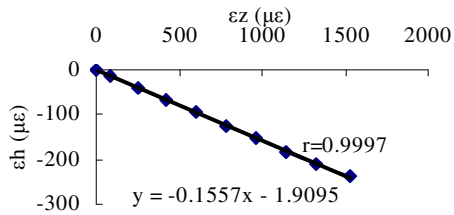

Fig.4 ε_h-ε_z curve (120 order fiberglass)

The direct tension modulus is:

$$E_t = \frac{\Delta P}{b \cdot h \Delta \ \varepsilon_z} \tag{3}$$

In equation (3), $\Delta\varepsilon_z$ is the strain increment in axial direction.

The Poisson's ratio is:

$$\mu = -\frac{\varepsilon_h}{\varepsilon_z} \tag{4}$$

where, $\varepsilon_h = \frac{(\varepsilon_{h1} + \varepsilon_{h2})}{2}$, $\varepsilon_z = \frac{(\varepsilon_{z1} + \varepsilon_{z2})}{2}$。

The direct tension strength is

$$\sigma_t = \frac{P_b}{b \cdot h} \tag{5}$$

In equation (5), P_b is the maximum loading when the specimen was broken in the direct tension experiment.

1.3 Analysis on Experiment Results

1. The maximum value of flexural tension strength and flexural tension modulus are from the fiberglass pavement plate with the fineness of 120 order. The values were respectively 244.06MPa and 13284.63MPa. The results indicate that the flexural property of FRP pavement plate was affected by the fineness of fiberglass and the optimum fineness request of fiberglass existed.

2. The direct tension property of FRP pavement plate with the fineness of 120 order was better (201.59MPa, 15.73MPa) in the experiment.

3. The results of flexural tension experiments and direct tension experiments can be used in the data computing and analysis. The result of finite element simulating indicates FRP pavement was mainly affected by flexural tension stress on the bottom between the loading points and direct tension stress between during the loading circle induced by airplane. The computed stress value was about 20MPa to 30MPa, which were far below the actually obtained flexural and tension strengths.

4. The actually obtained flexural and tension property of FRP pavement plate was better than the similar materials used abroad.

Tab.1 Experiment Results of Material Property of FRP pavement plate

Serial Number	Fineness of Fiberglass (order)	Flexural Tension Strength $_f$（MPa）	Flexural Tension Modulus E_f（MPa）	Direct Tension Strength $_t$（MPa）	Direct Tension Modulus Et（GPa）	Possion Ratio μ
1	80	212.61	9258.16	160.40	10.97	0.17
2	120	244.06	13284.63	201.59	15.73	0.16
3	150	203.80	11624.07	197.84	13.53	0.15
4	200	210.79	10772.96	180.34	16.53	0.14

Tab.2 Proper Index of FRP Pavement Plate Abroad

Serial Number	Name of Index	Value of Index
1	Flexural Tension Strength(MPa)	198.55
2	Direct Tension Strength(MPa)	117.2
3	Direct Tension Modulus(GPa)	10.34

2 Simulating Experiment

Using the original cement concrete pavement with a thickness of 30cm, the simulated crater with the diameter 4m and the maximum depth 1.4m was dug. Subgrade was backfilled with the disintegrated slag in excavation to the distance of 70cm from pavement surface and not compacted. Graded gravel was backfilled on the disintegrated slag layer, whose maximum particle size is 40mm and virtual pavement depth is 5cm. The graded gravel layer was compacted 8 times with 8 ton compactor and then leveled manually. Because the compactor is too light, the compact ratio can not reach the desired level. The case machine was used to compact for second round. Finally the surface was leveled with a plate vibratory compactor. Cement mixing chip was paved on the graded gravel lever and the FRP pavement plate with the fiber of 120 order was placed on it.

The loading experiments were executed with a special loading simulating the moving airplane tire, whose pressure is 1.8MPa and the single tire load is 1500kg, to simulate the passing of airplane on the pavement. The passing speed is controlled between 5 to 10km/h. Because the subgrade of repaired pavement structure is flexible , the plastic deformation can be observed after only some passing times. The out of joint of FRP plate is very obvious but it is not removed. After 160 passing

times, the FRP plate was removed, the maximum deformation of the subgrade can be observed as 5.2cm. The subgrade was not damaged, and the FRP plate was paved again. After 244 passing times, the deformation of the subgrade can be observed as 6 cm, and the area around the tested points had upheaval. The rutting was then backfilled with the chip of maximum size 10mm, and compacted by a plate ram. After compaction, the FRP was paved, continuing to pass 434 times. The FRP plate was not broken during the entire testing period. But after more than 400 passing times, the FRP plate was observed with some extent of plastic deformation. It was discovered that the damage of FRP plate was mainly induced by out of joint between plate and subgrade, or tension damage from bottom to top on the plate.

3 Conclusions

It is important and meaningful to have the rapid runway repair with the assembly pavement plate. This paper presented an analysis of the characteristics and using request of modified unsaturated polyester fiberglass reinforced plastic pavement plate. The results indicate that the toughness of FRP plate and tension resisting capacity can carry some times passing of simulated airplane loading although the plastic deformation of subgrade is big during the experiments. The experimental results are consistent with the simulation results. Considering the smoothness request of pavement, the deformation of plate not exceeding 5cm was suggested as the control standard of repaired airport pavement.

ABSTRACT

In this paper, the microscopic mechanism of rutting formation is studied by the Discrete Element Method (DEM). The particles in discontinuous asphalt mixtures are discretized into circular rigid particles by DEM, then the initial model is created in accordance with the actual pavement. The displacement vector changes of particles under loading and the process of rutting formation are presented in this paper. The asphalt pavement model has been built to simulate the material properties of asphalt pavement by the PFC2D software. At the same time, the displacement vector changes in each layer have been analyzed under loading. In addition, the mechanisms of permanent deformation have been studied and the rutting formation process of asphalt pavement has been simulated. The results show that the Discrete Element Method used to study permanent deformation characteristics of asphalt pavement is reasonable and feasible.

KEY WORDS

Discrete Element Method (DEM) model, asphalt pavement, permanent deformation, microscopic characteristics

INTRODUCTION

The permanent deformation (i.e. rutting) of asphalt pavement is one of the most important forms of early damage in highway. Influencing factor diversity in high temperature characteristics and complexity in rutting formation are caused due to the inherent viscoelastic characteristics of asphalt mixture, and then permanent deformation has become a prevailing problem. Many countries and relevant associations began to pay attention to permanent deformation as early as in 1962. It is undeniable that permanent deformation is still one of the important study areas for mechanical properties of asphalt pavement.

In recent years, great achievements in understanding permanent deformation mechanisms have been made by asphalt pavement researchers. Novak, M. of the University of Florida studied the tire contact stresses and their effects on instability

rutting of asphalt mixture pavements based on three-dimensional finite element analysis (Novak, M. 2003). Brown, E. R. of Auburn University evaluated the rutting of the 2000 National Center for Asphalt Technology (NCAT) Test Track and compared laboratory rutting tests and field performance(Brown, E.R. 2004). Topal, A. and Sengoz, B. studied the relation between fine aggregate angularity and the resistance to rutting of hot-mix asphalt(Topal, A. 2005). Drakos, C. A. of University of Florida identified the differences between stress states under the Asphalt Pavement Analyzer (APA) loading device (hose) and stress states under radial truck tires, and interpreted rutting mechanisms(Drakos, C. A. 2006). Lee, S. J. of Clemson University studied the application of crumb rubber modifier (CRM) in asphalt mixtures to improve the properties of binder by reducing the binder's inherent temperature susceptibility and obtained a better rutting resistant hot mix asphalt (Lee, S. J. 2008).

The Particle Flow Code (PFC) software based on the Discrete Element Method can be used to study the microscopic characteristics of asphalt mixture. Discrete Element Method whose theoretical basis is Newton's second law was put forward by Cundall in 1971. The calculation method is relaxation iteration for mechanical parameters (such as force and displacement) in each step and the iteration process was iterated until the system reaches equilibrium. You Z.P. had used DEM for asphalt mixtures: Development of a Micromechanical Modeling Approach to Predict Asphalt Mixture Stiffness Using Discrete Element Method (You, Z. 2003), Discrete Element Modeling to Predict the Modulus of Asphalt Concrete Mixtures (You, Z. 2004), and Micromechanical Modeling Approach to Predict Compressive Dynamic Moduli of Asphalt Mixture Using the Distinct Element Method (You, Z. 2006). Furthermore, Rothenburg, L. studied the micromechanical model of asphalt concrete in connection with pavement rutting problems in permanent deformation of asphalt pavement (Rothenburg, L. 1992).

PARALLEL BOND MODEL OF DISCRETE ELEMENT METHOD (DEM)

Circles (two-dimension) or spheres (three-dimension) are used to represent the simulated particles in DEM. The parallel bond model which can transmit both forces and moments between particles describes the constitutive behavior of a finite-sized piece of cementious material deposited between two balls. A parallel bond is defined by the following five parameters: normal and shear stiffness, $\bar{k}^n$ and $\bar{k}^s$; normal and shear strength, $\bar{\sigma}_c$ and $\bar{\tau}_c$; and bond radius, $\bar{R}$. The total force and moment associated with the parallel bond are denoted by $\bar{F}_i$ and $\bar{M}_3$, with the convention that this force and moment represent the action of the bond on particle B of Figure 1(Itasca Consulting Group, Inc. 2004).

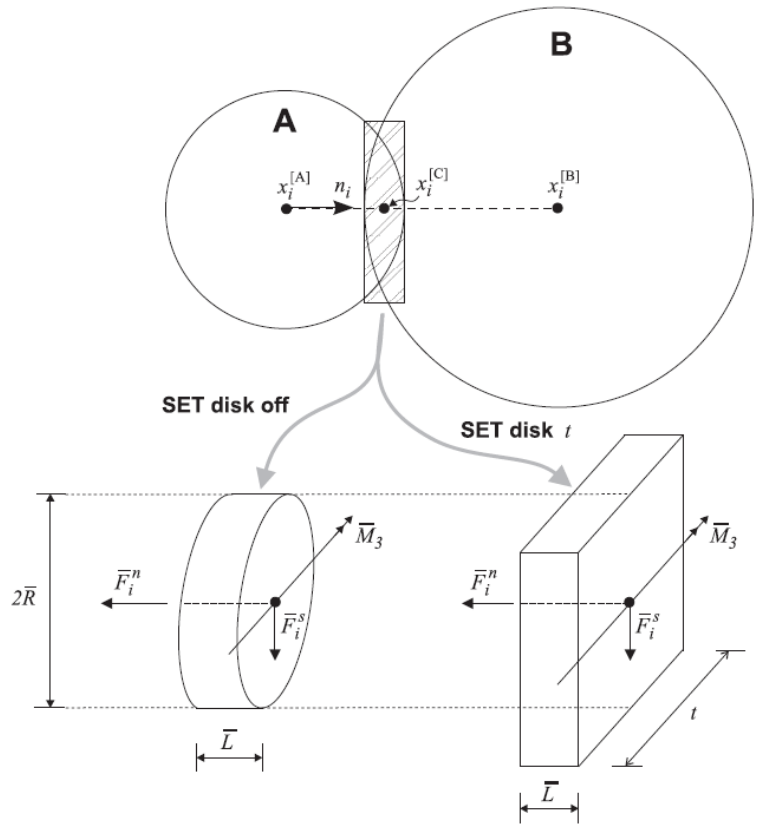

Figure 1. Parallel bond depicted as a finite-sized piece of cementious material

The force vector can be resolved into normal and shear components with respect to the contact plane as

$$\overline{F}_i = \overline{F}_i^n + \overline{F}_i^s$$

Where, $\overline{F}_i^n$ and $\overline{F}_i^s$ denote the normal and shear component vectors, respectively. The area of the bond cross-section is given by:

$$A = \begin{cases} \pi \overline{R}^2 & \text{(SET disk off)} \\ 2\overline{R}t & \text{(SET disk } t\text{)} \end{cases}$$

Where, $\overline{R}$ is the radius of the bond cross-section; SET disk off denotes that the bond cross-section is circular approximately; SET disk t denotes that the bond cross-section is rectangular approximately.

ASPHALT PAVEMENT MODEL

According to the structure of asphalt pavement, five structure layers are employed in the model (Figure 2 (a)). The voids of upper surface course is 4%, and the thickness in each structure layer is 5cm, 7cm, 8cm, 35cm and 20cm from top to bottom, respectively. Parallel bond model is employed for the 20cm asphalt concrete surface course to simulate the viscoelastic interaction between binder and aggregates; Base course thickness is 35cm using contact bond model. The reason is that

materials in this layer are mainly granular materials and the contacts between particles can be regarded as point contacts; Sub-base course thickness is 20cm using contact bond model as well.The particle contacts in this layer are also point contacts.

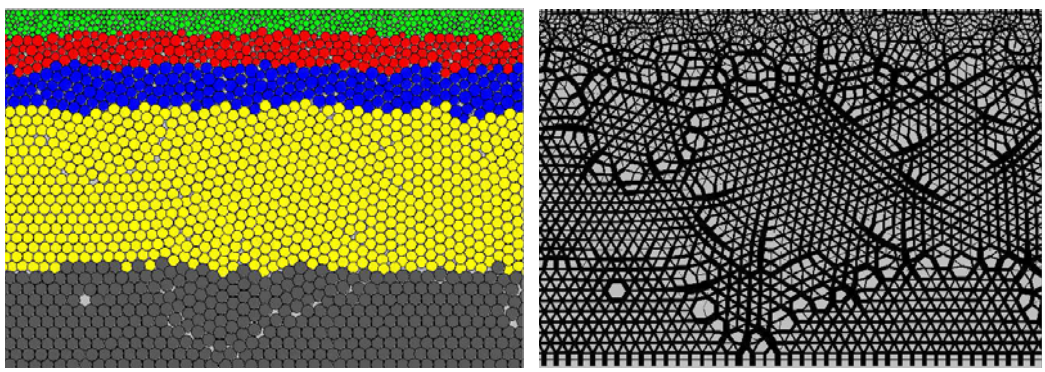
Table 1. Parallel bond model parameters of pavement materials

Parameters	Particle radius (mm)	Density (kg/m^3)	Normal stiffness (Pa/m)	Shear stiffness (Pa/m)	Normal strength (Pa)	Shear strength (Pa)
Upper surface course	2.5~5	2400	1×10^7	1×10^7	1×10^{10}	1×10^{10}
Intermediate surface course	5~8	2500	1×10^8	1×10^8	1×10^9	1×10^9
Lower surface course	7~9	2600	1×10^9	1×10^9	1×10^8	1×10^8

Table 2. Contact bond model parameters of base course and sub-base course materials

Parameters	Particle radius (mm)	Density (kg/m^3)	Normal strength (Pa)	Shear strength (Pa)
Base course	8	2300	1×10^7	1×10^7
Sub-base course	9	1800	1×10^7	1×10^7

The contact forces between particles in the model can be traced by PFC2D after generating the model meeting voids requirement, which is shown in Figure 2 (b). The types of contact forces include compression and tension, the size of lines denotes the magnitude of the contact forces, i.e. the thicker lines represent larger contact forces. The model is run by PFC2D to reach equilibrium state before applying loading to it. The range of mean contact force is from 5.899e+002N to 5.899e+002N. Consequently, the mean contact force keeps constant. The range of mean unbalanced force is from 4.580e-003N to 8.021e+002N, then the final mean unbalanced force is close to zero. The results of mean contact force and mean unbalanced force indicate that the system reaches the equilibrium state.

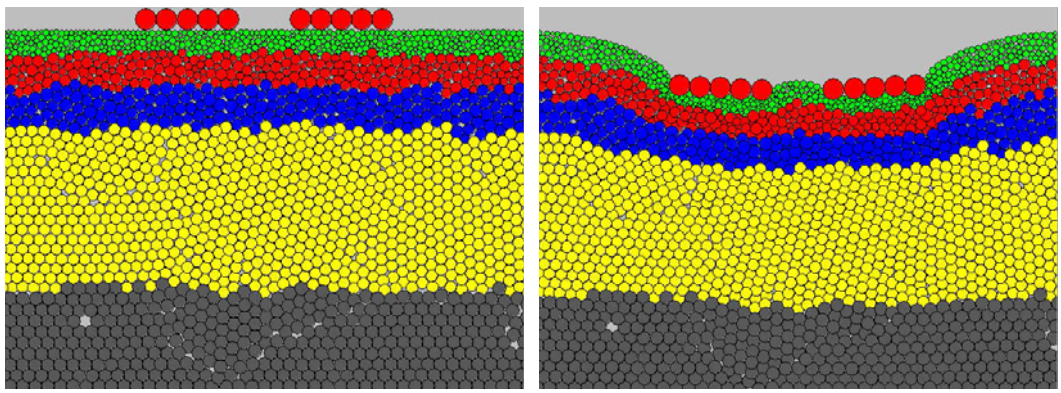


(a) Asphalt pavement model **(b) Contact force vector between particles**

Figure 2. Asphalt pavement model and contact force vector between particles

RESULT AND DISCUSSION

Five balls connected together represent one tire in loading model. The space between two tires is 10.65cm (i.e. half of the diameter of the equivalent circle) and the loading model is shown in Figure 3(a). The pavement structure produces deformation after loading. Then, the magnitude of pavement permanent deformation is obtained by tracing the vertical displacement of particles contacting between upper surface course and tires. The model after loading is shown in Figure 3 (b).



(a) Loading model **(b) The model after loading**

Figure 3. The models before and after loading

In the process of simulating rutting formation by PFC2D, particles' vertical displacements are traced at seven positions in each layer, which are external edge of left wheel mark, center of left wheel mark, internal edge of left wheel mark, middle of two wheel marks, internal edge of right wheel mark, center of right wheel mark and external edge of right wheel mark, respectively. The vertical displacement curves at seven positions in each layer are shown in Figure 4. The shape of three displacement curves of the surface course is "W" approximately, i.e. rutting depth at wheel marks is larger than that at the middle of two wheel marks, which are consistent with rutting of actual pavement. Due to the fact that rutting caused by two wheels are basically the same, the particle vertical displacements under the left wheel mark are selected to show rutting depth change in each layer (Figure 5). The figure shows that rutting depths at internal, external edges and center of left wheel mark are the same basically, and the change trend of rutting depth curves is consistent. However, the curve at the middle of two wheel marks is different from other curves. Rutting depth in initial stage is less than that at other three positions, then the second half curve tends to be consistent with other curves gradually. The reason is mainly that vehicle loadings at the middle of two tires are less than those at the wheel marks along traffic direction and the vertical displacements under loading are small. Furthermore, the vertical displacements in each structure layer decrease as the structure layer depth increase gradually, which makes the curves' change trend to be the same basically.

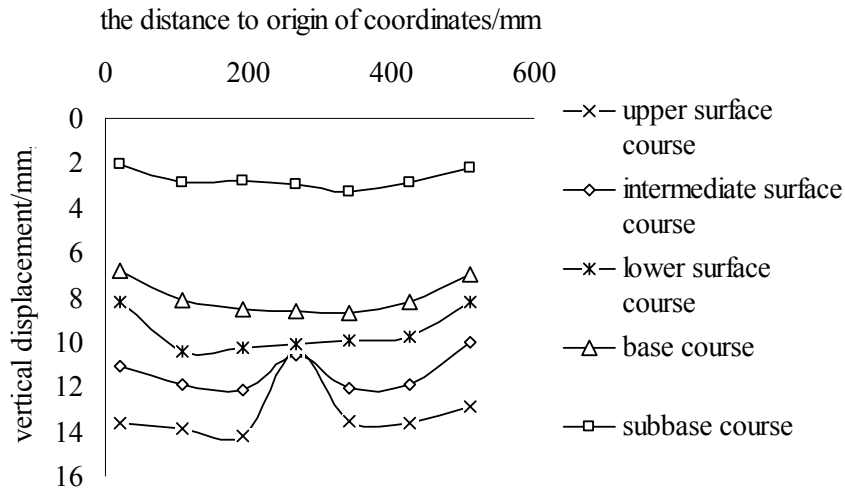


Figure 4. Vertical displacement curves at seven positions of each course

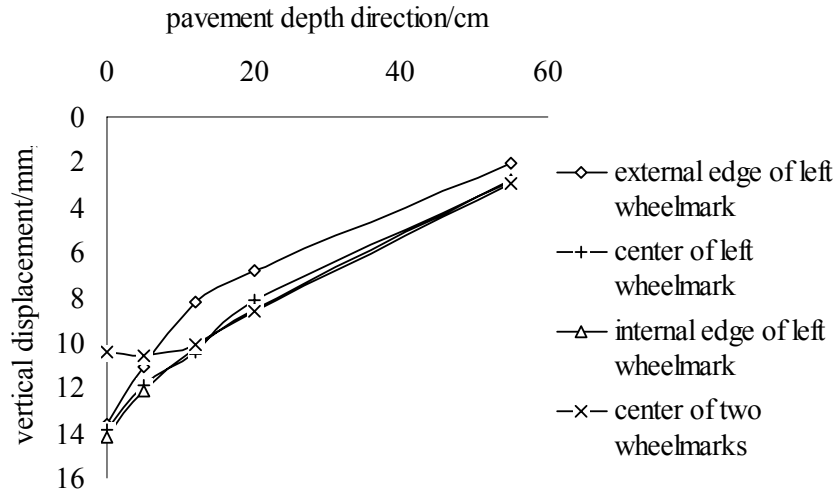

Figure 5. Displacement curves along pavement depth direction

Particles' displacement vectors of the model are described in Figure 6, and the vectors density indicates the degree of displacement change. The arrows in the figure indicate the movement direction of particles and the length of the arrows indicates the magnitude of particle displacements. The longer arrows represent larger displacements. The shape of the rutting profile is "W" approximately, which is similar to the curve shapes in Figure 4. Additionally, particles' displacement vectors contacting with tires are closest and the displacement is barely produced between particles far from tires position. Because the maximum loading is applied to particles contacting with tires, and the loading applied to particles decreases along depth direction gradually, producing smaller vertical displacement correspondingly.

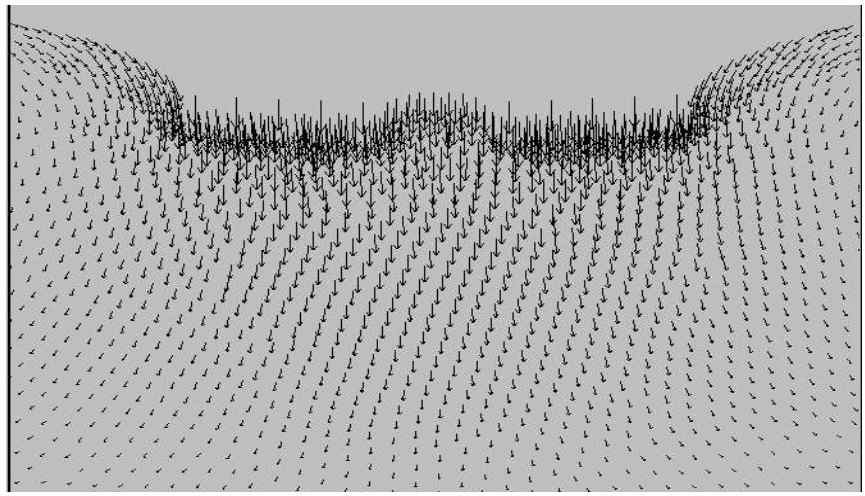

Figure 6. Particles displacement vector after loading

CONCLUSION

According to the results of the numerical simulation, the traced displacement changing curves with time steps and displacement vectors of particles contacting with tires and comparing the rutting depths of each structure layer, the conclusions are as follows:

(1) The rutting changing curves based on DEM are consistent with actual rutting results, which shows that Discrete Element Method used to study the microscopic characteristics of asphalt mixture is feasible.

(2) Figure 6 shows that particles' displacement vectors are similar to the movement of aggregate particles under repeated loading in actual pavement.

(3) The microscopic mechanical response of surface course structure established based on parallel bond under loading can be used to explain permanent deformation to a certain extent.

The above conclusions prove that simulating the structure composed of granular and binder materials by DEM is reasonable. However, the mechanical response of asphalt mixture is complicated under many factors' comprehensive action. Consequently, it is necessary to select reasonable parameters to simulate viscoelastic properties of asphalt mixture using the parallel bond model. Though the method can be employed to simulate rutting formation process, deviations still exist. On the one hand, circles representing particles in PFC2D are different from three-dimensional shapes of aggregates used in asphalt pavement. On the other hand, the model parameters are different from actual pavement parameters.

ABSTRACT

Road condition surveys show that the long and steep climbing section of asphalt pavement is one of the regions with the most significant rutting that seriously affects the road performance. And rutting is more serious for steeper longitudinal slope. In this paper, the changing rule of shear stress and its distribution characteristics in pavement are analyzed on conditions of different longitudinal slope and different horizontal attachment coefficients by a finite element method. The results show that the maximum shear stress is less subjected to the component of gravity when the longitudinal gradient changes. Due to the existence of longitudinal gradient, the changes of the adhesion between tires and road affect the shear stress significantly. The peak maximum shear stress gradually moves to the surface with increasing the horizontal force coefficient. The research results presents guides on how to prevent and control distresses for asphalt pavements on a long and steep slope. .

KEY WORDS

Long and steep climbing section, asphalt pavement, rutting, slope, adhesive coefficient, maximum shear stress

INTRODUCTION

With construction and development of freeways in mountainous areas in recent years, the “long” and “steep” slope has been inevitably faced in road design. Higher rutting resistance is demanded for asphalt pavement in mountain freeways. Road condition surveys have shown that rutting is most likely to occur in the climbing sections of mountainous freeways . The degree of rutting, particularly in the longer section of the larger and climbing slope, is far greater than that in flat sections., Therefore the road destruction of these sections starts earlier. This is the most

prevalent form of early destruction in mountain asphalt pavement. Mechanics analysis indicates that the major reason of the severe rutting is mainly due to the shear resistance of asphalt mixture that is insufficient at high temperature. Therefore it leads to shear slip. Shear stress is of great importance to control rutting.

Highway researchers are very interested in shear strength, which is an important index of pavement mechanical properties. Norman, W. M. carried out a systematic study from the shear resistance stability of pavement under static load conditions. He considered the internal force distribution in tires and the horizontal shear stress under braking and accelerating (Norman, W. M. 1951). In order to study the stress distribution in roads, Subbaraju, B. H. buried sensors into the specimens and imposed loading to test and analyze the shear stress simultaneously, and gave the specific mechanics formula(Subbaraju, B. H. 1965). Edward, S. B. gave the stress state for roads when the pavement is subjected simultaneously horizontal shear stress and vertical shear stress. He pointed out that horizontal shear stress must be taken into account in road design. Shear stress arising from road increases greatly under combined vertical and horizontal force , bringing down the road stability (Edward, S. B. 1965). In China, the corresponding studies are mainly as follows: Professor Dai, J. L. of Chang'an University developed DLG-A road material shear apparatus and studied the shear resistance properties for the material between pavement layers with the shear apparatus. Professor Sun, L. J. of Tongji University researched the shear resistance properties for asphalt mixture by uniaxial penetration test and unconfined compression test. Three-dimensional finite element analysis was used to demonstrate the feasibility of the method in his research (Sun, L. J. 2005).

The above studies show the importance of shear strength in pavement mechanics research. However, the long and steep slope sections have never been taken as a special topic. In addition, the influence of shear stress changes on pavement structure, which are caused by gradient, slope length and speed change in the process of climbing, has never been studied. In this study, finite element simulation is carried out and the influences of different gradients, horizontal force coefficients, temperature and loading on shear stress in long and steep slope pavement are analyzed.

FINITE ELEMENT MODEL FOR CLIMBING SECTIONS

Vehicle movement is mainly formed by the external transmission force that depends on the contact between tires and pavement.. When vehicles move uniformly and in a straight line on a horizontal road, it is important to overcome the rolling resistance from the ground and the air resistance. The vehicles must also overcome the gravity force component along the ramp as well in the climbing process. Additionally, it is important to overcome the acceleration resistance when the vehicles speed up (Wang, B. G. 1992). The gravity force component along the ramp and the air resistance are not considered for studying the mechanical properties of climbing sections. The driving resistance i.e. the force paralleling to the driving

direction in climbing is as follows:

$$F_R = F_f + F_i$$

Where, F_R is the driving resistance; F_f is the rolling resistance, $F_f = Gf\cos\alpha \approx Gf$;

F_i is the gravity force component along the ramp, $F_i = fG\sin\alpha \approx fG\alpha$.

In order to simulate the mechanical state of pavement in climbing sections, different horizontal loadings are applied to the tires positions in a finite element model for different longitudinal slopes and horizontal force coefficients according to the above equation.

PAVEMENT STRUCTURE MODEL AND MATERIAL PARAMETERS

Pavement material parameters. In order to reflect the mechanical properties of long and steep climbing slope, three typical pavement structures as presented in Table 1 are selected for this study (Sun, L. J. 2005):

Table 1. Three typical pavement structures and material parameters

Structure type	Jinan-Qingdao Freeway		Beijing-Tianjin-Tanggu Freeway		Capital Airport Freeway	
	Thickness /cm	Modulus /MPa	Thickness /cm	Modulus /MPa	Thickness /cm	Modulus /MPa
Upper surface course	4	1200 (350)	4	1300 (350)	4	1200 (350)
Intermediate surface course	5	1000 (500)	6	1100 (500)	6	1000 (500)
Lower surface course	6	700	8	700	13	700
Base course	34	1500	18	1500	20	1500
Subbase course	18	550	31	1500	30	550
Soil matrix	200	35	200	35	200	35

（Note: the moduli in parentheses are at high temperature）

Loading. Loading is simplified to be circular and uniform distribution loading in traditional pavement stress analysis. But this simulation approach will mutate at loading circumference, which makes theoretical values of some stress components at surface circumference approach infinity and cause singular point problems under uni-directional horizontal force, then leading to the difference between theoretical values and measured values. A large number of references indicate that the shape of the tires acting on pavement is roughly rectangular (Shen, J.N. 2001). Based on the relevant surveyed data, the rectangular loading is used in this paper whose area is 18cm * 20cm. The distance between the middle of the two tires is 30cm. The standard axle load is 100kN and pressure is 0.7MPa.

RESULT AND DISCUSSION

Influence of horizontal force coefficient on pavement structure. The changes of maximum shear stress σ_{max} and maximum shear strain ε_{max} beneath the wheel center are shown in Figure 1 and Figure 2, which include three pavement structures with horizontal force coefficients being 0.1, 0.3 and 0.5, respectively. σ_{max} and ε_{max} in the figures increase with increasing the horizontal force coefficient beneath the wheel center and the curve is nonlinear. Furthermore, σ_{max}/f and ε_{max}/f increase when the horizontal force coefficient f increases. For general pavement, there is always a certain horizontal force which is not of large influence on pavement maximum shear stress and maximum shear strain; For the long and steep slope sections, speeding up before climbing and slowing down during the course of climbing for vehicles especially the driving at low speed of overloading and heavy-load vehicles, will produce greater horizontal force coefficient which brings about significant influence on σ_{max} and ε_{max} of the pavement. Therefore, the maximum shear stress for design should be considered additionally for long and steep slope special sections (near the grade change point).

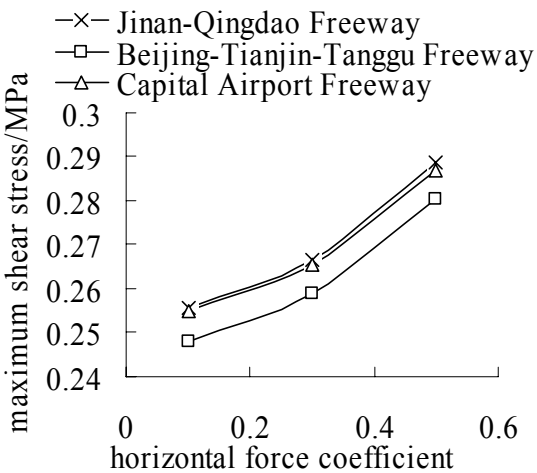

Figure 1. The relation between horizontal force coefficient and σ_{max}

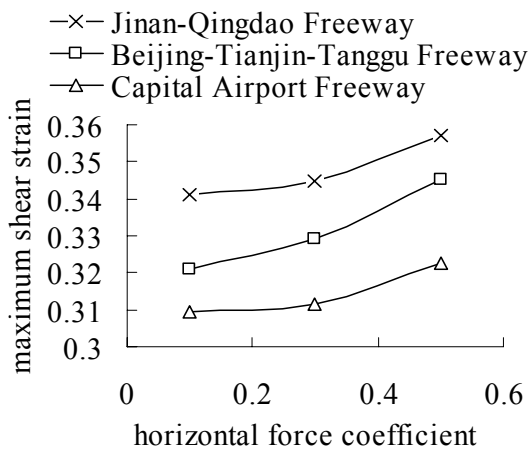

Figure 2. The relation between horizontal force coefficient and ε_{max}

Influence of road longitudinal slope on pavement structure. The influence of road longitudinal slope on pavement structure mainly lies in the force component along the ramp during the course of climbing for vehicles. Maximum shear stress and maximum shear strain below the wheel center are shown in Figure 3 and Figure 4, which include three pavement structures with longitudinal slope

gradients being 1%, 3% and 5% respectively. The relation between σ_{max}, ε_{max} and the gradient is linear in Figure 3 and Figure 4. Without considering other factors, the influence of gradient increase on pavement maximum shear stress and maximum shear strain is small. . Consequently, the influence on the mechanical properties of the integral pavement structure is small. However, when the slope increases, the vehicle speed decreases and the pavement attachment coefficient increases. Combined with the overloading and high temperature effect, it leads to more significant pavement distresses on the long and steep longitudinal slope. Gradient is a key factor for the structural design of long and steep pavement.

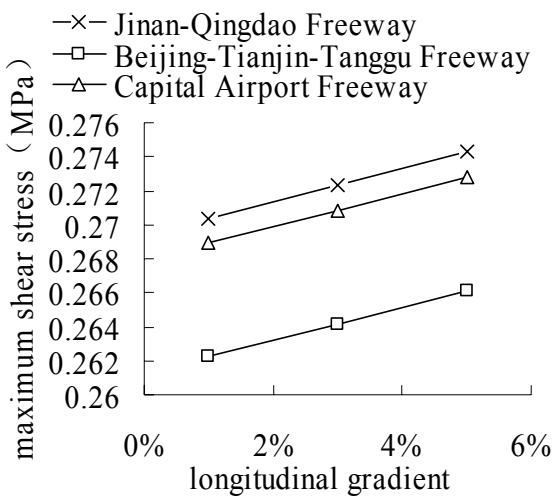

Figure 3. The relation between longitudinal gradient and σ_{max}

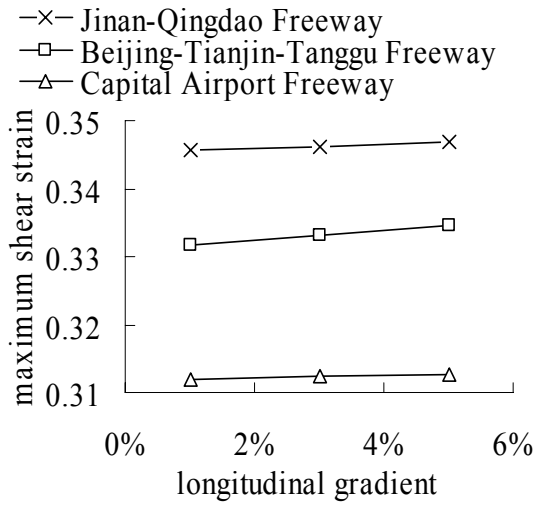

Figure 4. The relation between longitudinal gradient and ε_{max}

Influence of environmental temperature and overloading on pavement structure of long and steep slope. The stress and strain for the three pavement structures under high temperature and room temperature are calculated for the evaluation of the influence of environmental temperature and overloading. The results are shown in Table 2. At the same time, σ_{max} and ε_{max} are calculated for the three pavement structures when the overloading ratio is 30%, 60% and 90% respectively. The results are shown in Table 3. It can be seen that the influence of environmental temperature on asphalt pavement is most significant. Asphalt mixture's strength drops significantly as temperature increases because of the temperature sensitivity of asphalt mixture. The results in Table 2 show that σ_{max} increases by 10.3%, 9.18% and 9.52%, respectively, and the corresponding ε_{max} increases by 218.2%, 225.4% and 253.1% for the three pavement structures. The

shear strain increases significantly; the influence of overloading on pavement structure is also significant. Shear stress and shear strain increase with the overloading rate in the same proportion as well.

Temperature state	Jinan-Qingdao Freeway		Beijing-Tianjin-Tanggu Freeway		Capital Airport Freeway	
	σ_{max} /MPa	ε_{max}	σ_{max} /MPa	ε_{max}	σ_{max} /MPa	ε_{max}
Normal temperature	0.267	0.345	0.259	0.329	0.265	0.311
High temperature	0.295	1.097	0.282	1.070	0.291	1.099

Table 3. σ_{max} and ε_{max} for the three pavement structures under different overloading rates

Overloading rate	Jinan-Qingdao Freeway		Beijing-Tianjin-Tanggu Freeway		Capital Airport Freeway	
	σ_{max} /MPa	ε_{max}	σ_{max} /MPa	ε_{max}	σ_{max} /MPa	ε_{max}
0%	0.267	0.345	0.259	0.329	0.265	0.311
30%	0.347	0.448	0.336	0.428	0.346	0.405
60%	0.427	0.551	0.414	0.526	0.425	0.498
90%	0.507	0.655	0.492	0.625	0.504	0.592

Influence of pavement structure thickness. Three typical pavement structures including Jinan-Qingdao freeway, Beijing-Tianjin-Tanggu freeway and the Capital Airport freeway are chosen for this study. The three asphalt pavements have semi-rigid base course and the main differences are the thickness of the urface course. The specific thickness is as follows: Surface course structure of Jinan-Qingdao freeway is "4cm +5cm +6cm"; Surface course structure of Capital Airport freeway is "4cm +6cm +8cm"; Surface course structure of Beijing-Tianjin-Tanggu freeway is "4cm +6cm +13cm". The analysis indicates that the shear stress decreases as the surface course thickness increases, but the shear strain has not decreased accordingly. τ_{max} in Beijing-Tianjin-Tanggu freeway is between that in Jinan-Qingdao freeway and Capital Airport freeway under a variety of factors. ε_{max} in Beijing-Tianjin-Tanggu freeway is lower than that in the other two pavement structures; The relation between the horizontal force coefficient and maximum shear

strain in Beijing-Tianjin-Tanggu freeway is relatively weak as shown in Figure 2. Therefore, the influence of pavement thickness on the long and steep longitudinal slope is significant. Based on the analysis in this research, the pavement structure combination of "4cm +6cm +8cm" is recommended by the authors.

Discussion to key structure course. Generally speaking, the upper surface course is mainly a function course for drainage and noise reduction in pavement structure design. The intermediate surface course is mainly as structure course for bearing vehicles loading. The lower surface course is mainly for resisting fatigue bending and tensile stress (Zhang, D. L. 2003). This paper focuses on horizontal force's increase in long and steep slope pavement caused by low speed of vehicles. The maximum shear strain for the three pavement structures along the pavement depth distribution is analyzed as shown in Figure 5, Figure 6 and Figure 7. The shape of maximum shear strain with pavement depth from the figures is close to an "M". Two maximum shear strains appear at about 4cm and 10cm, which are at the interface between the upper surface course and the intermediate surface course, and between the intermediate surface course and the lower surface course. Thereby, the interfaces of each surface course should be treated specially in the long and steep slope pavement design. Furthermore, the surface deformation intensifies with the horizontal force coefficient's increase and the maximum shear strain location tends move to the surface. The distribution of $\varepsilon_{\max}$ along the pavement depth under high temperature is shown in Figure 8. It can be concluded that the maximum shear strain transfers from the interfaces between each course to the upper surface course as temperature increases . The maximum shear strain calculated in this paper under high temperature is at a distance of 3cm from the surface.

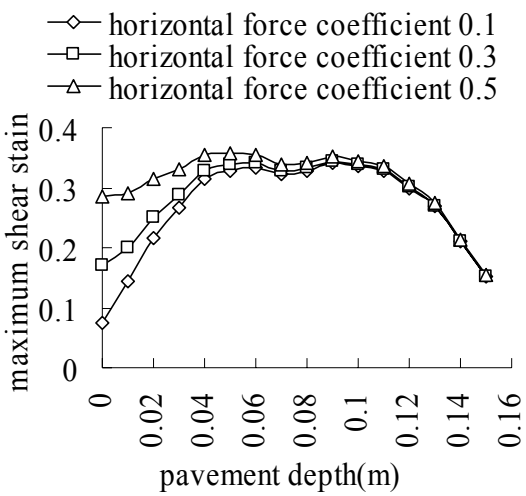

Figure 5. Distribution changes of $\varepsilon_{\max}$ in Jinan-Qingdao freeway along pavement depth

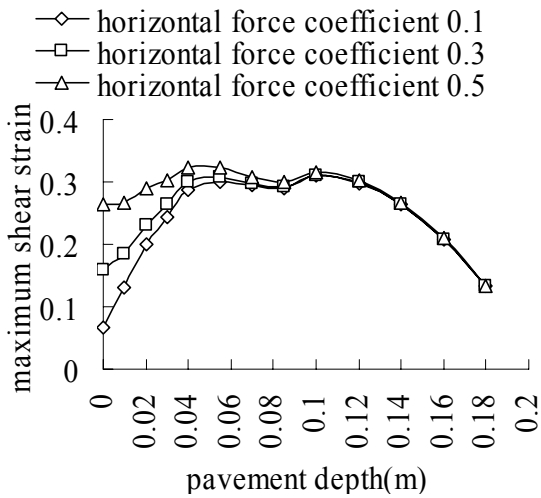

Figure 6. Distribution changes of $\varepsilon_{\max}$ in Capital Airport freeway along pavement depth

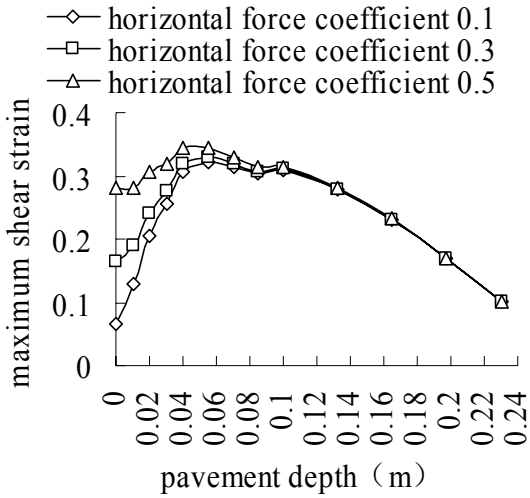

Figure 7. Distribution changes of ε_{max} in Beijing-Tianjin-Tanggu freeway along pavement depth

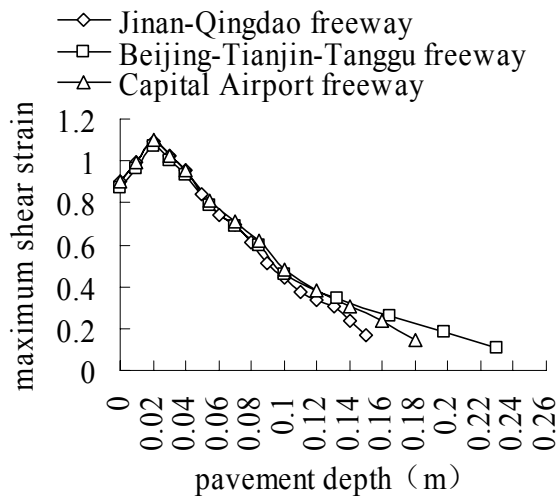

Figure 8. Distribution changes of ε_{max} under high temperature along pavement depth

CONCLUSIONS

The conclusions are as follows:

(1) The key factor of the difference between long and steep slope and flat slope is horizontal adhesive force between tires and pavement caused by longitudinal slope. The maximum shear stress of pavement increases, then the maximum shear stress of pavement and the peak shear strain locations move to the surface gradually as the horizontal adhesive coefficient increases. The maximum shear stress is less affected by gravity component on the pavement caused by longitudinal gradient changes.

(2) Considering the horizontal force, the pavement structure combination of "4cm +6cm +8cm" is recommended in this research and is more favorable for long and steep sections through calculating three different thickness combinations of surface courses.

(3) It is discovered that the maximum shear strain is at the joints of each surface course and its locations move to the surface under higher temperature in summer. Based on the calculation results in this research, the maximum shear strain is at the middle and lower part of the surface course

ABSTRACT

In order to study the safety stability of shallow tunnels under unsymmetrical pressure and traversing existing roads, a 3D numerical model of considering real surface elevation changes was established for a different construction scheme in a different range according to the Changshao neighborhood tunnel engineering on the Xi-kang Expressway. The construction process of traversing the S102 road was simulated in the entrances' range. The deformation law, the stress distribution, the deformation characteristics of middle wall and lining supporting structure, and the settlement law of existing highway surface were obtained for range of the shallow covering excavation and shallow hiding excavation. The safety evaluations on the engineering construction of traversing the existing highway were made. The analyzed results had positive effects on the successful construction of the Changshao neighborhood tunnel.

INTRODUCTION

China is a mountainous nation. The land is about 75% mountainous region or hills. The mountain area in the west is more than 90%. The medium or short tunnels and bridges adapt to the characteristics of the mountainous area and are in the highest proportion in the highway construction of mountainous regions. For example, the bridge-tunnel on the Shi-Tai speedway is 60.1% of total length; that on the Xi-Han Freeway is 76%; that on the Xi-Kang Freeway is about 68%; that on the An-Chuan Freeway is 77.8%; that on the Ya-Xi Freeway is 54.5%, etc. By strengthening the environmental awareness and improving the construction technology, double parallel mountain tunnels and small spacing tunnels increase considerably. Many scientific workers have made a lot of researching results in neighborhood tunnel design and construction technology, such as the dynamic elastic-plastic numerical simulation of construction process for the neighborhood tunnel on the Beijing-Fuzhou Expressway (Jin X, 2003), the visco-elastic-plastic finite element analysis on the stability of close

double tunnel excavation and support (Zhang Y., 1999), the three-dimensional numerical simulation of the tunnel traversing building foundation engineering (Li J.,2005), the numerical simulation study on the interaction and environmental geotechnical problems of tunnels for fold shield tunneling (Wang M.,2002), the detailing mechanical analysis on the construction process of shallow small spacing tunnels in soft rock by using the finite element method (Liu H., 2003), and so on (Qu X., 2002, Li Y., 2006). However, with the shallow tunnel with bias pressure having complex topography and geology environment, the construction conditions and the excavation methods of tunnels are usually different, and the interaction mechanism between the surrounding rock and the structure of tunnels is still not fully known and understood. Thus, the entire construction process of the tunnel entry of traversing the S102 highway is simulated by using the three-dimensional numerical method based on neighborhood tunnel engineering at Changshao. The deformation laws of rock around neighborhood tunnels and the deformation characteristics of middle wall and lining supporting structure as well as the settlement laws of highway road surface are given. Also, the security of traversing construction is evaluated, and the important reference information for neighborhood tunnel engineering is obtained.

ENGINEERING SUMMARY AND NUMERICAL MODEL

The Changshao Tunnel (18 bidding) is located at 10 km to Zhen-An county town in Shaanxi province. The entry and export segments of tunnels traverse the S102 highway. The geological plan and section of tunnels are shown in Figure 1 and Figure 2. The surrounding rock of the left and right tunnels at the entry is strong weathering phyllite with joint development and poor stability. Tunnel entrances belong to over-shallow burying tunnels. The bidding segment of the left line is LK108 + 780 ~ LK108 + 845. The construction is divided into three segments, and the lengths of each segment excavation are respectively 15 m, 30 m, and 20 m. The overlying layer in LK108 + 780 ~ LK108 + 825, burying deep in 4 m-6 m, is filling soil and loose. The construction ways all adopt covering excavation. Support uses composite lining structure. The entrance of the right line tunnel is the shallow tunnel with bias pressure, which is located in RK108 + 760 ~ RK108 + 845. The engineering segment of traversing provincial highway S102 is located in RK108 + 755.76 ~ RK108 + 806, and its burying depth is about 4 m. Also the segment RK108 + 806 ~ RK108 + 845 is a shallow bias pressure tunnel. The tunnel spacing between the left and right lines at the entrance segment is about 11.1 m. The remaining core soil method is adopted for right line excavation.

According to the geochemical condition of the Changshao Tunnel, a 3D simulating model is set up as shown in Figure 3. The upper boundary of the model is on the surface of the mountain. The elevation of the lower boundary is 446 m. The ranges of horizontal boundaries are x [200 m, 440 m], and y [150m, 390 m]. The

coordinates of starting points are respectively 303.84 m, 293.71 m, and 519 m for the left line and 283.12 m, 279.80 m, and 519 m for the right line. Those of ending points are respectively 440 m, 311.4 4 m, and 519 m for the left line and (440 m, 287.28 m, and 519 m) for the right line. The number order of construction steps is given in Figure 3. The number of mesh elements is about 43.1 million, and the computational mechanical parameters are listed in Table 1.

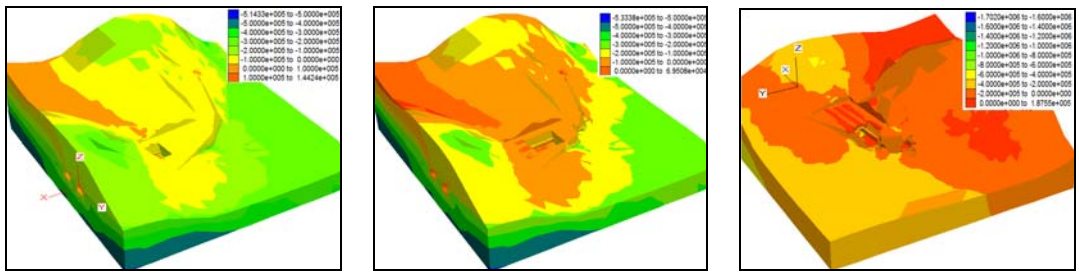
Surrounding rock of V classification	0.15	27	0.38	1.5	19.5

RESULTS OF NUMERICAL SIMULATION

According to engineering, the construction process is divided into three states. First, construct the secondary segment of the left line about 15 m; next, construct the third segment of the left line and the third segment of the right line about 30 m.

Finally, construct the fourth segment of the left line about 20 m, and construct the fourth segment of the right line about 57.6 m.

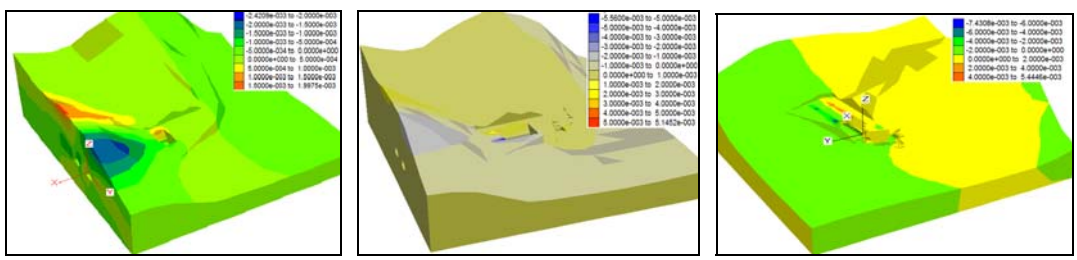
The stress distribution laws under the above three states are shown in Figure 4. From Figure 4 analysis, the maximum tensile stress under state 1 is less than 0.4 MPa; the maximum compressive stress is less than 3.0 MPa; and the surrounding rock does not have obvious bias pressure phenomenon. The maximum tensile stress under state 2 is less than 0.5 MPa; the maximum compressive stress is less than 5.0 MPa; and the surrounding rock has obvious bias pressure phenomenon. The maximum tensile stress under state 3 is less than 0.6 MPa; the maximum compressive stress is less than 5.0 MPa; and the surrounding rock has obvious bias pressure phenomenon.



(a) state 1 **(b) state 2** **(c) state 3**

Figure 4. Stress distribution under three kinds of states.

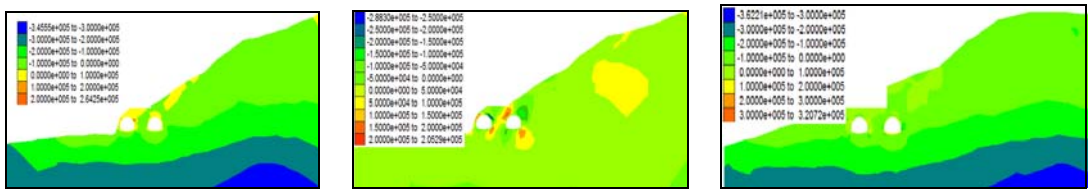
From Figure 5 analysis, the horizontal deformation caused by excavation under state 1 is symmetric in the deforming trend, and the deformation of surrounding rock at two sides of the tunnel is convergent. The deformations at the side wall of tunnels are symmetric in the area of excavating influence, and their magnitudes vary between $-1 \times 10^{-3} \sim 1 \times 10^{-3}$. The deformation under state 2 is similar to that under state 1, but the side wall deformation of the left tunnel becomes symmetrical, and two side deformation of the right tunnel is asymmetrical due to right tunnel excavation. Also, the whole tunnel including the middle wall has the moving trend toward the left tunnel. The horizontal deformation of two side rock around excavation area caused by excavation under state 3 obviously has the displacement trend along the same direction, and other deformation laws are similar to that under state 2.



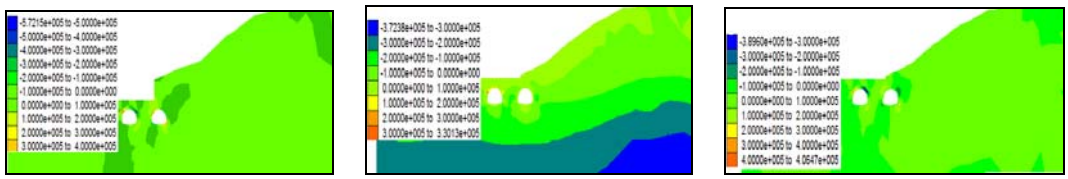
(a) state 1 **(b) state 2** **(c) state 3**

Figure 5. Horizontal deformation laws under three kinds of states.

The peripheral rock of the left and right tunnels in section 3 (LK108 + 780) is basically in tensile state along single direction from Figure 6, especially on the left side and vault of the left tunnel. The distribution laws of minimum principal stresses of peripheral rock around two tunnels are the same. There is a shear zone of maximum shear stress at the intersection between the right tunnel surface and the bias pressure mountain. In addition, the zone is through the middle wall and the right side springing of the left tunnel. The other shear zones are also formed from the left spandrel to the right springing of each tunnel, but shear stress values are all less than 1 MPa. The tensile state along single direction of the left and right tunnels in section 2 (LK108 + 806) appears only at the left and right spandrels and springing. The obvious bias pressure zone occurs at the top of the right tunnel. The middle wall also undergoes the obvious bias pressure action. The maximum shear stress in section 2 appears at the spandrels and springing of two tunnels, but the magnitudes are all less than 1 MPa. Section 1 (LK108 + 837) is located at the junction of deep and shallow burying change. The mountain bias pressure of the right side of the right tunnel is also low. The stress distribution law in the section is smoother than section 2, and bias pressure of the tunnel is relatively small. The maximum shear stress also appears at spandrels and springing.



(a) σ_1 **in section 3** **(b)** τ_{max} **in section 3** **(c)** σ_1 **in section 2**

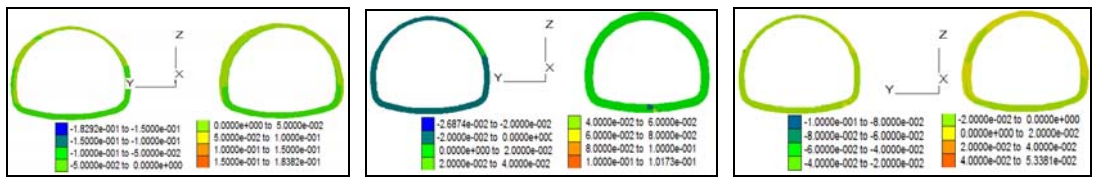


(d) τ_{max} **in section 2** **(e)** σ_1 **in section 1** **(f)** τ_{max} **in section 1**

Figure 6. Stress distributions in three typical sections.

From the analysis of Figure 7, the vault area of lining structure of the left and right tunnels in section 3 is moved toward the left side, and the maximum offset on the right is 6 ~ 8 times of that on the left. Even though the right tunnel floor areas have upward displacement, the lining deformation of the left and right tunnels is basically downward displacement, and the deformation of the right line is more than that of the left line. The two tunnel lining structures are both asymmetric. The lining

deformation on the top right side of the right and left tunnels is greater. Thus, the section of the lining structure becomes narrow and irregular deformation occurs. The lining deformation laws at section 2 and section 1 are similar to those at the section 3.



(1) section 3 (2) section 2 (3) section 1

Figure 7. Lining structure deformation in three sections.

CONCLUSION

(1) For the shallow and bias pressure tunnels, the maximal displacements appear at the deep burying area of the right tunnel and the shallow burying area of the left line, and the displacements within the middle wall are greater than the other parts around tunnels. The vertical deformation on the tunnel top in deep burying region is greater than that in shallow burying region, and that in backfilling area is greater than that in the shallow area of the right tunnel. The middle wall has a moving trend toward the left side, and that in deep burying region is obviously greater than in shallow region.

(2) During the construction, the plastic areas mainly appear in deep burying area and the middle wall, and the area magnitude is greater only in the gully region of the right tunnel. Also, the area extends to the surface so during the construction of the right line, the region should be focused.

(3) The lining structure in the tunnel entry segment is basically in a one-directional tensile stress state, but maximum tensile stress values are smaller and will not affect the stability of the lining structure. Except for the lining floor areas in the tunnel entrance region, the lining deformation is basically downward displacement. The lining deformation in shallow burying area is irregular and has a moving trend toward the left side. Therefore, the suggestion is presented that the bias pressure and shallow burying neighborhood tunnels that support and lining structure should adopt asymmetric geometric form to be more effective for the stability of tunnels.

[2]School of Highway, Chang'an University, Xi'an 710038; PH (029) 84787705; FAX (029) 84787705; email:wuxixuwei@163.com

ABSTRACT

In order to study the feasibility of new types of concrete in airfield pavement, the long-term performance of steel fiber concrete, polypropylene fiber concrete and latex concrete were evaluated by testing in parallel their flexural modulus, anti friction and anti filter performance, and their fatigue and anti freezing performance. The results show that latex concrete has low flexural module and is useful to reduce inner stress of pavement slab. However, the latex concrete has poor anti freeze performance and is therefore only applicable in non-freezing districts. Steel fiber concrete and polypropylene fiber concrete have excellent anti-fatigue and anti-freeze performance; therefore, they can improve the airfield pavement life.

INTRODUCTION

Airfield pavements differ from other types of pavements in that higher surface strength and durability are required. Dry-hard concrete was used usually in airport construction. In recent years, new kinds of concrete also come in use in architecture, hydraulic projects and road engineering. However, the application of these concrete has been little on airport due to the harsh field environment of airport and higher strength and durability requirements such as adaptability to environment, stress fatigue and surface performance. This article presents the results of the experiment evaluating the flexural tension modulus, wearing resistance, impermeability, frost resistance, and fatigue strength of plain concrete, steel fiber concrete and polypropylene concrete.

EXPERIMENT MATERIALS

The materials according to specifications were used in this experiment. The materials include Portland cement of 42.5Mpa, 20mm-40mm and 5mm-20mm crashed stone, sand of 2.9 fineness modulus, air-entraining and water-reducing additive of FSW-7 made in Xian, and the sheer-type steel fiber made in Jiangshu, China. The ratio between length and diameter is 50 for the steel fiber. Latex with the acrylate modifier of No. 2438 was adopted. Polypropylene fiber was adopted produced in Haichuan, China. The tests were conducted according to the Test Method of Cement and Concrete for Highway Engineering (JTG E30-2005).

FLEXURAL TENSION MODULUS

The flexural tension modulus of concrete was studied first. The mixing proportion of the concrete was shown in Table 1.

Table 1. Mixing proportion of concrete.

Water (kg)	Cement (kg)	Sand (kg)	Big stone (kg)	Little stone (kg)	Steel fiber (kg)	Latex (kg)	Polypropylene （g）	28days Flexural tension strength
6.57	15.5	33.67	16.7	25	0	0		4.6 MPa
6.57	15.5	33.67	16.7	25	3.18	0		5.5MPa
6.57	15.5	33.67	16.7	25	3.18	0.775		4.78MPa
6.515	15.5	33.67	16.7	25	3.18	1.55		4.37MPa
6.57	15.5	33.67	16.7	25	0	0	34	4.78MPa

Flexural tension moduli are given as follow:

Species of specimen	Polymer cement ratio	Flexural tension modulus
Plain concrete	0	3.500×10^{4} MPa
Steel fiber concrete	0	4.100×10^{4} MPa
Steel fiber latex concrete	0.25	2.797×10^{4} MPa
Steel fiber latex concrete	0.5	2.468×10^{4} MPa
Polypropylene fiber concrete	0	3.400×10^{4} MPa

According to the results of experiment, the flexural tension modulus of latex concrete decreased more significantly than the steel fiber concrete and the plain concrete. The flexural tension modulus continuously decreased with increase of latex content, which proved that the deformation resistance capability of steel fiber latex concrete was better. Flexural tension strength decrease was not obviously.

WEARING-RESISTANCE EXPERIMENTS

This part studied the wearing-resistance performance of steel fiber latex concrete, polypropylene concrete and plain concrete.

The abrasion loss of plain concrete is 1.8kg per square meter, and the abrasion loss of polypropylene concrete is 1.76kg per square meter. The average abrasion loss of steel fiber concrete is 2.45kg per square meter which is more than others. One reason for this higher loss is due to the poke-action induced by contacting between abrading wheel and steel fiber that leads to large bulks flaking off. Another reason for this is the existing of latex that could lead to the softening of concrete. The results of this experiment, therefore, do not represent the wearing-resistance; hence more reliable evaluating method was needed.

IMPERMEABILITY EXPERIMENTS

The experimental results show that there is no permeability observed when each sample was prepared at the mixing proportion of 5.0MPa. This phenomenon indicates that the impermeability performance is ideal of all the concrete above.

FROST-RESISTANCE EXPERIMENTS

Results of experiments. The mixing proportion shown in Table 1 was adopted in frost-resistance experiments. The fasten-frost method was used. The steel fiber concrete and polypropylene fiber concrete out-performed others after 300 cycles. These samples were shown in Figure.1.

Figure 1. Steel fiber concrete and polypropylene fiber concrete after the freeze-thaw test.

Analysis of results. The frost-resistance performance of concrete can be improved by adding steel fiber and polypropylene fiber. The improvement relates to the chemical ingredient of organic fiber and shape of the fiber. The latex concrete with low modulus and the good deformation resistance capability, showed worse frost-resistance performance. For the mixes using latex and steel together, the frost-resistance performance was not improved significantly.

The water consumption per unit of concrete must be controlled strictly in addition to controlling the water- cement ratio of for all tests to improve the frost-resistance of concrete. The water consumption should less than 150kg per stere.

FATIGUE EXPERIMENTS

Mixing proportion. The mixing proportion of plain concrete, steel fiber concrete and polypropylene concrete are given in Table 1.

Making method of specimen. The specimen for flexural fatigue test was made using a cubic-shaped mould with the dimension of 150mm×150mm×550mm. The specimen

of flexural fatigue experiments were divided into three groups: the plain concrete was marked as the A group, the polypropylene concrete was marked as the B group, and the steel fiber concrete was marked as the C group. The specimen was taken out from mould after 24 hours. Fatigue experiments started after 90 days of standard maintenance. The specimen was taken out from maintenance room 7 days before experiments start.

Method of fatigue experiments

(1) The quatre girder with a span of 450 mm was used in the flexural fatigue test. At least 3 specimens were tested for each mix. The flexural strength of each specimen and average flexural strength was calculated as the parameters of the fatigue tests. The results of flexural strength with static loading were shown as Table.2

Table 2. Results of average flexural tension tests using static loading.

Group	A	B	C
Flexural tension strength (MPa)	5.23	5.58	6.53

(2) The stress level of fatigue loading was defined as the ratio of actual loading stress to flexural tension strength under static loading, which are taken as 0.9, 0.85, 0.80 and 0.75.

(3) The minimum loading in fatigue experiments was used as 10 percent of maximum loading. The eigenvalue of fatigue cycle in experiment was taken as $\rho =$ 0.1.

$$\rho = P_{\min} / P_{\max} \tag{1}$$

(4) The fatigue test involves firstly a 100N load put on girder repeatedly to eliminate the error. When the machine and instrument ran normally, the fatigue experiment started. The loading used a sine wave and the frequency was 10Hz.

(5) The experimental data were analyzed statistically. The fatigue experiments result is rather disperse. The disperse data was eliminated from the regression for the fatigue equation.

Fatigue experiments result. The experiment result of concrete flexural tension strength was shown in Table 3. The experiment result shows a linearity relationship in single logarithm coordinate (see Figure 2.)

Analysis on fatigue experiments. The intercept and slope of fatigue equation of polypropylene fiber concrete and steel fiber concrete are higher than those of the plain concrete. The difference in intercept is bigger than that of the slope, which

indicates that adding of fiber not only improves the flexural fatigue performance but also decrease the stress sensitivity of concrete. The fatigue life of polypropylene fiber concrete and steel fiber concrete is longer than that of the steel fiber concrete for all stress levels. The improvement in steel fiber concrete is more than that in polypropylene fiber concrete. The reason for this is that the adding of polypropylene fiber and steel fiber not only improve the flexural tension strength but also increase the tenacity which involves partial plasticity destroying instead of the complete brittleness destroying.

Table 3. Experiment results of concrete flexural tension strength.

Number	Stress ratio	Times of fatigue experiments	Fatigue equation
A	0.90	95	$y = -0.0647\lg N_t + 1.0307$ $R = 0.9954$
	0.85	676	
	0.80	4396	
	0.75	18696	
B	0.90	364	$y = -0.0732\lg N_t + 1.0904$ $R = 0.9961$
	0.85	2326	
	0.80	8763	
	0.75	43478	
C	0.90	1415	$y = -0.0805\lg N_t + 1.1535$ $R = 0.9864$
	0.85	7244	
	0.80	18391	
	0.75	114637	

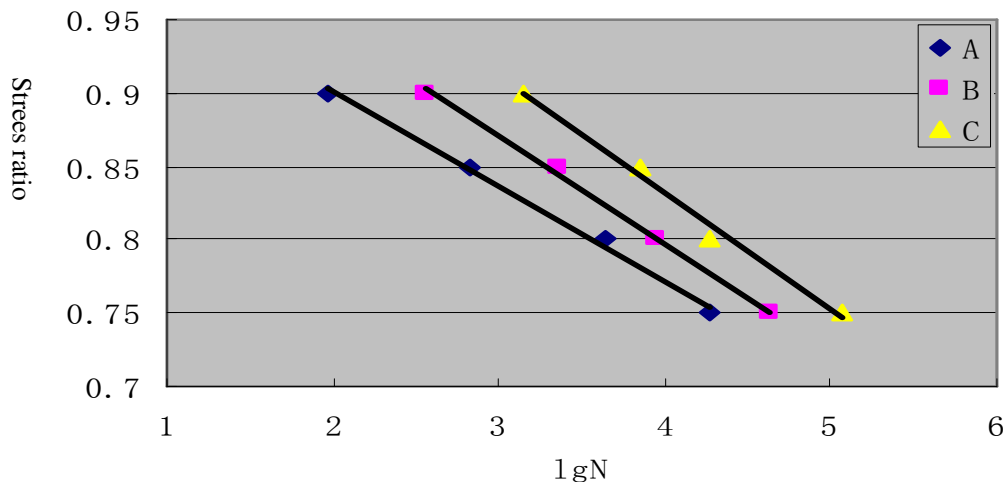

Figure 2. Fatigue logarithm curve.

CONCLUSIONS

According to experiment results, the wearing-resistance performance of polypropylene fiber concrete and steel fiber concrete is superior for airport use.

The dry-hard concrete and dry-hard steel fiber concrete are suitable for cold region use. The polypropylene fiber concrete can be used if the proper gas content can be ensured. However, the steel latex concrete, polypropylene latex content and polymer concrete is not proper for cold region use. The polymer concrete without any kinds of fiber should be forbidden for cold region use..

The fatigue life of polypropylene fiber concrete and steel fiber concrete is superior to that of the plain concrete, which shows that the fiber not only improves the flexural fatigue life of concrete but also prolongs the life of pavements.

ABSTRACT

Asphalt mixture, an important part of roadway construction, is a type of typical viscoelastic materials. Temperature, speed and time of applied load etc. have obvious effects on asphalt mixture's mechanical property. It is necessary to research the material's constitutive relationship. Especially, there is an increasing need for the use of numerical methods in road design. In this study, several basic viscoelastic theories-small strain theory, Burgers model and Generalized Maxwell model are introduced. It is worth mentioning that some methods are illustrated about how to apply experimental data to finite element software. Ultimately, the study is aimed at providing numerical simulation that attempts to increase the prediction accuracy of stress in asphaltic pavement for more reliable pavement design.

KEY WORDS: Asphalt Mixture, Constitutive Relationship, Finite Element

1. INSTRUCTION

Asphalt mixture becomes brittle at low temperatures and soft at high temperatures. This change due to temperature is called ‘‘temperature susceptibility”, which is the main reason for the distresses of the asphalt pavement (Al Hadidy, A.I. et al, 2009). The special viscoelastic material-asphalt mixture should be studied effectively before the distresses' mechanisms are predicted and the corresponding measure is developed. Some research has been done about the testing methods of the asphalt mixture. However, it is still difficult on how to obtain the viscous and elastic parameters from the testing information and to simulate the viscoelastic mixture and its mechanical property using the analysis software.

This study will focus on two aspects: 1)to introduce the asphalt mixture's viscoelasticity theory; 2)to apply the special performance to the analysis

software-ANSYS. All those are studied on the assumption that the asphalt mixture is isotropic and viscoelastic. Ultimately, the paper is aimed at providing numerical simulation to increase the prediction accuracy of stress in asphaltic pavement design.

2. SMALL STRAIN VISCOELASTICITY

A type of material is viscoelastic if its stress response consists of elastic parts and viscous parts(ANSYS, 2006; Mulungye, R.M. et al, 2007; Wang, J.Y. et al, 2008). Upon application of a load, the elastic response is instantaneous while the viscous part occurs over time. Asphalt mixture is this type of material. Generally, the stress function of the viscoelastic material is given in an integral form. Within the context of small strain theory, the constitutive equation for an isotropic viscoelastic material can be written as:

$$\sigma = \int_0^t 2G(t-\tau)\frac{de}{d\tau}d\tau + I\int_0^t K(t-\tau)\frac{d\Delta}{d\tau}d\tau \qquad (1)$$

Where σ is the Cauchy stress; e is the deviatoric part of the strain; Δ is the volumetric part of the strain; $G(t)$ is the shear relaxation kernel function; $K(t)$ is the bulk relaxation kernel function; t is the current time; τ is the past time; and I is the unit tensor. The kernel functions are assumed to satisfy a linear viscoelastic model of a generalized Maxwell model. For a majority of simulations, the kernel functions are represented in terms of Prony series, which assumes that:

$$G(t) = G_\infty + \sum_{i=1}^{n_G} G_i e^{(-\frac{t}{\tau_i^G})} \;;\; K(t) = K_\infty + \sum_{i=1}^{n_G} K_i e^{(-\frac{t}{\tau_i^K})} \;; \alpha_i^G = \frac{G_i}{G_0} \;;\; \alpha_i^K = \frac{K_i}{K_0} \qquad (2)$$

Where G_∞ and G_i are shear elastic moduli; K_∞ and K_i are bulk elastic moduli;

and G_0 and G_0 are the transient moduli.

$$G(t) = G_\infty + G_0\sum_{i=1}^{n_G}\alpha_i e^{(-\frac{t}{\tau_i})} \;;\quad K(t) = K_\infty + K_0\sum_{i=1}^{n_K}\alpha_i e^{(-\frac{t}{\tau_i})} \qquad (3)$$

Where: τ_i^G and τ_i^K are the relaxation times for each component.

3. CREEP PROPERTY OF ASPHALT MIXTURE

3.1 Constitutive model of creep property

Creep of asphalt pavement could cause rutting at high temperatures. The Burgers model can describe the deformation of the asphalt mixture effectively, especially on the course of loading by equation (4).

The change of deformation or strain of the asphalt mixture with time can be shown by creep test under dead load. The least-squares procedure is used for

establishing the viscoelastic model. Consequently the trend of the elasticity E_i and the viscosity η_i with time and temperature is brought forward.

$$\varepsilon(t)=\sigma_0\left[\frac{1}{E_1}+\frac{1}{\eta_1}t+\frac{1}{E_2}(1-e^{-\frac{E_2}{\eta_2}t})\right] \tag{4}$$

Where $\varepsilon(t)$ is the total stress; E_1 and E_2 are the elastic parameters; η_1 and η_2 are the viscous parameters; and σ_0 is the dead load. Especially, the creep stiffness modulus is the important parameter by equation (5):

$$S(t)=\frac{\sigma_0}{\varepsilon(t)}=\frac{1}{\left[\frac{1}{E_1}+\frac{1}{\eta_1}t+\frac{1}{E_2}(1-e^{-\frac{E_2}{\eta_2}t})\right]} \tag{5}$$

3.2 Application of creep model in the Finite Element

The numerical simulation has become more and more necessary now because the physical test is complicated and costly. As a result, it is very important to predict the asphalt mixture's mechanical property using modeling techniques.

In the study, the Burgers model is transferred to the Prony series(Chen, J.Y. et al, 2007). For example, equation (5) is transferred to equation (3) using the least-squares method. And a_i and t_i are obtained ultimately.

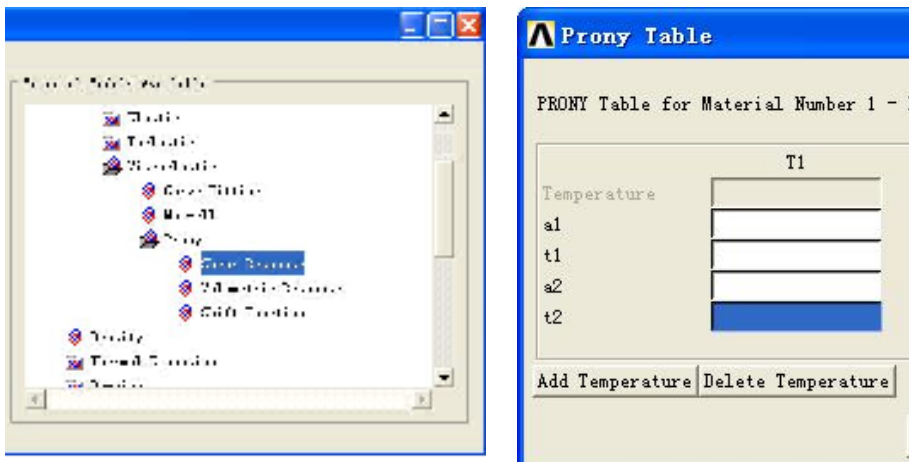

Figure 1. The inputting dialog box of the prony series

Where $\mu(t)$ is the mixture's Poisson's ratio. Figure 1 shows how to input the corresponding parameters in ANSYS about the Burger model. For the asphalt

mixture: $G_\infty = 0$. Especially, $G(t) = \dfrac{S(t)}{2(1+\mu(t))}$.

4. RELAXATION PROPERTY OF ASPHALT MIXTURE

4.1 Constitutive model of relaxation property

Asphalt mixture is easy to become relaxed at low temperatures, which will cause the cracking of asphalt pavements. However, the stress relaxation of the asphalt mixture will have to be considered when the environmental temperature is too low or the relaxation capability of the mixture is insufficient (Sheng, J.A., 2001; Liu, L.X., 2006).

The Generalized Maxwell model is used for the relaxation simulation of the mixture. When the load σ is applied, the total strain ε is the addition of the elastic strain ε_1 and the viscous strain ε_2, which is shown by equation (6):

$$\varepsilon = \varepsilon_1 + \varepsilon_2 \tag{6}$$

The Generalized Maxwell model consists of the Umpty parallel Maxwell models. The corresponding relaxation modulus is expressed by equation (7):

$$G(t) = \sum_{i=1}^{n} \frac{\sigma_i}{\varepsilon_0} = \sum_{i=1}^{n} E_i e^{-t/\tau_i} \tag{7}$$

Where $G(t)$ is the relaxation modulus; σ_i is the i th stress of the Maxwell model; $\tau_i = \rho_i$, which is the i th relaxation time of Maxwell model. The least-squares procedure is used for establishing the Generalized Maxwell model.

4.2 Application of relaxation model in the Finite Element

There are two methods which are used for inputting the Generalized Maxwell model in finite element analysis. One method that the Generalized model is transferred to the Prony series is the same as that for the Burgers model. Another method to input the Generalized model in ANSYS software directly needs 10 steps (ANSYS, 2006).

Figure 2 indicates the inputting dialog box of the 10-steps Generalized model. 95 constants (C1-C95) can be defined by Figure 2. The commonly constants to input include C46、C50、C51-C60、C61-C70. Where: C46 is the summation of all Maxwell model's E_i, $\sum_{1}^{n} E_i$; C50 is the number of Maxwell elements (10 max) used

to approximate the shear modulus relaxation; C51-60 are $E_i / C46$ of every Maxwell model element, as a result; $\sum_{1}^{n} E_i / C46 = 1$ and C61-C70 are η_i / E_i of the generalized model. However, the volume relaxation modulus is used rarely.

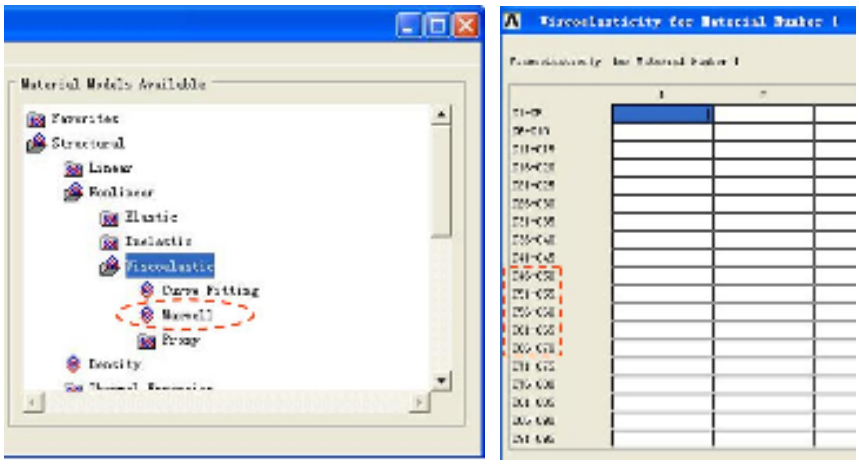

Figure 2. The inputting dialog box of the 10-steps Generalized model

5. AN EXAMPLE ABOUT THE VISCOELASTIC MATERIALS CRE EP

In the study an example is introduced about comparing the asphalt mixture's creep data to simulating model by ANSYS software. The uniaxial creep test is the common method to study the rheologic model of the asphalt mixture. The dense-graded asphalt mixture AC-13 was used in the test. The specimens were cylindrical . The height was 100mm and the diameter was 100mm too. And the universal testing machine (UTM) was used for this purpose. In the study the uniaxial dead-load compression creep test was conducted by applying a constant load equal to 0.1MPa, with a 3600-s loading. The environmental temperature was 40℃. In order to compare the experimental data to the finite element simulation result, Solid185 element with viscoelasticity, an eight-node element, and three degrees of freedom was used for modeling the above specimen. In order to model the actual creep test, the 3D model's boundary conditions are considered as the following: 1) The bottom nodes were fully constrained; 2)the 0.1MPa - load were applied at the top nodes.

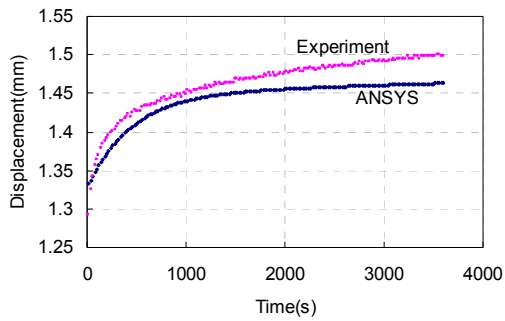

Figure 3. The creep curved drawing of asphalt mixture

Combining the foregoing theory, the corresponding parameters were shown in table

1. Figure 3 indicated that the correlation coefficient between the experiment and the finite element had achieved 94%.

Table 1. Properties of the elastic and viscoelastic material

Burgers model	Prony Series	Command stream of asphalt mixture's properties
$E_1 = 7.561$ $E_2 = 66.988$ $\eta_1 = 2036000.038$ $\eta_2 = 30113.296$ $\mu = 0.250$	$G_1 = 3.0245$ $a_1 = 0.1017$ $a_2 = 0.8983$ $\tau_1 = 403.8767$ $\tau_2 = 299706.7263$	Mp, ex, 1,7.561 !initial modulus Mp, prxy, 1, 0.25 !Poisson's ratio Tb, prony, 1,1,2,shear !Prony series Tbtemp, 45 !temperature Tbdata,,0.1017,403.8767,0.8983,2.997E5

6. CONCLUSION

[1] How to choose an appropriate model plays an important role in the viscoelastic materials' analysis. Burgers model can describe the creep of the viscoelastic material, however, the Generalized Maxwell model does the relaxation test better.

[2] More and more accurate numerical simulation has been requested by engineers for asphalt pavement designs. In the study the application of viscoelastic models in the Finite Element is introduced, which can be proved to be effective by the examples about the creep test's simulation.

Abstract: The safety of running trains on five bridges where the lateral vibration amplitudes surpass the limit values given by relative code is analyzed. The results suggest that the existing limit values of bridge lateral vibration amplitude for traffic safety are too conservative. A new method for establishing the limit value of bridge lateral vibration amplitude for traffic safety is proposed on the basis of the theory of energy random analysis for train derailment. The detailed steps of the method include the presentation of the condition for derailment prevention, the determination of the critical system of beam and pier for derailment prevention, and the calculations of the limit value of bridge lateral vibration amplitude of the system of beam and pier for traffic safety. The recommended limit value of lateral vibration amplitude for traffic safety for the 32 m-long T-shape pre-stressed concrete bridge is determined as L/4000.

Key words: limit value, derailment, traffic safety, railway bridge, vibration amplitude

1 Introduction

With the launch of the railway speed-up campaign in the China, lateral vibration amplitudes of part bridges has surpassed the limit value given by the Code for Rating Existing Railway Bridges and train speed has to be restricted under some value. While some bridges on the Jingtong line have been used for 30 years with lateral vibration amplitudes surpassing corresponding limit values, the trains have never derailed. Therefore whether the limit values given by the existing code are too conservative needs to be studied, and it is valuable to establish proper limit values with which the safety of running trains on bridges can be reflected properly.

In the Soviet Union, based on the operation criteria for the vehicle, the limit values of the basic natural period for bridges were established. The limit values of lateral vibration amplitude of typical beams for traffic safety were determined according to the control criteria of Q/P $\leqslant$0.8 (Gu, P.2000). The ordinary values of lateral vibration amplitude and lateral basic natural frequency of piers were put forward (Cao, X.Q., Wu, D.J., and Luo,W.W. 1998). The limit values of lateral

rigidity for light piers were determined according to the control criteria of Q/P ≤ 1.0(Li, Y.S.2005). There exist two fundamental problems in these methods. 1) Derailment cannot be judged well by means of the control criteria of Q/P ≤1.0(or 0.8)(Zhai,W.M. 2002). 2) The limit values of the system of beam and pier for traffic safety have not been presented. In this paper, the safety of running trains on five bridges with lateral vibration amplitudes surpassing limit values is analyzed. A new method for establishing the limit values of bridge lateral vibration amplitude for traffic safety is proposed, and the limit value of the lateral vibration amplitude of the 32 m-long T-shape pre-stressed concrete bridge for traffic safety is determined.

2 Analysis of Safety of Running Train on Bridge with Lateral Vibration Amplitudes Surpassing Limit Values

Based on the theory of energy random analysis for train derailment (Zeng, Q.Y., Xiang, J., and Luo,P. 2004), the safety of running trains on five bridges where the lateral vibration amplitudes surpasses the limit values given by existing code is calculated. The calculated results (Table 1) parallel the fact that derailment has not occurred on these bridges for many years. The results also prove that existing limit values for traffic safety are too conservative.

Table 1. Calculated results on safety of running train on five bridges

Bridge name	Train speed /(km·h^{-1})	A_{max1} /mm	A_{max2} /mm	Limit value /mm	Calculated results
Yanconggou bridge	50	8.46	8.51	3.52	No derailment
Donggou bridge	60	9.60	10.20	2.67	No derailment
Wuhu Yangze bridge	80	3.46	4.06	3.56	No derailment
Yinhe bridge	80	—	3.11	2.29	No derailment
Xinzhen Bridge	80	—	7.41	3.56	No derailment

Note: A_{max1} stands for maximal measured lateral vibration amplitude and A_{max2} stands for maximal calculated lateral vibration amplitude.

3 Method for Establishing Limit Value of Bridge Lateral Vibration Amplitude for Traffic Safety

3.1 Condition of Derailment Prevention

The theory of random energy analysis for train derailment was put forward (Zeng, Q.Y., Xiang, J., and Luo,P. 2004). The energy increment criterion for derailment evaluation is used to judge whether a train derails, which is expressed as Eqs. (1) and (2).

$\Delta\sigma_{cr} \geq \Delta\sigma_{pr}$ no derailment (1)

$\Delta\sigma_{cr} < \Delta\sigma_{pr}$ derailment (2)

Input energy increment of the train-bridge (track) system $\Delta\sigma_{pr}$ is obtained

from field measurements and the work increment done by resistant forces of the system is determined by theoretic calculation. There exists a small error in both the field measurements and the theoretic calculation. Accounting for the effect of the above error, a conservative means is adopted as follows. Assuming that the calculated value $\Delta\sigma_{cr}$ is larger than its true value by 10% and the measured value $\Delta\sigma_{pr}$ is likely to be less than its true value by 10%, the condition of derailment prevention with safety coefficient K (K=1.23) can be obtained by Eq. (3).

$$\Delta\sigma_{cr} \geq K\Delta\sigma_{pr} \tag{3}$$

3.2 Determination of critical system of beam and pier for derailment prevention

The calculation model for the spatial vibration of the train-beam-pier system is established and the safety of running trains on the system of beam and pier is calculated with the theory for train derailment. The system of beam and pier with different lateral rigidity consists of given beams and different piers with different lateral rigidity. With the height of the pier becoming larger step by step, the lateral rigidity of the pier decreases and the ability of the system of beam and pier for resisting derailment also decreases. When the lateral rigidity of piers decreases to a certain value, Eq. (3) cannot be satisfied. Eq. (3) can be satisfied with the lateral rigidity of pier used in the previous step. So the system of beam and pier used in the previous step is the critical system of beam and pier for derailment prevention.

3.3 Determination of limit value of lateral vibration amplitude for traffic safety for system of beam and pier

The smoothness and comfort of running trains on the critical system of beam and pier are calculated. If the indexes of smoothness and comfort satisfy the criteria for qualification, the critical system of beam and pier is the one with minimal lateral rigidity that can ensure the safety, smoothness, and comfort of the running train. If the indexes of smoothness and comfort cannot satisfy the criteria for qualification, the height of the piers needs to be lowered. The smoothness and comfort of running train on the new system of beam and pier are calculated sequentially, until the lateral rigidity of the pier that can ensure smoothness and comfort of the train is found. The system of beam and pier is just the one with minimal lateral rigidity that can ensure the safety, smoothness, and comfort of the running train. According to the calculated results of vibration response for the train-bridge system, the lateral vibration amplitude of the beam for the system of beam and pier with minimal lateral rigidity can be determined as limit value of bridge lateral vibration amplitude for traffic safety.

4 Limit Value of Lateral Vibration Amplitude for Traffic Safety for 32 long T-shape Prestressed Concrete Bridge

4.1 Calculation model and Calculation cases

Spot test and theoretical calculation both verify that vibration responses of the train-bridge system with the formation of full empty wagons C62 are larger than those with other train formations. Accordingly, the train with formation of full empty wagons C62 has the maximum probability of derailment (Xiang, J.,Kong F.B., and Zeng, Q.Y.2007). A train formed with 29 freight wagons C62 hauled by a locomotive DF4 is determined as the calculation model of the freight train for the analysis of the safety, smoothness, and comfort of running trains. Furthermore, a train formed with 14 passenger cars hauled by a locomotive SS8 is determined as the calculation model of passenger trains. The maximal calculation speeds for freight train and passenger train are chosen as 80 km/h and 180 km/h respectively. To reflect the lateral rigidity of multi-span simple supported bridge, a seven-span simple supported bridge (32 m-long T-shape pre-stressed concrete beam and pier with standard design No: 2019) is chosen as the bridge calculation model.

4.2 Determination of critical system of beam and pier for derailment prevention

The theory of energy random analysis for train derailment is used to calculate the safety of running trains on 32 m long T-shape pre-stressed concrete bridges. The height of the pier increases from 8.1 m to 23.1 m, 1 m for each step. Part results are listed in Table 2 and Table 3. According to the calculated results, when the height of the pier is less than 22.1 m, freight and passenger trains will not derail on the system of 32 m-long beam and pier. When the height of the pier is equal to 23.1 m and the speed of freight train is equal to 80 km/h, the condition of derailment prevention Eq. (3) cannot be satisfied. So the height of pier 22.1 m is determined as the critical pier height for the 32 m-long T-shape prestressed concrete bridge. The system of 32m-long beam and pier with height of 22.1m is the critical system of beam and pier for derailment prevention.

Table 2 Calculated results on safety of running freight train

Condition of bridge pier	*Train speed/(km·h^{-1})*	$\Delta\sigma_c/(cm\cdot s^{-2})$	$K\Delta\sigma_p/(cm\cdot s^{-2})$	*Whether Eq(3) is satisfied*
Bridge pier	80	61	45.0	Satisfaction
is not	70	36	25.7	Satisfaction
considered	60	32	20.9	Satisfaction
Height of	80	56	45.0	Satisfaction
bridge pier	70	32	25.7	Satisfaction
is 22.1m	60	28	20.9	Satisfaction
Height of	80	33	45.0	No satisfaction
bridge pier	70	30	25.7	Satisfaction
is 23.1m	60	29	20.9	Satisfaction

Table 3 Calculated results on safety of running passenger train

Condition of bridge pier	*Train speed/(km·h^{-1})*	$\Delta\sigma_c$ */(cm·s^{-2})*	$K\Delta\sigma_p$ */(cm·s^{-2})*	*Whether Eq(3) is satisfied*
Bridge pier is not considered	180	19	8.0	Satisfaction
	170	24	12.2	Satisfaction
	160	17	6.6	Satisfaction
Height of bridge pier is 23.1m	180	20	8.0	Satisfaction
	170	19	12.2	Satisfaction
	160	24	6.6	Satisfaction

4.3 Determination of limit value of lateral vibration amplitude of system of beam and pier for traffic safety

The vibration responses of the train-bridge system in normal conditions are calculated for the critical system of beam and pier for derailment prevention. The calculated results are listed in Table 4. When the speed of the freight train does not exceed 80 km/h, the Sperling index of locomotive is less than 3.45 and the Sperling index of vehicles is less than 4.25. They both satisfy the criteria for qualification of freight train. When the speed of the passenger train does not exceed 180 km/h, the Sperling index of locomotive is less than 3.45and the Sperling index of vehicles is less than 3.0. They both satisfy the criteria for qualification of freight train. Therefore, the smoothness and comfort of running trains can be ensured on the critical system of 32 m-long beam and pier for derailment prevention.

Table 4 Calculated results on smoothness and comfort of running train

Train type	*Train speed /(km·h^{-1})*	*Sperling index of locomotive*		*Sperling index of vehicle*		A_{max} */mm*
		Vertical	Lateral	Vertical	Lateral	
Freight train	80	2.96	3.37	3.89	4.22	8.04
	70	2.85	3.28	3.75	4.18	7.23
	60	2.78	3.13	3.62	4.13	5.86
Passenger train	180	3.04	3.28	2.87	2.91	3.11
	150	2.96	3.24	2.75	2.84	2.86
	120	2.87	3.15	2.66	2.70	2.73

Note: A_{max} stands for maximal calculated lateral vibration amplitude.

When the height of the pier is equal to 22.1 m, corresponding system of 32m-long beam and pier is called the system of beam and pier with minimal lateral rigidity, it can ensure the safety, smoothness, and comfort of running trains. The lateral vibration amplitude of the system of 32m-long beam and pier with minimal

lateral rigidity is equal to 8.04 mm. When bridge lateral rigidity is larger than the minimal lateral rigidity and the bridge lateral vibration amplitude is less than 8.04 mm, the safety, smoothness, and comfort of running trains can be ensured. When the bridge lateral rigidity is less than the minimal lateral rigidity and the bridge lateral vibration amplitude is larger than 8.04 mm, the safety, smoothness, and comfort of running train cannot be ensured So 8.04 mm (L/3980, L is the span length of beam, and its unit is mm) can be determined as the limit value of lateral amplitude for traffic safety of 32 m-long T-shape pre-stressed concrete bridges. Finally, L/4000 is determined as the recommended limit value of lateral amplitude for traffic safety of 32 m-long T-shape pre-stressed concrete bridges. The recommended limit value (L/4000) is larger than the limit value (L/9000) given by existing code.

5 Conclusions

1) The safety of running trains on five bridges where the lateral vibration amplitudes surpass the limit values given by relative code is analyzed. The calculated results prove that the existing limit values of bridge lateral vibration amplitude for traffic safety are too conservative.

2) A new method for establishing the limit value of bridge lateral vibration amplitude for traffic safety is proposed. The recommended limit values of lateral vibration amplitude for traffic safety of the 32 m-long T-shape pre-stressed concrete bridge on speed-raised lines are determined as L/4000.

ABSTRACT The box-girder with corrugated steel webs is a new type of steel-concrete structure in China. Corrugated steel webs are used to replace the concrete webs of the traditional box girder. In this paper, the program of ANSYS is used to build the finite element model of a curved continuous box girder with corrugated steel webs. changing tendency, the rule of distribution, and characters of shear-lag effect are analyzed by comparison with the changing radius of curvature, width-span ratio, distance of webs, eccentric load, etc… ,which can influence the shear-lag effect of curved continuous box girder with corrugated steel webs. Finally, the effective distribution width of the box girder is analyzed. It is proven that curvature radius, width span ratio, and eccentric load are important influence factors and the suggestions on diminishing the shear-lag effect in the design of curved continuous box girder with corrugated steel webs are made.

KEY WORDS corrugated steel webs, curved continuous box-girder, shear-lag effect, finite element analysis

INTRODUCTION

Corrugated steel webs are used to replace the concrete webs of box-girder. It is a new combinatorial structure using external pre-stressing force technology. The strong shear capacity of corrugated steel webs and the advantages of the high compressive strength of concrete are fully used. The internal forces in the structure are reasonable, and can be consistent with the demand of light-weight bridge structures compared to ordinary concrete box-girder bridges. In recent years, the application of corrugated steel webs to curved box-girder bridges is gaining more and more attention. For the curved continuous box-girder, considering the shear-lag effect would bring the coupling effect of bending, twisting, and shear-lag, which increases the complexity of calculation and analysis. The box girder in the longitudinal bending loads, due to shear lag-effect, will cause the width of wing plate to be reduced. There is still a lack of a reasonable calculation method for the effective distribution width of box-girders in the current bridge design specification in China.

In this paper, the calculation models of curved continuous box-girders with corrugated steel webs are built by finite element method. The shear lag-effect of curved continuous box -girders with corrugated steel webs is analyzed. Changing tendency, the rule of distribution, and characters of shear-lag effect are analyzed by comparison with changing radius of curvature, width-span ratio, distance of webs, eccentric load, cross-section type of box girder, etc…

FINITE ELEMENT MODEL

In this paper, the large-scale common program of ANSYS is used to calculate the bridge as space structures. Due to the difference of the force characteristics and thickness of members, the box-girder with corrugated steel webs uses the two different types of modules to simulate the box-girder structure. Three-dimensional solid element SOLID65 is used to build the model of the

roof and bottom plate. The thickness of webs is very thin, thus the plate elements are used to simulate. The roof, bottom plate, and corrugated steel webs of connections use sharing nodes. This article does not consider the action of external pre-stressed reinforcement; in the model, the pre-stressed reinforcement unit is not set up.

The calculation model is the three-span uniform section of the curved continuous box-girder with corrugated steel webs. There are 77937 model units, of which 14,876 are plate elements and 63,061 are three dimension solid elements, as shown in Figure 1.

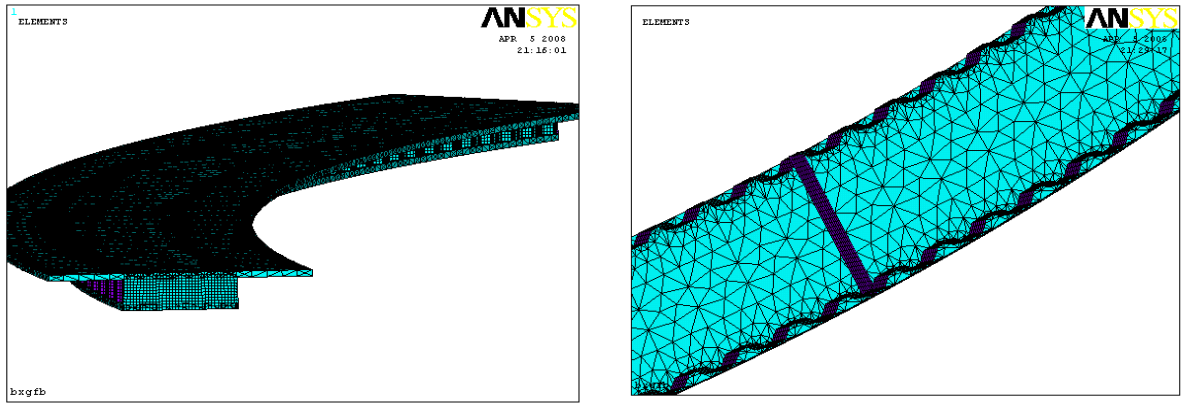

Figure.1. Finite element model of curved continuous box-girder with corrugated steel webs

In this paper, comparison is made withthe model tests of a 40m span pre-stressed simply supported box girder with corrugated steel webs on the Nanning to Baise expressway (Cheng Delin 2007); model scale ratio of 1:4 and uses the same boundary conditions of practical bridge. Compared with the finite element calculations and experimental measured values, the relative difference is less than 5%. It is proven that the finite element model can ensure the calculation accuracy of the box-girder with corrugated steel webs and the actual situation of the bridge is simulated accurately. Therefore, the finite element analysis model is correct and the calculation results are reliable.

ANALYSIS SHEAR-LAG EFFECT OF CURVED CONTINUOUS BOX GIRDER WITH CORRUGATED STEEL WEBS

1. Formula of shear-lag coefficient

Classic shear-lag coefficient is defined as:

λ＝the normal stress obtained by considering shear-lag effect / the normal stress obtained by elementary beam theory (1)

The normal stress is obtained by elementary beam theory, i.e. the average normal stress

$$\sigma_d = \frac{\int_0^b \sigma dy}{b_c} \qquad (2)$$

2. The influence of curvature radius on the shear-lag effect

The shear-lag coefficients of different curvature radius of curved continuous box-girder bridge under the load is calculated. The radius of curve R is chosen by four cases: 50m, 75m, 150m, and 300m and the calculation results are as follows:

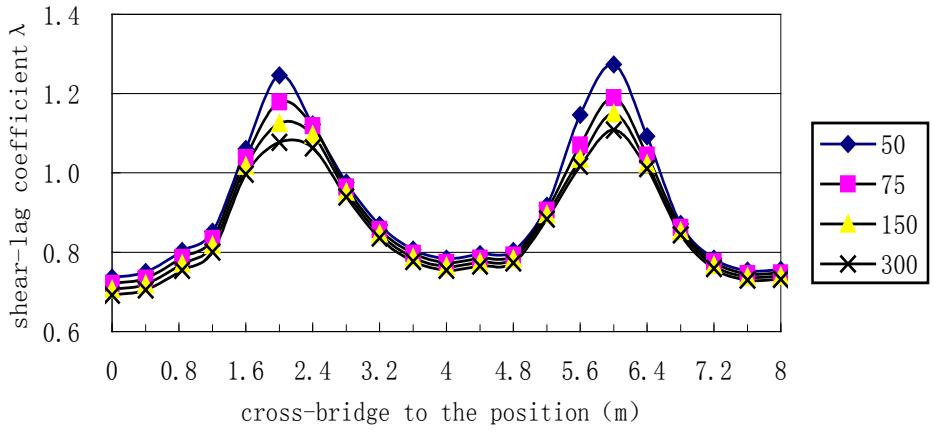

Figure. 2. The transverse distribution of the shear-lag coefficient for different curvature radius along the cross-section of box-girder

As shown in figure 2, as the curvature radius decreases, the shear-lag coefficient of the curved continuous box-girder increases. The shear-lag coefficients differs from outside to inside of the box-girder, it is larger on the outside.

3. The influence of width-span ratio of box-girder on the shear-lag effect

Set the calculation span L = 20m, and the width-span ratio of the box girder B / L as 0.1,0.2,0.3,0.4, and 0.5 with the width B of the roof slab of box girder as 2m, 4m, 6m, 8m, and 10m respectively. The bottom width changes along with the roof at a fixed rate. Under the load, the biggest shear-lag coefficients of the roofs of the box-girder along with the change of width-span ratio are computed separately.

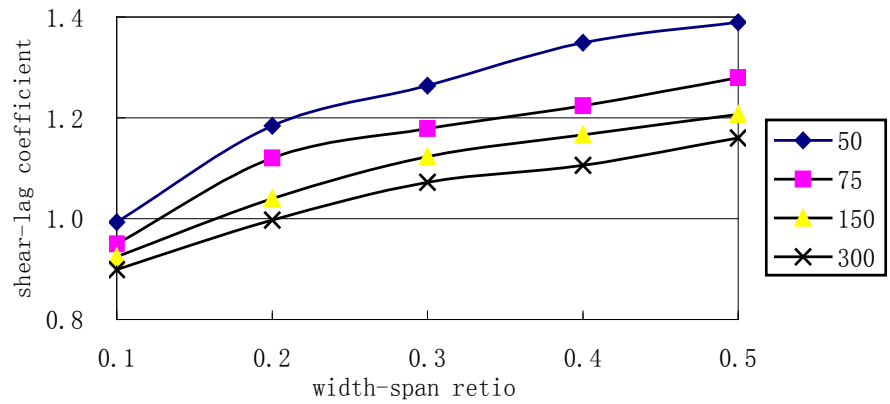

Figure.3. The transverse distribute of the shear-lag coefficient for different wide-span ratios along the cross-section of box girder

We can see from Figure 3, along with the increasing width-span ratio, the shear-lag coefficient λ increases. The curvature radius is smaller; the shear-lag coefficient λ increases quicker. If the curvature radius is 50m, when the width-span ratio B/L from 0.1 to 0.5, the shear-lag coefficient λ at the cross-section of mid-span will increase 39.9% at most.

4. The influence of spacing of box-girder webs on the shear-lag effect

With a certain width of the roof of box-girder, the method that reduces the distance between the webs to obtain the narrow bottom slab is used frequently, but the computed result show (see

Figure 4)that the too-small web spacing will cause the shear-lag coefficient of box-girder to increase.

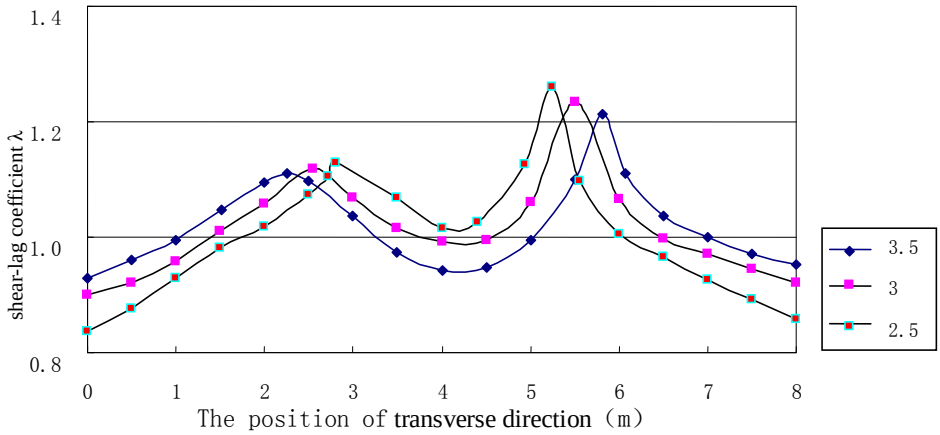

Figure.4. The transverse distribution of the shear-lag coefficient for different web spacing along the cross-section of box-girder

5. The influence of eccentric load on the shear-lag effect

As a result of the curvature existence, each section of the curved box-girder is under a combined stress condition due to the action of the bent, cut, and torque (Xu Yanqiu et al. 2003). As compared with the concrete web of box-girder, although the corrugated steel web of box-girders has many superiorities, its torsional stiffness is smaller than that of the concrete girder. At the same time, because the corrugated steel web is thin in comparison with the top and bottom concrete slab, its in-plane flexural rigidity is slight, enabling the crosswise frame function for limited the section distortion to decrease. In addition, the longitudinal rigidity of the corrugated steel web is very small. Thus, under the eccentric load, the warping normal stress produced by constraint torsion and distortion will rise to a higher level. Obviously, this could be disadvantageous to the stress condition of box-girder with corrugated steel webs.

As Figure 5 shows, the distribution of the shear-lag coefficient of box-girders with corrugated steel webs are non-uniform, extremely under the eccentric loads. The eccentric load side has a very high peak value, so certain amounts of cross diaphragms are needed to strengthen the lateral stiffness and the anti-distortion rigidity.

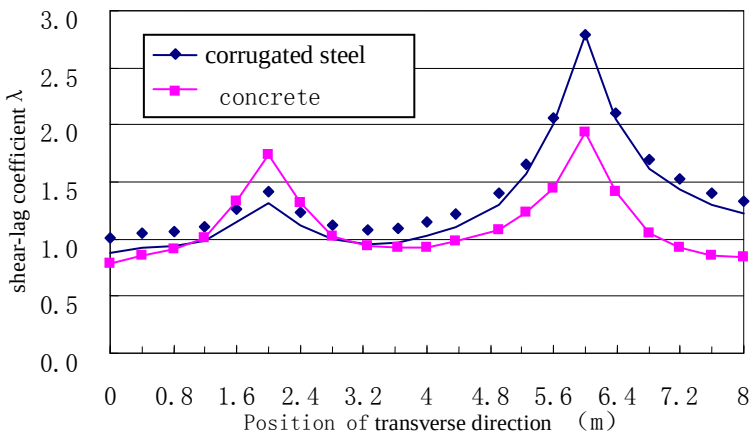

Figure.5. The transverse distribution of the shear-lag coefficient of the section of mid-span under

the eccentric loads

THE EFFECTIVE DISTRIBUTION WIDTH OF CURVED BOX-GIRDER WITH CORRUGATED STEEL WEBS

1. The formula for calculating the effective distribution width

The mathematical expression for the effective distribution width of box girder is as follows (Fan Lichu 1996):

$$b_c = \frac{\int_0^b \sigma dy}{\sigma_{\max}} \qquad (3)$$

In the formula: b_c— effective distribution width of flange, b — actual width of flange,

y— coordinate along cross-section width direction.

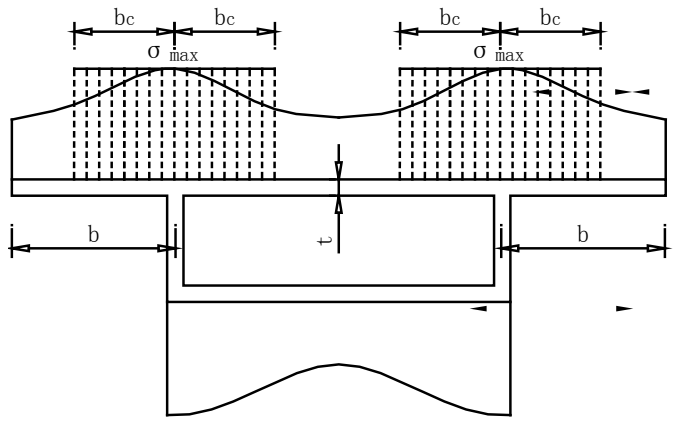

Figure.6. Effective distribution width of box-girder

The ratio of effective width to actual width is defined as the effective width coefficient. The effective width coefficient is used to weigh the effective distribution width.

2. The computation of the effective distribution width for the curve box girder

The effective distribution width of the concrete box girder and box girder with corrugated steel webs were calculated in this article. The results demonstrate that the effective width of the box girder with corrugated steel webs is smaller than the concrete box girder in the same section and the same horizontal position of the roof slab, as shown in figure 7. It illustrates that the effective width of box-girders with corrugated steel webs is narrower, which sets a higher requirement for the concrete pressive strength of box-girders with corrugated steel webs.

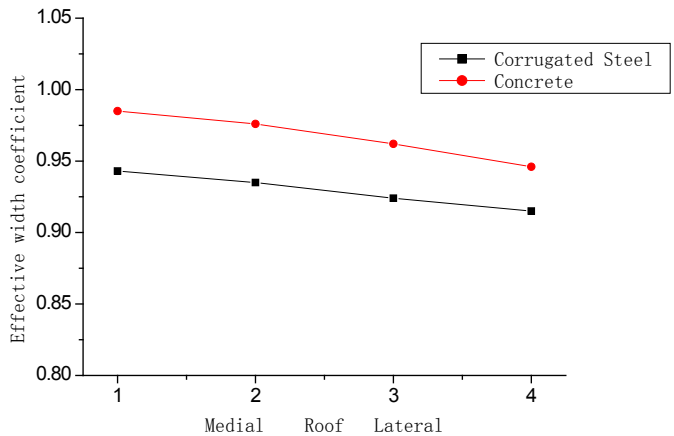

Figure.7. The effective width coefficient of the box-girders

CONCLUSION

(1) FEM analysis showed that the parameters, curvature radius, width-span ratio, and load eccentricity, etc…, would obviously influence the shear-lag effect of the curved continuous box-girder with corrugated steel webs. The curvature radius and eccentric loading are among the significant influence factors. Therefore, we should take it more seriously in engineering practice.

(2) The effective distribution width of the curved continuous box-girder with corrugated steel webs is narrower than that of the concrete box girder due to the shear-lag effect, so there are higher requirements for the concrete pressive strength for the roof slab and bottom slab of the box-girder with corrugated steel webs.

Abstract

Aimed for fire-resistant performance for reinforced concrete thin-wall box girders, the energy equation and compound boundaries conditions were created. Analyses were performed to study the time-dependent laws of deflection for reinforced concrete thin-wall box girders exposed to fire. The results indicate that the vertical-deformation ability of reinforced concrete thin-wall box girders effectively increases with the increment of concrete cover thickness. The vertical-deformation presents a nonlinear increasing trend with the increment of extending-fire time.

Subject heading

thin-wall box girders; deformation; nonlinear analysis; extending-fire time

Introduction

The reinforced concrete thin-wall box girder is a wide application. However, its structure wall is thin. Temperature inside the walls changes when high temperatures penetrate the thin wall with extension of fire time, thus fire-resistant performance is relatively weak (Zhang et al 2007). High temperature performance tests about new grade steel (Yu et al 2005), as well as concrete-filled steel tube (Han et al 2002) were performed by some famous scholars. Fire-resistant performance for columns (Lu et al 2006; Haksever et al 1981) including T-shaped cross sections (Wu et al 2007) were studied. Different fire procedures for reinforced concrete cross-sections exposed to fire (Daniel et al 2007) and test methods (Yu et al 2005) were put forward. Presented fire-resistant studies were commonly based on reinforced concrete solid members. Research on hollow, open, and thin-wall members was relatively scarce. Analysis for the deformation of reinforced concrete thin-wall box girders exposed to fire was necessary. A series of parameters, including thermal performance and material performance of steel and concrete, were presented. Some factors, including cover thickness and extending-fire time, contributing to deformation of reinforced concrete thin-wall box girders were studied.

Heat attack model

Heat conduction between concrete and crystal water (Daniel et al 2007) is considered, the energy equation can be expressed as follows:

$$Q(t)+\frac{\partial\left(k(t)\partial T(t)\right)}{\partial x^2}+\frac{\partial\left(k(t)\partial T(t)\right)}{\partial y^2}+\frac{\partial\left(k(t)\partial T(t)\right)}{\partial z^2}=\rho(t)c(t)\frac{\partial T(t)}{\partial t}+\frac{\partial L_w(t)}{\partial t} \quad (1)$$

Where $H(t)$ is the enthalpy, t is the time, $k(t)$ is the coefficient of heat conduction, $Q(t)$ is the heat quantity, $\theta(t)$ is the temperature, $\rho(t)$ is the density, $c(t)$ is the specific heat, and $L_w(t)$ is the latent heat function.

The compound boundaries conditions can be expressed as follows:

$$q=m_1\beta(T_{sur}-T_{air})^n+m_2 v\delta(\alpha e_{fire}T_{fire}^4-e_{sur}T_{sur}^4) \quad (2)$$

Where q is the heat flux, β is the heat convection coefficient, T_{sur} is the surface temperature of concrete, T_{air} is the air temperature, T_{fire} is the fire temperature, v is the radiation view factor, δ is the Stefan-Boltzmann constant, α is the absorptivity of surface, e_{fire} is the emissivity of the flame associated with fire, e_{sur} is surface emissivity of concrete, and m_1 and m_2 are partial factors.

Materials properties

According to the references (Lu et al 2006;Wu et al 2003), thermal performance of concrete, including thermal conduction and specific heat and density, is listed in Table 1.

Table 1.Thermal Performance of Concrete

Temperature	Thermal conduction	Specific heat	Density
20 ℃	1.6 W/(m·℃)	850 J/(kg·℃)	2489 kg/m^3
200 ℃	1.5 W/(m·℃)	939 J/(kg·℃)	2388 kg/m^3
400 ℃	1.3 W/(m·℃)	1038 J/(kg·℃)	2276 kg/m^3
600 ℃	1.2 W/(m·℃)	1136 J/(kg·℃)	2164 kg/m^3
800 ℃	1.0 W/(m·℃)	1235 J/(kg·℃)	2052 kg/m^3
1000 ℃	0.9 W/(m·℃)	1334 J/(kg·℃)	1940 kg/m^3

According to the references (Cai et al 2003;Lu et al 2006;Wu et al 2003), thermal performance of steel, including thermal conduction, specific heat, and density, is listed in Table 2.

Table 2.Thermal Performance of Steel

Temperature	Thermal conduction	Specific heat	Density
20 ℃	53 W/(m·℃)	612 J/(kg·℃)	7800 kg/m^3
200 ℃	50 W/(m·℃)	612 J/(kg·℃)	7800 kg/m^3
400 ℃	44 W/(m·℃)	612 J/(kg·℃)	7800 kg/m^3
600 ℃	34 W/(m·℃)	612 J/(kg·℃)	7800 kg/m^3
800 ℃	24 W/(m·℃)	612 J/(kg·℃)	7800 kg/m^3
1000 ℃	24 W/(m·℃)	612 J/(kg·℃)	7800 kg/m^3

According to the reference (Cai et al 2003), mechanics performance of concrete, including the ratio of Poisson, reduction coefficient of strength, and elastic modulus, are listed in Table 3.

Table 3.Mechanics Performance of Concrete

Temperature	Ratio of Poisson	Reduction coefficient of strength	Reduction coefficient of elastic modulus
20 ℃	0.15	1.000	1.000
200 ℃	0.15	1.000	0.700
400 ℃	0.15	1.000	0.540
600 ℃	0.15	0.584	0.370
700 ℃	0.15	0.388	0.300
800 ℃	0.15	0.192	0.280

According to the references (Cai et al 2003, Lu et al 2006), mechanics performance of concrete, including the coefficient of heat expansion, reduction coefficient of yield strength, and elastic modulus is listed in Table 4.

Tab.2 Mechanics Performance of Steel

Temperature	Coefficient of heat expansion	Reduction coefficient of yield strength	Reduction coefficient of elastic modulus
20 ℃	12.0×10^{-6}	1.000	1.000
200 ℃	13.6×10^{-6}	1.000	0.902
400 ℃	15.2×10^{-6}	0.674	0.763
600 ℃	16.8×10^{-6}	0.346	0.388
700 ℃	17.6×10^{-6}	0.182	0.200

Fire model

The standard fire curve (International Standard ISO384.1975) is expressed as follows:

$$T_{air}(t)=345\log_{10}(8t+1)+T_0 \quad (3)$$

Where T_0 is the initial temperature and $T_{air}(t)$ is the even air temperature after t minutes.

The simply supported beam exposed to ISO 834 fire is given (see Figure 1), even loads are applied on the upper plate whose value q=20kN/m^2, the span distance L=16m.

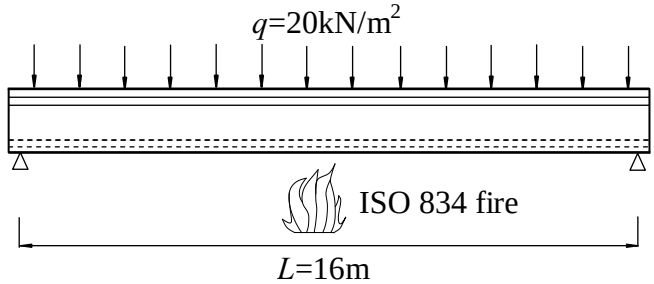

Figure 1. Model beam exposed to fire

The cross-section configurations of the simply supported beam, including section dimension and steel, are given (see in Figure 2.). The diameter of steel Φ=28mm, C represents cover thickness of concrete.

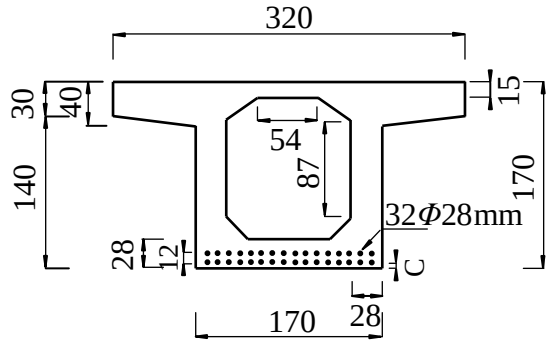

Figure 2. Cross-section configuration.(Dimension in cm)

Heat quantity is applied outside of the box section (except the upper plate) as a temperature-rise curve form of ISO 834 (see Figure 3.). The upper plate is exposed to the ambient temperature, which its value is 20℃.

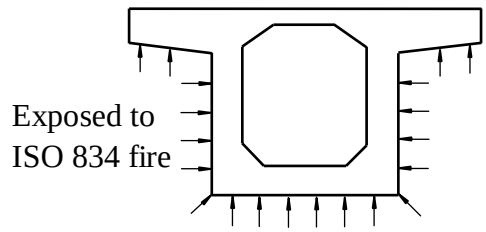

Figure 3. Fire field model for cross section

Some design parameters, including cover thickness, yield strength, and compressive strength, at room temperature for the model beam are listed in Table 5.

Table 5. Design parameters of model beam exposed to fire

Load cases	Cover thickness	Yield strength at room temperature	Compressive strength at room temperature
SSB1	3.0 cm	400 MPa	32 MPa
SSB2	4.0 cm	400 MPa	32 MPa
SSB3	5.0 cm	400 MPa	32 MPa

Case study

Time-dependent curves with deflection in the span centre for reinforced concrete thin-wall box girders with variations of cover thickness are presented (see Figure 4). Analysis results indicate: deflection hardly produces a variation within 20 minutes, deflection in the span centre modeled a type of parabola that is decreasing after 20 minutes.

As showed in Figure 4，under the condition of cover thickness equaling 3 cm，deflection in the span centre is 90 mm when the fire time is equal to 100 minutes, deflection in the span centre is 140 mm when the fire time is equal to 150 minutes, and deflection in the span centre is 220 mm when fire time is equal to 200 minutes.

Under the condition of cover thickness equaling 4cm，deflection in the span centre is 70 mm when the fire time is equal to 100 minutes, deflection in the span centre is 120 mm when the fire time is equal to 150 minutes, and deflection in the span centre is 170 mm when fire time is equal to 200 minutes.

Under the condition of cover thickness equaling 3cm，deflection in the span centre is 60 mm when the fire time is equal to 100 minutes, deflection in the span centre is 100 mm when the fire time is equal to 150 minutes, and deflection in the span centre is 150 mm when the fire time is equal to 200 minutes.

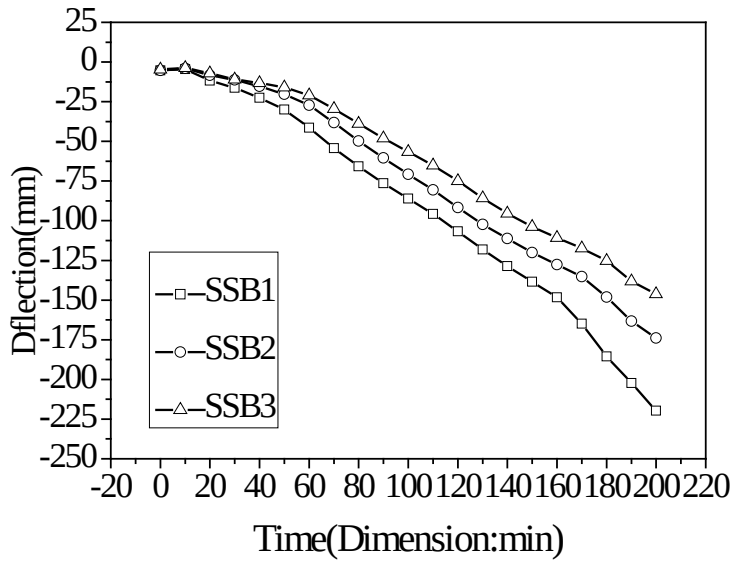

Fig.4 Time-dependent curves with variation of cover thickness

Conclusions

The concrete cover thickness and extending-fire time were considered in order to study the time-dependent laws of deflection for reinforced concrete thin-wall box girders subjected to fire. The study indicates that deflection in the span centre shows a nonlinear decreasing trend during the whole fire time. Meanwhile, variation tendency for deflection in the span centre shows a decreasing trend with the increment of cover thickness. Therefore, fire resistance can be promoted by the step of increment of concrete cover thickness.

ABSTRACT

This paper presents a new method of using ANN (Artificial Neural Networks) to control cable-stayed bridges at deferent erection stages during construction: predicting height mark deviation of main beams of cable-stayed bridges during construction given influencing factors (temperature at the moment of measurement, depth of stretched cross-section of main beams, depth of discussed cross-section of main beams, distance between the stretched cross-sections of main beams and axle wire of pylons, and distance between the discussed cross-sections of main beams and axle wire of pylons). A hybrid algorithm (G-Prop) that combines a genetic algorithm (GA) and back-propagation (BP) is used to train ANN with a single hidden layer. The case study shows that ANN based on GA and BP is a powerful instrument for predicting height mark deviation of main beams of cable-stayed bridges during construction and for construction control of cable-stayed bridges.

1 INTRODUCTION

It is a fact that control of endogen force and deformation of cable-stayed bridges at deferent erection stages during construction is very important for the cable-stayed bridges' safety and durability. But how to control them into permitted ranges is still a big challenge for bridge engineers.

Because of self-anchored cable systems, the cantilever method has been widely used for the main girder erection of cable-stayed bridges (Pao-Hsii Wang et al. 2004). The cantilever method is considered to be the natural and logical solution for constructing cable-stayed bridges of large span, where new girder segments are installed and then supported by new cable stays in each erection stage and the construction process keeps going stage-by-stage until the bridge is completed. Since no auxiliary supports are needed for constructing the bridge girder in the cantilever method, a lot of construction cost and time can be saved. There are two basic alternates to the cantilever method. One is named the single cantilever method and the other is the double cantilever method. In the former, the side span girders of the

bridge are erected on auxiliary piers and afterwards the stiffening girder in main span is erected by one-sided free cantilevering until the span centre or the anchor pier on the far end is reached. In the latter, the bridge girder is erected from both sides of the tower towards the anchor piers and the main span centre by double-sided free cantilevering (M. Virlogeux 1991).

For the cantilever method, only through adjusting the height mark of the formwork erection of every girder segment, can the shape of main girders be controlled successfully. In order to adjust the height mark of the formwork erection of every girder segment, the height mark deviation of the main beam should be predicted ahead of time.

It has been recognized that there are many influencing factors of the height mark deviation of main girders. Furthermore, the relationship between them is too complex to be represented by explicit mathematical functions. This paper presents a new method of using ANN (Artificial Neural Networks) to solve the problem: predicting the height mark deviation of the main beam given influencing factors, which aims to provide bridge engineers with an useful approach.

2 ANN BASED ON GA AND BP

2.1 Back-Propagation ANN

In this paper, a three-layer feed forward neural network, which is shown in Fig.1, is established to map the nonlinear relationship between influencing factors and the height mark deviation of the main beam. According to literature (Anbang Gu and Yongshui Zhang. 2005), the input layer of the network consists of six neurons: temperature at the moment of measurement, depth of the stretched cross-section of main beam, depth of the discussed cross-section of main beam, distance between the stretched cross-sections of main beam and axle wire of the pylon, and distance between the discussed cross-sections of main beam and axle wire of the pylon. They are the vectors $X: x_1, x_2, x_3, \cdots, x_6$ respectively. The number of neurons in the output layer is one, which corresponds to the number of outputs: the height mark deviation of main beam, which is the vector y.

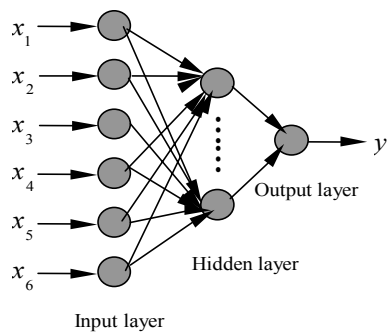

Figure 1. Architecture of back-propagation neural network.

2.2 Hybrid Algorithm Based on GA and BP

Even as BP methods are successfully used in many fields, due to its leaning ability, it does encounter certain difficulties in practice (P.A., Castillo et al. 2000): Convergence tends to be extremely slow and very dependent on the initial weights; convergence to the global optimum is not guaranteed, and learning constants and hidden layer size must be guessed heuristically or through systematic tests. Evolutionary neural networks are a more efficient way of searching, but still, they search over a subset of all possible parameters. The hybrid approach of GA and BP to train ANN makes use of the advantages of both algorithms: the ability of the GA to find a solution close to the global optimum and the ability of the BP to tune a solution and reach the nearest local minimum by means of local search from the solution found by the GA.

GA is used to modify the initial weights only, while BP is used to train from those weights. This makes a clean division between global and local search. The hidden layer size is searched for through the application of some new GA operators: substitution, addition, and elimination. These operators are developed to perform incremental (adding hidden neurons) or decremental (pruning hidden neurons) learning. For detail, refer to (P.A., Castillo et al. 2000). This paper used MATLAB to develop the calculating program.

3 APPLICATION, RESULTS AND EVALUATION

The objective of this study is to investigate the feasibility of using neural networks to predict the height mark of main girders of cable-stayed bridges during construction given the chief influencing factors. In order to use neural networks, a reliable comprehensive dataset is needed for training and testing the networks. Dataset used in this paper come from the construction process of an actual cable-stayed bridge over the Yellow River, which was completed last year. This bridge is a pre-stressed concrete cable-stayed bridge of 3 pylons and twin cable planes with spans arranged as (42 + 42 + 300 + 300 + 42 + 42) m. The cantilever method was used to construct it. The elevation view of the main span of this cable-stayed bridge is shown in Fig.2.

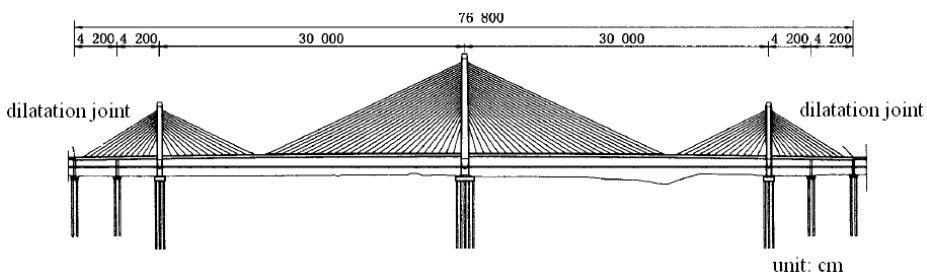

Figure 2. The elevation view of the main span.

According to the construction procedure, the patterns in the dataset were divided into two sets. The first set (obtained by measuring in the anterior construction procedures) is used for training the network. The second set (obtained by measuring in the posterior construction procedures) was used for testing the trained network. The overall procedure of this study is shown in Fig.3.

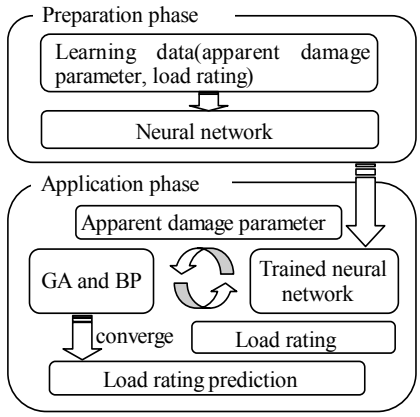

Figure 3. Load rating prediction procedure. There is a preparation phase and an application phase.

In the preparation phase, first the neural network was trained using training data. Error comparison is demonstrated in Fig. 4. Fig.4 shows that, for training data, the error between the prediction and actual values is dramatically less than the error between results obtained from the conventional computing method and actual values.

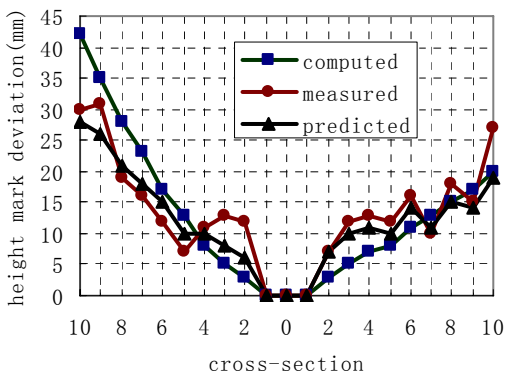

Figure 4. Comparison of relative error for training data.

In the application phase, after the neural network was trained using the training data, it was applied to test data. Error comparison is demonstrated in Fig. 5. Fig.5 shows that, for testing data, the error between the prediction and actual values is also dramatically less than the error between results obtained from the conventional computing method and actual values.

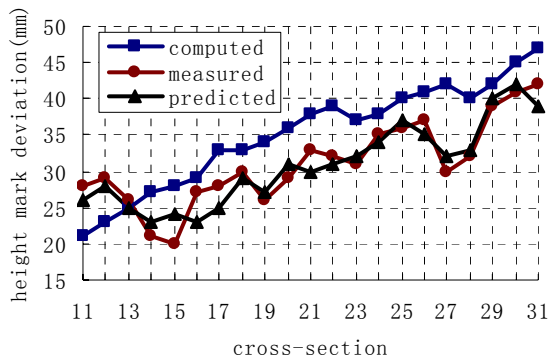

Figure 5.Comparison of relative error for testing data.

The real power of the network is demonstrated in Fig.4 and Fig.5, which show very good agreement between the predicted and actual values for both the training and testing data. The ANN trained by the hybrid algorithm of GA and BP obtains a much higher degree of generalization and can be used in practice.

4 CONCLUSION

In this study a neural network was designed and trained for predicting the height mark deviation of the main girder of cable-stayed bridges. This neural network had been used to control the construction of an actual cable-stayed bridge over the Yellow River. The cable-stayed bridge over the Yellow River has been utilized for two years safely, which demonstrates that ANN based on GA and BP can be used in the construction control of cable-stayed bridges.

ABSTRACT

The experimental investigation of the first precast bi-pre-stressing simple girder concrete bridge in China, the Da-Tun Bridge, is presented. The structure and fabrication of the bridge, especially the post-tensioning reinforcement setup of the upper end of the girder, are introduced. In addition, the details of the comprehensive tests on the Da-Tun Bridge, including pre-stressing loss measurement and analysis, static tests, and live loading tests, are also presented. The corresponding major building technologies are tested and improved after the experiments. Finally, the load carrying capacity of the girder and the operating performance of the Da-Tun Bridge are evaluated. Some issues arose in this bi-pre-stressing practice and a possible solution is presented as well.

Da-Tun bridge; precast bi-pre-stressing; experimental Investigation

INTRODUCTION

Beam reinforcement using compressed steel bars to make the upper end of the concrete beam under pre-tensioning force in addition to the conventional pre-stressing concrete technique was invented by Dr. H. Reiffenstuhl and applied to the construction of the Alm Bridge in Austria. In Poland, Dr. S. Drewnowski tested many beams with post-compressed reinforcement and presented a new type of anchorage system. This construction method is called the Bi-Pre-stressing System (Ye et al, 1990, Cormack, 1990, Barker and Puckett, 1997) in Japan and some bridges were built by this method recently. The traditional pre-stressed concrete systems could be grouped into pre-tensioning and post-tensioning systems. In the 1960s, with the development of higher strength steel, better attachment hardware, better construction techniques, and simplified design methods, the use of post-tensioning to reinforce structures became popular worldwide. The Bi-pre-stressing System is developed on the base of conventional post-tensioning concrete technology. It further strengthens the system by applying pre-tension force to the upper end of the concrete beam via embedded pre-compressed reinforcing steel bars. In China, the bi-pre-stressing system and corresponding technologies

have been studied since the 1990s. In this paper, the experimental investigation of the first precast, bi-pre-stressing simple girder concrete bridge in China, the Da-Tun Bridge, is presented.

BRIEF INTRODUCTION OF THE THEORY

Bi-pre-stressing system: upper end setup of the girder. Concrete is strong in compression and weak in tension. For the working girder in a bridge, its upper end is under compressive force while the lower end is under tensile force. The conventional "Pre-stressed concrete" is concrete that is pre-compressed by stressing the reinforcement in the lower end before loads are applied. Since the tensile force in the lower end under loads will be counteracted by this pre-stressed compressive force, the pre-stressing technology greatly increases the concrete's ability to resist tensile forces without excessive cracking. There are two types of pre-stressing systems: pre-tensioning and post-tensioning systems. Pre-tensioning systems are methods in which the strands are tensioned before the concrete is placed (PCI Design Handbook, Chen et al 1999). This method is generally used for mass production of pre-tensioned members. Post-tensioning systems are methods in which the tendons are tensioned after concrete has reached a specified strength. This technique is often used in projects with very large elements. The main advantage of post-tensioning is its ability to post-tension both precast and cast-in-place members (Chen et al 1999). Similarly, in this study, to further counteract the compressive force in the upper end when it is under loads, we can pre-compress the high-strength steel bars in the prepared duct with a jack and fix them later with an anchorage bolt. Therefore, after the jack is removed, the high-strength steel bars will cause the upper side of the concrete to be under tensile force. Together with the conventional post-tensioning technology applied in the lower end of the girder, the girder is further strengthened. One type of the upper end setup for the bi-pre-stressing system is illustrated in Figure 1.

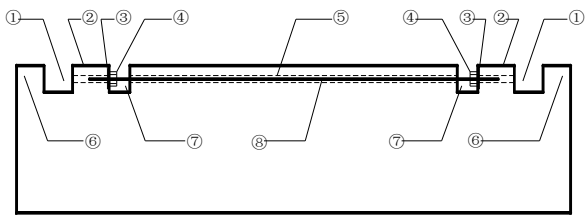

Figure 1. A type of upper end setup in the bi-pre-stress girder.

①jack slot,②anchorage bearing,③pad ,④archer bolt,⑤prepared duct,⑥jack counteract bearing ,⑦anchorage slot,⑧pre-compressed steel bar

The reason of girder thickness can be reduced without loss of equivalent load-carrying capacity. Suppose the girder cross section is rectangular, neglecting the weakening caused by the prepared duct, then under working load, as

illustrated in Figure 2, the stresses in the cross section should be subject to

$$\sigma_{hs} = \frac{N_y - N_y^{'}}{A} - \frac{N_y e_y + N_y^{'} e_y^{'}}{I} y_s + \frac{M}{I} y_s \le [\sigma_{ha}] \tag{1}$$

$$\sigma_{hx} = \frac{N_y - N_y^{'}}{A} + \frac{N_y e_y + N_y^{'} e_y^{'}}{I} y_x - \frac{M}{I} y_x \ge 0 \tag{2}$$

Where σ_{hs} and σ_{hx} are stress at the top and the bottom end of the cross section respectively, N_y and $N_y^{'}$ are the pre-stress caused by the strand at the bottom and pre-stress caused by the steel bar on the top respectively, e_y and $e_y^{'}$ are the distances of the N_y and $N_y^{'}$ to the central axis of the cross section, y_s and y_x are the distances of the top and bottom to the central axis of the cross section, M is the deflection moment of the cross section caused by the load, $[\sigma_{ha}]$ is the design stress, I is the inertia moment of the cross section, and $A = bh$ is the cross section area of the girder. Set $\sigma_{hx} = 0$, $y_x = kh$.

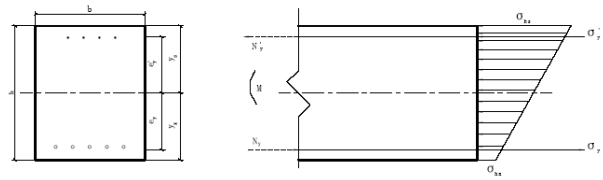

Figure 2. Stress analysis of the cross section in the girder.

Then solve Eq.(1) and Eq.(2), we have

$$\sigma_{hs} = \frac{N_y - N_y^{'}}{kbh} \tag{3}$$

For the conventional pre-stressed concrete girder, $N_y^{'} \equiv 0$. Suppose the width of the girder *b* is fixed, then σ_{hs} will increase when the thickness of the girder *h* decreases, When *h* is too small, $\sigma_{hs} > [\sigma_{ha}]$, the girder has failed. However, for the bi-pre-stressing girder, $N_y^{'} \neq 0$, when *h* decreases, by adjusting N_y and $N_y^{'}$, we still can keep $\sigma_{hs} \le [\sigma_{ha}]$. Therefore, in a bi-pre-stressing system, the thickness of the girder can be further reduced.

INTRODUCTION OF THE DA-TUN BRIDGE

The first precast, bi-pre-stressing simple girder concrete bridge in China, the Da-Tun Bridge, was constructed between 2000-2001, in LuanPing County, HeBei Province, China, over the Maoniu River. The total span of the bridge is 125m. The box girder span length is 40m, girder height is 1.35m and it employs the bi-pre-stressing setup as shown in Figure 1. The cross section of the box girder and corresponding steel bar layout is shown in Figure 3.

Figure 3 shows the Cross section of the box girder and corresponding steel bars layout, all sizes marked out in the figure are in mm.① #1-#6 pre-compressed steel bar, from left to fight, $\phi 32mm$,②pre-tensioned strand, $7 \times (7 \times \phi 5mm)$,③

pre-tensioned strand, $9\times(7\times\phi 5mm)$,④pre-tensioned strand, $9\times(7\times\phi 5mm)$,⑤ pre-tensioned strand, $12\times(7\times\phi 5mm)$ .Figure4 shows the field view of the cross section of the box girder.

Figure 4. Cross section of the box girder

EXPERIMENTS

Pre-stress loss experiments. The key of the bi-pre-stress technique is how to control or reduce the pre-stress loss in the upper end of the girder. The major pre-stress loss in the Da-Tun Bridge construction included loss due to concrete shrinkage, loss due to elastic shortening, loss due to creeping of concrete, loss due to relaxation of pre-stressing steel bars, and loss due to friction. In order to achieve the equivalent pre-stress effect, pre-stress loss experiments are designed and performed. The experimental setup is shown in Figure 5.

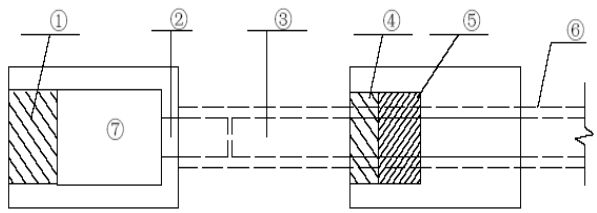

Figure 5. Pre-stress loss experiment setup.

①load Sensor #1,②retractable spear,③pre-compressed steel bar ,④load Sensor #2,⑤anchor bolt,⑥prepared duct, ⑦hydraulic jack

First, The load sensor #1 (BLR-1, 100T, Shanghai MB Automation Instrumentation Co.,Ltd, Shanghai, China) is used to measure the input pressure generated by the hydraulic jack (MJD100-300, Shanghai Liliang Hydraulic Co., Ltd, Shanghai, China). Then we fix the anchor bolt as shown in Figure 6 and remove the

hydraulic jack (MJD100-300, Shanghai Liliang Hydraulic Co., Ltd, Shanghai, China). Next, from the load sensor #2 (BLR-1, 100T, Shanghai MB Automation Instrumentation Co., Ltd, Shanghai, China), we can read the residual pressure of the steel bars. The difference between the readings of the two load sensors is believed to be the pre-stress loss at the exposed end of the reinforcing steel bar in the experiment.

The corresponding field view of the pre-stress loss experiment is shown in Figure 6.

Figure 6. Pre-stress loss experiment field view

For a girder later making up the Da-Tun Bridge, the pre-stress loss experiment is executed on the 6 reinforcing steel bars in the upper end, as marked out in Figure 3. The results are shown in Table 1. The input pressure is read from the load sensor #1 as shown in Figure 5 and the output pressure is read from the load sensor #2 as shown in Figure 5 after 24 hours.

Table 1. Pre-stress loss experiment result

Number of the reinforcing steel bar	Input pressure (*kN*)	Output pressure after 24 hours (*kN*)	Loss (*kN*)	Loss ratio %
1#	589.9	441.8	148.1	25.1
	627.8	517.1	110.7	17.6
2#	605.4	525.9	79.4	13.1
	559.6	452.6	107.0	19.1
3#	568.5	415.2	153.3	27.0
	582.0	483.3	98.7	17.0
4#	589.9	480.8	109.1	18.5
	535.0	471.9	63.1	11.8
5#	617.2	432.1	185.1	30.0
	596.6	419.7	176.9	29.6
6#	586.7	527.0	59.7	10.2
	592.0	438.3	153.7	26.0
Average	587.6	467.1	120.4	20.4

As shown in Table 1, the pre-stress loss ratio shows a maximum of 30%, a minimum of 10.2%, and an average loss of 20.4%, while the design pre-stress loss ratio is <15%. In order to meet the design loss, we examined the procedures and made some revisions:

1)Make the thread groove finer for the anchor bolt and try to further fasten the anchor bolt.

2)Reduce the length of the exposed ends of the reinforcing steel bars, to reduce the pre-stress loss due to flexion of the exposed end.

3)Compress the two ends of the reinforcing bars simultaneously, slowly, and smoothly.

After the revision, in repeated tests and corrections on multiple girders, the pre-stress loss could be lowered to below 15%.

Girder load capacity experiments. The static load capacity experiments scene is shown in Figure 7.

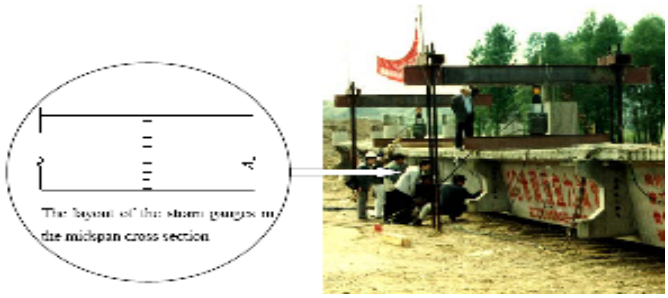

Figure 7. Going-on static load experiment of a single girder.

We apply load to the girder at two locations at the same time and at each location the basic setup of the supporting setup is shown in Figure 8.

Figure 8. Static load experiment setup.

The supporting setup is anchored underground, as shown in Figure 8, counteracted by the hydraulic jack (MJD300-300, Shanghai Liliang Hydraulic Co., Ltd, Shanghai,, China), which is now used to apply load to the steel beam laid on the girder and therefore equivalently. A line load is applied to the girder at this location. Load is applied to the girder in three rounds, each including 7 steps from 0kN to 368kN. Strain gauges (XT-5, Xingtai Electronic Equipment Factory, China) are attached on the surface of both sides of the tested girder, 4 cross sections, and on each sections 9 locations from the bottom end to the top end of the girder, as pointed out in Figure 8, totaling 36 measurement points, so for both sides, totaling 72 points. Some typical results are shown in Figure 9 and Figure 10. In Figure 9, the plane section hypothesis is tested on the mid-span cross section of the girder. On the mid-span cross section, the strain-load relation is approximately linear and the deflection is regarded as elastic, which means the plane section hypothesis fits.

For the hypothesis evaluation of the girder mid-span section under various loads, the x-axis stands for the height of the strain gauge location from the bottom of the girder and the y-axis stands for the strain under various loads.

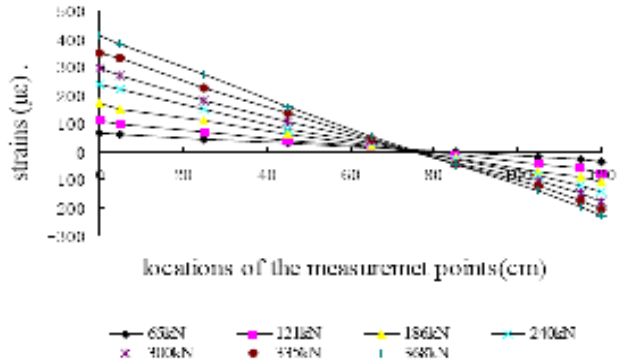

Figure 9. The plane section.

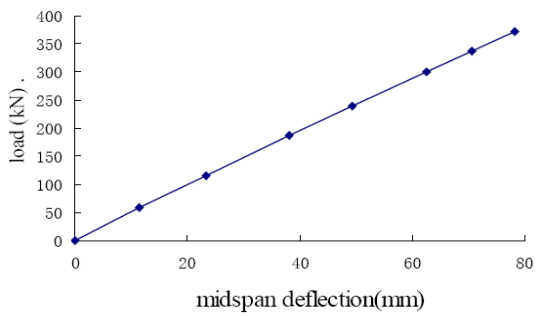

Figure 10. The load-deflection relation curve in the mid-span cross section of the girder.

Eventually, the Da-Tun Bridge was constructed with 3x5 matrix of the girders we studied before. The overview of the bridge was already shown in Figure 5.

We tested the static load property of the bridge, as shown in Figure 11, in a similar way to the girder experiments. The bridge cross section also agrees to the plane section hypothesis, indicating the bridge is working in an elastic way. The curve of the deflection - load is nearly linear. The approximate deflection-span ratio is 1/1826, meeting the requirement of the design ratio, which is <1/600. It also shows sufficient emergency capacity.

Figure 11. Static load experiment of the Da-Tun Bridge.

We also did some experiments to test the dynamic deflection and oscillation response of the bridge. A heavy truck is asked to move over the bridge at a velocity of 10*km/h* to 60*km/h* and along middle of the bridge width. The maximal dynamic deflection turns out to fall between 1.26-1.46mm and the maximal shock factor in the experiments is 1.039. When the truck's velocity is 40*km/h*, though the design shock factor is 1.0375, the difference between the design and measured maximal shock factor is less than 0.1% , therefore the shock factor is regards as acceptable. A typical test curve is shown in Figure 12. It is believed that because the higher measured shock factor is partly due to the fact that the actual rigidity of the bridge is higher. We also tested the oscillation property of the bridge by driving a heavy truck onto the bridge, then over a temporary bump (deliberately laid there), and breaking quickly after the truck passed over the bump. In the repeated experiments, the maximal oscillation amplitude is 1.479mm. Oscillation is the first order transverse deflection oscillation mode, with frequency = 2.403Hz and damping constant = 0.025. A typical test curve is shown in Figure 13.

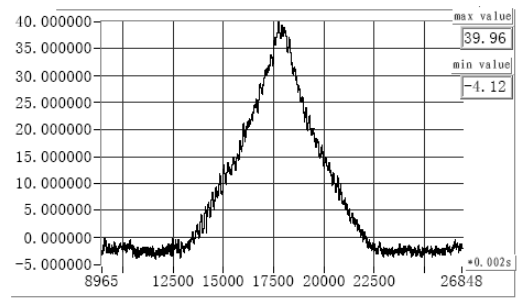

Figure 12. Typical working bridge test curve when the truck velocity is 40km/h. X-axis, y-axis stands for time and deflection amplitude respectively.

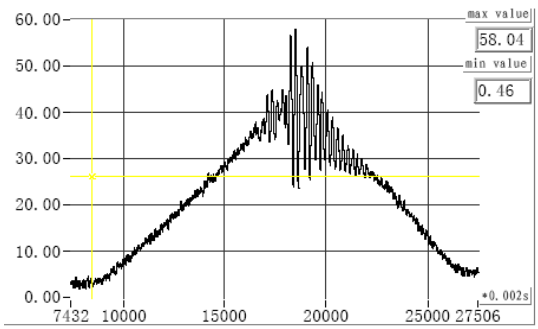

Figure 13. Typical working bridge shock test curve. X-axis, y-axis stands for time and deflection amplitude respectively.

All experiments in this section follow the Code of "Design of reinforced concrete and pre-stressed concrete highway bridges and culverts, JTJ023-85" of Chinese Ministry of Communications and the code of "Standard Methods for Testing of Concrete Structures, GB 50152-92" of the Chinese Ministry of Construction. (Chinese Ministry of Communications 1985, Chinese Ministry of Construction 1992).

CONCLUSIONS

The bi-pre-stressing technique is promising in China, especially for long span, large-scale, precast bridge construction, such as overpass bridges, flying bridges, and fly-over crossing bridges in the districts where the highway traffic is heavy or the river network is intensive. The comprehensive experiments on the Da-Tun Bridge shows that, 1) The construction technology presented in the paper is feasible, 2) the elastic property of the bi-pre-stressing simple girder bridge is satisfactory and the emergency capacity is sufficient, and 3) the problems of the anchorage system and pre-stress loss could yet be improved.

ABSTRACT

Long-term tests (864 days) were conducted on three types of columns, including plain concrete (PC) columns, reinforced concrete (RC) columns and concrete-filled steel tube (CFST) columns. The shrinkage and creep performance and the ultimate strength of the columns were tested and analyzed. The results show that the shrinkage strain of RC columns is about 87.6% of that of PC columns, the shrinkage strain of the CFST columns is about 34.8% of that of PC columns, and that the effect of expansion agent on shrinkage strain is about 2% for the PC columns. It was also found that the smaller the loading age, the greater the creep coefficient. Reinforcement can significantly reduce the creep deformation of PC columns. The creep coefficient of steel pipe surface is larger than that of inner concrete for CFST columns, leading to a longer life due to the creep of inner concrete to achieve stability. The loading age and the reinforcement have great impact on extreme compressive strain and ultimate strength. The hoop effect of RC columns is obvious. Loading rate influences the stress redistribution of CFST columns. The stress redistribution effect is relatively small for columns with loading course. However, the effect on the ultimate strength is very small for columns with or without loading courses. The difference of two is only 2.4%.

INTRODUCTION

Concrete-filled steel tube (CFST) members as axial compression members or eccentric compression members have been used widely in actual projects. The creep performance is one concerned problem in the actual project applications (Zhong 2003, Wang and Han 2000). The shrinkage and creep problems of CFST are more complex than plain concrete since CFST is a composite structure composed of steel pipe and core concrete. The curing of core concrete in steel pipe is different from that of common concrete (Yao et al. 2007). During the creep process of CFST members, stress redistributes in the steel pipe and concrete, leading to a three dimensional stress state for the steel pipe and concretes. The stress redistribution caused by creep is even

more complex (Han et al, 1999).

Furlong discovered that creep had great effect on the mechanical properties of CFST through the experimental studies (Furlong 1968). This is the earliest research report on creep properties of CFST members. Afterwards, many domestic scholars have studied the creep of CFST members and led to some research results. Tan et al. carried on the long-term load experiment for the CFST compression members (Tan and Qi 1987). Wang and Han carried on the thorough analysis to the axial compressive CFST structures (Wang and Han 2000, Han et al. 2007)Han et al. studied the ultimate strength and deformation properties of axial compressive square CFST columns under long-term load (120d) (Han et al. 2001). A more than 2 year's experimental studies was conducted by Yao et al. based on the Mao Caojie bridge in which Yao studied the shrinkage and creep performance of the CFS^T (Wang and Han 2000). In this paper, long-term tests (864 days) were conducted on three types of columns, including plain concrete (PC), reinforced concrete (RC) and CFST columns. The shrinkage and creep performance, and the ultimate strength were tested and analyzed.

SPECIMEN DESIGN

Thirteen circular short column specimens were manufactured, including PC column, RC column, and CFST columns. Specimens are 150mm in diameter, 600mm in height. Loading age, loading stress, with/without reinforcement and mixing expansion agent of specimens were considered. Eight specimens were studied for the long-term load experiment, and 5 specimens were used as shrinkage contrast specimens. The basic parameters of specimens are given in Table 1. The concrete strength grade is C50; and the mixing amount of expansion agent is 6%. The reinforcement ratio of RC column is 1.49%; and the inner strain gauges of concrete for long-term tests were placed in 1#, 4#, 11#, and 13# specimens. The mechanical properties of concrete are given in Table 2, and themechanical properties of steel bars can be found in Table 3.

SHRINKAGE DEFORMATION

Shrinkage was tested on the 3#, 6#, 9#, 13# specimens that were cured for 7d. The longest observation time is 871 days. The range pole was installed in specimens' surface symmetrical position (test distance is about 280 mm). Shrinkage deformation of concrete was measured using dial gauge. Concrete strain gauges were pre-embedded in the 13# specimen (CFST columns) to test the shrinkage deformation of core concrete. All of tests were conducted at the ambient temperature and humidity. The actual temperature ranged from -1.2 to 39.4°C, and the actual environment humidity ranged from 37 to 87%.

Table 1. Basic parameters of specimens

196	/	46.4	/	/	/
393	69.8	47.7	69.0	63.9	/
896	72.4	49.2	71.2	69.5	49.5

Table 3. Mechanical properties of steel

Content	Diameter or thickness /mm	Yield strength /MPa	Tensile strength /MPa	Elastic modulus /GPa	Elongation after fracture /%
steel bar	8.20	548.2	594.3	195	6.2
steel pipe	0.80	222.8	258.7	205	8.4

Figure 1 shows the shrinkage strain comparison curve of the 3# and 6# columns, and Figure 2 gives the shrinkage strain comparison curve for the 9# and 13# columns. The following conclusions were obtained based on the measured results:

(1) From Figure 1, the shrinkage strain of the RC column (6#) is about 87.6% of that of the PC column (3#). The RC column and the PC column however show the same change tendency in shrinkage strain. The shrinkage strain development of earlier period was rather quick. For the PC column, shrinkage completed in 1 month, 2 months, 3 months, 6 months, and 1 year were 53.1%, 70.7%, 79.7%, 90.6%, 97.5% of the total shrinkage, respectively.

(2) From Figure 2, the shrinkage strain of the CFST column (13#) is about 34.8% of that of PC column (9#). The curing of core concrete in steel pipe is different from that of common concrete, causing the small shrinkage deformation for core concrete of the CFST. Shrinkage deformation of both columns develops quickly in earlier curing period, which contributes to the long time stability.

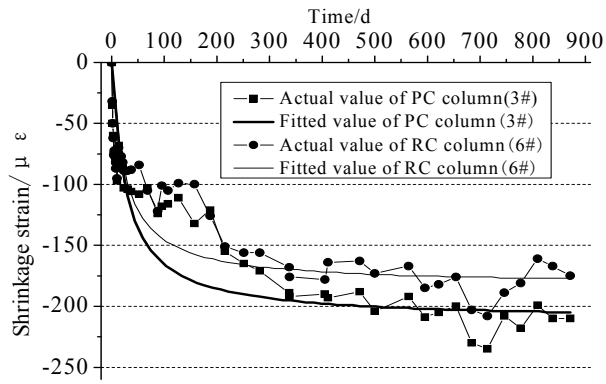

Figure 1. Shrinkage strain comparison of 3# and 6# columns

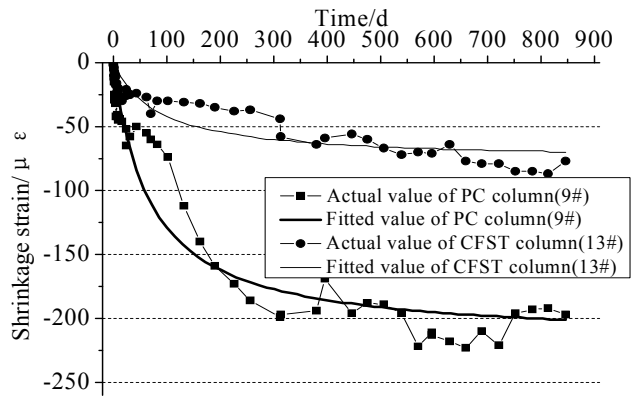

Figure 2. Shrinkage strain comparison of 9# and 13# columns

(3) Contrasting shrinkage strain curve of the 3# specimen to that of the

9# specimen shows that shrinkage strain development in earlier stage would be relatively slow for PC column (9#) using mixed expansion agent, which achieved stability for a longer time. The effect of expansion agent on shrinkage strain is about 2% for PC columns.

CREEP DEFORMATION

Creep deformation. Long-term tests (864 days) conducted on the three types of columns using creep loading device are shown in Figure 3. The loading age, loading stress, with/without reinforcement or mixing expansion agent were considered.

Figure 3. Loading device for creep test

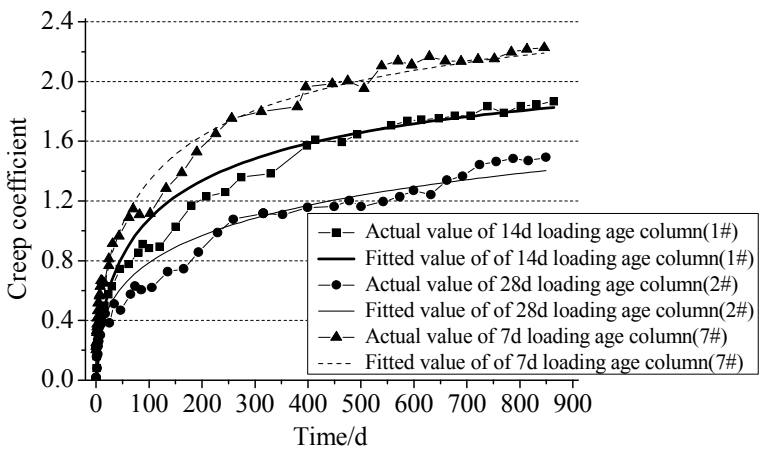

Figure 4. Effect of loading age on creep coefficient

Figure 4 shows that the creep curve of PC column has the same change tendency at different loading ages. the creep development in earlier period is fast, and the development in later period is relatively slow. The younger the loading age is, the greater the creep will be. Creep coefficient of the specimen loaded on the 7 day (7#) increased about 20.0% compared to that of the 14-d

loading age (1#). Creep coefficient of the 7-d specimen (7#) increased about 56.2% compared to that of the 28-d specimen (1#).

Figure 5 shows that reinforcement can significantly reduce the creep deformation of concrete columns. Creep curve of RC columns and PC columns have the same change tendency. The creep development in earlier period is quick, while the creep development in later period is relatively slow. Creep coefficient of the 14-day RC column (4#) is about 35.2% less than that of PC column (1#). Creep coefficient of the 28-day RC column (5#) is about 24.2% less than that of PC column (2#).

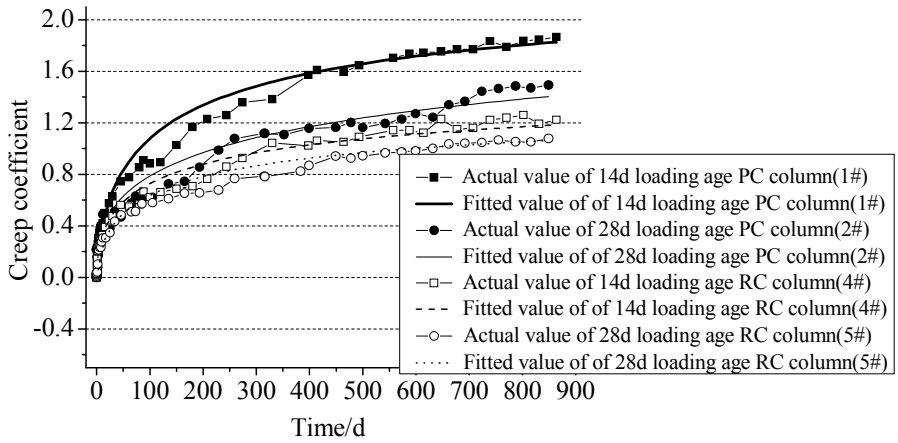

Figure 5. Effect of reinforcement on creep coefficient

Creep analysis. Based on the actual creep coefficient, the fitting curve obtained according to the expression proposed by Branson et al. (Zhou and Chen 1994) and the comparison to two kinds of common creep coefficient model, including ACI-209R-92 mode (ACI 1992) and CEB-FIP(MC90) mode (CEB-FIP 1990), are shown in Figure 6 and Figure 7.

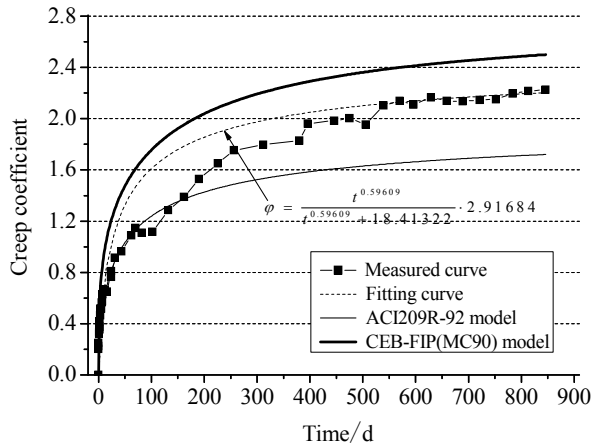

Figure 6. Creep coefficient comparison of 7d loading age

(1)Figure 6 shows that the 7-d loading PC column (7#) holds load for 846 days, and that the creep coefficient calculated using the ACI209R-92 model is 21.9% less than fitted value. The creep coefficient calculated using the CEB-FIP (MC90) model is 13.4% higher than the fitted value. Therefore, creep coefficient can be more accurately predicted according to CEB-FIP (MC90) model.

(2)Figure 7 shows that the 28-d PC column (2#) holds load for 850 days, and that the creep coefficient calculated using the ACI209R-92 model is 2.0% less than the fitted value. The creep coefficient calculated using the CEB-FIP (MC90) model is 30.1% higher than the fitted value. Therefore, creep coefficient can be more accurately predicted according to the ACI209R-92 model.

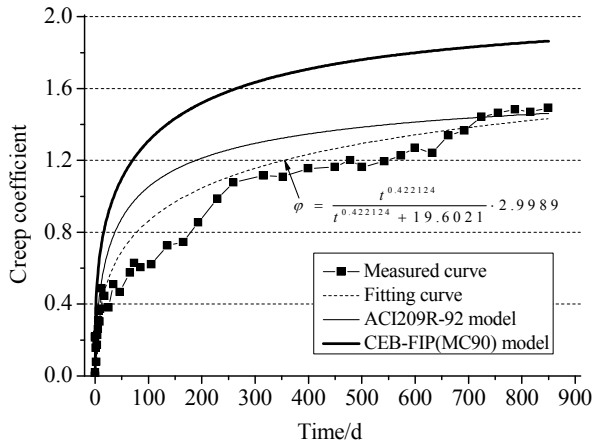

Figure 7. Creep coefficient comparison of 28-d loading age

ULTIMATE STRENGTH EXPERIMENT

Test results. When unloaded after a 2-year testing period, the longitudinal pressure strain was measured, and the destruction shape of specimens as shown in Figure 8. Test results are shown in Table 1. The destruction characteristic of the specimens is as follows:

(1) For PC columns, the longitudinal crack appeared on both the bottom and the top of the specimens, which later on shifted to the middle. It was the shearing failure that caused the loss of supporting capacity for the specimens.

(2) For RC columns, when load level reaches the supporting capacity, bulging deformation was observed at the middle of specimen. Both the bottom and the top of specimen crushed. It was the steel bar compressive buckling that caused the loss of supporting capacity for the specimens.

Figure 8. Destruction shape of specimens

(3) For CFST columns, when load level reaches the supporting capacity, bulging deformation was observed at the middle of steel pipe. It was the steel pipe compressive buckling that caused specimen losing supporting capacity.

Test result analysis. Load-strain relation of columns with and without mixing expansion agent is shown in Figure 9. The figure shows that the ultimate strength of PC column (8#) with expansion agent was 32.4% higher that that of PC column (7#). Under the same load condition, the outside strain of CFST column without loading course (12#) was about -11.9%~52.0% larger than that of CFST column with loading course (11#). The deviation is small at the initial period, while that near destruction is big. The stress redistribution effect is relatively small for the column with loading course (11#). However, the effect of loading course on the ultimate strength is very small, and the difference is only 2.4%.

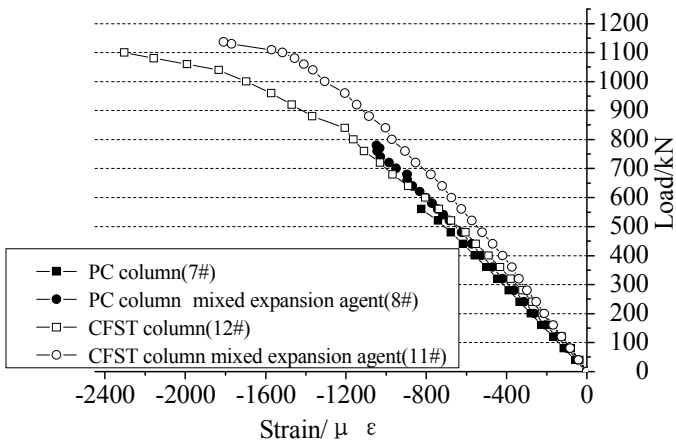

Figure 9. Load-strain relation of columns with/without expansion agent

CONCLUSIONS

Based on the results of the long-term and ultimate strength experiments, the following conclusions can be drawn:

(1) The shrinkage strain of RC columns is about 87.6% of that of PC columns; the shrinkage strain of the CFST columns is about 34.8% of that of PC columns; the effect of expansion agent on shrinkage strain is about 2% for PC columns.

(2) The smaller the loading age is, the greater the creep coefficient will be. Reinforcement can significantly reduce the creep deformation of concrete columns. The creep coefficient of steel pipe surface is larger than that of inner concrete for CFST column. Owing to the creep of the inner concrete, long-term stability can be achieved.

(3) The creep coefficient can be more accurately predicted using the CEB-FIP (MC90) model for the 7-d PC columns; the creep coefficient is more accurate according to the ACI209R-92 model for the 28-d PC columns.

(4) The loading age and the reinforcement have great impact on extreme compressive strain and ultimate strength. The hoop effect of RC columns is obvious. Loading course influence the stress redistribution of CFST columns. The stress redistribution effect is relatively small for column with loading course. However, loading course has little the effect on the ultimate strength, the difference of ultimate strength with loading course and without loading course is only 2.4%.

ABSTRACT

The author has carried on an outdoor long-term temperature field observation experiment of a full-scale concrete component which is used in the Mudanjiang Bridge in Yilan, which is a half-through arch bridge with concrete-filled steel tubes, for nearly three years. Through the test, we obtain the disciplinarian of the temperature field on the cross section of the ribs, which is due to the solar radiation, the atmosphere temperature, and natural reasons. Using the heat transfer theory principle and finite element method, the paper proposed a computational method for the arch rib section's temperature field of concrete filled steel tubular arch bridges. The paper provides the basis and the reference for the construction of this kind of bridge, which built is in an area where the temperature difference is large. The study also provides reference for the determination of temperature effect in the construction and design standard of concrete filled steel tubes arch bridges, which will be established in the future.

Keywords:*concrete filled steel tubes;arch bridge; temperature field; solar radiation*

1 INTRODUCTION

Massive domestic and foreign research papers related to temperature characteristics and the temperature field of bridges were researched on reinforced concrete bridges, pre-stressed concrete bridges, and steel bridges. Moreover, most bridge cross sections are the box section and many countries' standards of bridges also have the corresponding stipulation. Just a few papers research on the temperature characteristics and temperature field of steel-concrete composite girder bridge. In the research field on temperature characteristics and arch rib temperature of concrete filled steel tubes arch bridges, only professor Chen Baochun, from Fuzhou University, had tested the temperature field of a concrete filled steel tubular member from when it was cast to hardening for nearly a month. The diameter of the steel tubular is 0.55 meter. Professor Chen Baochun introduced the influence of the hydration heat of concrete and the ambient temperature with emphasis and he established the corresponding finite difference procedure (Chen Baochun et al. 2000). In the temperature characteristic research of concrete filled steel tubes arch bridges in his paper, he arranged very few measuring points and supposed that

the arch rib section's temperature field had axial symmetry. Because the component stands in the outdoor visor place throughout the entire test process and the different regions have different climatic conditions, the analysis cannot reflect the real temperature field on the cross section of the ribs, which was under the combined action of the solar radiation and the ambient temperature (Xu aiming et al. 1993).

This paper takes the test results of the arch rib section's temperature field of the concrete filled steel tubular arch bridge built in Yilan as the foundation and proposes a computational method for the arch rib section's temperature field of concrete filled steel tubular arch bridges by using heat transfer theory principle and finite element method. The paper provides the basis and the reference for the construction of this kind of bridge, which is built in areas of large temperature difference. The study also provides a reference for the determination of temperature effect in the construction and design standard of concrete filled steel tubes arch bridges, which will be established in the future.

2 SIMPLE INTRODUCTION ABOUT THE EXPERIMENT

In order to determine the section's temperature distribution characteristics and rules of the concrete filled steel tubular component, we have carried out a outdoor long-term temperature field observation experiment of a full scale concrete component which is used in the Mudanjiang Bridge in Yilan, which is a half-through arch bridge with concrete-filled steel tubes, between 1998 to 2000. The data acquisition time interval was 3 hours and the test contents are as follow:

1) Determination of the time change regulation of the ambient temperature and the component's temperature in the season with the greatest date temperature difference;
2) Determination of the ambient temperature and component's temperature in the most bumper year temperature difference season;
3) Component's temperature field and the surrounding environment of the component's surface.

The detailed dimension of the cross section of arch rib component and the measuring point's position are show in figure 1. The units are centimeters in the chart. The digit 1~10 are the temperature measuring points. 4 points are arranged in the steel tube surface. 5 points are arranged in the core concrete. 1 point is arranged in the side toward the sun . All of the measuring points are arranged in equal intervals and symmetrical pattern.

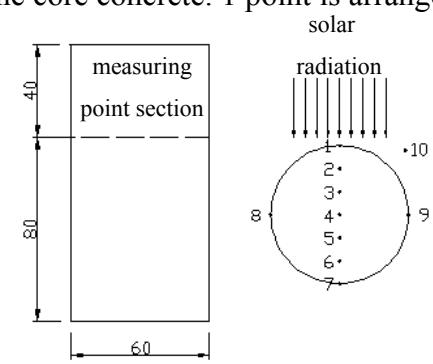

Figure 1. Component measuring points

3 THE RESULT ANALYSIS

This article uses the mean value of the measured data of the same spot position on two components as the data of experimental analysis and the statistical analysis software to analyze and compute the test data.

3.1 Influence of daily temperature difference

The measured typical curves of each moment of the arch rib section's temperature field of the concrete filled steel tubular arch bridge in the hot summer are shown in Figure 2 and for the cold winter in figure 3.

Through the analysis and comparison of massive data measured in the summer high temperature and winter low temperature conditions, we can draw the following conclusions:

1) The change of temperature in the core concrete is obviously lagging relative to the steel tube surface.
2) In one day, temperature change of the sun-facing side's surface is large, but the shady surface's and the core concrete's change is small.

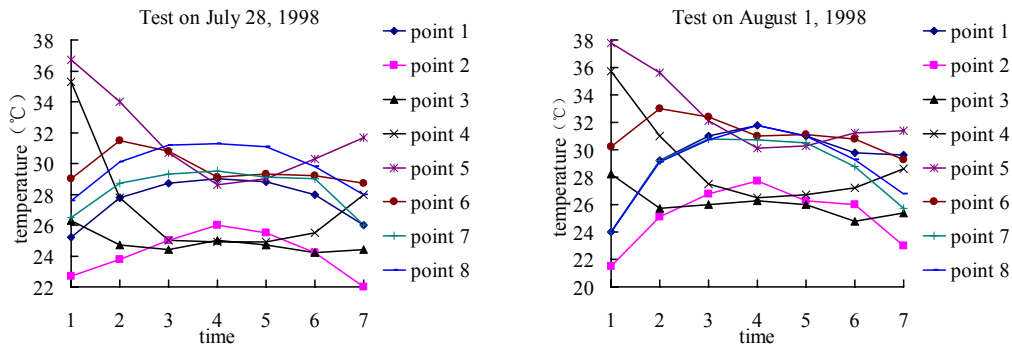

Figure 2. component section actual temperature field tested in summer

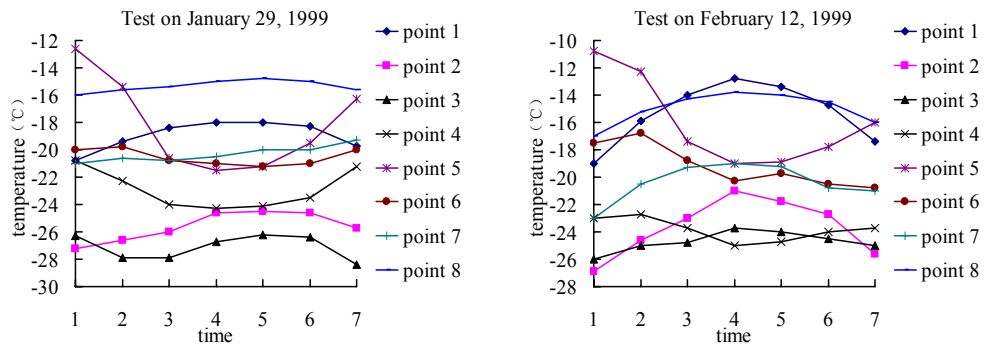

Figure 3. component section actual temperature field tested in winter

3.2 Influence of year temperature difference

The Harbin area has continental climate, the four seasons are distinct and temperature difference between the summer and winter is large. The steel tube surface temperature is deeply affected by factors such as ambient temperature and solar radiation. But the core concrete is less affected than the steel tube. The maximum disadvantageous ambient temperature and the component temperature obtained in the summer and the winter, which has great influence to the long-term temperature difference, are shown in Table 1. We can see from Table 1 that the section average temperature of the concrete filled steel tubular is higher than the free air temperature in summer and lower in winter.

Table 1. The highest, the lowest temperature actual value in a year of component different position

Project	Position				
	Ambient temperature	Steel tubular in sun side	Steel tubular in shady side	Core concrete	Atmospheric temperature
The highest temperature in summer(℃)	34.3	39.6	30.7	33.3	30.5
The lowest temperature in summer(℃)	-28.7	-28.1	-27.6	-25.8	-24.2

4 THEORETICAL ANALYSIS AND CALCULATION OF ARCH RIB SECTION'S TEMPERATURE FIELD OF CONCRETE FILLED STEEL TUBULAR ARCH BRIDGE

The section's temperature field of concrete filled steel tubular arch bridges is a transient three-dimensional temperature field. As the simplified computation, the hypothesis is as follows:

1) The concrete filled steel tubular arch bridge is a homogeneous and isotropic continuum.
2) The arch rib is a tall and slender structure. We suppose the structure temperature field along the arch rib axial direction is uniform and the interface of the arch rib and the pier is the heat insulation boundary. In other words, there is no heat conduction along the arch axis direction. The arch rib section's temperature field of the concrete filled steel tubular arch bridge is simplified to the plane problem of the arch rib section :

$$T=f(x,y,t) \tag{1}$$

3) The concrete and steel tubular have good contact and the temperature and heat flow on the contact face is continuous, which is the completely contacting boundary condition (Fourth kind of boundary condition) .

Based on above hypotheses and the Fourier heat conduction theory, we can determine the no inner heat source two-dimensional transient heat conduction equation:

$$\frac{\partial T}{\partial t}=\frac{k}{\rho c_p}\left(\frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 T}{\partial y^2}\right) \tag{2}$$

In the formula: $T[°C]$——transient state temperature of the object;

$t[s]$——time of the process；

$k[w/(m\cdot°c)]$——the coefficient of heat conductivity of material, which is a constant;

$\rho[kg/m^3]$——density of material, which is a constant;

$C_p[J/(kg\cdot°c)]$——the specific heat at constant pressure of material, which is a constant;

$x, y[m]$——Decca rectangular coordinates.

We determine the initial condition by the reference, unifying the actual situation of Harbin area, and the actual result. Before the sun rising, the temperature remains constant for several hours. The temperature of the internal place of the component approaches the exterior temperature (the temperature gradient is 0). Therefore this article uses the temperature mean value of every point in 5 o'clock as the initial uniform temperature to compute the summer sunshine's influence. Likewise, we consider 15 o'clock as the initial time to compute the winter cold night divergent radiation and use the temperature mean value of every point in 15 o'clock as the initial uniform temperature.

The boundary conditions of the arch rib section's temperature field of the concrete filled steel tubular arch bridge divide into two parts, which are the sun side and the shady side. According to the principle that "the quantity of heat on the boundary surface does not extinguish" and by using the weighted residual method, we can deduce the basic equation using the finite element method of the no inner heat source two-dimensional transient temperature field (Qu zhaojun et al. 2000).

$$\iint_D [k(\frac{\partial W_l}{\partial x}\cdot\frac{\partial T}{\partial x}+\frac{\partial W_l}{\partial y}\cdot\frac{\partial T}{\partial y})+\rho c_p W_t\frac{\partial T}{\partial t}]dxdy-\oint_\Gamma kW_l\frac{\partial T}{\partial n}ds=0\ (l=1,2,...,n) \quad (3)$$

In the formula: D——the Definition Domain of the temperature field;

T——undetermined parameter;

W_l——weighted coefficient;

Other symbols are the same as the previous formula.

We have established a calculating program with the finite element method in the foundation of formula (3), which also considers the characteristics of the arch rib section's temperature field of the concrete filled steel tubular arch bridge we have researched. The element shape of the program is the triangle (figure 4) and this element can be use to solve the two-dimensional stable state, the transient state, and the axial symmetry questions.

We choose the structure's temperature field to confirm the computational accuracy of the procedure, which is at the most disadvantageous time in the high temperature summer: 11o'clock and 14 o'clock. The calculated results and actual value comparisons are show in Fig. 5.

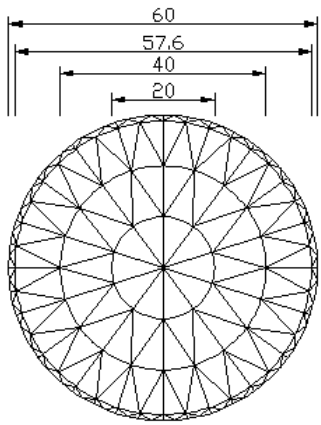

Figure 4. finite element unit division of calculation model

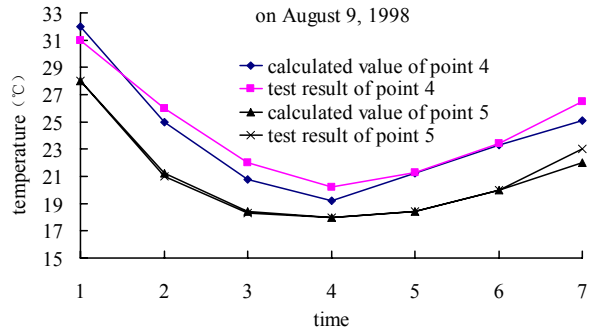

Figure 5. Temperature field actual value and calculated value of the component

5 CONCLUSION

This study has shown that the distribution of the section's temperature field of the concrete filled steel tubular members are as follow:

1) The change laws of the steel tube surface temperature and ambient temperature are basically synchronous. But the change of temperature in the core concrete is obviously lagging.
2) The temperature on the sun side of the concrete filled steel tubular members is far higher than the ambient temperature. The biggest differential value may achieve 10℃.
3) The change range of section's temperature field of concrete filled steel tubular members is far greater than that of the ambient temperature field.

Influencing Factor Analyses of Section Types on Vehicle-bridge Interaction of Concrete Box Girder with Corrugated Steel Webs

Baodong Liu[1], Pengfei Li and Lingxiang Xue

[1]School of Civil Engineering, Beijing Jiaotong University, Beijing 100044, China, email: baodongliu@vip.sina.com

ABSTRACT

Along with the further study on concrete box girder bridges with corrugated steel webs, its dynamical characteristics, including vehicle-bridge vibration response, received much concern. Section types of concrete box girder bridges with corrugated steel webs have a great influence on its dynamic performance. Two parallel boxes double cells and single box double cells are common in practical applications. By constructing the finite element models of girders with these section types, the natural vibration characteristics are obtained and compared**.** The vehicle-bridge coupling response is discussed while vehicles are on different lanes and at different speeds. The comparison shows that the torsional rigidity and integrity of the two parallel boxes double cells girder is weaker than the single box double cells girder. The change of deflection at mid-span is linear when the number of vehicles increase, and the vehicle-bridge vibration response is more remarkable when the excited frequency is close to the bridge's first natural frequency.

Keywords: Box girder with corrugated steel webs, Vehicle-bridge coupling vibration, Section types, Natural vibration characteristics

INTRODUCTION

The concrete box girder with corrugated steel webs is a new structure, which is formed with concrete roof and floor, external and internal prestressed reinforcement, and corrugated steel webs. The concept of the concrete box girder with corrugated steel webs was put forward by French engineers in 1975. The Connac Bridge, the first concrete box girder with corrugated steel webs, was built in France in 1986. So far, there are many of this of type bridge in European countries and Japan (Song et al, 2002). In China, the development is relatively slow and only five bridges with this kind of girder have been built. Since the first concrete box-girder bridge with corrugated steel webs was built, the performance study of this kind of bridge has caused the close concern of many scholars. There have been a considerable amount of research work about the working performance under the static bending and shear forces (Liu et al, 2008; Khalid Y A et al, 2004), but the research about the dynamic performance is still very scarce (Chen et al, 2007). The dynamic performance of the structure is the foundation of dynamical response. The dynamic performances of different section types are compared by the finite element method. Based on the principles of the modal synthesis method, a comprehensive model is set up to simulate the dynamic responses of the vehicle-bridge system while the vehicle is passing the

concrete box girder with corrugated steel webs. The dynamic responses with one or more vehicles, different vehicle parameters, and different vehicle speeds are considered respectively.

THE MODEL OF VEHICLE-BRIDGE

The vehicle-bridge coupling system is very complex. In order to reduce the degrees of freedom, the modal synthesis method is chosen to obtain the dynamic response of the concrete box girder with corrugated steel webs. Only limited numbers of modes should be considered. The natural vibration characteristics of the girder can be calculated using the finite element method. The limited numbers of modes can be decided considering the vertical mode participation mass. As to the simplified model of the vehicle, the three-axle vehicle can be simplified to body, spring suspension device, axle, and tire. Vehicle vibration is mainly summarized as vertical vibration, longitudinal rocking vibration, and transverse rocking vibration of car body and vertical vibration and longitudinal rocking vibration of wheelset. Figure 1 is three-axle vehicle model (Xue Lingxiang, 2008).

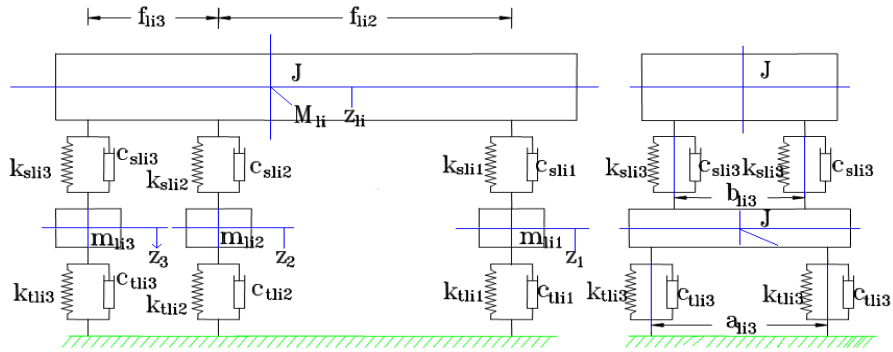

Figure 1. Three-axle vehicle model

Assuming the wheels and the bridge deck have the same displacement, the vehicle and bridge can be combined as a united dynamical system. The vibration time can be separated to many time intervals△t, the dynamic equilibrium equation can be built at the beginning and end of each time interval. The dynamic responses of the vehicle and the girder in every moment are calculated by the Newmark-β step-by-step integration method (Wang and Xu, 2000).

NATURAL VIBRATION CHARACTERISTICS

A real concrete box girder with corrugated steel webs in Qinghai province is taken as the research object. The section types are single box double cells and two parallel boxes double cells. The strength of the corrugated steel is Q345 and the thickness is 12mm. The concrete grade is C50. The specific sizes are shown from Figure 2 to Figures 4.

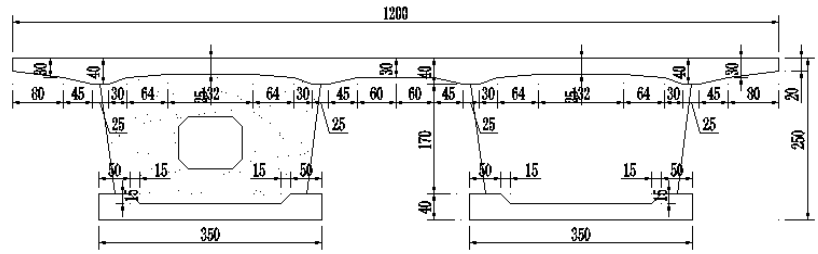

Figure 2. Section size of two parallel boxes double cells girder

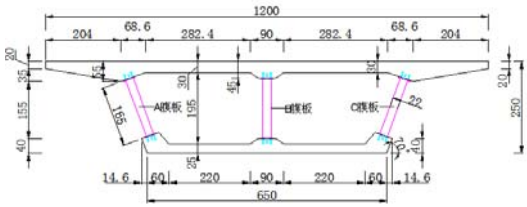

Figure 3. Section size of single box double cells girder

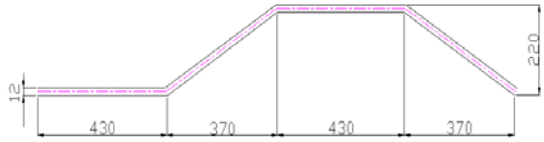

Figure 4. Size of corrugated steel webs

The models of the box girder with corrugated steel webs are built by the finite element analysis program MIDAS. The span length is 49.92m. The concrete roof and floor use the solid element and the corrugated steel webs use the plate element.

The first twenty order modes of each box girder are calculated and compared. The vertical mode participation mass of the first twenty modes is almost ninety percent for both models. The natural vibration characteristics are the basis of the structure's dynamic response, so the natural vibration characteristics of box girders with different section types are compared in the Table 1.

Table 1. Comparison of the first four order modal shapes and frequencies

mode	single box double cells（Hz）	two parallel boxes double cells（Hz）
First	First-order vertical bending(2.765)	First-order vertical bending(3.343)
Second	Horizontal vibration(6.602)	Torsional vibration(6.513)
Third	Second-order vertical bending(6.782)	Second-order vertical bending(8.616)
Fourth	Torsional vibration(7.244)	Horizontal vibration(8.880)

Table 1 shows that the natural vibration characteristics are greatly different between the single box double cells girder and the two parallel boxes double cells girder. Although the first order modal shapes are similar, the frequency of the single box double cells girder is 82.7 percent that of the two parallel boxes double cells girder. So the vertical rigidity of the two parallel boxes double cells girder is larger. The torsional vibration of the two parallel boxes double cells girder appear in second-order mode while the torsional vibration of the single box double cells girder appear in fourth-order mode. The torsional frequency of the two parallel boxes double cells girder is 88.8 percent that of the single box double cells girder. So the torsional rigidity of the two parallel boxes double cells girder is small and the integrity of the girder is weaker.

COMPARISON OF VEHICLE-BRIDGE COUPLING VIBRATION

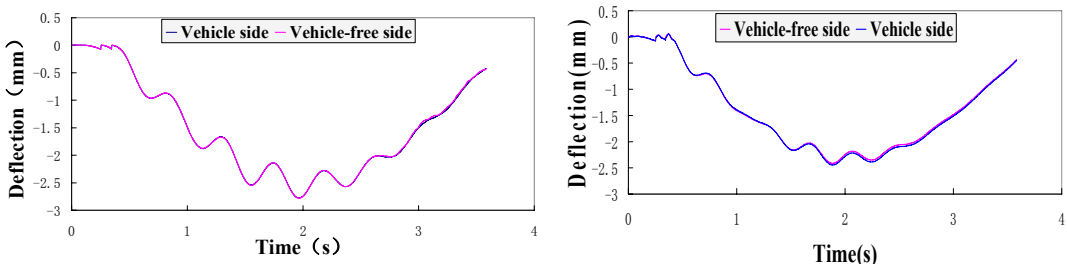
The three-axis vehicle, whose total weight is 325kN, is used to simulate the dynamical responses of the vehicle-bridge system. The front axle's weight is 65kN, and both medial axle and rear axle's weight is 130kN. The specific parameters are shown in Table 2.

Table 2 Vehicle parameters

axle	axle weight（kN）	pendulum spring stiffness (kN/m)	pendulum spring Damping（kN/m/s）	tire stiffness（kN/m/s）	tire damping (kN/m/s)
front axle	65	500	10	1000	4
medial and rear axle	130	1200	16	2300	16

The dynamic responses of box girders with different section types are calculated while the vehicle is passing the bridge. The effect on dynamic responses of bridges are discussed when vehicles are on different lanes and with different speeds.

(1)The mid-span's time-deflection curves for one vehicle passing the outside lane of the girder at 50km/h are shown in Figure 5.

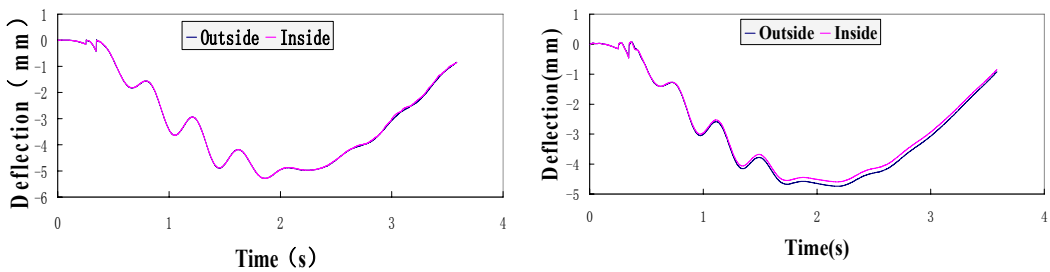


(a) Single box double cells **(b) Two parallel boxes double cells**

Figure 5. Mid-span time-deflection curve when one vehicle passing outside lane

According to Figure 5, the mid-span responses of both lanes are very similar for the single box double cells box girder. So the partial vehicle load has little influence on single box double cells box girder. For the girder with two parallel boxes double cells, the mid-span deflection of the vehicle side is slightly larger than the vehicle-free side, which shows that the partial vehicle load has some influence on it. Compared with the whole bridge's weight, the weight of vehicle body is so small that the effect of the influence is not remarkable. The vertical deflection of the single box double cells girder is a little bigger than that of the two parallel boxes double cells girder, which is because its vertical rigidity is comparatively small.

(2)The mid-span's time-deflection curves for two vehicles passing the girder in parallel at 50km/h are shown in Figure 6.



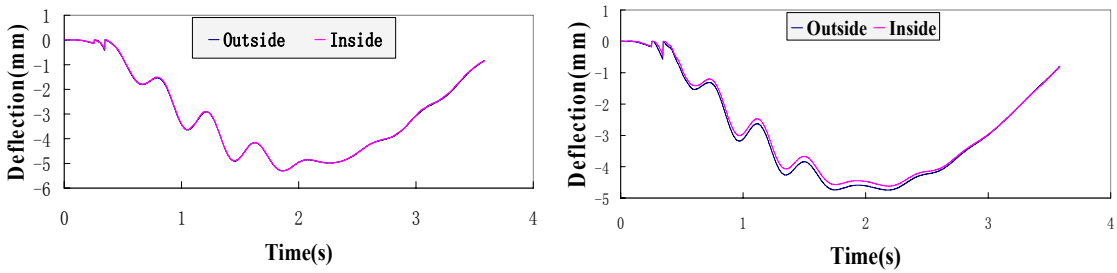
(a) Single box double cells **(b) Two parallel boxes double cells**

Figure 6. Mid-span time-deflection curve when two vehicles passing in parallel

According to the Figure 6, the mid-span deflections of both lanes are very similar for the single box double cells box girder. For the two parallel boxes double

cells girder, the mid-span deflection of the outside lane is somewhat larger than the inside lane. The participation of the torsional vibration mode is the main reason for this difference. The torsional rigidity of the two parallel boxes double cells girder is small and the integrity of the girder is weak. The deflection while two vehicles are passing the bridge is about twice that of one vehicle, which means that the bridge's response is linear under this loading.

（3）The mid-span's time-deflection curves for two vehicles passing the girder in opposite directions at 50km/h are shown in Figure 7.

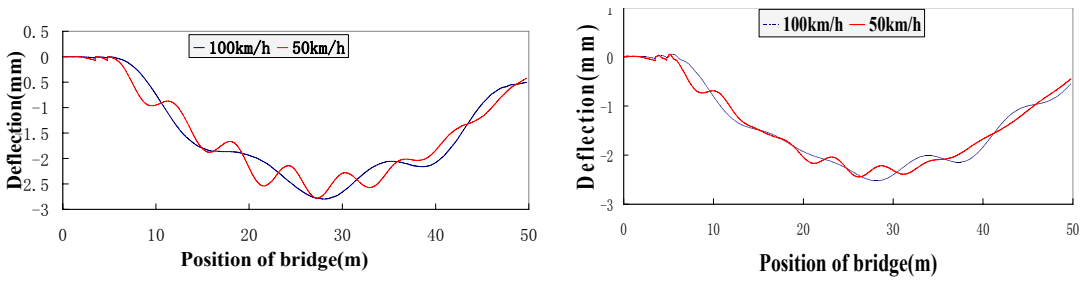


(a) Single box double cells **(b) Two parallel boxes double cells**

Figure 7. Mid-span time-deflection curve when two vehicles passing in opposite

According to the Figure 7, the vehicle-bridge vibration response of two vehicles passing the bridge in opposite directions is the same with that in parallel due to structural symmetry.

(4) In order to compare the vibration response of the girder when the vehicles are passing the bridge at different speeds. The deflections of the mid-span are calculated while the vehicles are at different positions. The mid-span's position-deflection curves for one vehicle passing the bridge at 50km/h and 100 km/h are shown in Figure 8.



(a) Single box double cells **(b) Two parallel boxes double cells**

Figure 8. Mid-span position-deflection curve when one vehicle passing the bridge at different speed

According to the Figures 8, the average of dynamic deflection at 50km/h is similar with that at 100km/h, but the deflection disturbance is more significant than that at 100km/h. Time between the vehicle's front axle and rear axle through the same point can be taken as a cycle. When the vehicle's speed is 50km/h, the excited frequency is about 2.894Hz, which is close to the single box double cells girder's first natural frequency (about 2.765Hz), so its dynamic response is more remarkable. The more the excited frequency is closer to the bridge's first natural frequency, the more remarkable the bridge's dynamic response.

CONCLUSIONS

The natural vibration characteristics of different section types are obtained and their dynamic characteristics are compared. The vehicle-bridge dynamic interaction system model is set up and composition is programmed to get the vehicle-bridge's dynamic response while vehicles are passing the bridge.

The following conclusions have been drawn from the above analysis:

(1) The torsional rigidity and integrity of the two parallel boxes double cells girder are weaker, so the mid-span deflections of different lanes are not coincidental.

(2) The vertical deflection of the single box double cells girder is a little larger, due to its vertical rigidity being comparatively small. The change of bridge's deflection is linear with the number of vehicles increased.

(3) The more the excited frequency is closer to the bridge's first natural frequency, the more remarkable the bridge's dynamic response.

Abstract : Jiangdong Bridge in Hangzhou is a spatial cable, self-anchored suspension bridge. In order to research structural system transformation through a model test, a total bridge test model has been designed according to geometric scaled ratio of 1:16 and force scaled ratio of 1:4. During the test, five pairs of temporary hangers were first tensioned to make the main cables form spatial space curves. Then the permanent hangers were tensioned symmetrically step by step from bridge tower to mid-span. Temporary hangers were dismantled gradually when their role was substituted by permanent hangers. Based on the control requirement, the force of the intermediate temporary hangers needed to be adjusted several times. The control target of hanger tension was according to unstressed length of the hangers in calculations. However, in practical experiments, the final target was hanger tensile force reaching the calculated value after the hanger was installed. The tests indicate that both control results are consistent. In this paper, the test scheme of system transformation, test process and results of test research are emphatically introduced.

Keywords : self-anchored suspension bridge; total bridge model test; structural system transformation; spatial cable; unstressed length of hanger

1 Introduction

The main bridge of Jiangdong Bridge in Hangzhou is a three-span single-column pylon, spatial cable plane, separate steel box and single-span suspended self-anchored suspension structure with a span arrangement of (83+260+83)m. The stiffening girder was designed as a separated twin-box girder connected by the box section beam. The width of the stiffening girder is 47m. The horizontal ratio of rise to span of main cables is 22/260, the largest ratio in the world. The structural form of the Jiangdong Bridge is similar to the Yongjong Bridge in Korea. But the

Yongjong Bridge is a highway and railway suspension bridge which adopts the steel truss stiffening girder. Compared with the Jiangdong Bridge, the height and rigidity of the stiffening girder is relatively large, and the bridge width is relatively narrow (Ochsendorf, J.A. 1999). For the Jiangdong Bridge, it is necessary to find the reasonable sequence of hanger installation, verify pre-displacement and pushing process of saddles by model experiments. These test conclusions can help to guide construction control and construction process of real bridge.

2 Test model design

Considering the requirements of structural parameters, model materials, fabrication technology and laboratory conditions, the geometric scaled ratio of the model was 1:16, and the force scaled ratio was 1:4. Full length of the model was 26.625m. In the model design, the geometric relation between the main cable and the stiffening girder should strictly satisfy the similarity ratio requirement. The test model was composed of double main cables, 26 pairs of hanger, steel box, horizontal connection box, anchoring beams at the end, pylons, saddles, temporary piers and test system. Figure 1 shows the general view of the test model. In this paper, the symbol "LS" expresses a temporary hanger and "S" expresses a permanent hanger.

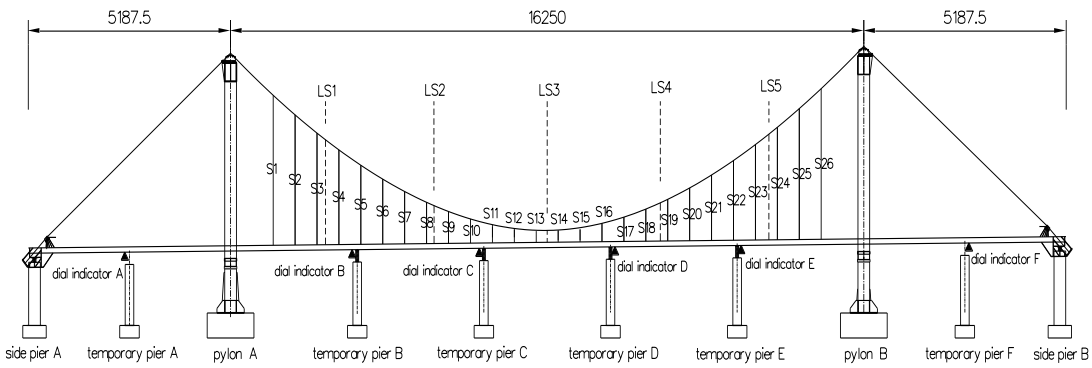

Figure 1. General view of the test model (unit: mm) .

The test model was designed according to the relations of deformation and force similar to actual bridge. Due to material constraints, it is currently impossible for all parameters to meet law of similarity. Based on the structure mechanical properties, the main parameters should satisfy the law of similarity (Yao, Z. 1996). Table 1 lists the similarity relations of main parameters.

Table 1. Similarity relations of main design parameters

Parameter	Similarity law	Similarity coefficient (real bridge/model)
Cross-sectional area	$A_m = mn^2 AE/E_m$	1024
Bending moment of inertia	$I_m = mn^4 IE/E_m$	262144
Torsion moment of inertia	$J_m = mn^4 JG/G_m$	262144
Mass moment of inertia	$I_{\rho,m} = mn^4 I_{\rho,\rho}$	262144
Concentrated load	$P_m = mn^2 P$	1024
Distributed load	$W_m = mnW$	64
Linear displacement	$Y_m = nY$	16
Angular displacement	$\phi_m = \phi$	1
Axial force	$N_m = mn^2 N$	1024
Moment	$M_m = mn^3 M$	16384
Support reaction	$R_m = mn^2 R$	1024

Note: m expresses the force reduced scaled ratio, n expresses the geometric reduced scaled ratio. Parameters with subscript m are design parameters of the test model.

3 Model test research of structure system transformation

The system transformation for self-anchored suspension bridges refers to transferring the weight of the stiffening girders to the main cables and pylons by means of a certain hanger tension procedure, implementing the stiffening girder separation from the construction brackets. Theoretically speaking, the erection process of hangers is similar to that of stay cables. The methods, such as jacking up the stiffening girder, jacking up the saddles, preloading the main cables and directly tensioning the hangers, can be adopted. For long-span, self-anchored suspension bridges, especially for the single-span suspended structures, because the pre-offsetting of main saddles is large, the elevation difference is also large at the main cable erecting stage compared with the configuration at the finished bridge state. The main cables of the Jiangdong Bridge form three-dimensional curves, and before the main cable spatial curves form, many hangers can't be installed. Therefore, the feasible method of the hanger installation scheme is tensioning hangers directly.

For the directly tensioning method of self-anchored suspension bridges, the method of calculation is the stress-free state method. Based on the unstressed length of hangers, determine hanger tension and structure internal force (H.-K. Kim 2002). Because force measurement precision is higher than that of length measurement in model tests, we stretch hangers according to hanger tension rather than the unstressed length of the hangers. For elastic structures, both have a corresponding relationship each other. The situation is reverse in field construction, so the control

idea is the length control mainly, and force checks as servant.

This experiment has carried out three test schemes. As space is limited, we introduce the recommended scheme and omit the other two schemes in this paper. The recommended scheme is the planned demolishing of the temporary pier of side span before system transformation, and appropriately adjusting the order of hanger tensioning to improve installation angle of hangers.

3.1 Principle of determining system transformation scheme

The system transformation of the Jiangdong Bridge is necessary to satisfy the following requirements.

(1) Force and alignment of structure members meet the design requirements during the system transformation.
(2) Dip angle of the line connecting the cable band center and anchoring point should not exceed the permissible angle value range of steel pipes in the longitudinal and lateral directions. The designed value is 4 degrees, and the practical dip angle should be less than the allowable value.
(3) The safety coefficient of the permanent hanger tensile force can't be too low during system transformation. Hanger tension should be controlled under 230t in a real bridge and the corresponding value in the test model is under 2246N.
(4) Considering some factors such as temporary hanger anchorage, cable band installation and temporary hanger tension control. The maximum tension of temporary hangers is less than 120t in real bridges and the force should be controlled below 1171N during the test.
(5) The allowable displacement of the pylon top should be controlled below 6mm during system transformation of the model bridge.
(6) The stiffening girder stress can't exceed the allowable value during system transformation.

3.2 Description of the test

In this experiment, five pairs of temporary hangers were first tensioned step by step. The purpose of this action was to stretch the main cables to form spatial curves, which had little difference with the final alignment, and be helpful to installing the permanent hangers. Installation direction of the permanent hangers was from the bridge towers symmetrically to the center of the main span. Temporary hangers could be removed gradually when their role was substituted by permanent hangers. The temporary hangers at mid-span needed to be relaxed several times when the tensile forces had exceeded the normal value. Once the towers' longitudinal offset reached a certain value, pushing of the saddles should be executed. The frontal test found that the tension of each temporary hanger especially the middle ones would increasingly deviate from theoretical value, which led to the tensile forces of all permanent hangers deviating greatly from their theoretical values later in the

construction period. It was key to guarantee the permanent hanger tension reached a reasonable target value under the completed bridge stage by ensuring the temporary hanger forces were up to the design value in each working condition. Therefore, the tension of all temporary hangers should be adjusted to the calculated value after five pairs of temporary hangers had been anchored.

The calculated results showed that the problem, the traverse angle of S9/18 being more than 4 degrees when installing, could be solved by adjusting temporary hanger tensile forces; however there were still ten hangers whose installation angle exceeded by 2 degree. In the range of 1/4 span~3/8 span, the calculated angle difference of cable bands before and after hangers were installed was slightly large. In addition, due to the influence of LS2/4, the initial tension of S8/19 was extremely small and S8 appeared the situation of work in the later stages after anchored, that it was difficult to ensure construction quality.

In order to solve the above problem, a proposal scheme was put forward. The main idea of this approach was now that the installation angle of ten pairs of hangers was more than 2 degrees and transverse angle variation of the hangers in 1/4~3/8 span was large. The problem could be solved in the two pairs of hangers' installation, thus thoroughly solving the problem of the other hangers' installation? After repeated calculations (the finite element analysis software is Bridge Nonlinear analysis system BNLAS (Tang, M. 2003) developed by Southwest Jiaotong University), it was found that by adjusting the installation procedure of several permanent hangers it could greatly improve the transverse angle difference of hangers between the hangers' erection stage and finished stage, that is to say, after installing S6/21, measures were taken to install S9/18 in advance. In this case, the angle difference variation of the hangers which had not been installed was rather small; cable clamps were not influenced by subsequent process and could fix ahead of time. It was very favorable for quickening engineering schedule and improving construction quality. The sequence and control parameters of the recommended system transformation scheme are presented in Table 2.

Table 2. Sequence and control parameters of the recommended scheme .

Step	Operation content
1	Installing LS1 with 158.6N and LS5 with 155.7N
2	Pushing saddles toward mid-span by 0.02m at first time
3	Installing LS2 with 496.2N and LS4 with 480.9N
4	Pushing saddles toward mid-span by 0.017m at second time
5	Installing LS3 with 746.6N
6	Pushing saddles toward mid-span by 0.007m at third time
7	Adjusting all temporary hangers to the design value
8	Installing S1 with 401.5N and S26 with 410.2N
9	Installing S2 with 523.1N and S25 with 540.1N
10	Decreasing LS3 tensile force to 586N
11	Installing S3 with 488.3N and S24 with 500.4N; demolishing LS1/5
12	Installing S4 with 601.1N and S23 with 623.4N
13	Decreasing LS3 tensile force to 804.2N
14	Installing S5 with 488.9N and S22 with 517.4N
15	Installing S6 with 457.9N and S21 with 506.6N
16	Increasing LS2 tension to 892.7N and LS4 tension to 859.7N
17	Installing S9 with 867.6N and S18 with 1084.4N
18	Installing S10 with 1646.2N and S17 with 1699.4N
19	Pushing saddles toward mid-span by 0.007m at fourth time
20	Demolishing LS2/4
21	Installing S7 with 801.3N and S20 with 802.6N
22	Installing S8 with 559.5N and S19 with 555.5N
23	Installing S11 with 2192.6N and S16 with 2210.7N
24	Installing S12 with 1882.8N and S15 with 1883.9N
25	Pushing saddles toward mid-span by 0.006m at fifth time
26	Installing S13 with 1026.2N and S14 with 1021.1N
27	Pushing saddle toward mid-span by 0.0022m at fifth time
28	Demolishing all temporary hangers and temporary supports
29	Adjusting all hangers tension
30	Applying secondary dead load

3.3 Partial experimental results

As shown in Figure 2, the variation rule of hanger tension is described as follows: for a certain hanger, the anchoring force was relatively great. The tensile force decreased rapidly when installing a pair of hangers nearby. Moreover, the variation of the hanger tension tended to stability after a pair of hangers nearby it had been anchored.

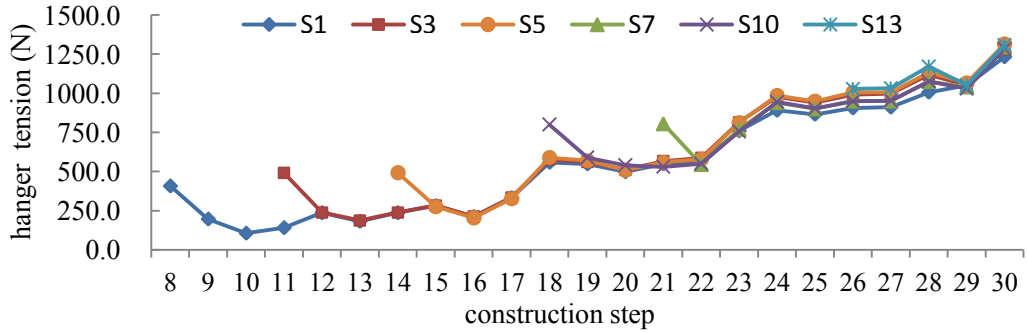

Figure 2. Tension of hangers in the construction process.

Figure 3 shows the experimental curves of support reaction of temporary piers. From the diagram it may be seen that support reactions gradually decreased with the construction progress, which suggested the weight of stiffening girder had transferred to the main cables from temporal piers by installing hangers. In later stages, the bearings on the two temporary piers near to pylons had no contact with the stiffening girder, but the ones close to mid-span bore a little pressure and the temporary piers could be safely demolished in order to complete system transformation.

Figure 4 shows the measured deflection curve of the stiffening girder during system transformation. We can see that the stiffening girder had almost no vertical displacement before the stiffening girder broke away from the bearings on temporary piers. However, once disengaging occurs, the vertical displacement changed obviously, thus the deflection at mid-section in the middle span was about 2.5cm under secondary loads.

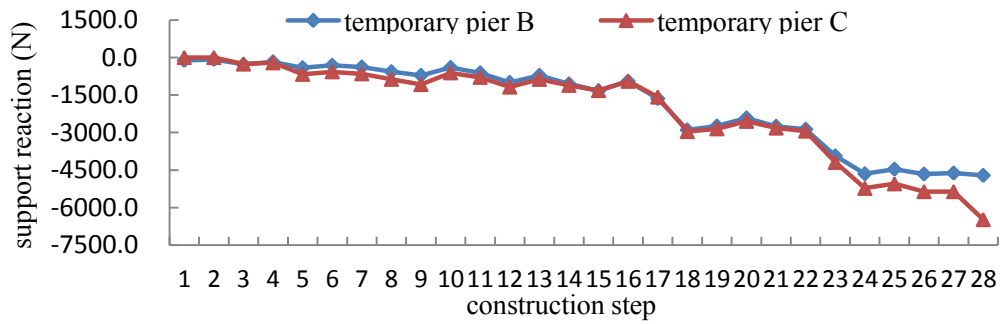

Figure 3. Support reaction of temporary piers in the construction process.

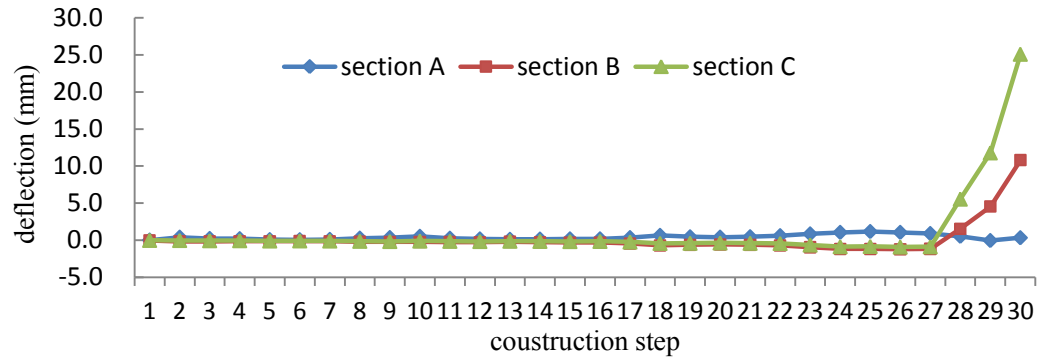

Figure 4. Deflection of stiffening girder in the construction process .

Figure 5 shows the envelope diagram of the transverse angle difference of hangers in the construction process compared with the finished bridge state. It can be seen that transverse angle difference of hangers was less than 2 degrees except that of LS9/18 and LS10/17 which were close to 4 degrees.

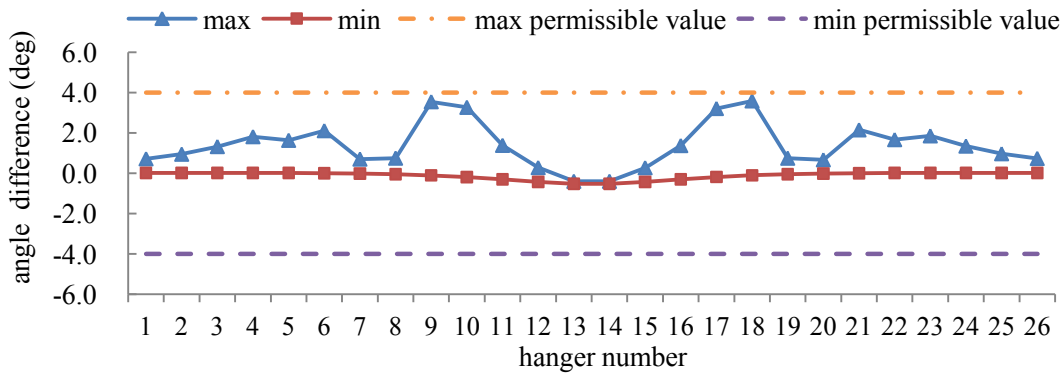

Figure 5. Envelope diagram of transverse angle difference of hangers .

4 Concluding remarks

Through the above research, the main conclusions are drawn as follows:

(1) The measured values of hanger tension and main cable configuration were identical to the calculated results satisfactorily. It shows that the calculation method ensures enough precision in cable force control and linear control, and can completely reflect the force state of the actual structure despite the width of the stiffening girder reaching to 3m.

(2) System transformation of the spatial cable self-anchored suspension bridge was implemented under the conditions of ensuring every temporary hanger tension at each step and reasonable tension sequence. The tensile forces of all hangers had almost attained the target value when all hangers were installed. Only individual hanger had the needed adjusting in fine. The alignment of the main cables and the stiffening girder was smooth.

(3) Once the stiffening girder was separated the from construction brackets, elevation variation of the stiffening girder was significant if the tensile force of every hanger increased or decreased a certain value on the whole. Individual adjustment of a certain hanger would have an obvious effect on the force of hangers nearby and play limit action for improvement of the stiffening girder alignment. According to this result, if the distribution of hanger tension is uneven, individual hanger tension can be adjusted. When the alignment can't achieve the demand, hanger tension needs to be adjusted one by one in order to make all the hangers increase or decrease by a certain value.

(4) In the model test, the problem of excessive installation angle of several hangers was solved successfully by adjusting the tension sequence of the hangers. In practical construction, after preliminary stretching S9/18, S10/17 was stretched, then tensile forces of the above four hangers were adjusted to achieve the design values simultaneously.

(5) The measured deformation of main cables and stiffening girder was in fair agreement with the calculated value. These indicated that main cable configuration and pre-displacement of saddle, etc. coincided with practical situation.

ABSTRACT

To improve the mechanical properties and durability of bridge deck pavement, four types of concrete are involved in this study, that is Plant concrete(PC), steel fibers reinforced concrete(SFC), steel fibers and polypropylene fibers reinforced concrete(SF-PFSC) and SF-PFSC with air-entraining agent (SF-PFSC+). The experimental researches on mechanical properties, impermeability and frost resistance of above four types concrete were done. The experimental results show that, comparing with other concrete with the same fibre volume ratio, , SF-PFSC, in which the steel fabre was partial replaced with polypropylene fibers, presents better flexural strength, flexural toughness and good durability, impermeability and frost resistance. By adding air-entraining agent, SF-PFSC+ shows not only excellent mechanical properties but also better impermeability and frost resistance. therefore, the SF-PFSC and SF-PFSC+ are suitable in the bridge deck pavement and can prolong the service life of bridge deck.

KEY WORDS: steel fibers(SF), polypropylene fibers(PFS), Concrete, mechanical properties, durability

INTRODUCTION

Presently most of the built and being built bridge deck pavements are the asphalt concrete. There are various premature damages of asphalt pavements on deck effected by environment and vehicals. these deterioration would have influence on performance and lifetime of bridge. The steel fibers reinforced concrete (SFC) applied to the deck pavement can improve the mechanical properties and toughness. The research results show that multi fibers reinforced concrete can make up the insufficiency of single fiber and improve obviously mechanical properties and durability of concrete. In this study, the mechanical properties and durability of the concretes which are the SF, the steel-fibers and the polypropylene fibers reinforced concrete (SF-PFSC) and the SF-PFSC with air-entraining agent (SF-PFSC+) were concerned with, and the influence on SF-PFSC durability by adding air-entraining

agent were also researched.

EXPERIMENT DESIGN

Based on the researches done by Dun F.Q.,and Zhang E. L (Dun 2008; Zhang 2008), While the volume ratio of SF and PFS are 0.5~0.7% respectively, SF-PFSC presents better mechanical properties and durability, more volume ratio of fibre can affect the concrete workability. In this study, the volume ratio of steel fibre is 0.7% and PFS is 0.5% in SF-PFSC. The volume ratio of SF is 1.2% in SFC. the content of air-entraining agent is 0.03% of amount of cement in SF-PFSC+. concrete proportion of specimen were shown in Table 1.

Table 1. concrete proportion of specimens

Type	Cement	Water	Sand	Coarse Aggregate	Expansion Agent	Water Reducing Agent	SF	PFS	Air-entraining Agent
PC	419	155	806	986	25	10	0	0	0
SFC	475	175	806	986	25	10	93.6	0	0
SF-PFSC	475	175	806	986	25	10	54.6	4.6	0
SF-PFSC+	475	175	806	986	25	10	54.6	4.6	0.143

The tests of concrete workability, mechanical properties, impermeability and frost resistance were done according to the *Experiment Method of the Steel Fibers Reinforced Concrete (CECS 13:89,1996)*.The specimen is 100 mm cube for compressive strength, there are three specimens for each group. The specimen for flexural strength and toughness is beam which the dimension is 100mm*100mm*400mm, three specimens for each group. The specimen for impermeability is truncated cone with the size 175mm*185mm*150mm, there are six specimens for each group. Approach to frost resistance is rapid freeze/thaw cycle, and measuring the compressive strength and flexural toughness after freezing and thawing..

Table 2. Experimental Results of mechanical properties.

Specimen	Slump (cm)	Compressive Strength (MPa)	Flexural Strength (MPa)	Flexural Toughness Index		
				I_5	I_{10}	I_{30}
PC	16	51.1	5.26	5.24	6.12	6.12
SFC	10	45.0	6.48	6.88	9.16	11.54
SF-PFSC	17	38.2	4.45	5.40	11.68	33.70

DISCUSSION OF EXPERIMENT RESULTS

Concrete workability. The slump of fresh concrete are shown in Table 2. The results show that PC workability is the better than that of other concrete, adding fibers can decrease the slump. The slump of SF-PFSC increases 40% than that of

SFC and can meet the requirement of flowability. It is concluded that when the total volume ratio of fibers is same, the replacement of partial SF with PFS is advantageous to improve SFC working performance.

Compressive strength The specimen curing age is 28-day and 100-day. The experimental results of compressive strength are shown in Table 2 and Table 4, respectively. From Table 2, The results show that the SFC and SF-PFSC 28-day compressive strength are slightly lower than that of PC. The SF-PFSC 28-day compressive strength is slightly higher than that of SF.

However, from the results showed in Table 4, when the curing age of concrete is 100d, the SF and SF-PFSC compressive strength are higher than that of PC.

Flexural strength The specimen curing age is 28d. The experimental results of 28-day flexural strength are shown in Table 2. The fibers could improve the PC flexural strength; the SF-PFSC flexural strength is the biggest of all the specimens, which increases 23.7% than that of PC. When the fibers ratio is the same, the SF-PFSC flexural strength is slightly higher than that of SFC.

Flexural toughness. Flexural toughness is expressed by the toughness index according to ASTM C1018 (Ashour, 1993). This method regards 3δ, 5.5δ and 15.5δas specified deflections(shown in Figure 1),here,δ is the deflection in accordance to the initial cracking,. The flexural toughness indexes(I_5, I_{10}, I_{30})are calculated by equation (1)~(3):

$$I_5 = \frac{A_1 + A_2}{A_1} \qquad (1)$$

$$I_{10} = \frac{A_1 + A_2 + A_3}{A_1} \qquad (2)$$

$$I_{30} = \frac{A_1 + A_2 + A_3 + A_4}{A_1} \qquad (3)$$

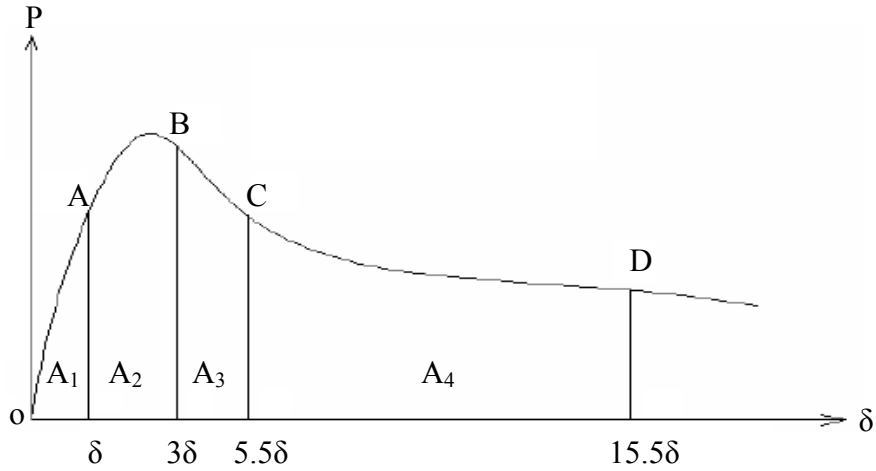

Figure 1. Toughness index of ASTM C1080.

The flexural toughness experimental results are shown in Table 2, and the Load-deflection response is shown in Figure 2.,From the toughenss test results, it can be seen that the flexural toughness indexes of SFC and SF-PFSC are bigger than

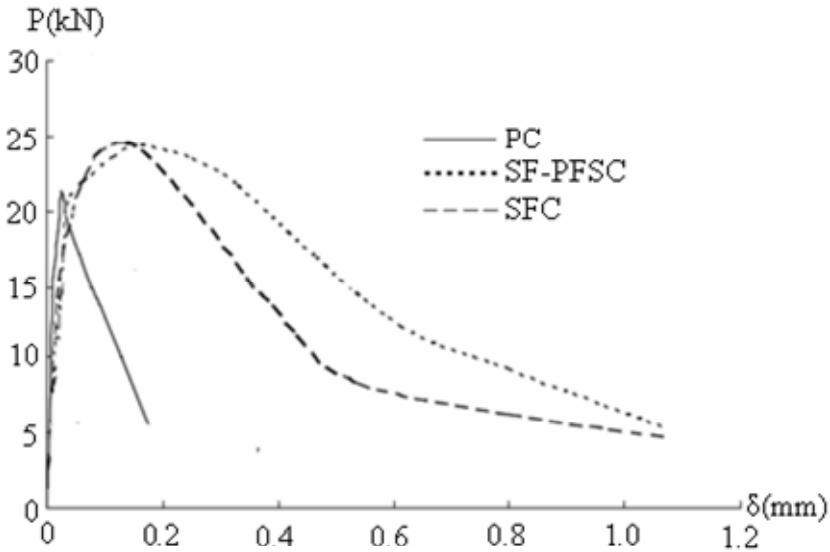

Figure 2. P-δ response of concrete

those of PC; I_{10} and I_{30} of SF-PFSC are the biggest of all, which respectively increase 113% and 479% than those of PC. Comparing the P-δ curves, the SF-PFSC descending stage is slowest, I_{10} is up to11.68, a growth of 122% on I_5, andI_{30} increases 172% than I_{10} as well. SF-PFSC presents better ductility of post peak. When the fibers total volume ratio is same, the partial replacement of SF with PFS can improve SFC flexural toughness.

Experimental results of impermeability. three PC specimens were

seepaged when the pressure is 2.0 MPa,. For SF, SF-PFSC and SF-PFSC+, there were no seepaged specimens untill seepage pressure reached 3.0 MPa and seepage depths were measured. The experimental results are shown in Table 3.

Table 3. Experimental Results of Impermeability.

Specimen	Load Time (h)	Seepage Pressure (MPa)	Average seepaged Depth (mm)
PC	64	2.0	permeable
SFC	224	3.0	53
SF-PFSC	224	3.0	37
SF-PFSC+	224	3.0	31

From the test results, the impermeability of fibers reinforced concrete is better than that of PC. Comparing the average seepage depths of SFC and SF-PFSC, it is can find that the seepaged depths of SF-PFSC is 70% that of SFC, the impermeability of SF-PFSC is better than that of SFC when the seepage pressure is same. Because the fibers of different sizes and properties are distributed to be An openwork fabric or structure in the cement matrix, the fibers spacing is decreased, and superimposed and strengthening effect of various interface layers is created in three dimensions. The pore structure of concrete is optimized, the size and open air of pore is decreased, it would cause the decrease of water permeate (Sun D.S., 2004, Wang H.X., 2004). It is concluded that the replacement of partial SF with PFS is advantageous to improve impermeability of SFC, when the fibers total volume ratio is same. The average seepage depth of SF-PFSC+ is 84% of SF-PFSC. It can be seen that adding air-entraining agent can improve impermeability of SF-PFSC.

Experimental results of frost resistance. After 150 times of freezing/ thawing cycles, weight loss of specimen began to increase obviously, the various spalling damages occurred on the specimen surface finished, and then the mechanical properties and flexural toughness tests were done. . The curing age of the specimen is 100-day. The test results are shown in Table 4. The frost index are present by AFT/BFT.

the Frost index of the peak load and compressive strength of SF-PFSC are lower than those of SFC after the freezing and thawing test, the decrease ratios of flexural toughness indexes of SF-PFSC are near to those of SFC. It is concluded that the replacement of partial SF with PFS can improve frost resistance of SFC when the fibers total volume ratio is same. The decrease ratios of SF-PFSC+ peak load and compressive strength are 24% and 70% of PC respectively, 45% and 85% of SF-PFSC respectively. The decrease ratios of SF-PFSC+ peak load and compressive strength are 24% and 70% of PC respectively, 45% and 85% of SF-PFSC

respectively. The decrease ratios of I_5 and I_{10} for SF-PFSC+ are 3.6%, 5.9% (As shown in Table 4), they are near to those of SF-PFSC and SFC. I_{30} of SF-PFSC+ is the biggest, the decrease ratio of it is 4.1%, and it is lower than those of SF-PFSC and SFC. It can be draw a conclusion that adding air-entraining agent can improve frost resistance of SF-PFSC.

CONCLUSION

Through the analysis of test results, we may draw the following conclusions.

(1)The replacement of partial SF with PFS can improve workability, mechanical properties, impermeability and frost resistance of SFC when the total volume ratio is same.

(2)Adding air-entraining agent can improve impermeability and frost resistance of SF-PFSC. SF-PFSC+ shows not only excellent mechanical properties but also better impermeability and frost resistance..

ABSTRACT

As an industrial waste, fly ash has been widely used in bulk and low strength concrete. Bridges have to endure numerous freeze-thaw cycles and the erosion of air pollution when exposed to air. Therefore, the durability investigation of fly ash concrete bridge in the extremely cold area is necessary. In this paper, the concrete (designated as C50 fly ash concrete) was prepared by mixing II degree fly ash with water, cement, and water reducing agent. The water-cement ratio was selected by contrast analyses of several samples. The strength of C50 fly ash concrete was tested after 150 freeze-thaw cycles and corrosion in Na_2SO_4 and HCl solutions of different concentrations, respectively. The strength declination was achieved, which is similar to the ordinary concrete. As the erosion liquid concentration increased, its influence on strength of concrete also increased. The conclusions of this paper provide important reference data for the design and application of fly ash concrete in cold regions.

INTRODUCTION

In the extremely cold regions, bridges exposed to air are frequently subjected to acid rain, corrosive gas or liquid, and the impact of freeze-thaw cycles. These adverse environments severely affect the durability of the bridges; therefore a lot of bridges in the far north of China have to be reinforced before they meet the designed life span.（Pu 1994) In the extremely cold areas, the complete or partial loss of bearing capacity of the concrete under the impact of corrosive freeze-thaw cycle is one of the main factors that shortens the life of bridges. Therefore, to improve the durability of concrete in cold areas is one main method to improve the durability of concrete bridges in the extremely cold areas.（Tang 2007) Although the research on enhancing the quality of the concrete through Ⅰ degree fly ash has a wide range of applications,

Ⅰ degree fly ash accounts for only a small part of the ash in the plants. The higher prices also hindered its effective utilization. In contrast, II degree fly ash, with a larger output, can be mixed into the concrete to produce high quality concrete. Therefore, it is an effective way for the cement concrete industry and the environment to achieve sustainable development.（Wu 2004)

In this paper, II degree fly ash mixed with super-plasticizer was used to prepare the fly ash concrete. Meanwhile, the rule of strength variation of different-volume fly ash concrete was also explored using repeated freeze-thaw circles under the corrosion of Na_2SO_4 and HCl solutions. These results will provide an important reference for the durability design and application of fly ash concrete in cold regions.

MATERIALS PREPARATION AND TEST METHODS

Materials Preparation. Materials were prepared following the steps below:

(1) Cement: ordinary Portland cement 52.5 made in Benxi, Liaoning;

(2) Fly Ash: II degree fly ash, made by Shenhai Thermoelectricity Plant in Shenyang Liaoning, particle fineness modulus 17.5;

(3) Aggregate: a) fine aggregate: sand, well graded; b) coarse aggregate: limestone gravel, graded good (maximum diameter 25mm);

(4) Water: general water, pH value of 7.2;

(5) Admixture: super-plasticizer made in Shenyang;

Ratio and samples. Newly mixed concrete with II degree fly ash at the contents of 10%, 18% and 25% and 1% super-plasticizer were used to produce 100 × 100 × 100mm cubic specimens using the standard test casting. In the standard conservation room, the specimens was conserved for one day, demodulused, numbered, and then continued to be conserved in conservation-boxes. After 28 days, they were placed in the indoor environment at 20-25 ^{o}C. The strength values after 7d, 14d, 28d, 60d, 90d and 120d were measured using 6 individual specimens as shown in Table 1. The representative value of the strength was obtained by removing the maximum and the minimum values and averaging the strength value of the four specimens.

30 groups of allocated proportion and strength tests were carried out according to “A Practical Handbook for the Concrete Mix” and “Concrete Standards and Engineering Applications”（Li 2007, Leng and Zhang 2005). 7 representative groups of the allocated proportion data were listed in Table 2 with the unit as kgm^{-3}.

Concrete freeze-thaw cycle test. In order to stimulate the real building corrosive conditions in nature, the strength variation of concretes with water-cement ratio of 0.38, sand rate of 29%, and content of II degree fly ash at 0%, 10%, 18%, 25% were

subjected to freeze-thaw cycle tests. In detail, the concrete samples were frozen first and then treated by Na_2SO_4 or HCl solutions. The two-step procedure was repeated 150 times. The concentrations of the Na_2SO_4 solution were 0.05, 0.1, and 0.5 $molL^{-1}$, respectively. The pH value of the HCl solutions was 3, 4, and 5, respectively. Figure 1 shows the strength variation curves of the concretes after 150 freeze-thaw cycles using Na_2SO_4 (left) and HCl (right) as the corrosion solutions.

Table 1. Average compressive strength of concrete

Age Period	0%	10%	18%	25%
3 d	35.78	32.20	29.58	22.27
7 d	42.17	40.70	37.72	30.76

4	347.1	115.6	366.7	1324.7	166.5	3.471
5	462.5	154.2	258.7	1286.8	166.5	4.625
6	478.4	159.4	255.3	1297.0	166.5	4.784
7	365.1	121.7	460.3	1206.1	166.5	3.651

TEST RESULT AND ANALYSIS

Affect of ash fly quantity on concrete strength. All experimental results showed that under standard conservation conditions, the compressive strength of the concrete mixed with 25% fly ash increased slowly and doesn't meet the desired standard of the concrete C50. After 90 days, the compressive strength of concrete mixed with 10%, 18% and 25% II degree fly ash became equal to that of concrete C50 as shown in table 1. This means that the compressive strength of the fly ash concrete increased continually from the 28^{th} to the 120^{th} day; whereas the strength of the control non-fly ash concrete increased relative slowly. After 120 days, the strength of the fly ash concrete was close to or higher than that of the ordinary concrete, suggesting that the dense surface of the II degree fly ash particles slowed down the early development of

the strength. At the early stages, the internal energy of fly ash was not released; and the strength of the concrete was dominated by the hydrates in the cement. Therefore the reaction rate was relatively slow which resulted in lower strength in the early stages. SiO_2 and Al_2O_3 from fly ash and cement can hydrate $Ca(OH)_2$; then $Ca(OH)_2$ covers the surface of fly ash and generates calcium silicate and calcium acuminate. Due to the hydrolyzed layer between $Ca(OH)_2$ thin film and fly ash surface, Ca^{2+} gives a reaction with living tissue of fly ash and product gathers in layers. If the hydrolyzed layers aren't filled with products, the strength doesn't increase more. With the products filling in the hydrolyzed layers, fly ash and products form firm connection and lead to increased concrete strength, impermeability and abrasion resistance. This is the main reason for the lower early strength and the high mature strength（Hansson and Strunge 1985）.

Affect of freeze-thaw cycle on concrete strength. Figures 1 and 2 show that the compressive strength of II degree fly ash concrete and C50 concrete both decreased obviously after the freeze-thaw cycle test using Na_2SO_4 corrosion.（Liu and Ning 2005). With the increase of the Na_2SO_4 concentration, the fly ash II concrete strength decreased. In addition, the strength of the II degree fly ash concrete decreased more obviously than that of the ordinary concrete after treated with the same Na_2SO_4 solution; and the strength decreased more obviously with the increasing of the II degree fly ash content. The reason for this is that the effect of fly ash quantity on liquor concentration is insensitive and that the acid fastness fly ash is better than common concrete. The appropriate amount of fly ash makes the inside of concrete hydrate continually; and the products fill in the interval of concrete. The concrete become gas-tight and dense; consequently, the strength of concrete continues to grow. The change strengthens the chemical resistance, infiltration and frost resistance and improves the durability of concrete.

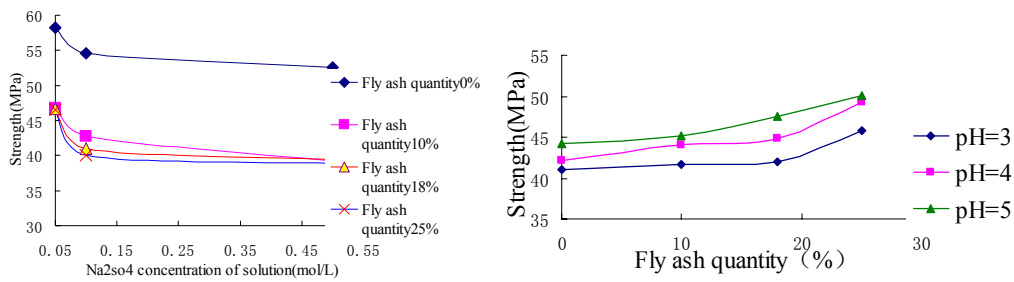

Figure 1. Strength variation curves of fly ash concrete taking Na_2SO_4 (left) and HCl (right) as the corrosion solution after 300 freeze-thaw cycles

Figure 2. The destruction process of concrete containing 18% quantity fly ash after 150 freeze-thaw cycles

CONCLUSIONS

In this paper, II degree fly ash was used instead of cement to produce the fly ash concrete. The reasonable usage of fly ash in concrete will save large amount of cement therefore lower the construction cost. Besides, the successful usage of the fly ash will provide valuable data for the production of other kinds of high quality concrete to satisfy the social and engineering requirements.

Four conclusions are drawn as follows based on the experimental study:

(1) The compressive strength of II degree fly ash concrete increased relatively slowly in its earlier period of conservation, and its strength did not meet the standard of C50 after 28 days. However, with extension of conservation time from the 28th day to the 120th day, its strength increased continually due to the interaction between the active components in the concrete. Finally the strength meets the standard of C50 after 120 days. This result suggests that the concrete contains reasonable amounts of fly ash II and super plasticizer can satisfy the strength standard of C50.

(2) The freeze-thaw cycle experiment showed that both SO_4^{2-} and H^+ ions had negative impact on the strength of the II degree fly ash concrete. Although the strength of both the ordinary and the fly ash II concrete decreased with the increasing of the ion concentration, , the decrease extent of the II degree fly ash was lower, suggesting the action of II degree fly ash in improving the concrete strength and corrosive abilities.

(3) Based on strength change from freeze-thawing tests of fly ash concrete at different fly ash quantities, once the II degree fly ash concrete became corroded and frozen, its strength could not match the strength standard of the ordinary concrete, suggesting that the II degree fly ash concrete be unsuitable for winter use. However, in conditions of non-freezing, the II degree fly ash can be used as an ingredient for high strength concrete with prolonged service life.

ABSTRACT

In seasonal frozen areas, shallow landslide hazards usually occur in soil slopes, which pose a serious threat to road safety. The factor leading to the soil slope failure is the shear strength reduction of the soil in the zone between the freezing and thawing surface. In this research, model experiments of freeze-thaw soil interface with different aggregate materials are designed by alternating the freeze-thaw cycling time and the water content of soil. Subsequently, the relationship between the shear strength and freeze-thaw cycling time is obtained. Finally a shear strength deterioration modal of the soil surface is proposed. The major parameters and influence factors of melting soil slope failure are related to the earth stress and slope geometry, so based on the fully understanding of the shear strength, the research result could not only present guidance to locate the landslide position, but also offer advices for slope design and stability analysis in seasonal frozen regions.

Key words: road engineering; deterioration model; freezing and thawing surface; shear strength; seasonal frozen regions

INTRODUCTION

Slope instability damages, earthquakes and volcanoes are three major global geological disasters. In seasonal frozen regions, because of water moving through the soil, as well as soil gravity, shallow landslide hazards in soil slopes usually occur in spring thawing period, which pose a serious threat to the safe operation of highways (Sally, 2008). The research of the impact of freeze-thaw (F-T) cycles on soil shear strength has not only a certain effect in accelerating the movement of frozen soil (Liu, 2006), but also a practical significance in engineering design, construction and management in cold regions (Chen, 2003).

After a few F-T circles, the soil structure changes, the frost water enlarges the soil voids, and reduces shear strength of the soils (Xu, 2006). At the same time, water in the F-T soil layer moves out and gathers above the F-T layer. This forms an interlayer between the soil, and the shear strength of the interlayer decrease

substantially, which results in the increase in the probability of a slide. It is believed that when the soil is melting, sliding will go along the freezing-thawing surface, which is parallel to the slope surface (Chen, 2008). Soil slope sliding depends largely on the soil shear strength indicator (Sean, 2001). When the slope angle keeps unchanged, as the slope thawing depth increases, the downslide force from the gravity of the thawed soil will increase. The normal part of the gravity of the upper thawed soil can offer certain compressive stress, but the increase rate is less than the increase rate of downslide part of the gravity .When the shear strength along the shear surface τ_f loses to some degrees, the safety factor of the slope will reduce, therefore the research on the deterioration of shear strength along the boundary surface of the freezing and thawing zones can serve as the starting point for slope stability analysis by means of the mechanical model.

Because of the difficulty in modeling a freezing - thawing interface, the present literatures have only presented the limited research on the shear strength of the entire zone of the melted soils. There is no research that has addressed the shear strength variation on freezing - thawing surface and shear strength parameter changes in the critical state, as well as the analysis of shear strength deterioration in the freeze-thaw cyclic condition. It is necessary to setup a reasonable experiment method for predicting and analyzing the ultimate shear strength of the freezing-thawing surface.

Experiment on shear strength of freeze-thawing surface

The basic principles and methods of the experiment

In order to analyze the shear strength deterioration on sliding surface under the circumstances of different freezing - thawing circles and water contents, when there is relative movement inside the soil mass, a direct shear testing plan is designed as follows.

Freezing point of salt water is lower than the common water, so in this research we use different water to model the supper and lower parts of the sample and get freezing-thawing surface at $-3°C$. We obtain a shear strength curve of the freezing and thawing surface, and then simulate the actual situation of the freeze and thaw effect on the shear strength of the freezing - thawing surface.

(1) The correction coefficient

In this experiment we adopt EDJ-Ⅰ strain-controlled direct shear equipment.

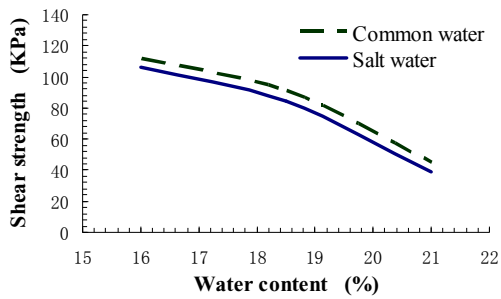

Figure1. Shear strength comparison with different water content between samples made by salt and water, respectively

Because of the use of salt water, taking into account the difference of salt water and common water, in this text we put forward the correction coefficient of the two materials.

$$\tau_S = \eta \cdot \tau_W \quad (1)$$

In which η is the correction coefficient of shear strength, τ_S is shear strength of the salt water sample, and τ_W is the shear strength of the common water sample.

In this text we take the correction factor as 0.946, with which to correct the shear strength value of the test samples (see Figure.1).

(2) The basic parameters of the soil

We alter the moisture content based on the optimum moisture content of the slope soil. We used a mould to make a soil sample with the diameter of 61.8mm and height of 20mm. We made 15 samples at every water content level. Then we get the shear strength through the curve. With the same method, we change the F-T times and compare the shear strength deteriorations.

The basic index is listed, such as natural water content, the largest dry density and the optimum moisture content (See Table 1).

Table1. The basic parameters of the soil

	Natural water content	Largest dry density	Optimum moisture content
Values	3.2%	1.68g/cm^3	21%

Analysis of the results

We compared the experimental results of the samples which experienced the F-T circles and the samples which did not, and we analyzed the levels of the shear strength deterioration under different water contents and F-T circle time.

From the failure mode of different samples, we know when the freezing-thawing surface slides, the upper part and lower part failed with the increasing strain. We can see ice crystal structure on the lower freezing surface. In addition, we observed that the readings of the direct shear machine often move back and forth. From the failure mode we can judge that when the freezing-thawing surface was subjected to shearing, the slippage occurred on the freezing-thawing surface, because the friction coefficient on the surface is less than the soil itself. That is why the shear strength of the freezing - thawing surface is lower than those of common samples.

The shear strength of the samples with the same water content is presented as follows (see Figure 2).

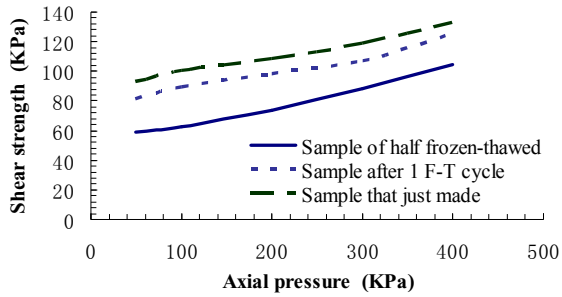

Figure 2. Comparison of the shear strength of the tested samples

Samples in group 1 are not frosted, in group 2 are after one time F-T circle, and in group 3 are in the semi-frozen state. We can conclude that the shear strength on freezing - thawing surface is obviously less than the other two conditions. Under the same normal stress，the shear strength of group 2 is just 74.4% of the shear strength of group 1.

The shear strength of the tested samples which are just separately made, through an F-T circle, and in the semi-frozen state are compared (see Figure 3). We can draw a conclusion that the shear strength on the freezing-thawing surface with different water contents are less than that on the surface of just-made samples and samples through F-T circles, the former is about 76.2% of the latter. As the water content increases, the decline is more obviously observed. As for the test samples with water content of 21%, the shear strength is 61.6% of the samples with water content of 16%.

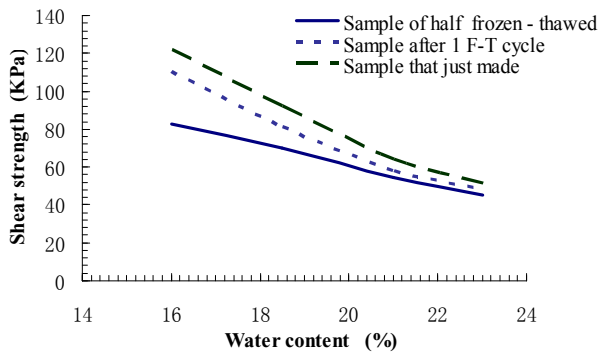

Figure3. Comparison of the shear stress strength at different water contents

The effect of water content on shear strength under the same normal pressure is compared in Figure 4.

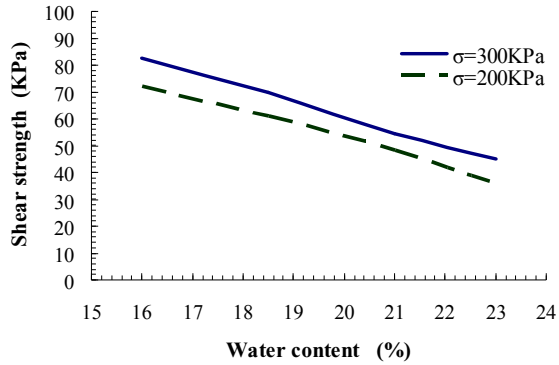

Figure4. The variation of shear strength of the interface with different water contents

We can find that with the increase of water content, the shear strength of the freezing-thawing surface decreases obviously. As the water content increases from 16% to 21%, the shear strength of the freezing-thawing surface has a decline of 32.6%. It illustrates that water in the soil plays an important role in the progressive slide, and water content reduction is the key to prevent slide. As the axial pressure increases from 200kPa to 300kPa, the shear strength of the freezing-thawing surface increases by 12.7%.

F-T shear strength deterioration model based on the test results

Considering the effects of F-T cycles on the shear strength of the freezing –thawing surface, we separately make samples with different types of water (salt water and common water). After the F-T cycles, they are directly sheared under the state of the half zone frozen. We analyzed the deterioration of the shear strength after the F-T circles (see Figure 5). The experiment data shows that the shear strength decreases with the increases in water content and the F-T circle times. With the same water content, the shear strength of the sample which went through 5 times F-T circles is 70.3% of the former shear strength.

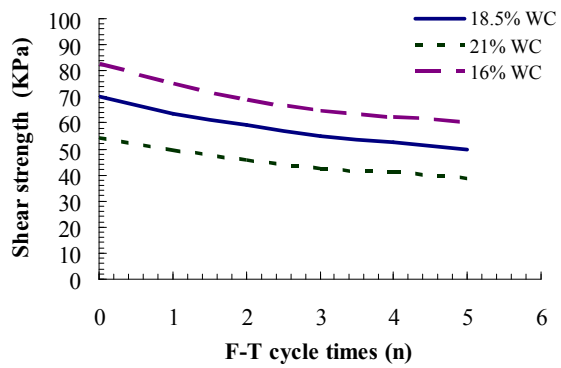

Figure 5. The shear stress strength of the interface under different F-T cycle times

In order to analyze the effect of F-T times on the shear strength, we propose the F-T deterioration model based on the test results. we take

$$\beta_n = \frac{\tau_n}{\tau_0} \qquad (2)$$

In which β_n is the deterioration coefficient, τ_n is the F-T shear strength after n times F-T cycles and τ_0 is the initial F-T shear strength.

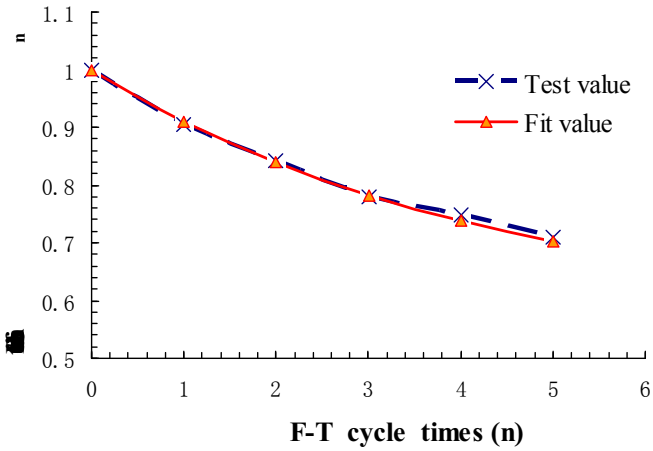

Figure 6. Curve fitting of the F-T deterioration model and experimental values

From equation (2), we got the curve of β_n and n through the experiment, which was presented in Figure 6), then had the curve fitting, and got the F-T deterioration model:

$$\beta_n = 0.47e^{-0.234n} + 0.57 \qquad (3)$$

In which, n is F-T circle times. The F-T deterioration model is based on the experiment results, and could present guidelines for analysis of soil slope stability in seasonal frozen regions.

CONCLUSION

1. In the paper, a testing method is discussed and applied a test method to locate freezing - thawing surface using the trait salt water which has low freezing point. The direct shear tests are conducted on the freezing - thawing surface for the soil samples are subjected to different F-T cycle times. The results show that the shear strength of the freezing - thawing surface decreases with the F-T circle times increased.
2. The water content is the main factor that affects the shear strength, as the water content varies from 16% to 21%, the shear strength decreases by 39.9%.
3. In the paper, curve fitting is employed to establish the shear strength deterioration model on the freezing-thawing surface. The model truly reflects the shear strength

deterioration of the inner freezing-thawing surface when the soil slope is melting.
4. The shear strength deterioration along the freezing-thawing surface that the research brought forward can provide guidance for future analysis of soil slope stability in seasonal frozen regions.

ABSTRACT

Reinforcing the bonding of the young concrete overlay and the old concrete with mechanical joint element (MJE) is an effective measure to repair the used concrete pavement. Splitting tests of the young and old concrete samples with MJE were carried out and the simulation results using the finite element method to assess mending effects by MJE under wheel load were analyzed. The design method and construction method to repair the used concrete pavement with reasonable MJE ratio is proposed. Example calculation results indicate that the repaired pavement with MJE presents good performance under the comprehensive fatigue stress of load and temperature in design period.

Key words: used concrete pavement; mechanical joint element; interface; design method; construction method

INTRODUCTION

At present, the repaving design of old concrete pavement is still in research stage in China. The lightly damaged old concrete can be used as the lower structure layer of the repaired roads. This measure makes use of waste to reduce environment pollution. Large quantity of base material and the expense of machinery and manpower to break the old concrete can be saved (Feng, X. D. 2007). But the bonding between the young and old concrete usually presents bad performance. Young and old concrete will crack easily at their joints under the wheel load. A design and construction method of overlay with MJE on used concrete pavement is proposed in this article. The performance of the used concrete can be improved greatly and the social and economic efficiency is considerable.

In the US, the anchor bolt was once used on the edge of the highway and the bridge pavement to prevent the edge rolling-up; in Switzerland, there was the application example of mechanical joint in the bridge, but in other countries the standard and the criterion were not formed yet. The design and construction method of repaving with MJE is put forward by use of research results about the young and old concrete with MJE of our team (Zhao, X.Y. 2004 and Xu, X.W. 2006). Performance under the fatigue stresses of wheel load and temperature of the repaired road with MJE is discussed.

DISCUSSIONS ON TEST AND NUMERICAL SIMULATING RESULTS

Splitting test specimens were described in reference (Zhao, X. Y. 2004). Specimen making and split test are indicated in Figure 1. The strength grades of the young and old concrete were C40 and C35 respectively. Splitting strength of the young and old concrete combining specimen with MJE embedded with epoxy resin mortar and the combining specimen without MJE were 2.43MPa and 1.95MPa respectively (Zhao, X. Y. 2009). The result indicates that the MJE can improve the combined performance of young and old concrete significantly. The models of the finite element analysis were described as reference (Xu, X.W. 2006). Results of numerical simulations of the repaving road slab with MJE ratio of 0% and 0.35% is indicated in reference (Xu, X.W. 2006).

Pre-cracking, the displacement in y direction of the model of 0.35% MJE ratio is approximately equal to that without MJE. Post-cracking, the shear stresses in x and y direction of the model with 0.35% MJE ratio are less than those of the model without MJE, which indicates that MJE can control the development of shearing stress and inhibit the development of crack in the young and old concrete interface effectively when the MJE ratio reaches 0.35%.

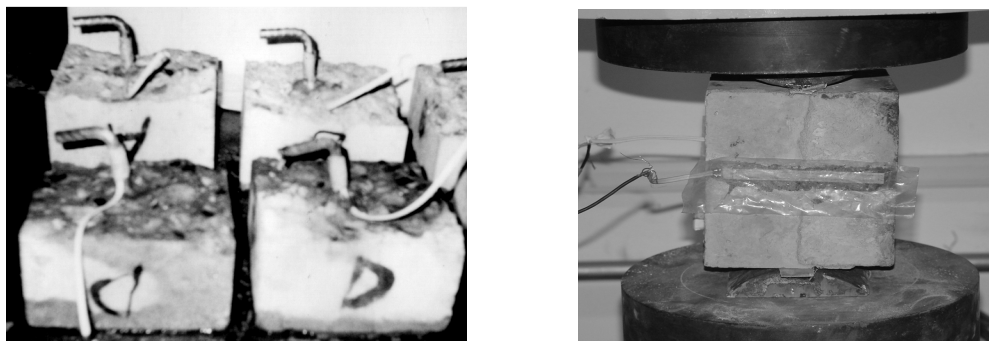

Figure 1. Specimens making and split test

DESIGN METHOD OF OVERLAY WITH MJE ON USED CONCRETE PAVEMENT

Specifications of Cement Concrete Pavement Design for Highway (Zhongjiao Highway Plan Design Institute, 2002) specified that the stress of the overlay and the old concrete slab is calculated according to the combined double slab when the combined overlay structure on used concrete pavement is designed. Thickness, flexural tensile strength, standard value of modulus and equivalent rebound modulus of base of old concrete slab are determined by measured values mentioned in section 8.4. The thickness of overlay is determined by the stress of the old concrete slab that meets the requirement of equation (3.0.3). The clauses and equations mentioned in this section are quoted from reference (Zhongjiao Highway Plan Design Institute, 2002).

Only the stress of the old concrete slab is calculated in this method, the stress state of the young and old concrete interface isn't considered. Considering that the interface will possibly be destroyed before the old concrete slab, it's necessary to validate the bonding performance. The design method that considered temperature fatigue stress of the young concrete overlay and the interface between the young and old concrete slab is discussed by the following example.

The surface course of a constructed highway in natural zoning for highway

Ⅱ is ordinary concrete, the board is 5m long, the longitudinal joint is the rabbet with tension bars. Traffic investigation indicated: standard axle load date function number of times is 3800 present and the highway is open to traffic for 10 years. Investigation evaluation showed that grading standard of pavement damage and load transfer capacity of the joint is good. The combined concrete pavement is planed to repair the concrete road.

Original concrete surface course is 0.3m thick, 1/3 thickness of slab is planed to be broken, and the residual old concrete slab is 0.20m thick. 0.12m thick young concrete layer is planed to be repaved on the old concrete slab. The original base is cement stabilized grain (cement content 5%) with a thickness of 0.18m. The cushion is the 0.15m thick low dose soil stabilized with inorganic binding materials. Design reference period of highway is 30 years. The safety class is I (first class). Wheel path lateral distribution coefficient in critical loading position is 0.22. The annual average rate of traffic growth is 5%. The accumulated standard load acting number on lane in design reference period calculated according to equation A.2.2 is 1009×10^4, so the road belongs to heavy traffic classes. (The letters' meanings in the equation is referred to <Specifications of Cement Concrete Pavement Design for Highway>. And so are the letters in the following equations.)

$$N_e = \frac{N_s\left[(1+g_r)^t-1\right]\times 365}{g_r}\eta = \frac{3800\times\left[(1+0.05)^{20}-1\right]\times 365}{0.05}\times 0.22 = 1009\times10^4$$

The standard value of flexural tensile strength of surface plain concrete is 5.0MPa. The standard value of modulus is 31GPa correspondingly. Rebound modulus of subgrade is assumed as 30MPa. Rebound modulus of the cushion and the cement stabilized grain base is 600MPa and 1300MPa respectively. The splitting strengths of the old concrete and the combine concrete of young and old concrete are 2.40MPa and 2.43MPa according to the test results. The standard values of their flexural tensile strengths are 4.13MPa and 4.15MPa correspondingly. The standard value of modulus of the old concrete is 27GPa. The equivalent rebound modulus of base top surface (Et) is calculated as 165MPa.

Traditional design of combining overlay with used concrete pavement. According to the appendix C, the stresses on critical loading position of the upper (σ_{ps1}) and lower concrete slab (σ_{ps2}) due to standard axle load are calculated as 0.27MPa and 0.66MPa. Correspondingly, the fatigue stresses on critical loading position are 0.67MPa (σ_{pr1}) and 1.63MPa (σ_{pr_2}) calculated according to equation B.1.2.

$$\sigma_{pr} = k_r k_f k_c \sigma_{ps} \qquad \text{(B.1.2)}$$

The maximum temperature gradient is taken as 88C/m according to natural zoning for highway. The thermal stress coefficient (B_x) is taken as 0.69 according to Fig.B.2.2. The maximum thermal curling stress of the lower slab of the combining concrete pavement (σ_{tm2}) is calculated as the following.

$$\xi_2 = 1.77 - 0.271\ln\left(\frac{h_{01}}{h_{02}}\frac{E_{c1}}{E_{c2}} + 18\frac{E_{c1}}{E_{c2}} - 2\frac{h_{01}}{h_{02}}\right)$$

$$= 1.77 - 0.27\ln\left(\frac{0.12}{0.2}\times\frac{31000}{27000}+18\times\frac{31000}{27000}-2\times\frac{0.12}{0.2}\right)$$
$$= 0.96$$
$$B_{x2} = \xi_2 B_x = 0.96\times 0.69 = 0.66$$
$$\sigma_{tm2} = \frac{\alpha_c E_{c2}(h_{01}+h_{02})T}{2} B_{x2}$$
$$= \frac{1\times 10^{-5}\times 27000\times(0.12+0.2)\times 88}{2}\times 0.66$$
$$= 2.51\text{MPa}$$

k_t is the thermal fatigue stress coefficient of ordinary concrete surface; σ_{tr} is the thermal fatigue stress at the critical loading position. They are calculated as 0.581 and 1.46MPa according to equation B.2.3 and B.2.1.

$$k_t = \frac{f_r}{\sigma_{tm}}[a(\frac{\sigma_{tm}}{f_r})^c - b] \qquad \text{(B.2.3)}$$

$$\sigma_{tr} = k_t \sigma_{tm} \qquad \text{(B.2.1)}$$

The safety class of the highway is First. The target reliability is 95%. The relative deflection level class is low, so reliability coefficient γ_r is determined as 1.33.

$$\gamma_r\left(\sigma_{pr}+\sigma_{tr}\right) = 1.33\times(1.63+1.46) = 4.11MPa < f_r = 4.13MPa$$

So the assumed thickness 0.12m of the concrete overlay can bear fatigue stress acting of wheel load and temperature in design reference period fully.

Calculating the temperature fatigue stress of the young concrete and the interface. The temperature fatigue stress is calculated according to two methods. The first method is taking the repaving as a separate type overlay; the other is taking the repaving as a new concrete monolayer. The higher value will be chosen to combine with the load fatigue stress.

If the temperature fatigue stress is calculated according to a separate type overlay, the maximum thermal curling stress of the upper slab of the separate type overlay (σ_{tm1}) is calculated as 1.23MPa according to equation C.2.2. Thermal fatigue stress coefficient of young concrete overlay (k_t) and thermal fatigue stress on critical loading position (σ_{tr}) are calculated as 0.360 and 0.44MPa according to equation B.2.3 and B.2.1. Thermal fatigue stress coefficient (k_t) and thermal fatigue stress on critical loading position (σ_{tr}) of the interface are calculated as 0.421 and 0.52MPa according to equations B.2.3 and B.2.1.

If the temperature fatigue stress is calculated according to the new concrete monolayer, the maximum thermal curling stress of the upper slab of the separate type overlay (σ_{tm}) is calculated as 1.13MPa according to equation B.2.2. Thermal fatigue stress coefficient (k_t) and thermal fatigue stress on critical loading position (σ_{tr}) of the upper slab are calculated as 0.33 and 0.37MPa according to equations B.2.3

and B.2.1. The thermal fatigue stress coefficient (k_t) and thermal fatigue stress on critical loading position (σ_{tr}) of the interface between young and old concrete are calculated as 0.393 and 0.44MPa according to equations B.2.3 and B.2.1.

$$\sigma_{tm} = \frac{\alpha_c E_c h T_g}{2} B_x \qquad \text{(B.2.2)}$$

The temperature fatigue stress of the young concrete overlay and the interface is taken as 0.44MPa and 0.52MPa individually to combine with relative load fatigue stress. So the stresses of the young concrete overlay and the interface between young and old concrete slab are:

$$\gamma_r\left(\sigma_{pr}+\sigma_{tr}\right)=1.33\times\left(0.67+0.44\right)=1.48MPa<f_r=5MPa$$

$$\gamma_r\left(\sigma_{pr}+\sigma_{tr}\right)=1.33\times\left(0.67+0.52\right)=1.58MPa<f_r=4.15MPa$$

The results indicate that the young concrete overlay and the interface of the young and old concrete with MJE can completely bear fatigue stress acting of wheel load and temperature in design reference period.

CONSTRUCTION OF OVERLAY WITH MJE ON USED CONCRETE PAVEMENT

Removing the old damaged concrete. The damaged concrete should be removed completely before the construction of combining repaving. Rap on the road surface with a steel stick or drag a piece of steel chain to detect the damaged concrete is a simple and reliable method. A shrill ring indicates the concrete is fine. The damaged concrete should be removed by light pick; the removing depth should not exceed one third thickness of the old surface.

Embedment of MJE. The second step is to drill on the remainder old concrete with percussion drilling of diameter 22mm. The holes with the depth of 50mm are arranged as cinquefoil pattern. The space between each other is 400mm, and the MJE rate is 0.35%. The surface of the old concrete and the hole should be cleaned by blasting or by high pressure water-jet. The old concrete should be waterlogged for 24h to be soaked completely, which could avoid insufficient hydration of young concrete. Then, the water on the old concrete surface and in the holes should be eliminated; the MJE should be embedded in the hole with epoxy resin mortar containing 10%U-type expansive agent. Then the embedded MJE should be cured for 24h.

Construction and maintenance of young concrete. Clean out the leftover residues from the old concrete surface with compressed air. Paving young concrete immediately after the interface bonding mortar layer is brushed on the old concrete surface. The grade of young concrete should be one grade higher than that of old concrete. Road Portland cement or ordinary Portland cement with less caloric and less shrinkage should be chosen as possible. Dual maintenances of sprinkling and film cover should be taken as possible. High quality curing agent with water retaining rate higher than 90% should be sprayed on the young concrete surface. The curing film should be placed when water film formed. Sand should be put on the curing film on joints uniformly to avoid the film being blown away. To prevent the young concrete cracking because of high temperature in the hydrated process water should be sprayed on the film. Curing time should not be less than 14d. In addition,

the raw materials, mixture ratio, technology of mixing and transportation as well as the construction and curing method should also conform to the specification of <Technical Specification For Construction Of Highway Cement Concrete Pavements> (Highway Scientific Institute, 2003) and <Technical Specifications of Cement Concrete Pavements Maintenance of Highway> (Ministry of communications of PRC, 2001).

CONCLUSIONS

The splitting test results indicate that MJE can improve the combine performance of the young and old concrete significantly. The MJE ratio of 0.35% is determined by finite element analysis. Based on the traditional design method of concrete pavement, performance of the young and old concrete road slab and their interface with MJE was discussed. Results indicated that the young and old concrete slab and their interface with MJE proved to have good performance under the fatigue stress of wheel load and temperature in design reference period. Construction scheme of this repairing method include pretreatment of the old concrete, MJE embedding and maintenance of young concrete.

ABSTRACT

In order to investigate the modulus growing rule of graded aggregate materials under long-term vehicle loads and confirm the long-term using characteristics of graded aggregate base asphalt pavement, the resilient modulus of graded aggregate specimen has been studied under the long-term condition of different confined stresses and dynamic stresses by using middle-type dynamic triaxial instrument. Test results showed that graded aggregate material's modulus are growing with increasing dynamic load repeating time and are confined by asymptote when dynamic load level is constant. The modulus curve can be regressed by logarithm or power equation, but it is more reasonable to adapt hyperbola model. Graded aggregate materials modulus is stabilized under long-term dynamic repeat load. It is not the traffic load accumulation causing pavement fatigue crack, but the softening of graded aggregate materials' modulus under asymmetrical traffic load.

INTRODUCTION

For granular materials, the degrees of deformation and the changes of resilient modulus are relevant to repetition frequency of load. However, there is less research on dynamic triaxial instrument test of graded aggregate material under long-term dynamic repeat load, there is no clear relationship between resilient modulus and long-term dynamic load repeat times, and the dominant damage of graded aggregate base asphalt pavement can not be predicted. So it is necessary to study the growing rules and impacting factors of the resilient modulus of graded aggregate material under long-term dynamic repeat load, which will set up the foundation for predicting the long-term characteristics of graded aggregate base asphalt pavement.

TEST EQUIPMENT AND METHODS

The middle-type dynamic triaxial instrument was adopted to study the resilient modulus of graded aggregate materials under long-term dynamic load. The specimen diameter is 20cm, height is 50cm.Graded aggregate materials used in the experiments are crushed by limestone and gradation is dense-framework type, the specimens are mold with vibration method (Wang 2005). Definite load control conditions simulating the physical and stress state of highway surface (Wang 2006), three kinds of confining pressure are used in test respectively, 50KPa, 100KPa and 150KPa, each confining pressure adopting three kinds of dynamic stresses to cover the critical state. Each specimen is experimented by vibrating 10,000 times with half-sine wave and loading time for 0.2s, unloading time for1.8s, cycling time for 2s.

THE RESILIENT MODULUS OF GRADED AGGREGATE MATERIAL UNDER LONG-TERM DYNAMIC LOAD

The design parameters of graded aggregate materials are calculated by the dynamic triaxial test in the provisions of dynamic load cycles, the dynamic cyclic loading frequency provided by literature is 200 times, fewer cycles in other civil engineering related industry (SL237 1999), with the aim of dynamic cyclic loading activity can not destroy the structure of the sample, which is appropriate corresponding to the actual state of static load or without greater plastic deformation. In fact, graded aggregate materials in pavement will receive millions or tens of millions times vehicle load. Standardized method to determine the parameters of the provisions specifications might not be reasonable to explore long-term using characteristics of graded aggregate base bitumen pavement for the modulus calculation results must be consistent with the structure state and stress state of the specimen.

The Relationship between Resilient Modulus and Dynamic Load Times

Figure 1 is the relation of modulus and dynamic load times of the dense-framework structure specimen in the conditions of the three confining pressure, nine dynamic stress and dynamic load for 10,000 times. As we can see from the figure, besides the curve which σ3 is equal to 50kPa and dynamic stress level is 1.15, the other curves of modulus are all growth trend. In the early stages of load (N <2000 times) the modulus increased rapidly in all three confining pressure, the growth rates are ΔM_{early}(100kPa) = 7.2%, and ΔM_{early} (150kPa) = 12.9%; when load times got into the medium-term (N = 2000-8000), modulus of growth slowed down, and they are ΔM_{middle} (100kPa) = 1.1%, ΔM_{middle} (150kPa) = 1.6 %; to the latter load times (N = 8000-10000), modulus is almost not increased, maintained at a stable state, the growth rates of the later modulus are ΔM_{later}(100kPa) = 0.2%, ΔM_{later}(150kPa) = 0.4%.

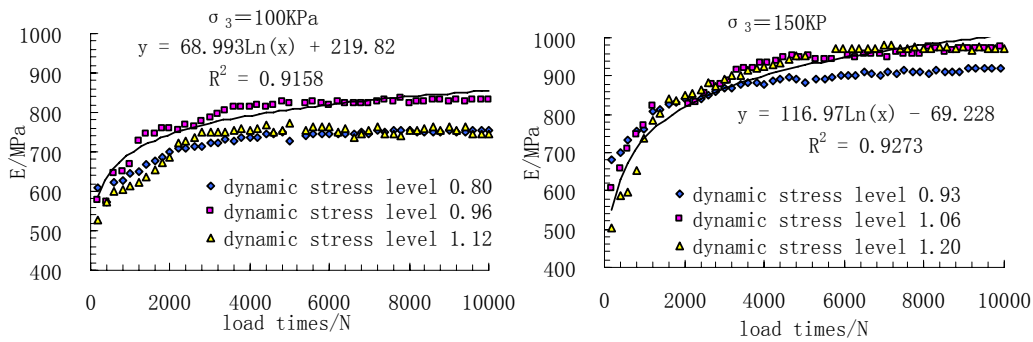

Figure1. The relation between load times and resilient modulus of longtime.

Under a number of dynamic load conditions, the resilient modulus of graded aggregate materials are always in a "hardening state", and there is no "softening state" after peak, the phenomenon shows that under vehicle loading, the resilient modulus of graded aggregate base is growing; when it grows to a certain extent level, it will become stable, that is the modulus growth confined by asymptote. Under the three confining pressures, the average growth rates of modulus are respectively 38%, 35% and 63%. The modulus growth rate is basically same under the same confining pressure and different dynamic stress level. When the dynamic stress ratio exceeds the certain limit (such as σ3 = 50kPa, dynamic stress level = 1.15), the structure of graded aggregate material rapidly destroys and modulus will attenuate in a straight line. Under normal state, the modulus curve can be regressed by logarithm or power equation, results are in figure 1.

The regression curve can be approximately expressed by resilient modulus changing rule with load frequency of graded aggregate material, but the regression curve modulus increase along with the number of load times, it can not express the characteristics that there is a limit (asymptote) when the resilient modulus of graded aggregate material increases with the number of load times. So we can divide integral into subsection based on the different modulus increasing rate, it is the early stage when loading times N ≦ 2000, this period is a rapid growth stage, it can be regressed by logarithm or power equation.

$$E = aN^b \qquad N \leqq 2000 \qquad (1)$$

When the number of loading times N ≧ 2000 times, the hyperbola model is adopted in order to accurately express how asymptote constrains the modulus growth.

$$E = \frac{N}{a + bN} \qquad N \geqq 2000 \qquad (2)$$

After simplification, it gets:

Table1. The asymptote regression equation in section of resilient modulus.

dynamic stress kPa	σ_3 kPa	dynamic stress level	regression equation	R^2	asymptote equation	using condition
269	50	0.69	E_1=203.6 $N^{0.1284}$	0.96	$E_{max}=588.2$	N<2000
			$E_2=\frac{N}{0.3488+0.0017N}$	0.93		N>2000

			$E_2=\frac{N}{0.4666+0.0016N}$	0.95		N>2000
449	50	1.15	E=-1.769 N + 540.08	0.96		state of destroying
449	100	0.80	E_1=391.62 $N^{0.0732}$	0.76	$E_{max}=769.2$	N<2000
			$E_2=\frac{N}{0.2704+0.0013N}$	0.98		N>2000
539	100	0.96	E_1=258.87 $N^{0.1421}$	0.91	$E_{max}=833.3$	N<2000
			$E_2=\frac{N}{0.2871+0.0012N}$	0.95		N>2000
628	100	1.12	E_1=300.92 $N^{0.1055}$	0.97	$E_{max}=769.2$	N<2000
			$E_2=\frac{N}{0.3461+0.0013N}$	0.82		N>2000
628	150	0.93	E_1=392.58 $N^{0.0995}$	0.96	$E_{max}=909.1$	N<2000
			$E_2=\frac{N}{0.2383+0.0011N}$	0.97		N>2000
718	150	1.06	E_1=295.16 $N^{0.1371}$	0.97	$E_{max}=1000.0$	N<2000
			$E_2=\frac{N}{0.3224+0.0010N}$	0.91		N>2000
808	150	1.20	E_1=131.17 $N^{0.2478}$	0.93	$E_{max}=1000.0$	N<2000
			$E_2=\frac{N}{0.3690+0.0010N}$	0.98		N>2000

$$\frac{1}{E} = a\frac{1}{N} + b \qquad (3)$$

Where, a and b are regression coefficients and with a more specific meaning: a=1/E when $N \rightarrow 0$, 1/a is initial resilient modulus; b is the reciprocal of resilient modulus as the N $\rightarrow \infty$, which 1/b is the largest resilient modulus (*Emax)* of graded aggregate material. The reciprocal of Resilient modulus (1/E) is linear relationship to reciprocal of load times (1/N), the regression equations are summarized in Table 1.

The Influence on Resilient Modulus of Graded Aggregate Material by Dynamic Stress Levels

In a confining pressure, the destruction state of the sample is defined as 4% plastic strain when dynamic stress repeats 10000 times and this stress is defined as the critical damage dynamic stress σ_{dcr}. The ratio of dynamic stress of test and critical damage stress is defined as dynamic stress level, and its value reflects the intensity level of the graded aggregate materials to receive dynamic load. Under long-term dynamic load and the same stress level, resilient modulus of graded aggregate material increases and keeps steady towards the end, but with different levels of dynamic stress, resilient modulus sometimes increases and sometimes decreases. The relation of dynamic stress level and resilient modulus of graded aggregate material is shown in figure 2. When the dynamic stress level is low (σ_d / σ_{dcr}<1), resilient modulus of graded aggregate material increases with the dynamic stress level increasing; when the dynamic stress level is high (σ_d/σ_{dcr}> 1), the resilient modulus decreases with the dynamic stress level increasing. The peak of resilient modulus appears near σ_d /σ_{dcr}=1, and 4% plastic deformation as the definition of critical stress is appropriate. It is validated by the resilient modulus changing rule.

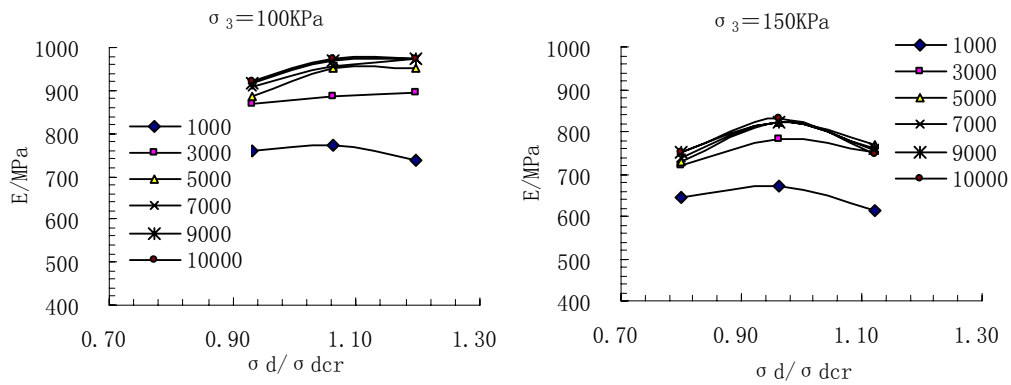

Figure2. The relation between dynamic stress level and resilient modulus.

Under long-term vehicle load, modulus reduction of graded aggregate base will in general lead to asphalt surface fatigue cracking, but experimental results in Figure 2 show that resilient modulus grows with the dynamic load times increasing

and keeps stabilized in the end at the same dynamic stress level.

It is illustrated that increasing the number load times can not lead to fatigue cracking on the same stress level; the more the number of loads, the smaller the possibility of fatigue cracking. In fact, the fatigue cracking of some graded aggregate base bitumen pavement is an objective reality; the reason is that the traffic wheel load intensity is in homogeneity. When the level of dynamic stress is $\sigma_d / \sigma_{dcr} > 1$ from Figure 2, the resilient modulus of graded aggregate material is decreasing, resulting in "softening strength", which leads to larger the tensile stress of asphalt bottom layer, appearing fatigue cracking. The statistical analysis of Literature (Hang 2005) shows that load spectrum level of vehicle load axle is uneven in China, the ratio of axle load exceeds 61% -71%. The literature (Hu 2005) tire pressure measurement showed that the grounding pressure of heavy vehicles is the tire pressure 0.9 ~ 1.7 times, the greatest pressure of touching the ground is the tire pressure 1.5 ~ 3.5 times, which illuminate that it is not the traffic load accumulation leading to pavement fatigue crack, but the modulus soften of graded aggregate materials under asymmetrical traffic load.

CONCLUSION

The main conclusions are as follow:

（1）The resilient modulus of graded aggregate materials are growing with dynamic load repeated time increasing and are confined by asymptote when dynamic load level is constant.

（2）The modulus curve can be regressed by logarithm or power equation， it is more reasonable to adopt hyperbola model.

（3）It is not the traffic load accumulation leading to graded aggregate base bitumen surface layer fatigue crack, but the graded aggregate material's "modulus soften" under asymmetrical traffic load.

ABSTRACT

It is important to predict roadbed settlement occurred during construction and post-construction periods for highway projects built on the soft ground. A creep damage mechanical model is constructed on basis of the rheological and structural properties of soft soil to predict the deformation of the roadbed. Deformation of the roadbed and variation of the pore water pressure during the different construction periods are analyzed. The settlement of post-construction is predicted in a case study. Calculation results are compared with the traditional model and the creep damage model. It is shown that the creep damage model can better describe the soft roadbed deformation in preloading and post-construction periods. Calculation results from the creep damage model show that creep and structural effects can not be ignored in soft roadbed deformation prediction.

KEY WORDS: Highway; Soft roadbed deformation; Foundation reinforcement

INTRODUCTION

With the rapid development of national highway network, experiences have been accumulated in highway roadbed treatment. However, problems such as pavement cracking and bridge slab staggering arise exist in some highways built on soft soil foundation shortly after being open to traffic.These problems mainly caused by the settlement or differential settlement of the roadbed, which can lead to a significant economic loss (Wang et al. 2005). Inadequate deformation forecast of subgrade construction of soft soil and inadequate understanding of the soft soil characteristics are main factors of the problem. Soft soils have the salient rheological property besides the ordinary characteristics of consolidation. Soft soil creep in the whole process of deformation leads to the accumulation of deformation during a long period after construction. Besides, the natural soft soil also has different levels of structural characteristics (Leroueil 1990). The additional deformation caused by structural rearranging after structural damage of soft soil. Since the disturbance of

soft soil in the course of foundation treatment changes structural properties of the original foundation, it is different between the undisturbed soil and the actual disturbed soil after reinforcement in physical mechanical index. These are the key reasons why the deformation calculated by using traditional methods is not accurate enough. In this paper, a creep damage mechanical model is proposed to describe the integrative action of structural and rheological characteristics of soft soil. Calculations of roadbed deformation and pore pressure development are carried out by using the finite element method.

CREEP DAMAGE MODEL OF SOFT SOIL

The mechanical characteristics of soft soil, such as elasticity, plasticity and viscosity,are very complex. It can be regarded as a kind of elastic viscoplastic body. Total strain increment is composed of instantaneous linear elastic strain, viscoelastic strain and viscoplastic strain. Sun (Sun et al, 2006) proposed a modified viscoelastic-viscoplastic creep model. The viscoelastic-viscoplastic flexibility matrix can be expressed as:

$$\left[C_{vep}\right]=\left[C_{ep}\right]+\frac{[A]}{E_1}(1-e^{-\frac{E_1}{\eta_1}dt})+dt\frac{1}{\eta_2}\left\langle \Phi(\frac{F}{F_0})\right\rangle \tag{1}$$

The model parameters can be determined by creep tests of soft soil (Zhao et al. 1996).

In order to describe the structural damage process of soft soil, it can be simplified as a process that the undamaged modulus attenuates gradually. So the effect from structural property of soft soil is considered as an attenuation factor added to the soft soil creep model. The structural damage variable can be expressed as:

$$\omega=1-\omega_0-e^{-D(\varepsilon_p'-\varepsilon_p^{\,0})} \tag{2}$$

Where $\varepsilon_p' = \int_0^t \dot{\varepsilon}_p' dt$ is cumulative plastic strain; $\varepsilon_p^{\,0}$ is the initial plastic strain; ω_0 is the initial damage factor; D is the model parameter reflecting structure damage speed. Damage variable includes the structural damage evolution rule, which can be obtained by fitting undisturbed and remolded soil compress curves (Sun et al. 1999). The formula of total strain increment is:

$$\{d\varepsilon\}=\left[C_{Dvep}\right]\{d\sigma'\} \tag{3}$$

Where $\left[C_{Dvep}\right]$ is the creep damage flexibility matrix. The soft soil creep damage model described in Eq.(3) can characterize the soft soil creep deformation and damage of the structural deformation with the finite element program.

EXAMPLE FOR DEFORMATION PREDICTION OF THE HIGHWAY SOFT

ROADBED

Overview of the highway soft roadbed reinforcement section. Surcharge preloading technique in combination with sand pad and dewatering plastic sheet is adopted to improve the soft roadbed. From top to bottom of the foundation layers are as follows: ①the surface soil is gray with the thickness of 0.5~1.0m, containing a few bricks and plant roots,mainly is silty clay; ②The liquid-and-plastic muddy clay layer is grey, saturated with the thickness of 10~12m, which is highly compressible and the main layer for treatment; ③the alluvial layer is sub-clay with the thickness of 14~18m, which is plastic and compressible. Reinforcing schemes are as follows: A sand pad with 60cm thick, inserted with two layers of mesh-based compound geo-textile fiber,is constructed on the top of the ground. The dewatering plastic sheets of type SPB–1, with the width of 100mm, thickness of 4.6 mm and length of 13m, are driven through the muddy layer. They are arranged in a quincunx layout with the spacing of 1.2m. An embankment, which is 4.18m high, 32m wide and with a grade ratio 1:1.5, is constructed on the top of the sand pad. The construction work is finished within 160 days. The loading can be considered as 4 steps (0.8 m, 1.2 m, 1.2 m and 0.98 m) in calculation. Each loading step lasts for 40 days including 25 days of loading and 15 days of interval.

The finite element model and calculated parameters. The creep damage model proposed above is used to predict deformation of the soft roadbed based on Biot's consolidation theory. In order to simplify the calculation, the plane finite element method can be used when the band drain is equivalent to sand drain. The actual sand drain foundation is replaced by sand wall foundation according to the principle of constant consolidation effects.

The equivalent diameter formula from band drain to sand drain proposed by Hansbo (1979) is as follows:

$$d = a\frac{2(w+t)}{\pi} \tag{4}$$

Where d is equivalent diameter; a is conversion coefficient (generally assigned 0.6~ 0.9); w is width of band drain; t is thickness of band drain.

According to the actual condition, the equivalent diameter of the band drain can be assigned 60mm. The radius of daub area is assigned 150mm. The permeability coefficient of soft soil needs to be revised when sand wall foundation replaces the sand drain foundation. The revising formula can be expressed as follows (Zhao et al. 1998):

$$\begin{cases} k_{rx} = D_x k_x \\ k_{rz} = D_z k_z \end{cases} \tag{5}$$

Where k_{rx} and k_{rz} are horizontal and vertical permeability coefficients of sand wall

after adjustment respectively, k_x and k_z are horizontal and vertical permeability coefficients of the original foundation; D_x and D_z are horizontal and vertical adjustment coefficients. In this paper, D_x and D_z are assigned 0.913 and 2.168 respectively. The sand wall span is adjusted as 4.0m. The course to install band drains may cause large disturbances on the soft soil.It may destroy the structure of the original foundation soil. The in-situ test formula of the scale of turbulence proposed by Wang et al. (2005) is as follows:

$$SD = \frac{S_u - S_u^*}{S_u} \times 100\% \tag{6}$$

Where S_u and S_u^* are peak vane shear strengths of the soil before and after installing band drains respectively.

Contrastive analysis has been done by the in-situ vane shear test before and after the installation of band drains in this study. The average disturbance degree of the foundation is about 31%. It shows that the effect on soil structure in the process of foundation reinforcement cannot be neglected. So the initial damage factor of the forecast analysis model in the finite element calculation is assumed to be 0.31. The poisson ratio of each layer is assigned 0.32, and parameter d_p of the mucky clay layer is assigned 0.25 in the calculation. Table1 lists the calculation results.

Table 1. Calculation Parameters of the soil layers

Soil Layer		Sand Mat	Mud	Clay
Horizontal coefficient of permeability	k_{rx} (10^{-5}cm/s)	100	0.323	1.49
Vertical coefficient of permeability	k_{rz} (10^{-5}cm/s)	100	0.246	1.28
Elasticity modulus parameter	K_G	100	15	60
Elasticity modulus parameter	n	0.65	0.9	0.8
Viscoelastic modulus parameter	E_1 (MPa)	7.8	1.6	3.9

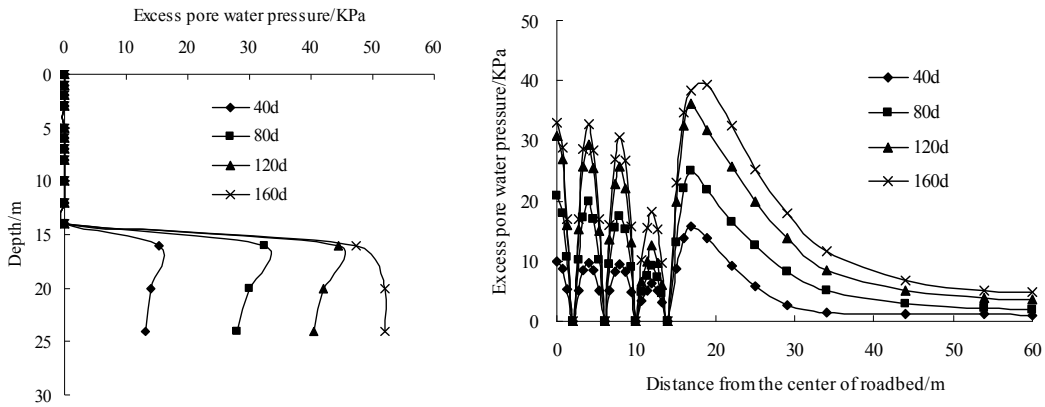
Viscoplastic coefficient of viscosity	η_2 (10^5kPa/d)	1000	0.23	2.56
Damage parameter	D		2.2	

RESULTS AND DISCUSSION

Excess pore water pressure forecast during construction period. The constructing load is simplified to a linear loading process. Variation curves of excess pore water pressure along the vertical and horizontal direction of the foundation are shown in Figure1. As is shown in Figure1(a), the pore water pressure decreases rapidly and primary consolidation deformation is completed quickly due to the

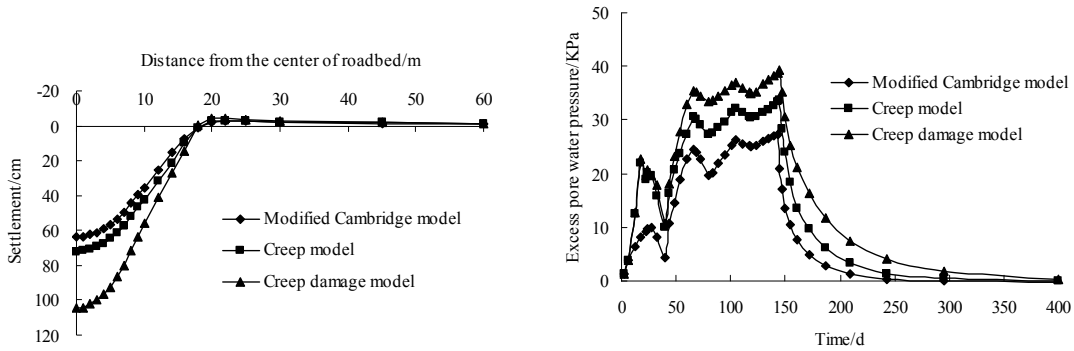
effects of band drains around the foundation reinforcement areas under different load. But the primary consolidation settlement of bottom layer after construction is one of the most important reasons for excessive post-construction settlement of the profound soft roadbed reinforced by preloading technique. Extending preloading period can effectively relieve the embankment settlement. As is shown in Figure1(b), the excess pore water pressure around the sand wall is zero. The soil between two sand walls is less than outer embankment, which weakens gradually near to far from the embankment under different load. It indicates that band drains play an important role in accelerating dissipation of the excess pore water pressure and the most deformation of soft soil layer during the construction. It also causes less post-construction settlement.



(a) Vertical direction (b) Horizontal direction

Figure1. Variation curves of excess pore water pressure of the roadbed

Comparative analysis of different models. Three different models**,** the common modified Cambridge model**,** the creep model and the creep damage model ,are used to predict the deformation of foundation in this paper. The results of foundation settlement and pore water pressure are showed in Figure2. From Figure2(a), the maximum deformation is calculated with the creep damage model. The second deformation is calculated with general soft soil creep model without considering the additional deformation generated from the structural damage of soft soil. The minimum deformation is calculated with the modified Cambridge model usually used for soft soils with the finite element method. The key reason for which is that the modified Cambridge model can not describe secondary consolidation settlement or structural damage of the soil. From Figure2(b), structural damage and creep of soft soil will influence the pore water pressure. the calculated pore pressure is relatively larger, and the soil deformation is affected by the pore water pressure.



(a) Settlement (b) Excess pore water pressure

Figure 2. Settlement and excess pore water pressure with different models

Prediction of post-construction settlement. Above-mentioned models are used to predict the roadbed deformation during and after the construction periods. The calculated values contrasted with on-site monitoring data are shown in Figure3. Figure3 indicates that there is little difference of the deformation in the preloading construction period between the calculated and the measured with the modified Cambridge model because the primary consolidation settlement of soft soils is basically completed. But the error is a bit large in post-construction periods because the additional deformation aroused from the creep and structural damage of soft soils can not be considered in the traditional model. Predictive results calculated with the creep damage model proposed in this paper agree better with the measured values during and after the construction periods. The creep damage model can quantitativly reflect the influence due to the damage based on band drains and rheology of soft soils. The creep deformation and the additional deformation caused by structural damage of soft soil exist in the whole process of consolidation, which lead to the larger settlement after construction of the roadbed. It also illustrates that the creep damage model can reasonably describe the intrinsic property of soft soil.

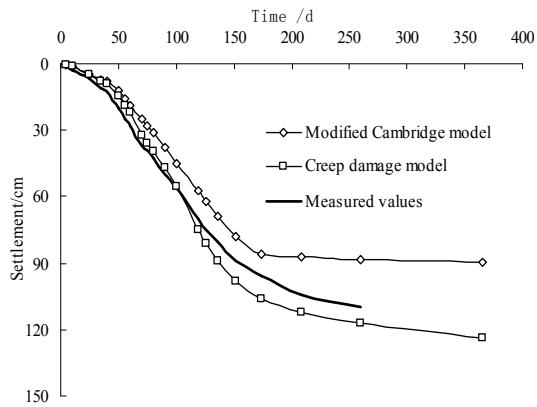


Figure 3. Predictive results with different models

CONCLUSION

A creep damage model is proposed to predict the deformation and variation of pore

water pressure in a highway roadbed reinforced with the preloading technique. The model is analyzed based on the finite element method. The major results are as follows: (1) The creep damage model, considering the structural damage and creep, can reasonably describe the deformation characteristics of soft soil, and effectively predict the settlement of roadbed during construction period and post-construction period. (2) The creep deformation and the additional deformation caused by structural damage of soft soil exist in the whole process of consolidation. The structural damage and creep will influence the development of pore water pressure and the pore water pressure will also influence the deformation of soft soil. (3) The primary consolidation settlement of bottom layer after construction is one of the most important reasons for excessive post-construction settlement of the deep soft roadbed with preloading technique. Therefore, determination of the reasonable reinforcement depth and preloading time are the two keys to reduce post-construction settlement of the highway on soft soil foundation.

Research on Relationship between Fine Aggregate Angularity and Asphalt Mixture's Anti-Shear Ability

[1]School of Transportation Science and Engineering, Harbin Institute of Technology, Haihe Street, Nangang District, Harbin; Phone:86+451+13766830235; email: zhouchangjun.hit@163.com

ABSTRACT

To compare fine aggregate angularity (FAA) of three different fine aggregates including a crushed sand, chips and a natural sand, two methods, i.e. modified Uncompacted Void Content Test and modified Sand Flow Test were carried out. Results indicate that crushed sand's FAA is similar to chips' and both of them are better than natural sand's. The modified Sand Flow Test is recommended. Under normal temperature, the static Triaxial Shear Strength Tests were carried out for SMA-13s and AC-13s, which are different in fine aggregate. These mixtures were made by standardized compaction or gyratory compaction method. It is discovered that that there is a direct correlation between FAA and mixture's anti-shear ability.

KEYWORDS: fine aggregate angularity, asphalt mixture, triaxial shear strength test, anti-shear ability

1 INTRODUCTION

FAA, reflecting fine aggregate' s shape, texture and roughness, has direct influences on the interlocking between aggregates and on the cohesion between aggregates and asphalt, which fundamentally affects asphalt mixture's anti-shear ability. In this article, tests, i.e. modified Uncompacted Void Content Test and modified Sand Flow Test were carried out to estimate FAA of a crushed sand, chips and a natural sand. And static Triaxial Shear Strength Tests under normal temperature were also tried out to compare anti-shear abilities among the three mixtures called crushed stone mixture, chips mixture and natural sand mixture, which contain different fine aggregate respectively. A relationship between FAA and asphalt mixture's anti-shear ability was established.

2 FINE AGGREGATE ANGULARITY

Presently there are mainly two methods to evaluate fine aggregate roughness and angularity including the Uncompacted Void Content (UVC) Test (Figure 1) originated from AASHTO 33 (SHRP) and the Sand Flow Test originated from AFNOR NF P l8-564/1981 from France (Figure 2). Both tests are adopted in China and are numbered T0344—2005 and T0345—2000 respectively in Test Methods of Aggregate for Highway Engineering.

In the SUPERPAVE design system uncompacted void content acts as one of identity characters of fine aggregates, which is commonly thought to be a paramount role when designing HMA with super performance. With regulating FAA, designers

hope to make HMA great internal friction and great anti-shear ability to resist rutting (Brian Prowell et al 2005). This article utilizes the FAA apparatus to get FAA of raw materials and single-size aggregates. Greater UVC means relatively greater internal friction angel, smaller content of spherical particles and rougher texture. It is hard to get an accurate bulk density in T 0344—2005 since experience plays an important role in results. So we adopted apparent density (ignoring open void). This would only magnify UVC, not changing the ranking of those aggregates' UVC.

Figure 1. Uncompacted Void Content Test Apparatus

Figure 2. Sand Flow Test Apparatus

Sand Flow reflects surface texture and roughness of fine aggregates. It has effects on the stability and plastic deformation of asphalt mixture. The Test regulates the same mass of aggregate to get the same bulk (Shen Jinan, etc, 2005). Instead of this approach, we just filled up the cylinder with aggregates and made the surface even. This simplifies the operation without sacrificing precision of the test.

UVCs and sand flow of the aggregates were obtained (Table 1 and Table 2).

Table 1. Results of Modified Uncompacted Void Content Test

Fine Aggregate	Uncompacted Void Content(%)		
	Crushed Sand	Chips	Natural Sand
Raw Material	42.3	42.8	38.9
1.18~2.36mm Aggregate	47.8	48.6	44.2

Table 2. Results of Modified Sand Flow Test

	Raw Material			1.18~2.36mm Aggregate			2.36~4.75mm Aggregate					
Funnel Aperture	18mm			16mm			18mm			18mm		
Fine Aggregate	CS	C	NS	CS	C	NS	CS	C	NS	CS	C	NS
Sand Flow/s	18.2	14.4	15.4	24.5	24.3	23.0	17.5	17.6	16.8	24.8	25.4	23.7

Note: CS, C, NS represent crushed sand, chips and natural sand, respectively.

Since gradations are different, UVC and sand flow could not give a clear ranking of FAA among raw materials of the three fine aggregates. Results of single size aggregate, 1.18~2.36mm for example, from the two methods could effectively show the ranking: FAA of chips and FAA of crushed sand are better than FAA of natural sand, while the former two are similar to each other. The reasons can be given like these: (1) Natural sand, weathered in billions of years, has slick shape and no crushed surfaces. All of these factors bring up good workability but poor FAA. (2) Chips, the scrap from stone pits, are weak parts of rocks and have crushed surfaces. Besides, chips own many elongated flaky particles. The FAA of chips is supposed to be good. (3) Crushed stones contain no soft or weathered rocks, and have more crushed surfaces and less elongated flaky stone pits than chips. All of these lead to good FAA. The results reflect the difference among these three fine aggregates, which reveals that it is proper to modify test methods of FAA.

Compared to the UVC test, sand flow test is easier to operate. As a result, it is a recommended method to evaluate FAA in China. However this method needs to be modified as mentioned before. We suggest the modified sand flow test as an alternative for evaluating FAA.

3 RELATIONSHIP BETWEEN FINE AGGREGATE ANGULARITY AND STONE MATRIX ASPHALT'S ANTI-SHEAR ABILITY

Asphalt mixtures, no matter from Marshall mix design procedure or other similar ones, although owning sufficient stability, could not prevent pavements from early damage. Empirical design procedures could neither describe actual state of pavement such as shear stability, nor pavement performance (Norman W. Mcleod, 1951). V. A. Endersby (1949) originally brought forward how to make asphalt concrete specimens for triaxial test and how to do the test. V. R. Smith (1949) elaborated the state of shear forces in pavement by virtue of elasticity theory, proposed a failure standard for mixture, and defined specific anti-shear abilities for mixture under varied loads with a nomogram. Edward S. Barber (1965) presented stress state of pavement when bearing horizontal shear forces and vertical forces at one time. In that situation, shear stress in pavement would increase evidently. Thus he declared that horizontal shear forces are indispensable in pavement design. W. S. Housel (1936), R. G. Hennes & C. C. Wang (1965) used triaxial test data to explain mixture performance from the point of mechanics respectively.

The stress state of a triaxial test is similar to the triaxial stress state of asphalt pavement, and can evaluate the material's mechanical parameters. Based on the Mohr-Coulumb Principle, we obtained the anti-shear parameters of asphalt mixture i.e. cohesion (c) and internal friction angel (φ), and explored the effects of FAA on c and φ. It is well known that temperature impacts on anti-shear strength of asphalt mixture. Temperature affects c significantly while affects φ little. FAA mainly affects φ. Thus triaxial tests under normal temperature can evaluate internal friction angels,

which reflect the variety among FAA of the three fine aggregates.

Basic parameters of fine aggregates and asphalt are shown in table 3 and table 4 respectively. An SMA-13 gradation is adopted for mixtures shown in Table 5. The three kinds of mixture shared an asphalt aggregate ratio, which was the optimal asphalt aggregate ratio of chips mixture. Triaxial test results are show in table 6.

Table 3. Parameters of fine aggregate

Items	Crushed Stone Value (%)	Apparent Density (g/cm^3)	Accumulated Density (g/cm^3)
Crushed Stone	18	2.720	1.62
Chips	25	2.689	1.53
Natural Sand	19	2.593	/

Table 4. Basic parameters of asphalt

Items	Temperature（℃）				PI_{lgPen}	T_{800}	$T_{1,2}$
	35	25	15	5			
Penetration（0.1mm）	118	86	44	6	-0.280	51.1	-16.6
Softening Point（℃）				47.3			
Ductility under 15℃（cm）				60.2			

Table 5. Gradation of SMA-13

Mass Percentages under Following Sieves(mm)（%）									
16	13.2	9.5	4.75	2.36	1.18	0.6	0.3	0.15	0.075
100	95	62	23	18	16	14.5	13	12	10.5

Table 6. Summary of SMA's Anti-Shear Strength Parameters

Forming Method	Asphalt Aggregate Ratio (%)	Parameters	Crushed Stone	Chips	Natural Sand
Standardized Compaction	5.8	c（kPa）	389.89	494.01	418.51
		φ（°）	59.02	50.83	48.83
Gyrating Compaction	5.8	c（kPa）	484.41	611.98	595.61
		φ（°）	33.07	32.61	31.36

Under the two methods, crushed stone mixture has biggest φ, natural sand mixture has smallest φ. This illuminates that fine FAA is good for interlocking among gravels, which enhances asphalt mixture's stability when bearing loads. Although chips and crushed stone have similar FAA, chips contain more elongated flaky particles which tends to break because of local stress concentration on these particles' tops. Natural sand, slick, dusty and without crushed surfaces, could not interlock well with each other and could not bond well with asphalt. And these will lead to aggregates dislocation under shear loads.

Since crushed stones are cleaner and have more crushed surfaces than chips, they can absorb more asphalt than chips. The asphalt content is optimal asphalt

content of chips mixture. Thus, with this asphalt content, asphalt membrane could not be formed thick enough in crushed stone mixture. That's why its *c* is relatively small. Without crushed surfaces, natural sand mixture has relatively small *c* too.

4 RELATIONSHIP BETWEEN FINE AGGREGATE ANGULARITY AND ASPHALT CONCRETE'S ANTI-SHEAR ABILITY

In asphalt concrete, the suspended dense structure, is different from stone matrix asphalt, dense framework structure. It is necessary to check the effects of FAA on asphalt concrete structure. So specimens of AC-13 was formed and tested too. The gradation and triaxial test results are listed in table 7 and table 8 respectively.

Table 7. Gradation of AC-13

Mass Percentages under Following Sieves(mm)（%）									
16	13.2	9.5	4.75	2.36	1.18	0.6	0.3	0.15	0.075
100	97	78	41	28	18	14	10	7	5.2

Table 8. Summary of AC's Anti-Shear Strength Parameters

Forming Mothod	Asphalt Aggregate Ratio/%	Parameters	Crushed Stone	Chips	Natural Sand
Standardized Compaction	4.3	*c*（kPa）	523.93	764.13	600.25
		φ（°）	59.77	53.84	55.89
Gyrating Compaction	4.2	*c*（kPa）	373.74	488.49	729.83
		φ（°）	54.98	49.25	35.92

Comparing data in table 6 with data in table 8, the conclusion can be made like this: regardless of standardized compaction or gyrating compaction, the effects of fine aggregate angularity on asphalt concrete is very similar to the effects of fine aggregate angularity on stone matrix asphalt.

5 CONCLUSIONS

In this article, FAA of a crushed stone, chips and a natural sand were obtained by virtue of two methods, i.e. modified Uncompacted Void Content Test and modified Sand Flow Test. Triaxial tests of SMA-13s and AC-13s specimens were also carried out. Through those tests, conclusions are summarized as following:

(1) Two methods, i.e. modified Uncompacted Void Content Test and modified Sand Flow Test are effective and feasible. Modified sand flow test is recommended to evaluate fine aggregate angularity because of its simplicity .

(2) FAA of crushed stone is similar to FAA of chips. Both of them are better than FAA of natural sand.

(3) Crushed stone mixture's internal friction is biggest, chips mixture's is smaller and natural sand mixture's is smallest. This result verifies the validity of the two modified FAA methods.

(4) Good FAA offers asphalt mixture relatively large internal friction angle , making interlocking among aggregates well, which ensures aggregates hard

to dislocate when taking loads, and then improves mixture's anti-shear ability. To be more precise, there is a direct correlation between FAA and mixture's anti-shear ability.

ABSTRACT

Steel slag is a solid waste discharged in large quantities by the iron and steel industry in China. The recycling of steel slag will inevitably become an important measure for the environment protection and therefore will be of great social and economical significance. Used in combination with Super-plasticizer admixture, steel slag powder can lead to economical high performance concrete for highway pavements with enhanced durability and reduced cement content. The properties of steel slag cement and concrete with different types of steel slag and different dosage of admixtures are studied in this paper. The effectiveness of using steel slag powder for suppressing Alkali Aggregate Reaction is also analyzed. The results show that properties and durability of concrete can be greatly improved steel slag powder.

INTRODUCTION

Steel slag is a solid waste discharged in large quantities by the iron and steel industry in China. The recycling of steel slag will inevitably become an important measure for the environment protection and therefore can lead to great social significance (Sun et al. 2007). The manufacturing of Portland cement is a highly energy-intensive process. One of the most significant activities stressed by the engineers and scientists related to concrete industry aims at a high percentage of replacement of clinker in cement with secondary raw materials, with the possibility of improvement of cement characteristics and durability of concrete. Via these approached, the consumption of natural raw materials, thermal and electric energy, together with the reduction of CO_2 emissions can be decreased. One less energy intensive materials being sought are industrial by-products that are easily available, require little or no pyro-processing and have inherent or latent cementitious properties. Such industrial by-products are commonly called as supplementary cementitious materials or mineral additives. Mineral additives are usually available in large quantities that can be used to replace Portland cement in concrete (Muhammad and Emmanuel 2007). These include fly ash, steel slag, blast-furnace slag, silica fume, natural pozzolans, rice-husk ash, and metakaolin.

Steel slag includes a certain scale mineral such as C_2S and C_3S, and can be

applied in cement and concrete as mineral admixtures (Zhu et al. 2005). When super fine steel slag powder is mixed into concrete as an active admixture, concrete properties will be improved greatly so as to produce high performance concrete. The hydration heat can be effectively decreased; resistance to abrasion and durability and the workability and mechanical properties of the concrete can all be enhanced. When compound mineral admixtures with steel slag powder and blast-furnace slag powder are mixed into concrete, the performance of concrete can be improved further due to the synergistic effect and activation of each other (Liu and Yang 2006, Sun and Huang 2006). Therefore, the mineral admixture will be a perfect component of green concrete and its utilization will be a valuable resource for recycling.

MECHANICAL PROPERTIES OF HPC WITH STEEL SLAG POWDER

Materials. Chemical composition and properties of steel slag powder and blast furnace slag are listed in Table 1. The 42.5R Portland cement was used in concrete, and the blast furnace slag (S95) was also used as a partial replaced material in the cement and concrete.

Table 1. Chemical composition and properties of materials.

Admixture	Constituent (wt %)						Property		
	SO_3	SiO_2	CaO	MgO	P_2O_5	fCaO	Specific surface area (m^2/kg)	Density (g/cm^3)	Fluidity ratio (%)
Steel slag	0.47	18.28	39.69	9.37	1.26	1.98	387	3.46	103
Blast furnace slag	2.78	32.10	39.26	9.27	0.023	0.12	382	2.94	102

Mix Proportions. The concrete specimens were prepared with two types of mineral admixtures, steel slag powder and blast furnace slag powder. The concrete specimens prepared with mineral admixture are summarized in Table 2.

Compressive strength of steel slag concrete. The compressive strength of concrete specimens were determined after the 3, 7, 28 days of curing, respectively. The variation of compressive strength of steel slag concrete was shown in Figure.1. As expected, the compressive strength increased with age in all the concrete specimens. The results showed compressive strength of concrete with only steel slag decreased with the mixed content; the compressive strength was lower than that of blast furnace slag concrete. However, increase in compressive strength of concrete with steel slag was higher than that with blast furnace slag between 7 days age and 28

days age. The compressive strength of concrete with compound mineral admixture (mix code 6) had the highest value.

Table 2. Mix proportion of steel slag concrete

Mix code	Cement content (kg/m^3)	Steel slag content (kg/m^3)	Blast furnace slag content (kg/m^3)	Water content (kg/m^3)	Sand content (kg/m^3)	Stone content (kg/m^3)
0	476.0			212.5	551	1228
1	428.4	47.6		212.5	551	1228
2	380.8	95.2		212.5	551	1228
3	333.2	142.8		212.5	551	1228
4	285.6	190.4		212.5	551	1228
5	333.2		142.8	212.5	551	1228
6	333.2	47.6	95.2	212.5	551	1228
7	333.2	71.4	71.4	212.5	551	1228
8	333.2	95.2	47.6	212.5	551	1228

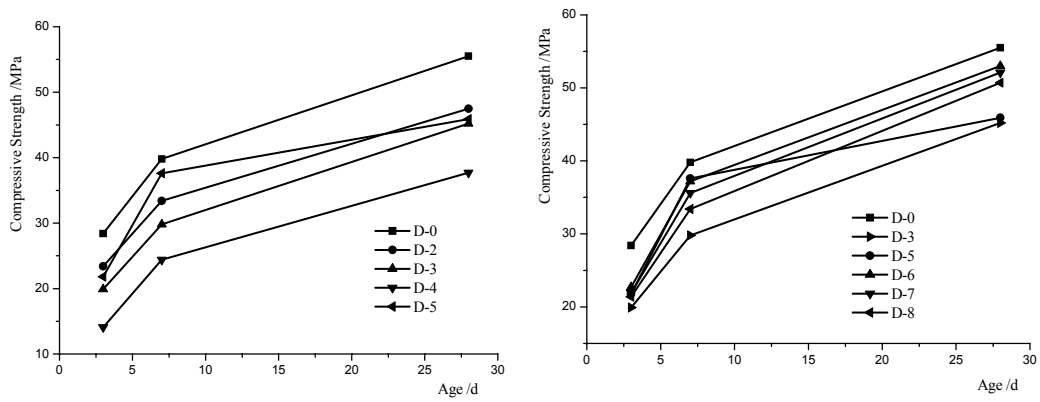

Figure 1. Compressive strength of concrete with mineral admixture

Flexural strength. The flexural strength of concrete with steel slag and blast furnace slag were also determined after the 3, 7, 28 days of curing. The variation of flexural strength of steel slag concrete was shown in Figure 2. Test results showed that flexural strength of steel slag concrete tended to increase fast compare to compressive strength at later age. When steel slag content was 10 percent of the total cement, the flexural strength was higher than that of the plain concrete at 28 days age. The flexural strength of concrete with compound mineral admixture showed the improvement due to the synergistic effect. The highest value was measured in concrete with steel slag powder to blast furnace slag ratio of 2.0.

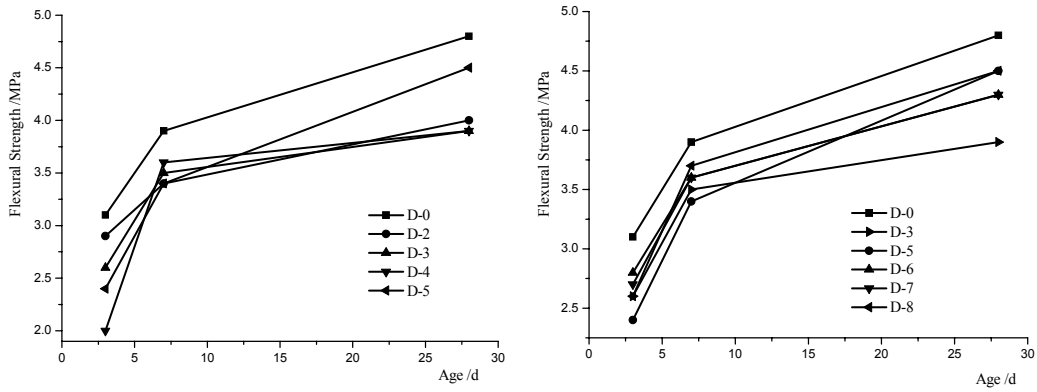

Figure 2. Flexural strength of concrete with mineral admixture

According to the test results, compressive and flexural strength of concrete with steel slag powder tend to decrease while the content of steel slag increases. Properties of concrete will be greatly enhanced when compound mineral admixture with steel slag powder and blast furnace slag is mixed into concrete. Steel slag and blast furnace slag show the synergistic effect and mutual activation in concrete. On the other hand, steel slag concrete has lower strength at early age; therefore, steel slag should be used to control hydration process so that high strength and high performance concrete can be obtained.

EFFECTIVENESS OF STEEL SLAG POWDER ON SUPPRESSING ALKALI AGGREGATE REACTION

ASTM C441 tests. ASTM C 441 uses Pyrex glass aggregate in mortars to accelerate the testing and provides reliable results. Mix proportion of AAR tests with Pyrex aggregate are listed in Table 3.

Table 3. Mix proportion of AAR test with Pyrex aggregate

Code	Cement (g)	Steel slag (g)	Blast furnace Slag (g)	Aggregate (g)	Water （g）	Fluidity (mm)	Curing temperature(℃)
1	400	0	0	900	166.5	103	40
2	300	100.0	0	900	181.2	112	40
3	300	0	100.0	900	182.4	111	40
4	300	33.3	66.7	900	184.3	113	40
5	300	50.0	50.0	900	179.7	110	40
6	300	66.7	33.3	900	178.7	107	40
7	320	80.0	0	900	183.3	114	40
8	280	120.0	0	900	182.5	107	40

The inhibition effect of steel slag powder and blast furnace slag on the AAR

expansion was shown in Figure 3.

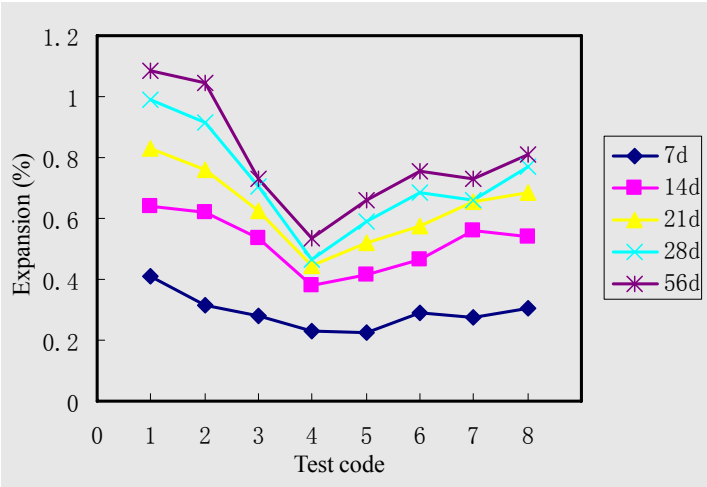

Figure 3. AAR expansion from ASTM C441 tests

It is seen from Figure 4 that the AAR expansion might be effectively inhibited by the addition of mineral powders, and the best result was achieved when steel slag powder and blast furnace slag were added (Code 4). The 56-day expansion of the mortar bar was decreased to about 50% of the expansion of the controlled specimens.

Accelerated tests. When actual aggregate was tested, a suitable method could be used to assessing the effectiveness of steel slag powder on suppressing AAR expansion with the temperature was higher and the alkali solution was more concentrated. The specimens were cured in the solution of 1mol/l NaOH at 80°C. Mix proportion of AAR tests with actual fine aggregate are listed in Table 4.

Table 4. Mix proportion of AAR test with fine aggregate

Code	Cement (g)	Steel slag (g)	Blast furnace Slag (g)	Aggregate (g)	Water （g）	Fluidity (mm)	Curing temperature(℃)
1	400	0	0	900	158	110	80
2	300	100.0	0	900	160	112	80
3	300	0	100.0	900	167	108	80
4	300	33.3	66.7	900	169	118	80
5	300	50.0	50.0	900	160	119	80
6	300	66.7	33.3	900	160	115	80

The inhibition effect of steel slag powder and blast furnace slag on the AAR was shown in Figure 4.

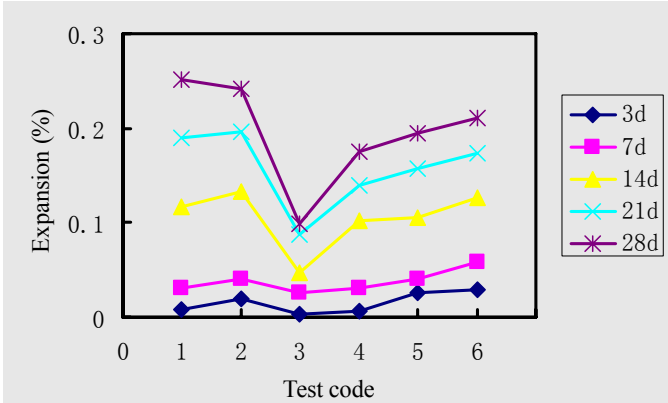

Figure 4. AAR expansion from accelerated tests

It is seen from Figure 5 that the AAR expansion with fine aggregate might be effectively inhibited by the addition of mineral powders, and the best result was achieved when blast furnace slag were added (Code 3). The 28-day expansion of the mortar bar was decreased to about 40% of the expansion of the controlled specimens.

CONCLUSIONS

The high performance concrete can be produced using mineral admixtures - steel slag powder and blast furnace slag. The recycling of steel slag can bring enormous economic benefit and environmental benefit.

Compressive and flexural strength of concrete with steel slag powder tend to decrease as the content of steel slag increases. Properties of concrete will be greatly enhanced when compound mineral admixture of steel slag powder and blast furnace slag is mixed into concrete. Steel slag and blast furnace slag show synergistic effect and mutual activation in concrete. On the other hand, steel slag concrete has lower strength at early ages; therefore, steel slag can be used to control the hydration process so that high strength and high performance concrete can be obtained.

The effectiveness of steel slag powder on suppressing AAR expansion was assessed using the method of ASTM C441 and the accelerated test method. Results show that mineral admixtures with steel slag powder as partial replacement for Portland cement in concrete is an effective means for controlling expansion due to AAR. At most a 50% decrease in expansion rate of mortar bars can be achieved. According to the research, properties and durability of concrete can be greatly improved using mineral admixtures such as steel slag powder.

ABSTRACT

Gravity abutment is a kind of commonly used understructure of highway bridges. It depends on its gravity to balance outside load and maintain stability. For some reason, many diseases appear on the gravity abutment in engineering practice. It is indicated by investigation that disciplinary disease appears on gravity when the height and width increase. It will extend rapidly once cracks appear and then construction in service is affected significantly. Therefore, it is urgent and necessary to investigate the reinforcement method of gravity abutment. According to resemble rule, the test project of the oblique U-shaped high abutment is designed. The message is recorded and analyzed in detail about the stress and displacement of the abutment model forced by outside load. The mechanical characteristics are achieved before and after reinforcement, for a different reinforcement project in the abutment process, under the action of solid force and outside load.

INTRODUCTION

In recent years, freeway construction has developed rapidly with large investment in highway construction in China. For special geographical conditions, it is necessary to traverse mountains or railways through the use of bridges, in which high gravity abutments covers higher proportions. On some gravity abutments cracks will appear with different grades on their front or side walls when their height exceeds eight meters or width exceeds fifteen meters. However, the high and wide abutment's disciplinary disease has not been the only problem of design or construction (Yang, 2002). In this paper, a resemble simulation test was implemented and stress and displacement of the gravity oblique high U-shaped abutment was investigated during a soil filling course. Angle-smoothening (Liu, 1998) and the carbon fibre reinforcement method (Li, 2003; Huang, 2005) were used and an improvement effect was achieved under the press of soil.

TESTING PROJECT OF GRAVITY OBLIQUE U-SHAPED ABUTMENT

Introduction of Bridge. The bridge at 46.15km of the Ji-Wu highway located in Shulan city has a U-shaped concrete gravity oblique abutment. Its length is 52.86m, design span is 2×16m, and oblique angle is sixty degrees. The width of this bridge is 14m plus 2×2m sidewalk. The structure of the main beam is a pre-stressed concrete simple beam and the infrastructure is an enlarged basement. However, cracks occurred at the abutment's body and side walls not long after its coming into service and vertical cracks were much more serious. It was been run-through and the

width of the cracks were very big as shown in Figure 1.

Model's Size and Material. According to the resemble rule of the abutment model test (Xu, 1995), the scale of the test model was determined to be ten to one. The height was one meter, the length of the front wall was two meters, oblique angle was sixty degrees, and the inner slope was three to one. Experimental materials included C15 chip stone concrete and 325 silicate cement. The ratio of the mixture of concrete was 1: 3.35: 5.50 (cement: sand: stone) and the ratio of water and cement was 0.52. Inside the abutment was adopted simulated sand soil and the ratio was 3:1:0.3(soil: sand: stone). Two models were constructed as shown in Figure 2. One was an U-shaped abutment with an oblique angle of sixty degrees and the other was constructed by angle-smoothening.

Figure 1. Vertical crack of abutment

Figure 2. Abutment model

Testing Instrument and Observed Location. Displacement and strain are recorded by a centesimal apparatus and static strain gauge, individually, loading by weighing sensor in steps.

The centesimal apparatuses were located in the top, middle, and bottom of the front wall's central section and the long side wall's tail, as shown in Figure 3.

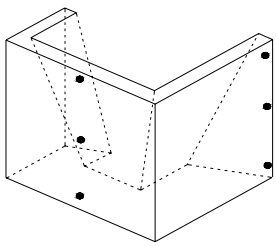

Figure 3. Location of displacement observation

Strain patches were located at the tail of the long side wall and the top, two-third of the way, and the middle of the intersection between front wall, long, and short side walls, just as Figure 4 presented.

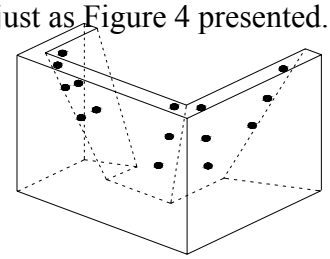

Figure 4. Location of strain observation

Loading Procedure. Loading level was set to be two tons. It was necessary to upload by level and unload after cracks appeared. The abutment model was held still for five to ten minutes after each uploading and then data was recorded. After the last uploading, ten to thirty minutes was needed to hold it still.

TESTING DATA ANALYSIS

General Oblique U-shaped Abutment. Height-directional displacement along the bridge of the general oblique U-shaped abutment front wall's middle part can be seen in Figure 5. Figure 6 presents the height-directional displacement through the bridge of long side wall's tail.

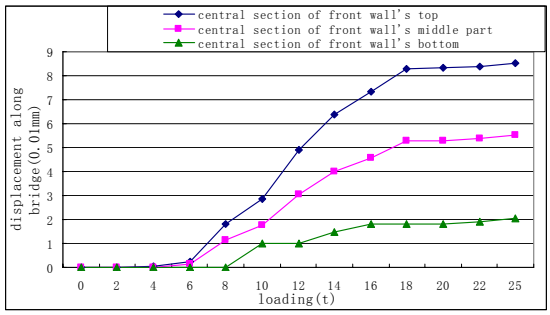

Figure 5. Displacement of front wall's central section of general abutment

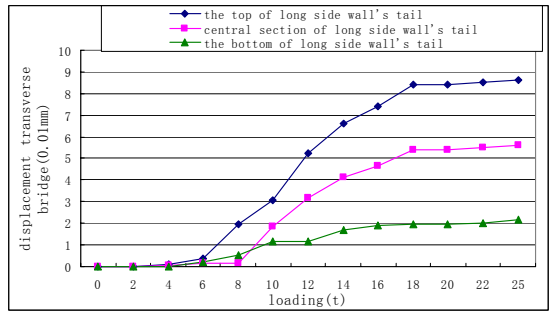

Figure 6. Displacement of long side wall's tail of general abutment

Recorded experimental data proved that displacement increased with the augment of load. When the load reached twenty-five tons, the maximum displacement along the bridge at the middle part of the front wall was 0.076mm and appeared at the top of the front wall. The maximum displacement through the bridge at the long side wall's tail was 0.086mm and appeared at the top of the long side wall's tail.

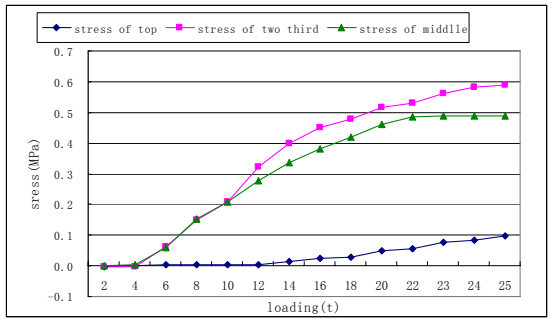

Figure 7.Stress of general abutment

The elastic modulus of C15 chip stone concrete equaled to 4.2×10^3 MPa. Stress was analyzed by recording strain data from multiple elastic moduli. The testing result showed that stress increased with the augmentation of load. When the load reached twenty-five tons, the maximum stress of the intersection between the front wall and long side wall was 0.588 MPa and it appeared at a location two-third of the way to the bottom, as shown in Figure 7.

Angle-smoothening Ablique U-shaped Abutment. Height-directional displacement along the bridge of the angle-smoothening oblique U-shaped abutment's front wall's middle part can be seen in Figure 8. Figure 9 gave the height-directional displacement through the bridge of long side wall's tail.

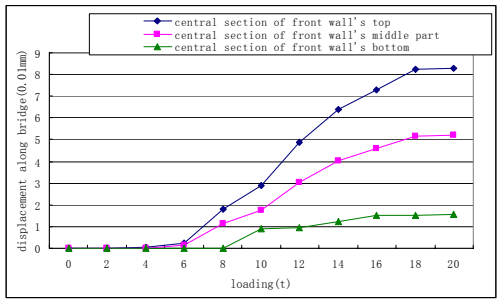

Figure 8. Displacement of front wall's central section of angle-smoothening abutment

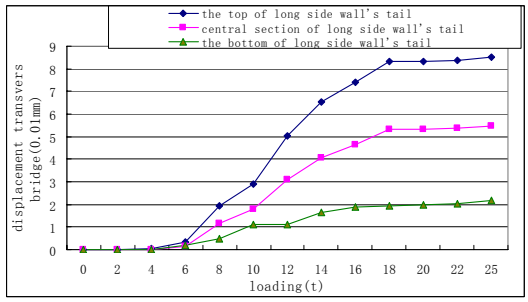

Figure 9. Displacement of long side wall's tail of angle-smoothening abutment

Test results show that displacement along the bridge increased with the augmentation of uploading. When the load reached twenty-five tons, the maximum displacement along the bridge at the middle part of front wall was 0.077mm, appearing at the top of the front wall. The maximal displacement through the bridge at the long side wall's tail was 0.085mm and appeared at the top of the long side wall's tail.

It also showed that stress increased with the augmentation of uploading. When the load reached twenty-five tons, the maximum stress of the intersection between the front and long side wall was 0.319 MPa and it appeared at a location two-third of the way to the bottom, as shown in Figure 10.

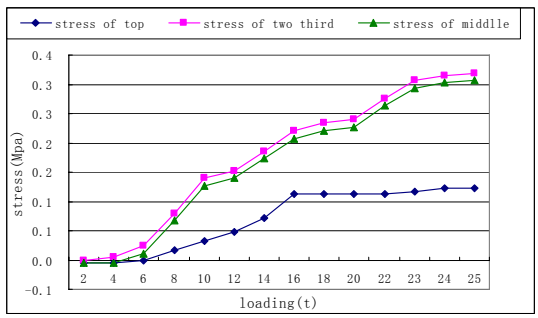

Figure 10.Stress of angle-smoothening abutment

Stress decreased greatly after the angle-smoothening reinforcement method was used. However, displacement showed little difference.

Carbon Fibre Reinforced Oblique U-shaped Abutment. The general abutment model was affixed with two rings of carbon fibre and the width of the carbon fibre was five meters. The first bar was affixed at the top of the abutment and the second's location was two-third of the way to the bottom. The angle-smoothening abutment model was affixed with only one ring of carbon fibre located at the top of the abutment.

This part was to analyze the model with one affixed ring of carbon fibre and the model with two affixed rings of carbon fibre. Displacement data along and through the bridge was listed in Table 1. It can be seen that the displacement was very small for carbon fibre. When the load reached 60 tons, vertical cracks appeared and the maximum displacement along bridge was 0.074mm and its location was the

top of the front wall's central section. The maximum displacement through bridge was 0.039mm and the location was the top of long side wall's tail.

Table 1. Displacement of abutment affixed one ring of carbon fibre unit: mm

load	displacement along bridge at central section of front wall			displacement throughbridge at the tail of long side wall		
	top	middle	bottom	top	middle	bottom
20t	0.005	0.003	0	0.007	0.005	0.003
30t	0.014	0.004	0	0.011	0.007	0.004
40t	0.029	0.019	0	0.025	0.017	0.007
50t	0.063	0.041	-0.01	0.027	0.021	0.010
60t	0.074	0.052	-0.02	0.039	0.026	0.017

Displacement data along and through the bridge of this model was listed in Table 2. Maximum displacement along the bridge was 0.018mm and its location was the top of the front wall's central section. The maximum displacement through the bridge was 0.033mm and the location was the top of the long side wall's tail. The displacement of the two rings of carbon fibre reinforced model was less than that of the one ring of carbon fibre reinforced model. Therefore, it can be concluded that the effect of carbon fibre reinforcement is better than the angle-smoothening method to decrease displacement. The effect of two rings of carbon fibre was better than that of one ring.

Table 2. Displacement of abutment affixed two rings of carbon fibre unit: mm

load	displacement along bridge at central section of front wall			displacement transverse bridge at the tail of long side wall		
	top	middle	bottom	top	middle	bottom
20t	0.007	0.004	-0.005	0.006	0.004	0
30t	0.011	0.007	-0.005	0.007	0.004	0
40t	0.015	0.01	-0.006	0.009	-0.005	0
50t	0.017	0.011	-0.01	0.032	0.006	0
60t	0.018	0.012	-0.01	0.033	0.025	-0.01

For stress data analysis, it mainly covered two issues: the model with one affixed ring of carbon fibre and model with two affixed rings of carbon fibre.

Stress data of this model was listed in Table 3 and the maximum stress was 0.764MPa when loads reached 60 tons with two-third of the way to the bottom as the location.

Table 3. Strain and stress of abutment model affixed one ring of carbon fibre

load	strain (με)			stress (MPa)		
	top	two third	middle	top	two third	middle
20t	-6.67	44.76	-4.76	-0.003	0.188	-0.020
30t	28.57	94.76	23.81	0.120	0.398	0.100
40t	65.71	115.24	40.95	0.276	0.484	0.172

50t	57.14	162.86	66.67	0.240	0.684	0.280
60t	16.19	181.9	121.43	0.068	0.764	0.510

Stress data of this model was listed in Table 4. We can see that the maximal stress was 0.463Mpa when the load reached 60 tons and the location was two-third of the way to the bottom. Different from one ring of carbon fibre, stress decreased markedly.

Table 4. Strain and stress of abutment model affixed two rings of carbon fibre

load	strain (με)			stress (MPa)		
	top	two third	middle	top	two third	middle
20t	-0.95	0.95	-0.95	0.000	0.004	-0.004

60t	15.24	110.29	107.62	0.064	0.463	0.452

CONCLUSION

For the gravity oblique high u-shaped abutment, conclusions can be drawn as follows by investigation.

(1) Displacement and stress increases with the augment of load. The maximum displacement along the bridge appears at the top of the front wall's middle part and the maximum displacement through the bridge appears at the top of the long side wall's tail. The maximum stress appears at the location of two-third of the way to the bottom of the intersection between the front wall and long side wall.

(2) The maximum displacement along the bridge is 0.076mm for the general abutment, it is 0.077mm for the angle-smoothening abutment, and it is 0.074mm and 0.018mm for the abutments with one and two affixed ring(s) of carbon fibre, respectively.

(3) The maximum displacement through the bridge is 0.086mm for the general abutment, it is 0.085mm for the angle-smoothening abutment, and it is 0.039mm and 0.033mm for the abutments with one and two affixed ring(s) of carbon fibre, respectively.

(4) The maximum stress is 0.588 MPa for the general abutment, it is 0.319 MPa for the angle-smoothening abutment, and it is 0.764MPa and 0.463Mpa for the abutments with one and two affixed ring(s) of carbon fibre, respectively.

(5) Good effects can be obtained using the angle-smoothening and carbon fibre reinforcement method.

(6) The effect of two rings of carbon fiber reinforcement is better than that of one ring to decrease both the abutment's displacement and stress.

Abstract: With respect to the construction of large bridge cushion cap concrete without poured joint in deep water, thermal stress during concrete hardening is destructive to durability. In this paper, a concrete thermal stress physical formula represented by the deformation component and variable temperature component is given based on the analysis of temperature stress influence. The calculation parameters of the main cushion cap with dimension of 113.75 m long, 48.1 m wide, and 13.3m high are determined. Comparison is made between the monitoring value and calculated results, which are obtained by simulation analysis of thermal stress variation during concrete hardening. The analysis shows that rational controlling temperature standard, cooling with cold water pipes, and curing in time play an important role in cracks protection. The dangerous age and the location where cracks could occur are given. These could provide valuable a reference for the design and construction of the other similar projects.

1. Introduction

The crack caused by the temperature stress of concrete has a great impact on concrete's durability, which has drawn wide attention in engineering. In construction, because of the heat of hydration produced in the process of hydration of concrete, at the early stage, the inside temperature of concrete goes up so quickly that concrete expands out of shape. The concrete's elastic modular is small, consequently, the stress caused by expansion distortion controlled is small too. With the gradual dropping of temperature, concrete creates contraction distortion while its elastic modular increases. The controlled distortion caused by the dropping of temperature produces compressing stress inside the concrete and tensile stress on the surface.

If the surface tensile stress exceeds concrete's maximum tensile strength, cracks will appear on the surface of concrete（YUAN, 2002）. When the concrete's temperature drops gradually, the volume of concrete becomes smaller. Meanwhile concrete emerges with contraction distortion due to the carbonization and evaporation of extra moisture in the hardening process. However, limited by the condition of foundation and structural boundary, concrete cannot distort freely, thus temperature stress comes into being. When the two stresses pile up and exceed concrete's maximum tensile strength, shrinking cracks appear around the juncture of

concrete's base plate and inside（WANG, 1997; ZHU, 1999）.

Based on an oversize bridge cushion cap construction in deep water, this paper has adopted the finite element method to do some research into the change patterns of the heat stress field in the process of concretion of concrete's components and made comparison and analysis between calculated temperature stress and the temperature stress measured in practical construction. The conclusion may serve as a reference for similar projects.

2. Heat Stress Calculation Theory

Analysis of the concrete hardening process is based on the elastic deformation stage to judge temperature cracks appearance according to whether the tensile stresses exceed the tensile strength of concrete. With the assumption that linear expansibility is invariable when temperature varies with time, the strain component of each point in the elastic solid is given as:

$$\begin{aligned} &\varepsilon_x = \varepsilon_y = \varepsilon_z = \alpha T \\ &\gamma_{yz} = \gamma_{zx} = \gamma_{xy} = 0 \end{aligned} \qquad (1)$$

Where T is variable temperature in the elastic concrete; α is linear expansibility. The physical equation of heat elastic mechanics is:

$$\begin{aligned} \varepsilon_{\mathrm{x}} &= \frac{1}{E}\left(\sigma_x - \nu\sigma_y\right) + \alpha T \\ \varepsilon_{\mathrm{y}} &= \frac{1}{E}\left(\sigma_y - \nu\sigma_x\right) + \alpha T \\ \gamma_{xy} &= \frac{2(1+\nu)}{E}\tau_{xy} \end{aligned} \qquad (2)$$

The stress component is given from equation (2).

$$\begin{aligned} \sigma_{\mathrm{x}} &= \frac{E}{(1-\nu^2)}\left(\varepsilon_x + \nu\varepsilon_y\right) - \frac{E\alpha T}{1-\nu} \\ \sigma_{\mathrm{y}} &= \frac{E}{(1-\nu^2)}\left(\varepsilon_y + \nu\varepsilon_x\right) - \frac{E\alpha T}{1-\nu} \\ \tau_{xy} &= \frac{E}{2(1+\nu)}\gamma_{xy} \end{aligned} \qquad (3)$$

The theory with calculating the temperature stress field of concrete with the finite element method is that the strain increment of concrete is composed of elastic strain increment $\Delta\varepsilon_{\mathrm{n}}^{f}$, temperature strain increment $\Delta\varepsilon_{\mathrm{n}}^{T}$, authigenic volumetric deformation increment $\Delta\varepsilon_{\mathrm{n}}^{0}$, time deformation increment $\Delta\varepsilon_{\mathrm{n}}^{c}$, and shrinkage deformation increment $\Delta\varepsilon_{\mathrm{n}}^{\mathrm{s}}$（ZHU, 1999）. According to linear elastic theory, the

relationship of stress and strain under complex stress conditions can be defined as:

$$\Delta\sigma_{\mathrm{n}} = D_n\left(\Delta\varepsilon_n - \eta_n - \Delta\varepsilon_n^T - \Delta\varepsilon_n^0 - \Delta\varepsilon_{\mathrm{n}}^{\mathrm{s}}\right) \quad (4)$$

Where $\Delta\sigma_n$ is the stress increment matrix; $\Delta\varepsilon_n$, total strain increment; η_{n}, time deformation influence factor; and D_n, modified elastic matrix. From the balance equation of the finite element, the primary equation can be given as:

$$K\Delta\delta_n = \Delta P_n^T + \Delta P_n^C + \Delta P_n^0 \quad (5)$$

Where K is the stiffness matrix of structure; $\Delta\delta_n$, nodal displacement increment; ΔP_n^T, temperature load vector; ΔP_n^C, equivalent load vector yielding by creep, and ΔP_n^0, authigenic volumetric deformation load increment.

3. Analytic Model

The main cushion-cap is dumb-bell shaped with dimensions of 113.75m long, 48.1m wide, 13.324m high, and plane blocking 51.35×48.1m. A total of 42271m^3 C35 concrete is deposited.

（1）Elastic modular

Elastic modular E on different ages is calculated by formula (6) and the E is increasing with age is shown in Figure1.

$$E = 3.9\frac{t+0.885}{t+7.75} \quad (6)$$

（2）Compression strength

7d and 28d compression strength is R_7=31.8MPa and R_{28}=45.0MPa respectively.

（3）Adiabatic temperature rise

Heat of hydration of cement Bao-lei P.O 42.5 is 270J/g in 3 days and 292J/g in 7 days respectively. Taking θ_0=42.0℃ as the final adiabatic temperature rise, it is calculated by（7）at different ages and the result is shown in Figure2.

$$\theta = 42.0\frac{\mathrm{t}-0.682}{\mathrm{t}-0.325} \quad (\mathrm{t}\geqslant 1.2) \quad (7)$$

There, t—age, θ - adiabatic temperature rise at age t.

（4）Coefficient of temperature conductivity

The coefficient of heat conductivity λ can be computed as λ=11.02kJ/m.h.℃ according to the proportion of concrete so that the coefficient of temperature conductivity a=0.0048m^2/h can be obtained.

（5）Poisson ratio is 0.167 and linear expansion factor is taken as α=8.5×10^{-6}（1/℃）by the detection of results of the other cushion cap brought into effect already.

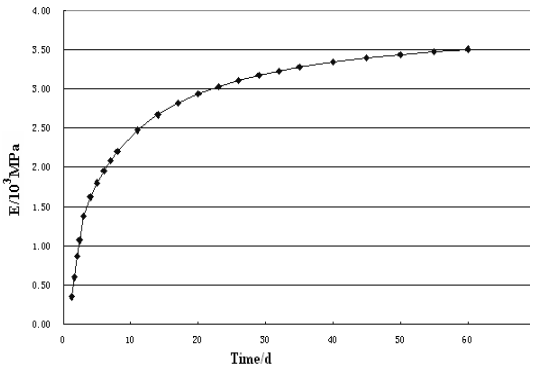

Fig.1. Variation of elastic modular

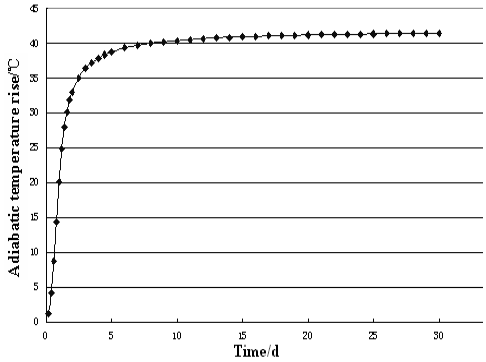

Fig.2. Adiabatic temperature rise

4. Calculated Result

The temperature field and stress field are treated in the same meshing and program adopting the three-dimensional finite element method. The influence of the cooling water pipe is considered and the concrete creep is calculated by the relaxation method（Code, 1987）.

（1）Characteristic number of stress

The characteristic number of stress shows larger tensile stress in the surface of the 2, 3, 4 layer. The largest inner tensile stress（3.08MPa）is found in the first layer in. Although the fourth layer in reaches the smallest tensile stress, it cannot be ignored due to yielding at an early age.

（2）Curve of stress variation

Figure 3 shows the curves of stress, change of stress point, and the curve of concrete tensile strength. Inner points are compressing stress in 4 days and tensile stress will come into being afterwards. The tensile stress increases quickly after the next layer of concrete being poured to reach the largest value in about 17 days. Surface points are almost tension in the beginning and reach the largest value in about 3-5days, then decrease gradually and become compression after 10 days.

Compared to the tension curve of concrete, surface tensile stress of every layer in 4 days is almost in proximity to the tensile strength of concrete, which the assurance coefficient is about 1.12～1.20 in 3 days. It is the danger period to develop cracks. Meanwhile the inner tensile stress of the first layer is approximately the same as the tensile strength of concrete at the age of 17～20 days but it is far lower than the tensile strength at the other ages.

Calculation results show that every layers' concrete tensile stress is less than tensile strength in the corresponding age, but the danger age during which the assurance coefficient is lower to quite a few cracks appear.

5. Detect Test Result

（1） Law of stress variation

Figure 4 shows the stress change of first layer concrete. $\sigma_{1.2}$, the stress point located on the distance of 57.5cm of lower surface, indicate that tensile stress is low in early ages and mostly compression stress later. $\sigma_{1.5}$ and $T_{1.5}$ represents inner stress

and temperature variation, respectively, located 40cm under top surface. It indicates that tensile stress appears immediately when the next layer of concrete is poured and it shows compression stress at an early age. The tensile stress enhances quickly reaching a maximum value of 3.52MPa , which is close to the tensile strength of concrete, and then reduces gradually. $\sigma_{1.8}$ represents the stress point near the steel suspension box-cofferdam that tensile and compression stress are all lower.

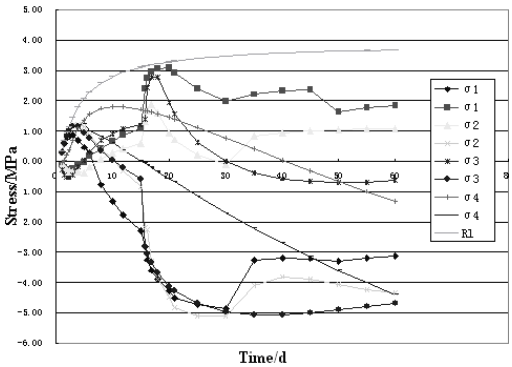

Fig.3. Inner and outer stress variation.

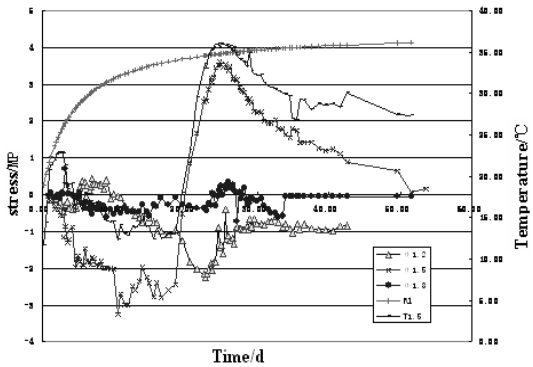

Fig.4.The first layer stress variation

Figure5 shows the second layer concrete stress variation. $\sigma_{2.5}$ and $\sigma_{2.6}$ represent the inner stress variation of the stress point located 40cm under the upper surface. $\sigma_{2.8}$ represents the stress point near the steel suspension box-cofferdam that tensile stress appears at an early age and compression stress mainly later.

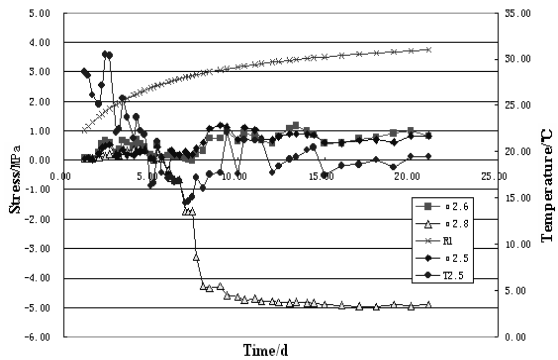

Fig.5. The second layer stress variation

（2）Characteristic number of stress

The tensile stress at the lower part and middle part of the cushion cap and side surface of the steel suspension box are not larger. There will be a big tensile stress in the first layer inner point near the top surface after upper concrete is poured; the tensile stress value is almost the concrete tensile strength.

6. Discussion

（1）According to the comparison of the monitoring result and calculation result, we know the calculation result corresponds to the monitoring result well. However, there exist errors between the two because the superficial point in the monitoring distance from the surface is more than 30cm.

（2）Interlamellar pouring intermission, water cooling time, local variation of

cooling pipe spacing, the difference between initial conditions and boundary conditions, the instability or inhomogeneity of concrete property, and more influence the monitoring result and calculation result.

（3）Thermal cracks can be avoided by strictly implementing temperature control standards and measures, paying attention to concrete prophase maintenance, and reduction of temperature difference between the upper and lower layer.

7. Conclusion

（1）The temperature control calculation provides the basis for temperature control in construction. The temperature monitoring plays an important role in testing the rationality and validity of temperature control standards, checking the safety condition of crack resistance, and holding temperature information timely.

（2）The temperature difference is large when the concrete pouring intermission is too long, 5～10 days later there will be large tensile stress in the sloping surface, which can causes the surface to crack. In addition, it is necessary to pay attention to the stress concentration caused by the wedge-shaped structure.

（3）The superficial tensile stress is larger in 4 days and cracks easily appear on the surface in this period. Active temperature control measures and an emergency plan should be taken.

（4）The monitoring result shows that the cooling water pipe is a very efficient method for temperature control in concrete. Shortening the concrete pouring intermission is beneficial to decreasing the temperature difference. Superficial thermal retardation and maintenance plays a very important role in preventing the surface cracking. The research provides scientific data and experience for temperature control of large cushion cap.

ABSTRACT

Asphalt pavement performance in seasonal frozen region is affected severely by the freeze-thaw cycles. Gradation has important effects on asphalt mixture's freeze-thaw durability. This paper presented the standard test methods of freeze-thaw cycles and analyzed the freeze-thaw durability of asphalt mixtures with different gradation. The test results showed that the freeze-thaw damage of asphalt mixtures goes through three stages. With the increase of freeze-thaw cycles, the splitting strength of mixtures decreased and the volume expanded gradually. The performance stabilized until the next rapid deterioration caused by the loss of interfacial adhesion between the asphalt and aggregate. The results also indicated that the mixtures with dense gradation had the best freeze-thaw stability than others, and the semi-open graded mixtures performed worst. The study results can be used in technical guideline for freeze-thaw durability of asphalt mixtures in seasonal frozen region.

Keywords: asphalt mixtures; freeze-thaw cycling; gradation; splitting strength; volume; interfacial adhesion

FOREWORDS

Asphalt mixture is a typical viscoelastic material. It's properties are affected by the temperature. In the seasonal frozen regions of China, the variation of water phase state due to changing temperature was the prime reason of asphalt mixture deterioration. There were researches on the freeze-thaw performance of asphalt mixture under the temperature cycles ranged from -20℃ to 20℃ (Pan et al. 2003, Hou et al. 2006), which mainly considered the temperature change within one year without consideration of the temperature range during years of asphalt pavement life cycle. Considering the combined impact of freeze-thaw cycling and traffic load on service life, the accumulative deterioration of asphalt mixtures would be severe.

Furthermore, the existing studies on the freeze-thaw performance of asphalt mixture mainly concerned the strength such as indirect tensile strength and fatigue life (Pan et al. 2003, Cao et al. 2004, Huang et al. 2005). There were only few studies on the variation of asphalt mixture samples' saturated weights (Hassan et al. 2002).

The objective of this paper was to characterize the asphalt mixture performance under freeze-thaw cycles using mechanical method and physical properties.

1 TEST METHODS AND MIXTURES CHARACTERIZATION

1.1 Introduction of test methods

The existing freeze-thaw stability test mainly considered the environmental effects within one year, which could be defined as "small cycles". And the range of temperature could be from -20℃ to 20℃. However, in the service life, the asphalt pavement would be also under the effects of high temperature along with low temperature. The temperature could range from -20℃ to 60℃ and should be included to analyze the asphalt pavement performance. In this experiment, three types of hot mix asphalt (HMA) mixtures were selected. For each type of HMA, three specimens were unconditioned, and the other specimens were water conditioned by vacuum saturation with distilled water for 15 minutes. Then for each of the three type of HMA mixtures, freeze-thaw cycles up to 8 cycles or to failure was conducted. Each cycle consisted of freezing for 8 h at -20℃ followed by soaking for 4 h at 60℃. Indirect tensile strengths were determined at 0, 2, 4, 6 and 8 cycles for conditioned specimens. Besides strength, the volume and weight were measured in the process of freeze-thaw cycles for every two cycles.

1.2 Materials

Crushed limestone aggregate was used in this experiment. Penetration grade 80-100 asphalt cement was used for AC and AM mixtures and rubber asphalt was used for OGFC mixtures. Properties of binders are shown in Table 1.

Asphalt mixtures for this experiment consisted of AC-16, AM-16 and OGFC-19. Mixtures design was performed according to Marshall Mixture Design Method. The final gradations are shown in Table 2.

All mixtures were added with hydrated lime to improve the ability of anti-stripping. The basic properties of the mixtures are shown in Table 3.

Table 1. Properties of Binders

Test	Ordinary Binder Properties	Rubber Asphalt Properties
Penetration at 25℃/0.1mm	93.7	62.3
Softening point /℃	45.9	63.6
Ductility at 15℃/cm, 5cm/min	>150	—
Retained penetration after RTFOT/%	60	61.1
Retained ductility at 15℃ after RTFOT/cm, 5cm/min	149	—
Viscosity at 180℃, Pa·s	—	2.31

Table 2. Mixtures Gradations

Sieve size (mm)	Percentage passing (%)		
	AC-16	AM-16	OGFC-19
19	100	100	100
16	95	97	95
13.2	84	78	80
9.5	70	63	57.5
4.75	48	36	20
2.36	34	22	15
1.18	25	15	12
0.6	18	10	9.5
0.3	13	7	7.5
0.15	10	4	5.5
0.075	6	3	4

Table 3. Mixtures properties

Mixtures	Properties	
	Percent air voids (%)	Asphalt content (%)
AC-16	6±1	5.2
AM-16	12±1	4.2
OGFC-19	18±1	5.2

2 RESULTS AND DISCUSSION

2.1 Impact of freeze-thaw cycles on mixture strength

The results of indirect tensile strength (ITS) and tensile strength ratio (TSR) for the three types of asphalt mixtures under different freeze-thaw cycles were shown in Figure 1.

It can be seen that the tensile strength of the three types of asphalt mixtures decreased with the increase of freeze-thaw cycles. In the first several cycles, the strength of mixtures have a sharp decrease, and then keep steady except AM mixtures. For AM mixtures with semi-open gradation, the strength kept reducing with the increase of the freeze-thaw cycles. Comparing with AC and OGFC mixtures, it could be concluded that there should been also a steady state of strength for AM mixtures in the next several cycles. The different strength decrease curve indicated the impact of gradation on the mixture performance in freeze-thaw cycles. The ITS of OGFC with skeleton-gap structure is smaller than AC and AM mixtures. The AC mixture with dense structure had best performance.

However, the change of TSR among the three mixtures gave different results. After 2 cycles, the TSR for OGFC reduced sharply to 60 percent for unconditioned specimens, and then gradually decreased until to 40 percent. As for AC mixture the values for the two similar states are 80 and 60 percent accordingly. However, for AM mixture, the decrease of strength does not have the steady state like the other two

mixtures. After the first cycle, the TSR of AM is higher than OGFC. After the last cycle, AM showed worst performance. Therefore the effect of gradation on asphalt mixture's freeze-thaw performance was important. Mixtures with dense structure and small air voids had the best performance.

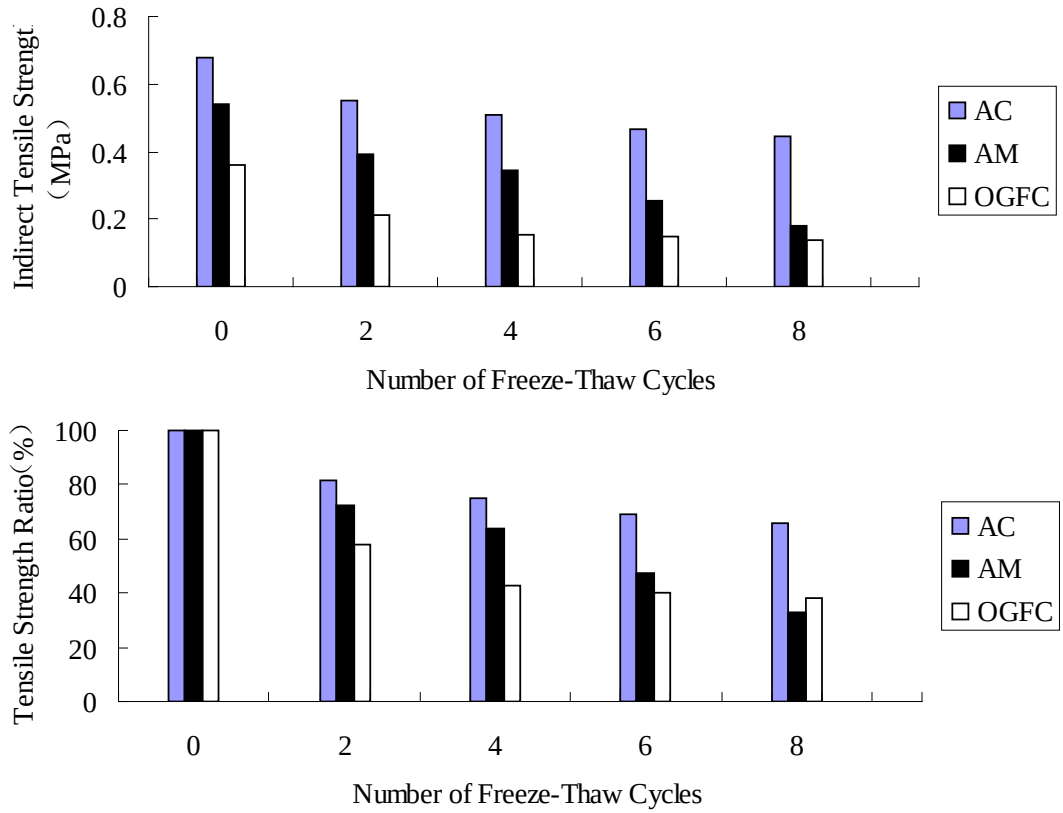

Figure 1. Impact of freeze-thaw cycles on ITS and TSR of three types of asphalt mixtures

Moreover, due to the interconnected air voids in OGFC mixture, the water could flow freely, which could reduce effect of water expansion at low temperature. Thus mixtures with middle percent air voids (from 8 to 13 percent) had the worst freeze-thaw performance, because the water entering into mixtures could not flow away freely.

The test results also indicated that the three types of asphalt mixtures performance decreased with the increase of freeze-thaw cycles. All the three curves had a relatively steady stage with the slope keep relatively smooth. However, the steady stage occurred after different cycles: for OGFC and AC mixtures, steady stage occurred after 4 cycles at which TSR was 60 percent for AC mixture and 40 percent for OGFC mixture. As for AM mixture, the steady stage occured when TSR was less than 30 percent. Considering the cumulative damage in the service period of pavement, it could be deduced that the three types asphalt mixtures would fail after more freeze-thaw cycles in service life due to the cumulative impact. In this research, surface raveling occurred in some specimens of OGFC and AC mixture in the last

several cycles which indicated the failure of interfacial adhesion between the asphalt binder and aggregate. As a conclusion, the deterioration of asphalt mixture under the impact of freeze-thaw cycles could be divided into three stages: strength decrease, performance stabilization and interfacial adhesion failure.

2.2 Impact of freeze-thaw cycles on physical properties of mixtures

Under freeze-thaw cycles, the physical properties of all specimens changed. The volume was obtained by measuring the height and diameter, while weight was obtained by weighing the dry mixture after splitting test. The variations of physical properties after freeze-thaw cycles are shown in Figures 2~5. It is noted that all specimens used to test the volume undergo 8 cycles.

The volume for all specimens increased during the first several cycles and then kept relatively steady. This could be explained by the viscoelastic properties of asphalt mixture. For viscoelastic material, the structure could have certain volume expansion to compensate the effect of water expansion. Therefore the mixture would have residual creep deformation due to expansive load. When the air void volume in specimens expanded to fit the expansion of water, the whole volume would not change too much. After this stage, the intrusion of water on the interface between asphalt and aggregate would be the main factor influencing the mixtures performance.

Figure 5 indicates the variation of weight for all mixtures under freeze-thaw cycling, which can be defined as weight loss rate Δm_m:

$$\Delta m_m = \frac{m_0 - m_n}{m_0} \times 100$$

where Δm_m = accumulated percentage of weight loss;

m_0 = initial sepcimen weight;

m_n =weight of undamaged particles in the specimen after n freeze-thaw cycles.

The line in Figure 5 was based on the average value. It could be seen that the weight loss rate increased sharply in the last cycles, which characterized the failure stage of the specimen. The weight loss rate developed differently for three types of asphalt mixtures. For AC mixture, the weight loss rate was small. However, for AM mixture, there was rapid weight loss during the last several cycles which agreed with the continuous decrease of strength. For OGFC mixture, although the weight loss rate was also large (>5%), the ITS remained to keep steady since the weight loss mainly appeared in the edge of specimens and did not cause the structure failure.

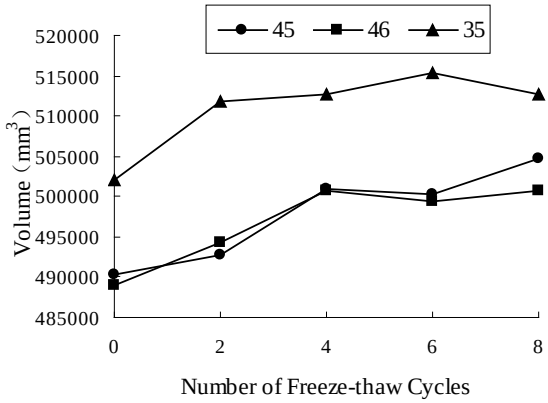

Figure 2. Volume change for AC

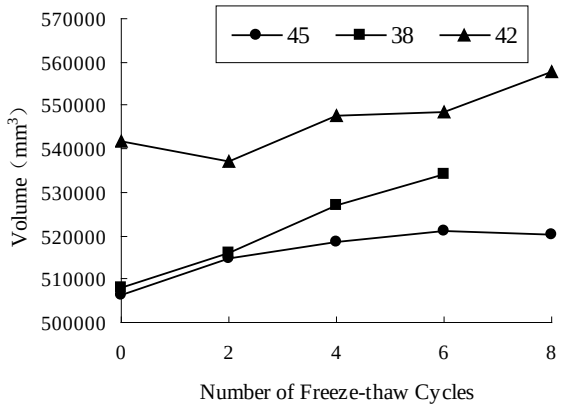

Figure 3. Volume change for AM

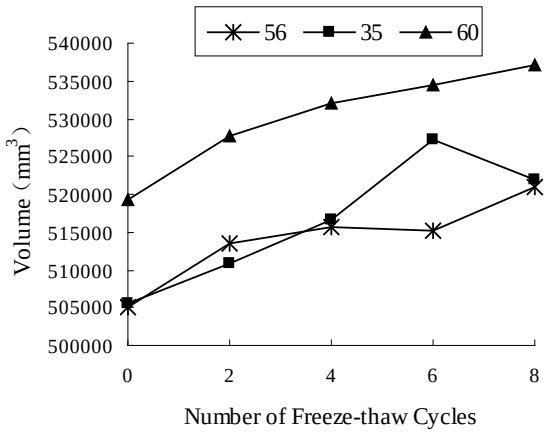

Figure 4. Volume change for OGFC

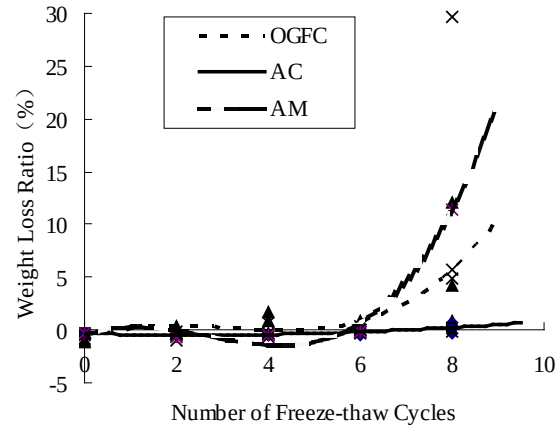

Figure 5. Weight change for all mixtures

3 CONCLUSIONS AND RECOMMENDATIONS

This study mainly focused on the freeze-thaw performance of three types of mixtures. The following conclusions were drawn:

(1) Gradation had important effect on the freeze-thaw performance of asphalt mixture. AC mixture had the best performance in the under freeze-thaw cycling, and AM mixture with the semi-opened gradation worst.

(2) The failure of asphalt mixture specimens in freeze-thaw cycles could be divided into three stages. For different mixtures, the TSR varies in terms of performance stability.

(3) With the increase of freeze-thaw cycles, the volume of mixtures increased, while weight loss rate decreased.

ABSTRACT

A full–range shear experiment of 6 groups with 18 specimens was carried out to investigate the effective adherence of new and old concrete in structure strengthening. The influence of various techniques to interface shear properties is examined. The experiment results show that the shear strength of the interface can be improved remarkably with bonded-in reinforcement. Based on the research results, the practical calculation formula was put forward which can take account of the influence of roughness, agent and bonded-in reinforcement. The formula was also validated by other experiments and can be used in the strengthening design for concrete structure.

INTRODUCTION

It is a common practice in the repair and strengthening the existing structure to add new concrete on the top of the old element of reinforcement concrete. The effective adherence of the interface is a key factor to assure new and old concrete bearing load together. It could usually be improved by enhancing shear capability of the interface. Many researchers (Gao, 2001; Guo, 2003; Han, 2003 and Yuan, 2001) focus their works mainly on the properties such as: tensile, direct shear, collapse model test or multi-axial stress. The factor of bonded-in reinforcement at the interface, widely used at present in strengthening engineering, is usually ignored. Shear experiment with Z-shape specimens are carried out in this paper. The factor of boned-in reinforcement at the interface between new and old concrete is taken into account as well as roughness, agent factors. Based on the research results, the practical calculation formula was put forward and validated by other experiments and can be used in the strengthening design for concrete structure.

SHEAR EXPERIMENT

Figure 1 shows a Z-shape specimen with dimension 300mm×100mm×350mm and load management. The dimension of interface between new and old concrete is

125mm×100mm. The strength grade of old concrete is C30 and of new concrete C40 with casting time space 4 months. All the 18 specimens are divided into 6 groups marked A, B, C, D, E, and F. Specimens in A, B, and C groups have only different face management and with no bonded-in reinforcement at interface. D and E groups have 4 ϕ 10 shear reinforcements at interface in each specimen with planting depth 5cm and 10cm respectively.

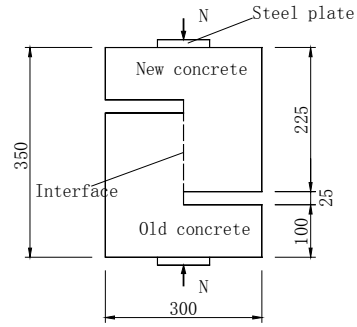

Figure 1. Z-shape specimen and load management(unit:mm)

EXPERIMENT RESULTS

Results of shear strength of concrete interface are shown in table 1. From the results of A, B, and C groups, the shear strength of B group with neat cement is the highest and the casting directly sample has the lowest strength. However, the strength of all specimens with three agents are smaller than that of F group, in which all specimen are casted at the same time for new and old concrete.

On the other hand, bonded-in reinforcement at interface could remarkably improve the shear strength of specimens in D and E groups by 8.77Mpa and 14.73MPa respectively.

Table 1. Results of shear strength of concrete interface

Specimen No.	Agent type	Interface Roughness /mm	Planting depth/cm	Broken load/kN	Shear strength /MPa	Average strength/ MPa
A-1	Casting directly	1.93	—	63.8	5.1	4.13

LOAD- STRAIN CURVE OF SPECIMENS

All the Load- strain curves for the specimens without bonded-in reinforcement are shown in Figure 2. Results from specimens with reinforcement are shown in Figure 3.

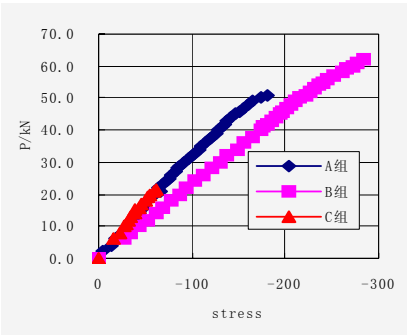

Figure 2. Load-strain curves of specimens without bonded-in reinforcement

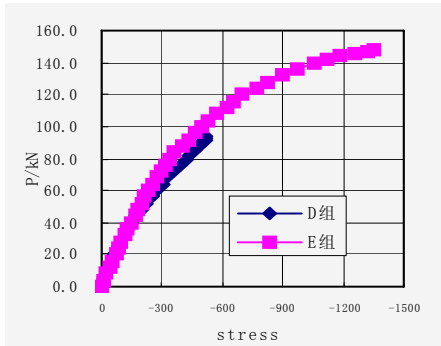

Figure 3. Load-strain curves of specimens with bonded-in reinforcement

The stress of the specimens in A, B, and C groups is smaller than 300 μ ε as shown in fig.2 and it increases linearly. It implies a brittle fracture failure mode. The stress of the specimens in D and E groups with bonded-in reinforcement are more than 600 μ ε even more than 1200 μ ε as shown in Figure 3 which can be considered as ductile fracture at the interface.

PRACTICAL FORMULA OF SHEAR STRENGTH

Based on the experiment, the shear capacity denoted by V_n of the interface could be decomposed into three parts (Equation 1). The first is cohesive force V_J, the second is friction force V_M caused by bonded-in reinforcement, and the third is V_D provided by bolt pin action of bonded-in reinforcement.

$$V_n = V_J + V_M + V_D \tag{1}$$

5.1 Practice formula for total shear strength of interface τ_J

From the experiment results, τ_J is related with concrete interface roughness, agent type and the cube compressive, which is denoted by Equation 2.

$$\tau_J = V_J / A_c = \zeta_1 \zeta_2 f_{cum} \tag{2}$$

Where, A_c is area of interface concrete, ζ_1 is roughness factor, ζ_2 is agent factor, f_{cum} is average compressive strength of new and concrete. ζ_1 could be fitted by experiment data. So Eq. (2) could be rewritten by

$$\tau_J = 0.06956\zeta_2 \cdot f_{cum} \tag{3}$$

5.2 Practice formula for friction shear strength τ_M provided by friction force

There are mainly three failure modes in the interface with bonded-in reinforcement: cone-bond compound failure, bond failure and reinforcement failure.

(1) Cone-bond compound failure

in this case, τ_M could be rewritten by

$$\tau_M = \frac{\mu \cdot F_G}{A_c} = \frac{\mu \rho_e f_t D^2}{d^2}\left(\frac{\tau_u}{f_t} - 1\right)\left(\frac{\tau_u}{f_t} + 1\right) + \frac{4\mu \rho_e D \tau_u}{d^2}\left(h_{ef} - \frac{D}{2}\left(\frac{\tau_u}{f_t} - 1\right)\right) \tag{4}$$

where f_t is tensile strength of concrete, ρ_e is steel ratio of bonded-in reinforcement of the interface, and d is the diameter of reinforcement.

(2) Bond compound failure

$$\tau_M = \frac{\mu \cdot F_G}{A_c} = \frac{4D\rho_e}{d^2} \cdot \mu h_{cf} \tau_u \tag{5}$$

(3) Cone-bond compound failure

$$\tau_M = \frac{\mu \cdot F_G}{A_c} = \mu \cdot \rho_e \cdot f_y \tag{6}$$

5.3 Shear strength τ_D caused by bolt pin action

Introduce the shear factor β caused by bolt pin action, τ_D could be written as

$$\tau_D = \beta \tau_M \tag{7}$$

Therefore, total shear strength of interface at different failure mode could be written by Eq. (8) (9) and (10)

(1) Cone-bond compound failure

$$\tau = 0.06956\zeta \cdot f_{cum} + \frac{\gamma\mu\rho_e f_t D^2}{d^2}(\frac{\tau_u}{f_t} - 1)(\frac{\tau_u}{f_t} + 1) + \frac{4\gamma\mu\rho_e D\tau_u}{d^2}\left(h_{ef} - \frac{D}{2}(\frac{\tau_u}{f_t} - 1)\right) \tag{8}$$

(2) Bond compound failure

$$\tau = 0.06956\zeta \cdot f_{cum} + \frac{4D\rho_e}{d^2} \cdot \gamma\mu h_{cf}\tau_u \tag{9}$$

(3) Cone-bond compound failure

$$\tau = 0.06956\zeta \cdot f_{cum} + \gamma \cdot \mu \cdot \rho_e \cdot f_y \tag{10}$$

Where ζ is agent influence factor. No agent $\zeta = 1$; only neat cement $\zeta = 1.5$. $\gamma = 1 + \beta$.

The formula is applicable only when the roughness is within 1.7mm and 3.0mm.

5.4 Formula validation

In Eq.(1), the first term V_J is the shear force of interface concrete in the case of no bonded-in reinforcement and the second and the third terms are the shear force provided by bonded-in reinforcement. The Comparison of calculation results by formula and experimental results are shown in tab.2

Table 2. Comparison of calculation results by formula and experimental results

Specimen No.	Concrete strength old/new /MPa	Interface Roughness/mm	Agent type	Planting depth/cm	τ_J /MPa	τ_G /MPa	τ /MPa	Test shear strength τ_0 /MPa	τ / τ_0
A	55/60	1.93	Casting directly	—	4.0	0	4.0	5.10	0.78
	55/60	1.93		-	4.0	0	4.0	3.40	1.18
	55/60	2.03		-	4.0	0	4.0	3.90	1.03
B	55/60	2.04	Neat cement	—	6.0	0	6.0	5.95	1.01
	55/60	3.00		-	6.0	0	6.0	5.90	1.02
	55/60	2.38		-	6.0	0	6.0	6.25	0.96

C	55/60	2.07	Mercha	-	2.0	0	2.0	2.15	0.93
	55/60	1.90	ndise	-	2.0	0	2.0	1.95	1.02
	55/60	1.86	agent	-	2.0	0	2.0	2.00	1.00
D	55/60	1.82	bonded -in	4～5	4.0	4.73	8.73	9.50	0.92
	55/60	2.10	einforcem ent	4～5	4.0	4.73	8.73	8.90	0.98
	55/60	1.79		4～5	4.0	4.73	8.73	7.90	1.11
E	55/60	1.97	bonded- in reinforc ement	9～10	4.0	10.6	14.6	13.50	1.08
	55/60	2.23		9～10	4.0	10.6	14.6	15.80	0.93
	55/60	2.15		9～10	4.0	10.6	14.6	14.90	0.98

From data shown in Tab.2, an average value of τ / τ_0 term $\bar{X} = 0.995$, the standard deviation $\sigma = 0.089$ and the coefficient of variation $\delta = 0.09$ could be obtained. This validates Eq. (1) proposed in the paper.

Eq.(1) could take fully account of different influence factors such as interface roughness, agent type, strength of new and old concrete and the planting depth of bonded-in reinforcement. Furthermore, the formula was also validated by other experiments and could be used in the strengthening design and calculation for concrete structure.

CONCLUSIONS

Based on the shear capacity experiments of new and old concrete with Z-shape specimens, the practical formula of shear strength of interface is proposed in this paper. Several conclusions could be drawn as following:

(1) The shear strength of interface, with roughness and agent pushing on old concrete surface, is smaller than that of whole specimen. In the specimens with agent pushing, neat cement is the most effective.

(2) With bonded-in reinforcement, the shear strength of interface could be increased remarkably, that could achieve level of the strength of whole specimen. And that strength quantity value is determined by planting depth, steel ration of bonded-in reinforcement, and compressive strength of concrete and epoxy resins.

(3) According to the experiment results, mechanics of shear failure at interface is analyzed. Practical formula for shear strength of interface calculation is put forward in the paper, which is applicable to the roughness within 1.7mm and 3.0mm. And the formula is also validated by experiment data.

ABSTRACT

Highway tunnels are mostly paved with asphalt concrete pavement. One of the components, asphalt is inflammable. And once it is ignited, large quantities of heat, smoke and poisonous gas are released and spread quickly, in tunnel fire, which will cause the difficulties of the escape and rescue seriously. This paper presents research on mineral-inorganic flame-retardant used in asphalt concrete pavement to avoid the huge damage caused by tunnel fires. The mechanism of flame retardancy was investigated systematically based on plenty of tests. Results indicated that the flame-retardant technique can slow the fire spreading and prolong the time of escape and rescue.

Foreword

Most highway tunnels were paved with asphalt concrete pavement because of its many advantages. However, serious tunnel fire incidents often occurred in many countries around the world, such as the famous tunnel fire disaster in Mont Blanc tunnel, and tunnel fire in Limao Mountain in Zhejiang Province of China. In both cases the asphalt concrete pavement was severely damaged and it caused serious economic losses. During the tunnel fire, temperature can reach 800℃ and higher in a short period. Although asphalt is difficult to burn in normal temperature, it can burn at high temperatures and release large quantities of smoke and toxic gases. Researchers at home and abroad have carried out some research about it. However, there is a lack of research about the heat, toxicity, smoke density and issues involving the escape and rescue conditions of security.

1 Research on the flame retardancy of mineral powders and aluminum hydroxide (ATH)

The so-called fire retardancy of material is the ability to postpone or terminate the combustion process under certain conditions. Flame Retardant Materials are designed to enhance the flame retardancy, and to ensure adequate time for fire-fighting or self-help.

1.1 Evaluation method of flame retardancy

Limit Oxygen Index (LOI) has been adopted as the index to evaluate the flame retardancy of materials by most international organizations, such as ISO04589, the United States ASTM2863, and Japan JISK7201. Besides, China developed a national standard "plastic combustion performance test method of oxygen index"

(GB/T2406-2006). LOI is defined as the minimum oxygen concentration in air of N_2 and O_2 to maintain burning. If the LOI is greater than 27%, the materials will be self-extinguishing.

1.2 Evaluation of the flame retardancy of Mineral powders

Mineral powders proportion in asphalt mixture is about 5%~10%, almost 1-1.5 times of asphalt. If mineral powders occur endothermic and dehydrated chemical reactions near asphalt, fire-retardancy of materials can be achieved through interruption of heat exchange.

Many tests were carried out for the study of flame-retardancy of mineral powders. AH-90 asphalt was used in the tests, and whose limiting oxygen index was 19.3%. The LOIs of several mineral powders are listed in Table 1. The ratio of powder to asphalt is 1:1 in these cases.

Tab.1 Limiting Oxygen Index (LOI) of mineral powders

mineral powders	DC	T	S	G	DA	Y
LOI (%)	24.3	27.0	25.1	23.9	25.0	23.0

It can be seen from Table 1 that T has a significant flame-retardancy performance. Two other mineral powders were tested in order to eliminate the dilution effect of powder on the asphalt. The results are listed in table 2.

Tab.2 Comparison of LOI for mineral powders

mineral powders	Content of mineral powders				
	70%	80%	100%	120%	150%
T	24.7	25.8	27.0	27.6	28.0
DA	24.9	25.0	25.0	25.2	25.1
Y	22.5	22.8	23	22.9	22.5
Assuming the role of the added value of dilution	4.4	4.6	4.7	4.8	4.5
Definite enhancement of T %	1.0	1.9	3.0	3.6	4.2

Flame-retardant performances of mineral powders are presented in Figure 1.

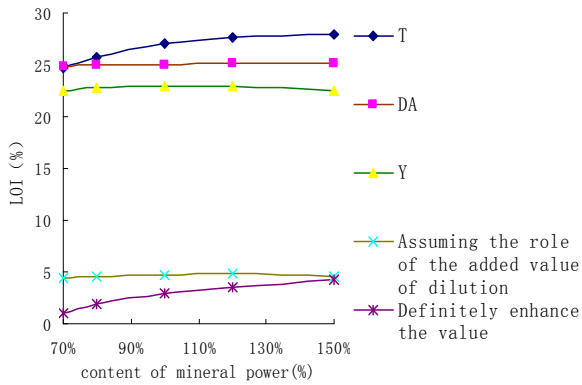

Fig.1 Flame retardancy analysis of mineral powders

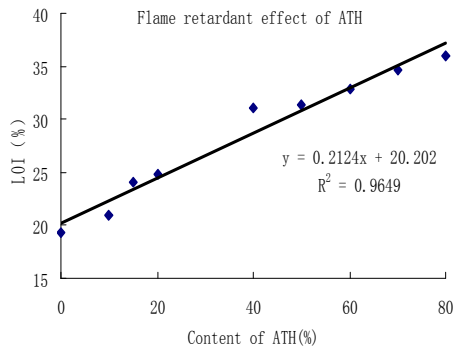

Fig.2 Flame retardant effect of ATH

Assuming DA and Y mineral powders are added as a dilution role, LOI of T was improved markedly as their contents increase. Usually the proportion of mineral powders to asphalt is about 1.3~1.4, it can be seen that the mineral powder has significant flame retardancy.

1.3 Evaluation of the flame retardancy of aluminum hydroxide (ATH)

LOI of mixture with different contents of ATH are shown in Figure 2.

Figure 2 indicates that there exists a linear increase relationship between LOI and ATH content. When the content is greater than about 32%, the LOI is more than 27% and reaches the standard of self-extinguishing.

1.4 Flame retardant system design and performance evaluation

In order to guarantee flame retardancy and smoke suppression performance, ATH content is determined as 20% of asphalt. Ratio of mineral powders to asphalt is 1:1 and filler-asphalt ratio is 1.2:1 (named A-T), less than the normal filler-asphalt ratio. LOI test results have shown although the synergistic effects between the two are not obvious, the self-extinguishing performance of material has been achieved fully.

2 Flame retardancy mechanism

Combustion and flame retardancy are a very complex process, involving a lot of influencing factors. Fundamentally speaking, flame retardancy of asphalt is to affect or interrupt some stages during the combustion process by either a physical or a chemical way. Flame-retardant technology can be divided into gas flame retardancy, condensed phase flame-retardancy and interruption of heat exchange. Ideal temperature of flame retardant material is 230~400C, considering the ignition scope of asphalt, control conditions of asphalt mixture construction and the safety of the fire.

Studies on the flame -retardant mechanism were carried out by Differential Scanning Calorimetry (DSC). Test conditions are as follows: 5mg Samples, room temperature as the initial test temperature, 5℃/min heating rate, 20ml/min nitrogen flow rate. Test and analysis results are shown in Figure 3.

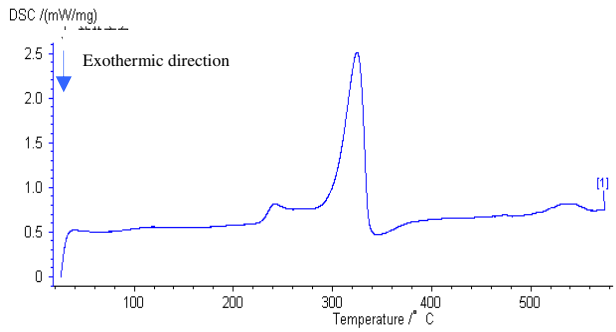

Fig.3 Curves of DSC

DSC data show there was a turning point at 220℃ and a peak of heat absorption at 300℃. Test results indicate that the sample heat absorption changes at this temperature and the material shows flame-retardant properties. The system has shown excellent flame retardancy at 300℃~340℃ because of obvious chemical or physical interaction.

3 Security Analysis of the System

To study the fire-retardant construction process, the use of stage and safety and environmental protection requirements under the conditions of fire, the following research and analysis were performed.

3.1 Security assurances of storage and processing - the flash point and ignition point tests

Flash point and ignition point are the indicator of construction security of asphalt mixture and they are measured by the Cleveland Open Cup (the COC). The test results indicated the flash point and the ignition point were 282℃ and 304℃ separately. When the temperature was up to 240℃, the bubbles spill from a asphalt specimen. The flash point and the ignition point can not be confirmed through experimentation methods. **Matrix asphalt, there will appear the phenomenon of water precipitation in the course of the experiment and it can be seen that the flame-retardant program will not affect the construction safety?.** At the same time, ATH shows bad temperature stability under the experimental conditions. In order to prevent fire retardant failures, the temperature of asphalt mixture must be controlled.

3.1 Comparison of 200℃ Volatile Components

Asphalt mixture construction **was under one certain temperature**?. It should be studied whether flame-retardant materials added into asphalt will volatile or make asphalt decomposed, resulting in environmental pollution, reducing the flame retardancy or harming health of workers, especially in the circumstances of ventilation adverse in tunnel. Based on these, headspace sampling-gas chromatography-mass spectrometry analysis method was adopted to compare volatile organic compounds under 200℃.

Agilent headspace sampling-gas chromatography-mass spectrometry analyzer was used in laboratory test, model Agilent 7964 headspace sampler, 6890N GC-5973N MSD?. Experimental conditions: Headspace, Vials heating temperature 200℃, heating time 30min, the sample temperature 200℃, transmission line temperature 200 ℃, injection time 1min. GC6890N-5973NMSD: GC injection port 220℃, do not split injection. HP5 30mΦ0.25mmΦ0.25mm capillary column, programmed temp erature, initial 35℃ (keep 10min) and then 15℃/min rise to 220 ℃ (keep 5min). MS monitors MSD: interface temperature 250℃, electron bombardment source EI, the quality of scanning range 15-300, NIST05 database search.

A-T test results are presented in Figure 4. The first peak in the figure is the air peak during the trial process. Test results have shown there is no release of organic matter except for water precipitation, resulting in the column loss and the safe system.

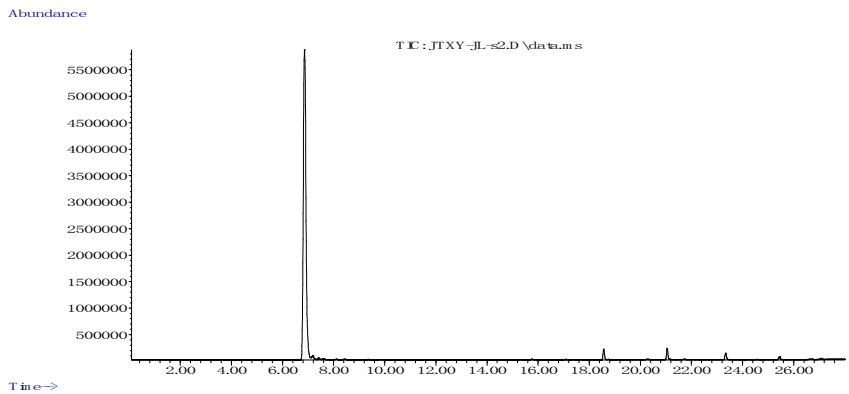

Fig.4 TIC of A-T flame-retardant asphalt

Figure 5 shows that there is release of three kinds of toxic organic compounds from the flame retardant asphalt, including 1,2-dichloroethane; 2-chloroethanol; and

three (2-chloroethyl) phosphate?.

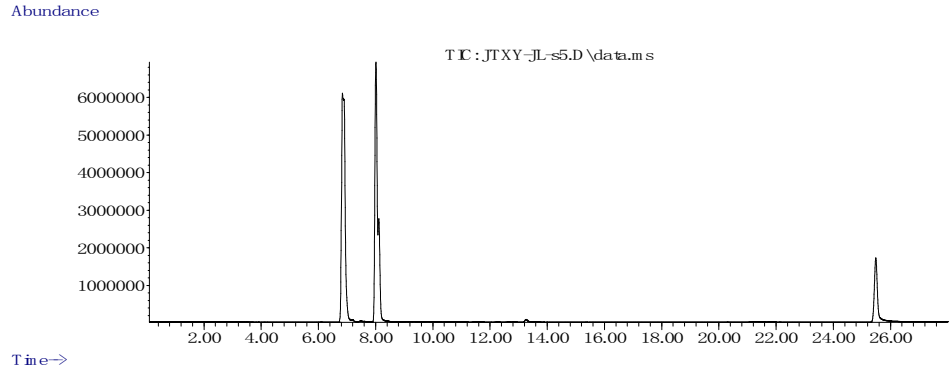

Fig.5 TIC of another one flame-retardant asphalt

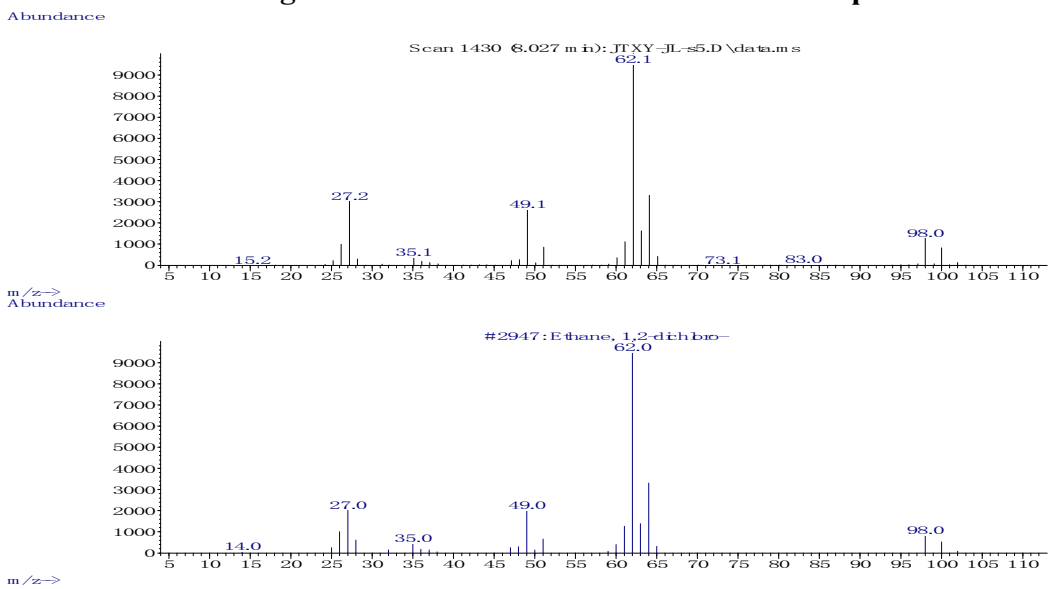

Fig.6 Index chart of 1，2-dichloroethane

3.2 Heat release and smoking characteristics

At present, cone calorimeter has been widely used to measure combustion characteristics of materials and evaluate their fire risks. The experimental environment and the actual fire are very similar and there was good correlation between experimental and model test results.

In general, when the fire developed to flashover, hot radiation flux of high temperature gas and flame are about 75kW/m^2. Therefore, the typical radiant flux Level of 25kW/m^2, 50kW/m^2 and 75kW/m^2 were selected. **In this test, 50kW/m^2, matrix asphalt and fire-retardant asphalt with 2.36mm and below the SMA-13 gradation value, 10.0% oil stone radio were used , with the British company FTT Cone Calorimeter (Cone Calorimeter).** The results are in Table 3.

Tab.3 Cone calorimeter radiation test results

Test indicators	Ignition time	exothermic rate (kW/m^2) Maxi-mum	exothermic rate (kW/m^2) average	Mass loss rate (%)	smoke generation rate (m^2 • m^2 • g^{-1})	exothermic rate (MJ/m^2 • g^{-1})	Specific extinction area SEA (m^2 •kg^{-1})
Matrix asphalt mixtures	114s	195.0	58.6	11.7	11.2	0.45	839.3
A-T mixtures	122s	85.4	36.0	9.8	3.0	0.3	292.3

Weight-loss curve?, heat release rate and smoking rate curve of the two asphalt mixture are shown in Figure 7 and Figure 8.

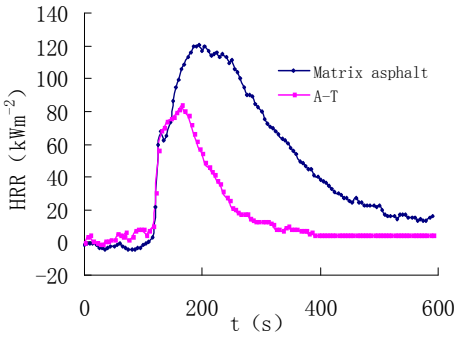

Fig.7 Heat release rate curves

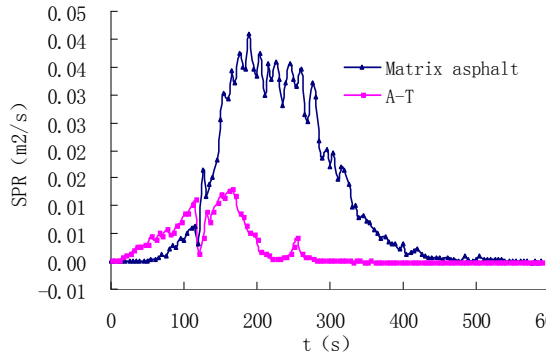

Fig.8 Smoking rate curves

Test results indicate:

(1) the ignition time are similar; in the radiation intensity, the flame retardant performance was not obvious.

(2) matrix asphalt heat released rate (HRR) larger, which suggestes much heat was releaseed per unit during burning. Matrix asphalt mixtures heat release research peak quickly, and may maintain a certain time at a higher level. The A-T system can effectively reduce the temperature of the fire scene. Heat release rate of matrix asphalt mixtures is almost 1.5 times of that of modified asphalts (A-M)，which reduces heat release capacity of asphalt and avoid the sudden increase of temperature in fires and thus save time for escape.

(3) Smoking rate of matrix asphalt is almost 3 times of A-T. The smoking rate curve indicates that the smoking rate of matrix asphalt is very large, almost 4~5 times of A-T, and the high smoking rates can be maintained for a period of time. From A-T Asphalt Mixture the smoking rate curve indicates that in the combustion process, it will have **certain hours?** to reduce the smoking rate; a small peak appeared at **200~300C, because the isolated membrane of flame retardant, which interrupted the heat exchange, was damaged, and caused heat and smoke release suddenly (similar to exothermic rate curve)?.**

(4) Specific extinction area of matrix asphalt is 2.87 times to? A-T. It can be seen that A-T greatly reduces the ability of asphalt smoking.

(5) A-T program is a safe flame-retardant program, and there is no toxic gas release in the construction.

4 Feasibility study of ATH taking place of mineral powders ?

Screening test, density test, hydrophilicity test, plasticity index test, and heat stability test were required in "Highway Engineering Test Aggregate of Order (JTG E42-2005)". The conventional indicators of T, ATH, and A-T were carried out and the test results are shown in Table 4:

Tab.4 Conventional performance of flame-retardant mineral powder, ATH and A-T

Pilot project	T	ATH	ATH：T =1：5

Density（g/cm^3）	2.63	2.38	2.58
Hydrophilic factor	0.8	1.2	0.9
Heat stability	There is no change in color	Heated to 200℃, there is a small amount of water vapor produced, cooled slightly pale yellow	Heated to 200℃ produced a small amount of water vapor, after cooling the color did not change significantly

It can be seen that the basic indicators of the mineral powders can meet performance requirements. As for the construction of asphalt mixture to control the temperature, the general does not exceed 195C, therefore, requested that the construction process should strictly be according to construction specifications to ensure that the flame-retardant material would not be lost? .

5 Asphalt mixture test comparision

With the middle value of SMA-13 gradation, asphalt mixture were made by SBS modified and ordinary mineral powder, T mineral powder and flame retardant mineral powder (ATH:T= 1:5) and matrix asphalt mixtures ?. The performances of different mixtures were compared under the best the amount of asphalt (optimal asphalt content?). The results are in Table 5.

Tab.5 Performance comparison of asphalt mixtures

Asphalt case	Water immersion residue stability（%）	Freeze-thaw splitting intensity ratio（%）	Dynamic stability（Times •mm^{-1}）	limiting flexural strain（μm）
SBS	84.0	88.4	4846	4721
T	82.7	83.8	1876	2892
A-T	80.8	81.8	1760	3120

The indicators of flame-retardant mineral are less than powder modified asphalt, but the indicators all meet the norms. The residual stability and freeze-thaw stability ratio of mixture with ATH or not reduced near 2%, dynamic stability index were equal, and the limit of bending tensile strain still improved. Therefore, ATH mixture did not adversely affect performance.

6 Conclusion

(1) Flame retardancy of asphalt can be achieved by adding A-T and the self-extinguishing performance can be satisfied.

(2) Differential Scanning Calorimetry (DSC) shows A-T fire-retardant system has multi-flame-retardant mechanism such as endothermic, coverage, and dilution.

(3) Flash point, ignition point and toxicity of materials meet requirements of environmental protection and construction safety.

(4) Heat release and smoking characteristics of A-M are proved better than matrix asphalt, which help ensure visibility of fire site and the conditions of escape and rescue.

(5) Road performance of A-T retardant system can meet the requirements of

specification.

(6) A-T retardant technology provided a powerful guarantee for the safe operation of traffic tunnels.

ABSTRACT

In order to prevent or mitigate reflective cracking in road widening, which is always along the traveling direction up the joint of the new and existing bases resulting from their different properties, this study investigates the influence factors of crack propagation and the effect of geogird in widened asphalt pavements through extensive finite element analysis based on linear elastic fracture mechanics using the computer code ABAQUS. The results indicate that increasing surface hot-mix asphalt thickness and decreasing surface modulus could effectively mitigate the reflective cracking. The potential of reflective cracking propagation would be significantly reduced when the new and existing pavement bases have a uniform modulus. In addition, geosynthetics reinforcement could effectively reduce the degree of stress centralization and delay the reflective cracking of the widened asphalt pavements.

INTRODUCTION

For a road-widening project, the existing asphalt pavement surface is usually milled off and then a fresh asphalt mixture is paved across the new and existing bases. Because of the inherent differences between the new and existing bases, there is always a latent crack along the joint between them, which can propagate upwards under repeated traffic load and eventually result in reflective cracking in the asphalt surface along the traveling direction. This type of reflective cracking is the primary problem in HMA (hot mixture asphalt) pavement widening (Van Meurs A N G et al. 1999).

Several technologies have been identified to prevent or delay reflective cracking in in HMA pavements. These include: designing more crack-resistant asphalt mixtures (Barzin Mobasher et al. 1997), selecting alternative pavement structures, improving construction quality control, and applying crack insulating products such as geosynthetics reinforcement, etc… (Sam-Deok Cho et al. 2006). In addition, numerous studies can be found for the analysis of the crack growth process in asphalt pavement

(Birgisson B et al. 2002).

Nevertheless, little research can be found on the analysis of reflective crack propagation in widened asphalt pavements. Linear elastic fracture mechanics was employed to analyze various influence factors for the propagation of reflective cracking in widened asphalt pavements using the computer code ABAQUS (Hibbitt, Karlsson & Sorensen 2001) in this study. The effects of geosynthetic reinforcement in widened asphalt pavements were also investigated.

FINITE ELEMENT ANALYSIS

Finite element modeling

The HN Expressway starts from Shanghai, the biggest business center in China, to Nanjing, the capital of Jiangsu Province. It was widened in 2003. Figure 1 shows the latent crack between the new and existing bases. Under repeated traffic load, a reflective cracking of the asphalt surface along the traveling direction eventually appeared (Figure 2). In this project, a layer polypropylene geogrid under the surface was used and strided over the new and existing bases. The calculation model could be sketched as shown in Figure 3. Zero vertical deformation was assumed for the bottom of the subgrade. Similarly, zero horizontal displacement was assumed for the right and left boundaries of the base, subbase, and subgrade.

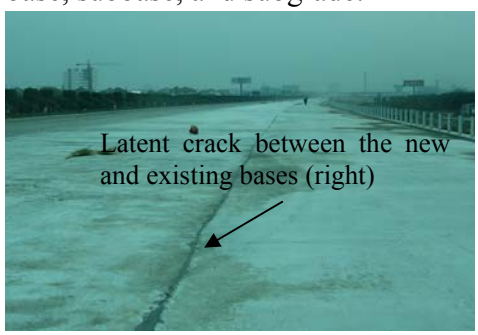

Figure. 1 Latent crack

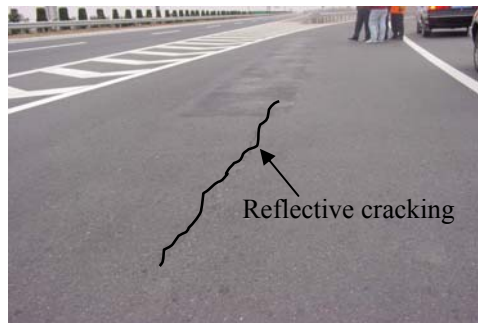

Figure. 2 Reflective cracking in road widening

To improve the finite element analysis (FEA) efficiency, plane strain conditions were assumed. The geogrid was simulated using two-node non-compression bar elements with linear elastic properties (T2D2). The pavement structure was described by elements with four-node bilinear displacement and reduced integration with hourglass control (CPE4R). Singularity at the crack tip was considered during the analysis.

Before fracture mechanics analysis, a *seam* that is a term in ABAQUS and used to define an edge must be created. It is originally closed but can open during an analysis. Its crack properties can be determined using contour integral analysis. Then, fracture mechanics analysis could be made using the software ABAQUS.

Under a relatively small deformation, the influences of interface behaviors between geosynthetics and pavement structure on the system performance are expected

to be less important (Han J and Gabr M A 2002). In this study, the interface was assumed to be fully bonded for simplicity. The keywords *Embedded Element* in ABAUQS was used to embed the geogrid elements to pavement elements in the numerical modeling.

Mode of traffic load

Because the design tire pressure is 0.7MPa in China, the applied load on the asphalt surface was 0.7MPa and the contact area was a square with sides of 30cm. Two load conditions, symmetrical load and unsymmetrical load, were selected (Figure 4). The "*y*" axle points to the depth of pavement. Assigning the surface thickness of HMA and the crack length as "*T*" and "*C*" respectively, four ratios of "*C/T*", 0.2, 0.4, 0.6, and 0.8, were considered during the finite element analysis.

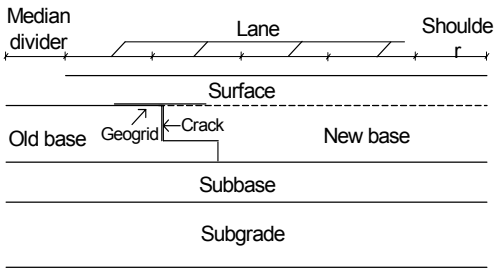

Figure. 3 Sketch of finite element model

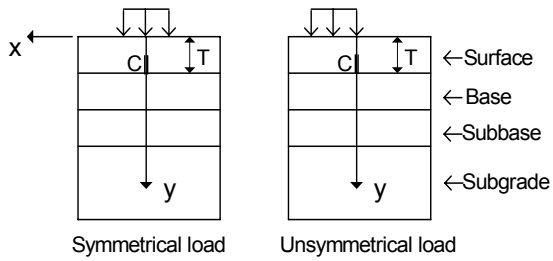

Figure. 4 Patterns of traffic load

CONSTITUTIVE MODELS AND MATERIAL PARAMETERS

Although asphalt mixtures exhibit visco-elastic and plastic characteristics, for pavement stress and strain analysis, linear elastic analysis generally provides quick and reasonable solutions. The materials were assumed to be linear elastic in the present analysis. Thus, two parameters, Youngs modulus and Poisson's ratio, were needed to adequately describe their mechanical properties.

For the reference model, the surface had a thickness of 18cm and a modulus of 1200MPa; the new and existing bases both had the same thickness of 40cm and the same modulus of 1500MPa; and the subbase was 20cm thick and had a modulus of 300MPa. In addition, a thickness of 400cm for the subgrade was selected according to several trial calculations. Its modulus was 40MPa. The Poisson's ratio of subgrade and other materials of pavement structure were 0.35 and 0.25, respectively.

The polypropylene geogrid had a tensile stiffness of 400kN/m. The tensile stiffness, *J*, is defined as the tensile force per unit width divided by the average strain in the geogrid. Three conditions: 1) Unreinforced, 2) a layer of gerogrid with *J*=400kN/m, and 3) a layer of gerogrid with *J*=1600kN/m, were considered during the FEA. The Poisson's ratio of geogrid was 0.18.

For a widening project, the modulus of the existing base is usually known. Thus, the influence of the new base on crack propagation could be obtained by changing the modulus ratios of the new and existing bases. Five modulus ratios, from 1 to 5, were

included. All of the calculation conditions described above are summarized in Table 1 and the values underlined are in the reference model.

Table. 1 FEA Plan

Variables	Value
Surface HMA modulus/MPa	1000, 1200, 1400, 1600, 1800
Surface HMA thickness/cm	14, 16, 18, 20
Modulus ratios (the new base/ the existing base)	1, 2, 3, 4, 5
Values of C/T (crack length/surface thickness)	0.2, 0.4, 0.6, 0.8
Geogrid	1)Unreinforced;2) J=400kN/m;3) J=1600kN/m

ANALYSIS OF INFLUENCE FACTORS CRACKING

Many factors, such as the thickness and modulus of the surface layer and stiffness of new and existing bases materials, could influence the reflective cracking in widened asphalt pavements. The following FEA focuses on the sensitivity of crack propagation to each of these factors. The stress intensity factors of K_1 and K_2, which are induced by tension and shear, were chosen to describe the crack-resistance of the widened asphalt pavements. When the calculated value of K_1 was negative, it was set to zero.

Influence of surface HMA modulus

Jun-hui ZHANG reported that K_1 is negative under symmetrical or unsymmetrical load (ZHANG Jun-hui 2006), which indicated that the widened pavement cracking was caused only by shear stress. Therefore, only the stress intensity factors of shear type K_2 was considered. Figure 5 presents the results of K_2 with different surface modulus under symmetrical and unsymmetrical load (right Y axis). It can be shown that K_2 increases as the surface modulus and the value of C/T increase. At the same time, the value of K_2 under the unsymmetrical load is significantly greater than the value under the symmetrical load. It can be concluded that unsymmetrical load conditions is more critical to the reflective cracking propagation in widened asphalt pavements.

Influence of surface HMA thickness

Figure 6 presents K_2 for the reference model under unsymmetrical load conditions with the variation of surface thickness. It can be seen that the increase of surface thickness can reduce K_2 more significantly when the C/T value is relatively low and K_2 increases more rapidly at the later state of crack growth. For example, when the surface thickness is 18cm, K_2 is 119.9kPa·m$^{1/2}$ and 209.2kPa·m$^{1/2}$ when C/T varies from 0.2 to 0.8, respectively. Therefore, the increase of surface thickness can delay reflective cracking in HMA pavement widening and this effect decreases gradually with the cracking propagation.

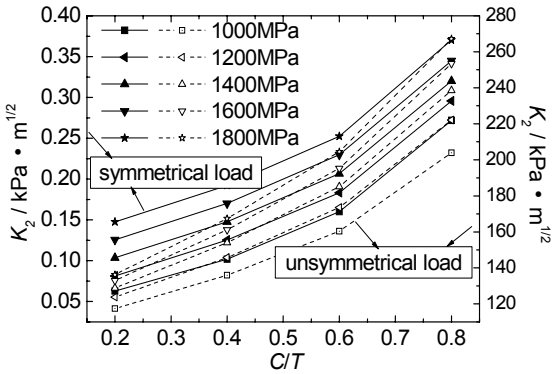

Figure. 5 Curves of K_2 with different surface modulus

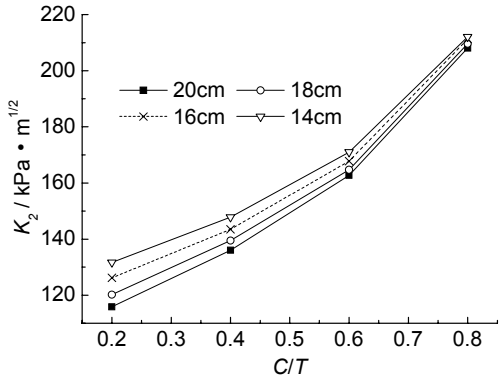

Figure. 6 Curves of K_2 with different surface thicknesses

Influence of base modulus

Because K_2 is caused by shear, the absolute value can describe the degree of stress concentration. As shown in Figure 7, the absolute value of K_2 decreases initially and then increases gradually with increasing modulus ratios under the symmetrical load (left Y axis). The minimum value of 0.1194kPa·m$^{1/2}$ is achieved when the modulus of the new pavement base is equal to that of the existing base.

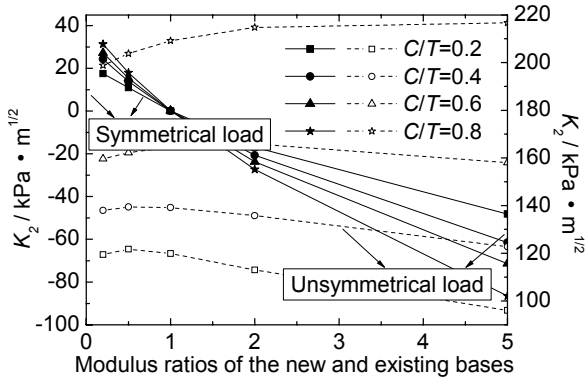

Figure. 7 Curves of K_2 with different modulus ratios of the new and existing bases

Studies suggested that the fracture intensity was about 400kPa·m$^{1/2}$~500kPa·m$^{1/2}$ (Miao-juan PENG et al. 1998), which is far greater than the maximum of K_2 216.7kPa·m$^{1/2}$ under the unsymmetrical load in this study. Although K_2 under the unsymmetrical load (right Y axis) is significantly greater than the ones under the symmetrical load, it is less sensitive to the variation of the modulus ratios, as shown in Figure 7. Since cracks propagate over the course of the pavement's service life and traffic load is a combination of both symmetrical and unsymmetrical loads, the selection of similar modulus between the new and existing pavement bases appear to be critical in preventing and/or mitigating the development of longitudinal reflective cracking in widened asphalt pavements. On the other hand, the similar modulus between the new and existing bases can reduce differential settlement (Jun-hui ZHANG 2006), which in turn will be beneficial to the crack-resistance of the widened asphalt pavement.

ANALYSIS OF EFFECT OF GEOGRID

Studies showed that the crack insulating effects of geosynthetics under the unsymmetrical and symmetrical loads in asphalt pavement widening were similar (Jun-hui ZHANG 2006). Only the effect of geogrid under the symmetrical load condition was evaluated in this study. Figure 8 presents the results of the tensile stress σ_x along the crack line with different crack lengths. It is shown that there is a tension stress (i.e. a positive value) near the upper asphalt surface when the crack length is less and there is a compressive stress near the upper asphalt surface when the crack length is larger (i.e. *C/T* is equal to 0.6). Although the crack tip is pressed this moment, the crack near the base bottom is open. Thus, the geogrid is also stretched to make the crack heal, which indicates the effects of delaying reflective cracking. These effects increase with increasing geogrid stiffness. In addition, no matter how long the crack is, the geogrid can reduce the degree of stress concentration at the crack tip all along.

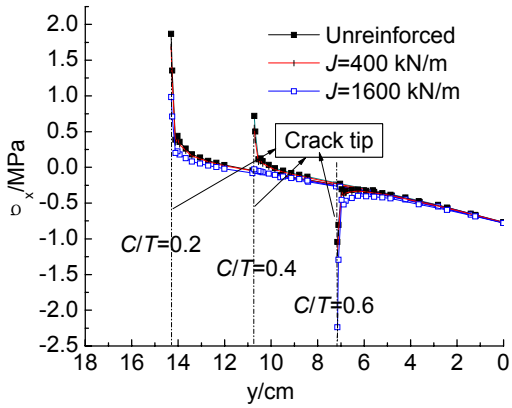

Figure. 8 Curves of σ_x with different crack length

DISCUSSION

In order to keep the modulus of the new and existing pavement bases close, the modulus of the existing base can be gained before widening in the field. Then, the mixture can be designed in the laboratory to make the modulus of the new and existing bases close.

To insert a geogrid layer between the surface and base cannot guarantee an effective prevention of reflective cracking because the risk that the debounding phenomena occur is very high. A prime coat should be sprayed above the base before geogrid construction. When it is dry, the geogrid can be laid across the joint between the new and existing bases. Then, a seal coat is paved, the stone spreader and asphalt distributor should be driven smoothly to avoid dragging the geogrid. Therefore, the link of the geogrid, base, and surface can be guaranteed this way.

CONCLUSIONS

1) The increase of the surface hot-mix asphalt modulus would enhance the reflective cracking propagation in widened asphalt pavements and should be avoided.

2) The increase of surface thickness could effectively reduce the potential for crack propagation in widened asphalt pavements.

3) Maintaining close (if not completely equal) values of modulus (stiffness) between the new and existing pavement bases is critical to reducing the potential for reflective

cracking propagation in widened asphalt pavements.

4) Finite element analysis indicated that the effects of geosynthetics in reducing the degree of stress concentration at the crack tip during crack propagation, which in turn, leads to improved cracking resistance of widened asphalt pavements.

ACKNOWLEDGMENTS

The effort of Xiao-ming Huang, the deputy dean of the Transportation School of Southeast University, in coordinating the project was highly appreciated.

ABSTRACT

In this paper, on the basis of the dynamic tri-axial test achievements of road base materials, the elastic-plastic constitutive model is constructed with the finite element software of ABAQUS to design computing models and analyze the results of numerical simulations, the sensitivity of road base materials mechanics parameters influential factor is studied. The calculated curves of the dynamical deformation behavior of silty clay are agreement with the measured ones. The effect of parameters such as cyclic load's magnitude, confining pressure, cyclic stress ratio, frequency, the number of cyclic load, and load wave is compared. It is found that confining pressure is the primary influential factor to the sensitivity of dynamical parameters. At the same time, it shows that the Finite Element Method (FEM) is valid to analyze the characteristics of mechanical parameters.

Keyword：road materials；dynamical parameters；sensitivity；numerical simulation

1 Introduction

At the present, the results of soil dynamic parameters mainly obtained from field and laboratory experiments are not consistent with the objective values. Therefore it is necessary to analyze the sensitive degree of the dynamic parameters influence factor on sub-grade structure property changes. In this study, on the basis of numerical simulations and laboratory tests, we carried on the analysis of factors that influence the sub-grade stability, provided some reference for soil test personnel, and presented a useful approach for the research on dynamic constitutive model and more complicated influencing factors of soil.

2 Dynamic tri-axial test and model establishment

2.1 Dynamic tri-axial test

The test soil samples are obtained from middle liquid-limit silty clay in the soil field of the Changchun Weixing road. The basic physical mechanical parameters are in table 1.

Table 1 physical mechanics index of test silty clay

Density	Optimum moisture content	Liquid-limit	Plastic limit	Plasticity index	Cohesive force	Internal friction Angle
ρ/（g/cm^3）	ω/%	ω_L/%	ω_P/%	I_p	c/kPa	φ
1.96	21	34	22.4	11.6	47	34

In this test, the soil sample is the cylinder compaction molding specimen. The diameter is 70 mm and the height is 140 mm (as shown in Figure 1). The test instrument is the Japanese DTC-306 multiple-function electro-hydraulic servo

dynamic tri-axial apparatus. According to the criteria (Soil test Technical Manual2003), the criteria of failure is that the failure strain ε_d, which is the sum of elastic strain and plastic strain, rise to 5%.

2.2 Elasto-plastic constitutive model

The stress-strain relationship of soil is nonlinear. The deformation increment of roadbed material consists of elastic and plastic parts. Elastic increment satisfies Hooke's law (Qian jiahuan,Yinzongze1996), while the plastic ones satisfies the flow rule. Therefore it is suitable to conduct numerical analysis using an elasto-plastic constitutive model. It is shown as follow.

$$\{d\sigma\} = [D_{ep}]\{d\varepsilon\}; \quad (1)$$

$$\{d\varepsilon\} = \{d\varepsilon^e\} + \{d\varepsilon^p\}; \quad (2)$$

$$\text{Where, } [D_{ep}] = [D] - \frac{[D]\left\{\frac{\partial g(\sigma)}{\partial \sigma}\right\}\left\{\frac{\partial f(\sigma)}{\partial \sigma}\right\}^T [D]}{A + \left\{\frac{\partial f(\sigma)}{\partial \sigma}\right\}^T [D]\left\{\frac{\partial g(\sigma)}{\partial \sigma}\right\}} \quad (3)$$

$[D_{ep}]$—elasto-plastic stiffness matrix.

2.3 The establishment of three-dimensional finite element model

Establish the three-dimensional finite element model by ABAQUS software (as shown in figure 2). Define the material attribute of the soil: density is 1.96g/cm^3; young modulus is 18MPa; Poisson's ratio is 0.35; the permeability coefficient is $1.0e^{-7}$ mm/s; porosity is 0.3; internal friction Angle is 34°; expansion Angle is 0°; and consolidated un-drained. Because the internal friction Angle is 22° bigger, the Drucker-Prager model can not approach to the Mohr-Coulomb model very well, it uses the Mohr-Coulomb model. The type of the load exerted on the sample is the sine wave and the soil sample weight is also taken into consideration. The sine wave frequency is 1Hz, i.e. q(t) = 0.5q_d +.05q_d sin2 π t, the q (t) stands for dynamic axial load value of any moments-t. They are divided into 975 crunodes and 742 units.

Fig1. Test soil samples

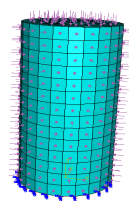

Fig2. Finite element model

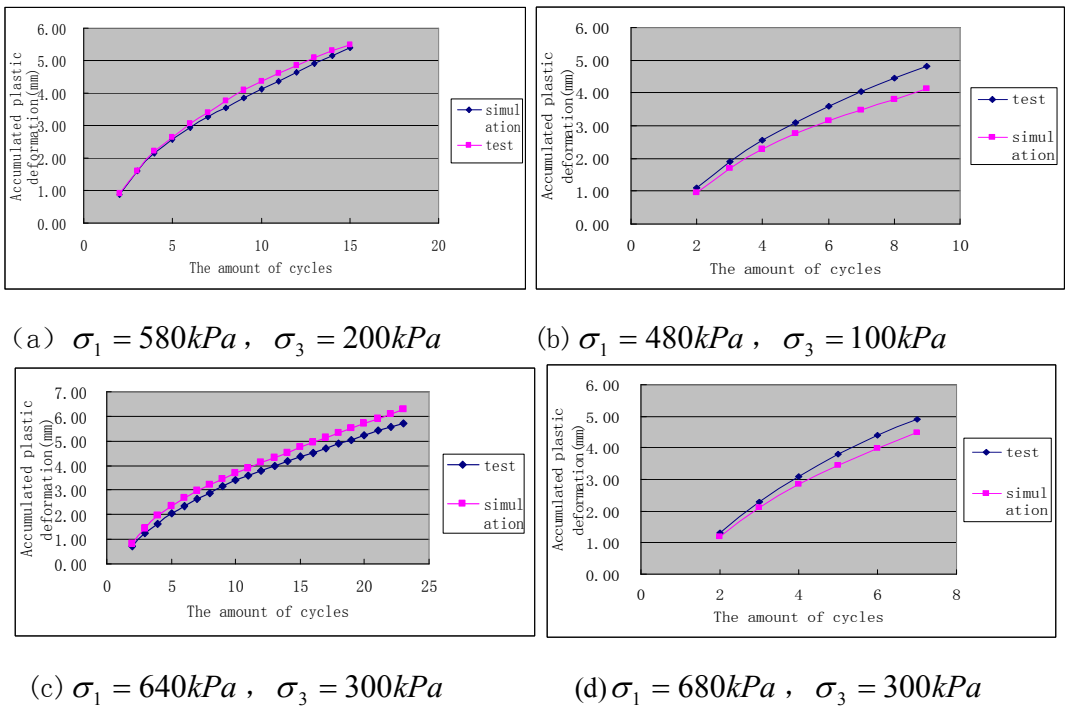
Due to the beginning stage of experiment being unstable, the nonlinear static load stage of the test and data processing is flexible and inaccurate. It takes the

second loading point as the beginning of processing and analysis of data. Plastic deformation of each cycle begins to be accumulated from the second loading. Then compare the numerical value of the experiment with the numerical value of finite element modeling. This paper takes four groups of data and carries on the analysis and comparison (as shown in figure 3). It is obvious that the cumulative plastic deformation increases gradually along with the increase of the number of cycles. In each group of data of the experiment and simulation, the plastic deformation is consistent with the variation trend of the cycle index-n. The simulated value and the experimental value of the i time ($1 \le i < n$) cyclic plastic deformation are very close. Namely, each cycle of plastic deformation and accumulative plastic deformation fit very well.



(a) $\sigma_1 = 580kPa$， $\sigma_3 = 200kPa$ (b) $\sigma_1 = 480kPa$， $\sigma_3 = 100kPa$

(c) $\sigma_1 = 640kPa$， $\sigma_3 = 300kPa$ (d) $\sigma_1 = 680kPa$， $\sigma_3 = 300kPa$

Fig3. The comparison between plastic deformation of simulation and experiment

Figure 4 is the deformation graph of the soil test piece under cyclic load. It causes certain residual deformation. There is certain contraction deformation on the upper piece and inflation deformation on the bottom.

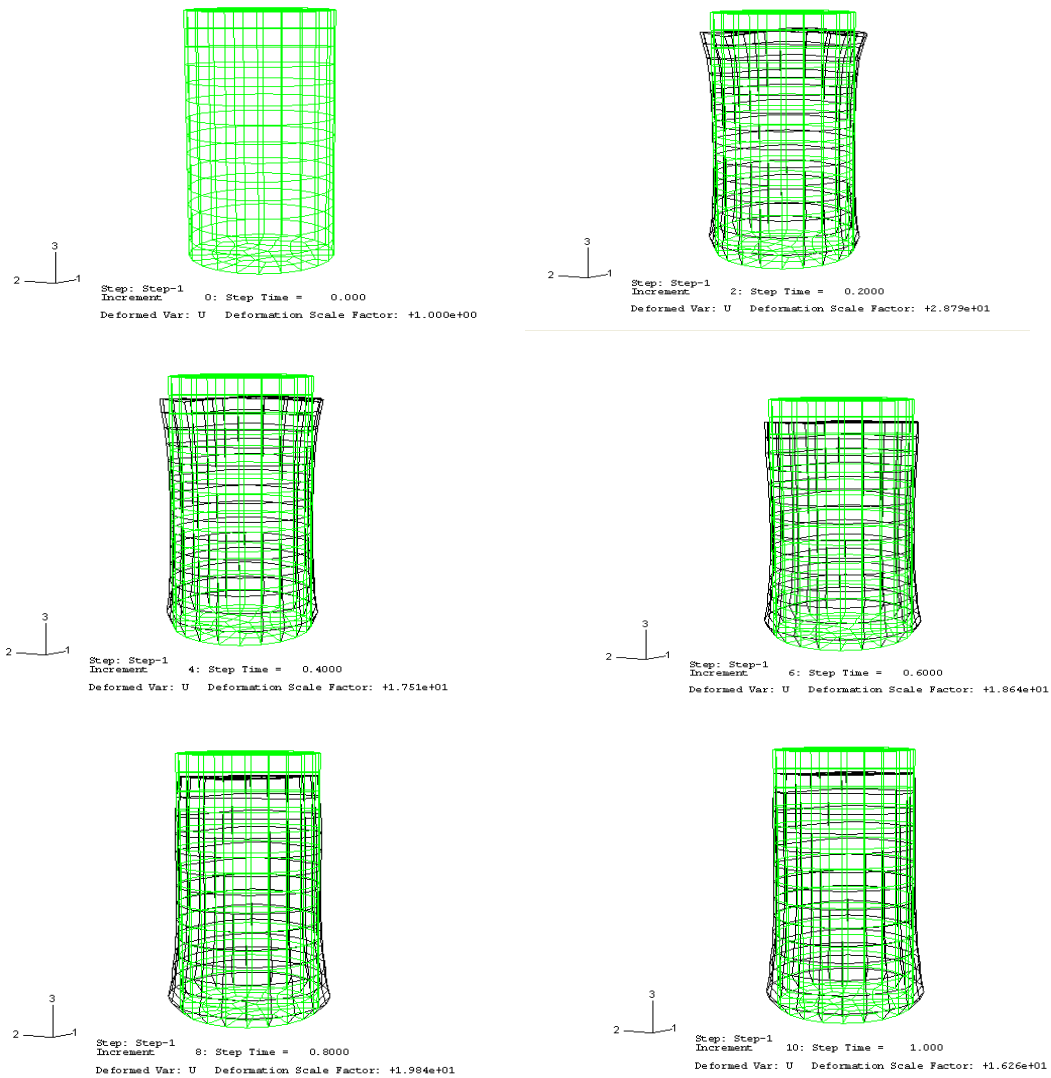


Fig4. The graph of deformation in one cycle

3. Results and discussions

The main influencing factors of soil plastic deformation are divided into two categories as external factors and internal factors. Numerical simulation methods are used to study the influencing factors of soil plastic deformation, which are the dynamic stress amplitudes, confining pressure (Simonesn E,Isacsson U.2001), frequency, loading waveform, and time of cyclic loading. Take the data of soil test ($\sigma_1 = 580kPa$， $\sigma_3 = 200kPa$), from which the simulation matches the experiment very well as the research object. Under the condition that other factors are invariable, analyze how each factor influences the soil plastic deformation through the change of one of the factors (Andersen K H,1980).

3.1 Stress amplitudes' influence on plastic deforma tion

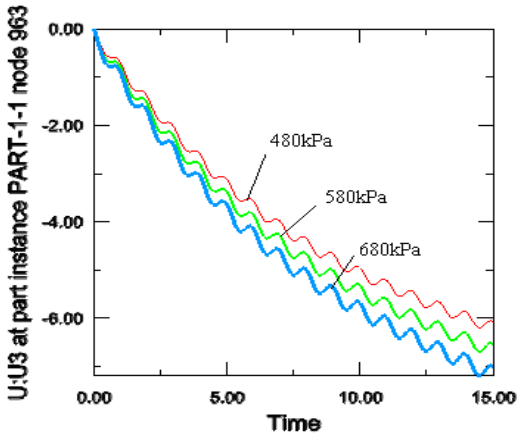

Fig5. Stress amplitude's influence

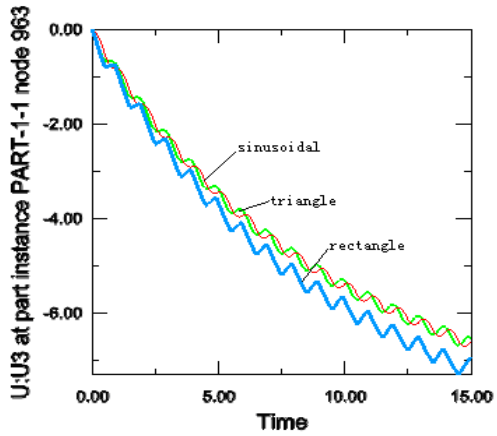

Fig6. waveform's influence

As shown in Figure 5, the accumulated plastic deformation increases gradually along with the increase of the stress amplitude. When the confining pressure is certain, the bigger the dynamic shearing stress that is exerted on the test sample, the bigger the plastic deformation. Through the analysis above, the increase of roadbed subsidence caused by traffic loading will follow = the increase of traffic volume and the carrying capacity of heavy-duty trucks. Roadbed subsidence caused by traffic loading will tend to be steadily increasing along with the passage of time and the time of traffic loading.

3.2 Different load waveforms' influence on plastic deformation

Figure 6 shows the characteristics of accumulated soil deformation. Under the action of the periodical load, it causes certain plastic deformation every time the cyclic load reaches the initial position. When the loading waveform is, respectively, a rectangle, a triangle, and a sinusoid, different waveforms have different effects on plastic deformation. The graph shows that the plastic deformation under the action of the rectangular wave is bigger than the one under the action of the sine wave and the one under the action of the triangle wave. The plastic deformations are very close under the action of triangle wave and sine wave. Thus, the plastic deformation under different waveforms depends on how long the maximum load has an effect on the soil sample.

3.3 Confining pressure influence plastic deformation

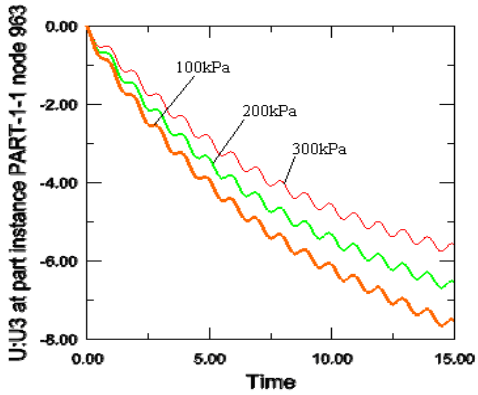

Fig7. Confining pressure influence

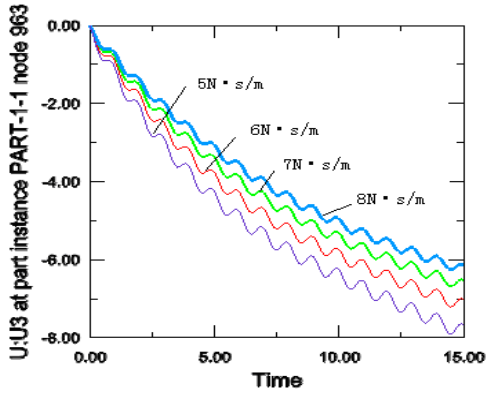

Fig8. Damping coefficient influence

From Figure 7 the relationship between displacement and time and the relationship between plastic deformation and cyclic times are shown. Plastic deformation increases gradually along with the growth of cyclic times. When the cyclic stress amplitude is certain, the greater the confining pressures, the slower the growth of the soil deformation.

3.4 Damping coefficient influence plastic deformation

Figure 8 shows that plastic deformation increases gradually along with the growth of cyclic times . When the cyclic stress amplitude is certain, the greater the damping coefficient, the slower the growth of the soil deformation.

3.5 Frequency's influence on plastic deformation

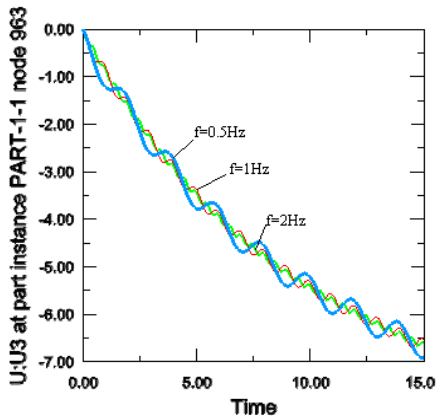

Fig9. Frequency's influence

As shown in Figure 9, the lower the frequency is, the bigger the amplitude of plastic deformation is; the higher the frequency, the smaller the amplitude of plastic deformation. The variation trend of the strain amplitude which works on the cumulative plastic deformation along with the change of frequency is the same. As frequency increases, the amplitude of plastic deformation decreases. At low frequency, the sample will be destroyed only under less cyclic weeks. Along with frequency increases, more cyclic weeks are needed to destroy the test sample.

4 Conclusions

1. It is convenient to achieve the optimum design of multi-factor experiment by the means of the ABAQUS. This provides a useful method for sensitivity analysis of rock mass mechanical parameters.

2. The research showed that the initial elastic modulus, damping coefficient, and load form have the greatest effects on plastic deformation of soil. The stress amplitude, confining pressure, frequency, number of cyclic, and the loading waveform has the least. We also found that the influence on the plastic deformation of the loading wave is dependent on the time length of the maximum load .

3. The results reflect the effect rule between the mechanical parameters of rock mass and sub-grade stability. It also provides a reference for engineering construction and feedback design.

ABSTRACT

In this paper, the dynamic response of a moving load on continuously reinforced concrete pavement is analyzed. The pavement rested on Winkler viscoelastic foundation is treated as orthotropic thin slab with a width of b and infinite value in length. The triangular series and Fourier transformation are introduced to analyze the response, and the solution of vertical displacement under a rectangle harmonic moving load is derived. Numerical results were obtained using the inverse Fourier transformation which was used to analyze the influence of load velocity, damp coefficient of ground and reinforcement ratio on the vertical displacement. This work provides useful theoretic references for the design of continuously reinforced concrete pavement.

INTRODUCTION

The present design of rigidity pavements is based on the theory of thin plate on Winkler soil (Yoder et al. 1975). For the case of low speed vehicles the theory is satisfied. However, as the increase of the speed of vehicles, the consideration of the vehicular dynamic effect on the pavement becomes more important. The response of slab to special dynamic loads has been studied using different methods by Cheng (1987), Zheng (1989), Huang (1990), and Hou (2003). Sun (1996) studied the transient response of infinity plate on elastic soils. Kim and McCullough (2003) studied the dynamic response of infinity plate on Winkler foundation under moving load of mutative amplitude.

Continuously reinforced concrete pavements (CRCP) are always subjected to moving loads; it is therefore more meaningful to study the dynamic response of CRCP under the moving loads. In this paper, the pavement rested on a Winkler viscoelastic foundation is treated as an orthotropic thin slab with a width of b and an infinite value in length. The triangular series and Fourier transformation are used to

analyze the response. The solution of vertical displacement under a rectangle harmonic moving load is derived.

GOVERNING EQUATION

The pavement rested on a Winkler viscoelastic foundation is treated as orthotropic thin slab with a width of *b* and an infinite value in length. The dynamic response is considered as a three-dimensional problem in the Cartesian co-ordinates of (x_1, x_2, t) as given in Figure 1. The load is considered as a harmonic rectangular one with the amplitude of $q_0 e^{i\omega t}$, the length of $2a_1$, the width of $2b_1$, and the velocity of c along the x_1 axis. The vertical displacement of the plate is $W(x_1, x_2, t)$, and the soil is considered as a Winkler model. The following assumptions are introduced to solve the dynamic equation of the CRCP model: (1) the steel bar is perfectly bonded with the concrete. The plate is considered to be an orthotropic thin plate with small thickness. (2) the pavement is of infinity along the longitudinal side with a width of *b*. Only the steel bar along the longitudinal side is considered.

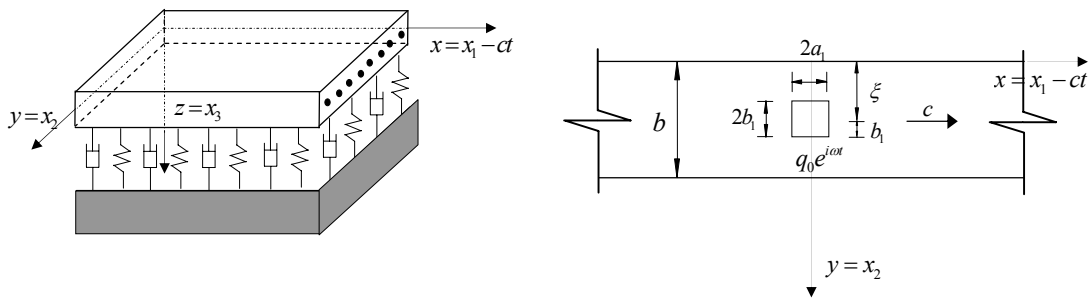

Figure 1. Calculating model.

The vertical displacement of the plate along *z* axis is $W(x_1, x_2, t)$. For the sake of simplifying the model of thin plate, the vertical strain of the plate is assumed to be small and negligible. The horizontal displacement of the plate is set as zero, and the strain caused by σ_z、τ_{xz}、τ_{zy} is also neglected. The equilibrium equations of the plate are given as:

$$\frac{\partial M_{x_1}}{\partial x_1} + \frac{\partial M_{x_1 x_2}}{\partial x_2} = \beta_{x_1} \tag{1a}$$

$$\frac{\partial M_{x_2}}{\partial x_2} + \frac{\partial M_{x_1 x_2}}{\partial x_1} = \beta_{x_2} \tag{1b}$$

$$\frac{\partial \beta_{x_1}}{\partial x_1}+\frac{\partial \beta_{x_2}}{\partial x_2}-F(x_1,x_2,t)-\rho_c h\frac{\partial W}{\partial t^2}=-q(x_1,x_2,t) \tag{1c}$$

in which M_{z_1}, M_{z_2}, $M_{z_1x_2}$ are the bending moment of the plate along the x_1, x_2 axis and the torsional moment along the x_1x_2 axis respectively; $q(x_1,x_2,t)$ is the load; $F(x_1,x_2,t)$ is the counterforce on the soil; $\rho_c h$ is the density of the plate of unite area; and *h* is the thickness of the plate.

The bending moment and the displacement of the plate satisfied the following equations:

$$M_{x_1}=-\left(D_{11}\frac{\partial^2 W}{\partial x_1^2}+D_{12}\frac{\partial^2 W}{\partial x_2^2}\right) \tag{2a}$$

$$M_{x_2}=-\left(D_{12}\frac{\partial^2 W}{\partial x_1^2}+D_{22}\frac{\partial^2 W}{\partial x_2^2}\right) \tag{2b}$$

$$M_{x_1x_2}=-2D_{66}\frac{\partial^2 W}{\partial x_1\partial x_2} \tag{2c}$$

in which D_{ij} is the rigidity of the plate, which can be expressed as:

$$D_{ij}=\int_{-h/2}^{h/2}C_{ij}z^2\mathrm{d}z \qquad (i,j=1,2,6) \tag{3}$$

in which $C_{11}=\frac{E_1}{1-\mu_1\mu_2}$, $C_{22}=\frac{E_2}{1-\mu_1\mu_2}$, $C_{12}=\frac{E_1\mu_2}{1-\mu_1\mu_2}$, $C_{66}=G_{12}$, $E_1\mu_2=E_2\mu_1$, E_1, E_2, μ_1, μ_2 are the moduli of the plate respectively; $E_1=E_fV_f+E_m(1-V_f)$, $E_2=\frac{E_fE_m}{E_mV_f+E_f(1-V_f)}$, $\mu_1=\mu_fV_f+\mu_m(1-V_f)$, $G_{12}=\frac{G_fG_m}{G_mV_f+G_f(1-V_f)}$, $G_f=\frac{E_f}{2(1+\mu_f)}$, $G_m=\frac{E_m}{2(1+\mu_m)}$, E_f, μ_f and E_m, μ_m are the Young's modulus and Poisson ratio of the steel bar and the concrete respectively.

The following equation can be derived from Equations (1) and (2):

$$D_{11}\frac{\partial^4 W}{\partial x_1^4}+2(D_{12}+2D_{66})\frac{\partial^4 W}{\partial x_1^2\partial x_2^2}+D_{22}\frac{\partial^4 W}{\partial x_2^4}+\rho_c h\frac{\partial^2 W}{\partial t^2}=q(x_1,x_2,t)-F(x_1,x_2,t) \tag{4}$$

The counterforce on the ground for the viscoelastic Winkler fou

ndation can be written as:

$$F(x_1,x_2,t)=K_L W(x_1,x_2,t)+\eta\frac{\partial W(x_1,x_2,t)}{\partial t} \tag{5}$$

in which K_L is the rigidity of the foundation and η is the damping coefficient.

DYNAMIC RESPONSE OF CRCP UNDER MOVING POINT LOAD

As the load moves at the velocity of c, the auxiliary spatial coordinate is introduced by letting $x=x_1-ct$， $y=x_2$. Then Eq. (4) and (5) reads:

$$\begin{aligned}&D_{11}\frac{\partial^4 W}{\partial x^4}+2(D_{12}+2D_{66})\frac{\partial^4 W}{\partial x^2\partial y^2}+D_{22}\frac{\partial^4 W}{\partial y^4}+\rho_c h\left(\frac{\partial^2 W}{\partial t^2}-2c\frac{\partial^2 W}{\partial t\partial x}+c^2\frac{\partial^2 W}{\partial x^2}\right)+\\&\eta\left(\frac{\partial W}{\partial t}-c\frac{\partial W}{\partial x}\right)+K_L W=q(x,y,t)\end{aligned} \tag{6}$$

The boundary of the pavement is assumed to be simply supported, therefore at $y=0,b$:

$$W(x,y,t)\big|_{y=0,b}=0\ ;\quad \left(D_{12}\frac{\partial^2 W}{\partial x^2}+D_{22}\frac{\partial^2 W}{\partial y^2}\right)\Big|_{y=0,b}=0 \tag{7}$$

The local harmonic load, a rectangular load, is introduced to simulate the vehicle load as shown in Fig. 1. By introducing $e^{i\omega t}$, the moving load can be expressed as:

$$q(x,y,t)=\begin{cases}q_0 e^{i\omega t} & \xi-b_1<y<\xi+b_1;\ -a_1<x<a_1\\ 0 & \text{elsewhere}\end{cases} \tag{8}$$

in which ω(rad/s) is the radius frequency; ξ is the distance between the load center and the boundary of the plate.

Adopting the approximate pattern of the displacement $W(x,y,t)$ and the load $q(x,y,t)$, and considering the simply supported boundary condition of the pavement, $W(x,y,t)$ and $q(x,y,t)$ can be expressed as:

$$W(x,y,t)=\sum_{m=1}^{\infty}X_m(x,t)\sin(\alpha_m y) \tag{9}$$

$$q(x,y,t)=\begin{cases}\sum_{m=1}^{\infty}q_m(x,t)\sin(\alpha_m y) & -a_1<x<a_1\\ 0 & \text{elsewhere}\end{cases} \tag{10}$$

in which $q_m(x,t)=\frac{4q_0}{b\alpha_m}\sin(\alpha_m\xi)\sin(\alpha_m b_1)$; $\alpha_m=\frac{m\pi}{b}$; b is the width of the pavement.

Substituting Eq. (9) and (10) into Eq. (6):

$$\begin{aligned} &D_{11}\frac{\partial^4 X_m}{\partial x^4}-2\alpha_m^2\left(D_{12}+2D_{66}\right)\frac{\partial^2 X_m}{\partial x^2}+\alpha_m^4 D_{22}X_m+\rho_c h\left(\frac{\partial^2 X_m}{\partial t^2}-2c\frac{\partial^2 X_m}{\partial t\partial x}+c^2\frac{\partial^2 X_m}{\partial x^2}\right)+\\ &\eta\left(\frac{\partial X_m}{\partial t}-c\frac{\partial X_m}{\partial x}\right)+K_L X_m=\begin{cases} q_m(x,t) & -a_1<x<a_1 \\ 0 & \text{elsewhere} \end{cases} \end{aligned} \tag{11}$$

Since the load is harmonic, the factor $e^{i\omega t}$ is neglected during the solving process. The Fourier transform is then introduced as:

$$\overline{f}(\beta)=\int_{-\infty}^{\infty} f(x)e^{i\beta x}\mathrm{d}x \tag{12a}$$

$$f(x)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\overline{f}(\beta)e^{-i\beta x}\mathrm{d}\beta \tag{12b}$$

In the frequency domain, Eq. (11) then reads:

$$\overline{X}_m(\beta,\omega)=\frac{\overline{q}_m(\beta,\omega)}{\overline{\varphi}_m} \tag{13}$$

in which

$$\overline{\varphi}_m=D_{11}\beta^4+2\alpha_m^2\beta^2\left(D_{12}+2D_{66}\right)+D_{22}\alpha_m^4+\rho_c h\left(-\omega^2+2c\omega\beta-c^2\beta^2\right)+\eta(\mathrm{i}\omega-\mathrm{i}\beta c)+K_L$$

$$q_m(x,t)=\frac{8q_0}{b\alpha_m\beta}\sin(\alpha_m\xi)\sin(\alpha_m b_1)\sin(\beta a_1)$$

The following equation is obtained by applying inverse Fourier transformation to Eq. (13):

$$X_m(x,\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{\overline{q}_m(\beta,\omega)}{\overline{\varphi}_m}e^{-i\beta x}\mathrm{d}\beta \tag{14}$$

Substituting Eq. (14) into Equations (9) and (2), the expression of the vertical displacement, bending moment and the torsional moment of the CRCP under moving load are obtained as follows:

$$W(x,y,t)=\frac{1}{2\pi}\sum_{m=1}^{\infty}\int_{-\infty}^{\infty}\frac{\overline{q}_m(\beta,\omega)}{\overline{\varphi}_m}e^{-i\beta x}\mathrm{d}\beta\cdot\sin(\alpha_m y)e^{i\omega t} \tag{15}$$

$$M_x=\frac{1}{2\pi}\sum_{m=1}^{\infty}\left[D_{11}\int_{-\infty}^{\infty}\frac{\overline{q}_m(\beta,\omega)}{\overline{\varphi}_m}\beta^2 e^{i\beta x}\mathrm{d}\beta+D_{12}\int_{-\infty}^{\infty}\frac{\overline{q}_m(\beta,\omega)}{\overline{\varphi}_m}\alpha_m^2 e^{i\beta x}\mathrm{d}\beta\right]\sin(\alpha_m y)e^{i\omega t} \tag{16}$$

$$M_x=\frac{1}{2\pi}\sum_{m=1}^{\infty}\left[D_{12}\int_{-\infty}^{\infty}\frac{\overline{q}_m(\beta,\omega)}{\overline{\varphi}_m}\beta^2 e^{i\beta x}\mathrm{d}\beta+D_{22}\int_{-\infty}^{\infty}\frac{\overline{q}_m(\beta,\omega)}{\overline{\varphi}_m}\alpha_m^2 e^{i\beta x}\mathrm{d}\beta\right]\sin(\alpha_m y)e^{i\omega t} \tag{17}$$

$$M_{xy} = -\frac{1}{\pi}\sum_{m=1}^{\infty} D_{66}\int_{-\infty}^{\infty} \frac{\bar{q}_m(\beta,\omega)}{\bar{\varphi}_m} \mathrm{i}\beta\alpha_m e^{\mathrm{i}\beta x}\mathrm{d}\beta\cos(\alpha_m y)e^{\mathrm{i}\omega t} \tag{18}$$

NUMERICAL RESULTS

A fast Fourier transformation is employed with a grid of 2048×2048 points over a range of $-16 < \beta, \gamma < 16$ to satisfy the precision of the calculation. The influence of load velocity, viscoelastic damping and reinforcement ratio on the vertical displacement is discussed and the results are given in Figures 2-4.

Table 1. Calculation parameter.

Modulus of Steel(E_f)	2×10^{11}Pa	Rigidity of ground(K_L)	138.6×10^{6}Pa
Poisson's ratio of Steel(μ_f)	0.28	Thickness of plate (h)	0.25m
Modulus of Steel concrete (E_m)	2.4×10^{9}Pa	Width of plate (b)	0.75m
Poisson's ratio of concrete (μ_m)	0.167	Width of load b_1	0.15m
Ratio of reinforcement (V_f)	0.008	Velocity and frequency	50m/s，10Hz
Damp coefficient of ground(η)	1.732×10^{6}Pa.s		

Considering the case of flexible pavements, the effect of the load velocity is shown in Figure 2. The maximum load velocity is $c = 200$m/s which is approaching the Rayleigh wave speed of the soil. Since the load is assumed to be moving at a constant velocity, the displacement of the soil is constant along the direction of the load, that is, the displacement response moves with the load.

Figure 2(a) gives the displacement varying with x at $y = b/2$ and Figure (2b) gives the displacement varying with y at $x = 0$. It can be seen that the displacement at the load center decreases with the increase of the load velocity which is given by Wang (2001). Due to the low velocity of the load, the displacement amplitude is symmetry to the axis $x = 0$; however as the load velocity increases，the displacement

becomes asymmetry. Since the plate is assumed to be simply supported along the width side, meaning that the displacement is zero at $y = 0$ and $y = b$, the maximum displacement occurs at the center of the load.

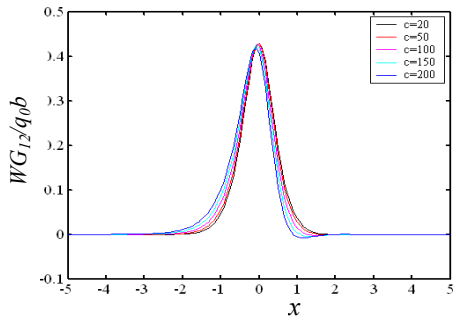

Fig.2(a) Curve of Vertical displacement along x axis with different speeds

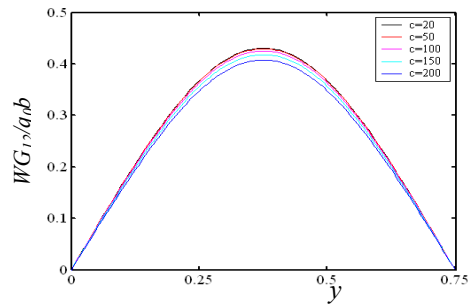

Fig.2(b) Curve of Vertical displacement along y axis with different speeds

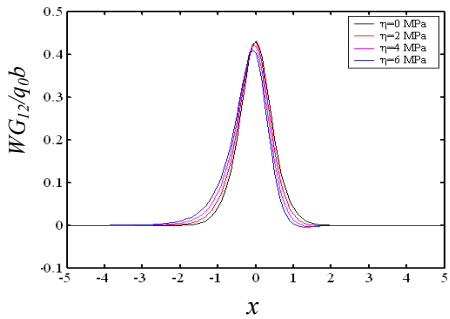

Fig.3(a) Curve of Vertical displacement along x axis with different damp coefficients

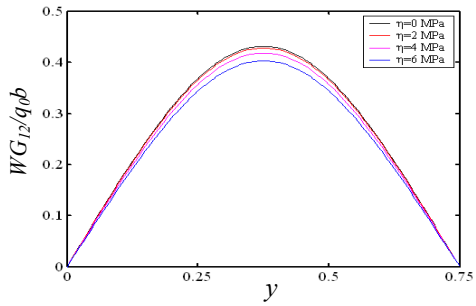

Fig.3(b) Curve of Vertical displacement along y axis with different damp coefficients

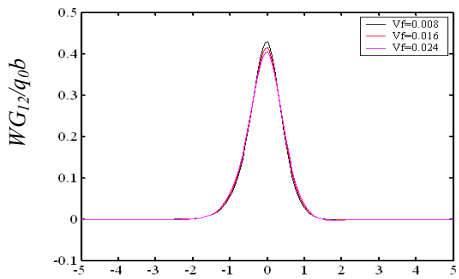

Fig.4(a) Curve of Vertical displacement along x axis with different ratios of reinforcement

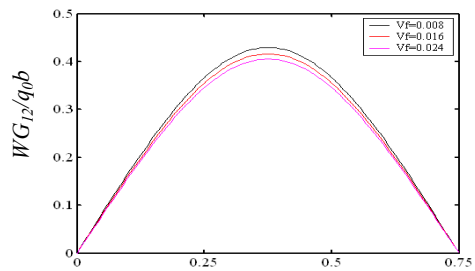

Fig.4(b) Curve of Vertical displacement along y axis with different ratios of reinforcement

Figure 3(a) gives the influence of the viscoelastic damping on the vertical displacement along x axis at $y = b/2$. Figure 3(b) gives the influence of the

viscoelastic damping on the vertical displacement along y axis at $x = 0$. It can be seen that the influence of the viscoelastic damping is similar to that of the load velocity. Figure 4 shows the effect of the reinforcement ratio on the displacement. The displacement response is symmetry to the center axis. The reinforcement ratio of the x axis only influences the displacement at the load center（a）; however the reinforcement ratio of the width side significantly influenced the displacement（b），and the displacement decreases as the reinforcement ratio increases.

CONCLUSION

The dynamic response of CRCP on viscoelastic soil under moving load is studied, and the influence of the parameters of the system is given through numerical analysis. It is shown that the vertical displacement of the CRCP decreases with the increase of the load velocity and is asymmetric at the center of the load. The influence of the viscoelastic damping is similar to that of the load velocity; the displacement of the pavement decreases as the reinforcement ratio increases.

ABSTRACT

Reflective cracking is one of the main distresses for the cement/lime/flyash stabilized base in China. Although a flexible base can and has been utilized as a sandwich layer to reduce reflecting cracks from the stabilized base, the repetitive truck traffic load may cause higher tensile stress at the bottom of the asphalt surface course due to a large deformation from the flexible base. This high tensile stress may lead to fatigue cracking. To minimize the tensile stress at the bottom of the asphalt layer, and to establish optimum structure design parameters to reduce the maximum tensile stresses at the bottom of the asphalt surface course, a nonlinear, finite element technique was utilized to support the experimental pavement in the Tonghua Highway in the Jilin province. Based on the analyses, to minimize the tensile stress at the bottom of the asphalt layer, the value of the flexible base modulus should be more than 400MPa and that of semi-rigid, sub-base modulus should be more than 1500MPa, which can guide the design and construction of the semi-rigid asphalt pavement with a flexible base.

INTRODUCTION

Reflective cracking is a major and costly problem in China. It occurs in the top surface layers, above existing cracks in the lower, stabilized layer. This type of cracking can lead to premature deterioration of the pavement structure through the infiltration of moisture. A flexible base has been successfully utilized to reduce reflecting cracks from the cement/lime/flyash stabilized base (He 1997). A flexible base is placed between the asphalt surface and the cement/lime/flyash stabilized base (sandwich structure). However, higher tensile stress could be produced at the bottom of the asphalt surface course for structures with a flexible base as the sandwich layer. Therefore, because flexible base material can produce elasto-plastic deformation, under the repetitive actions of heavy vehicle loads, an asphalt surface course cannot meet the needs of fatigue resistance performance. This phenomenon has been demonstrated with dynamic triaxial tests (He 1997, Ling 1999). Since the elastic layered system theory is different from the actual state of pavement (Ren 2001), the finite element technique was utilized by characterizing a flexible base as nonlinear (elasto-plastic) material (Bathe 1976).

The nonlinear, finite element technique was utilized to support the experimental pavement in the Tonghua Highway in the Jilin province. Lessons learned from the finite element analyses and some design parameters, suggest pavements used in the Tonghua Highway are expected to be applicable to a wide range of pavement projects.

MATERIAL ELASTO-PLASTICITY AND YIELDING RULE

The characteristics of the elasto-plastic materials are that deformation will be irreversible and perpetual when unloaded, as shown in Fig. 1. When material is loaded, it is impossible to tell if it is nonlinear elastic or nonlinear elasto-plastic. However, when material is unloaded, the difference is obvious as nonlinear elastic and/or elastic material will return to the original location (refer to Fig. 1). As shown in Fig. 1, depending on different loading history, elasto-plastic material yielded permanent deformation (Xue 2005, Drucker 1952, Xia 1991). Based on the dynamic triaxial test results, the behavior of flexible base deformation can be characterized as elasto-plastic material. Thus, to simulate the field condition, the elasto-plastic finite element technique was utilized to describe the pavement behavior.

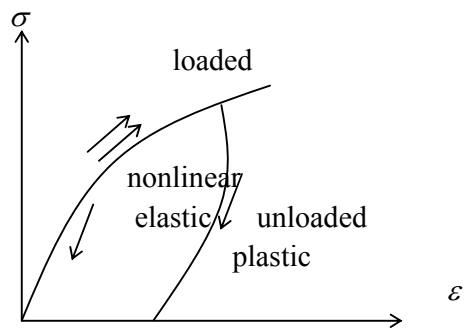

FIG.1. Nonlinear elastic and elasto-plastic.

This paper adopted linear Drucker-Prager yielding rule to describe the elasto-plastic behavior of flexible base. The linear Drucker-Prager yielding rule is very similar to that of Mohr-Coulomb, which is a modified yielding rule of VonMises (Drucker 1952, Xia 1991). The main difference of VonMises from linear Drucker-Prager and linear Mohr-Coulomb is that the yielding rule takes into account the influence of lateral pressure. According to reference (Xia 1991), linear Drucker-Prager yielding function is given as:

$$F = \sqrt{3}\alpha I_1 + \sqrt{3J_2} - \sigma_y = 0 \qquad (1)$$

where, I_1 is lateral pressure (in MPa); J_2 is the second stress invariable; σ_y is the yielding stress which relates to material's cohesion and internal frictional angle.

The yielding function of linear Mohr-Coulomb is shown in Eq. 2:

$$F = \frac{1}{2}(\sigma_3 - \sigma_1) + \frac{1}{2}(\sigma_3 + \sigma_1)\sin\phi - \cos\phi = 0 \qquad (2)$$

Where, ϕ is internal frictional angle; $\sigma_1, \sigma_2, \sigma_3$ are principal stresses. According to Equation 1, when the flexible base material was analyzed with the Drucker-Prager yielding rule by elasto-plastic finite element method, it should be determined if the yielding state is achieved or not. If achieved, it should be calculated with elasto-plastic theory; if not, it should be calculated with elastic theory.

The laboratory test results indicate that the cohesion of the flexible base material (grading macadam) is near 0 and the internal frictional angle ranges from 35^0 to 40^0. It has been observed that when there is a better construction quality control, the internal frictional angle can be increased to approximately 45^0 (He 1997). For this study, the internal frictional angle of 40^0 was selected.

SURFACE COURSE BOTTOM TENSILE STRESS ANALYSIS OF EXPERIMENTAL PAVEMENT IN TONGHUA HIGHWAY WITH NONLINEAR FINITE ELEMENT METHOD

Experimental Pavement in Tonghua Highway and Design Parameters

The typical structures with layer thickness and layer modulus of the experimental pavement sections in the Tonghua Highway are presented in Figure 2. A dual circular load with uniform pressure of 0.7MPa was adopted. The circular diameter is 21.3cm (CCCC Highway Consultants Co.,Ltd. 2006). Although the behaviors of an asphalt surface course and soil subgrade are all nonlinear, relative to a flexible base, they are insignificant. Therefore, all other materials, except for the flexible base, were treated as elastic materials.

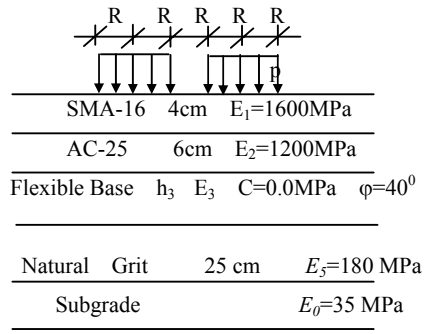

FIG.2. Experimental Pavement Structure of Tonghua Highway.

Since the load and geometric are symmetric, to simplify the analyses, a three- dimensional symmetric model was adopted. In addition, an eight-node spacial element was utilized in the analyses. Except subgrade Possion Ratio μ of 0.35, all other pavement layers have Possion Ratio μ of 0.25 (He 1997).

Analysis Results

To evaluate the impacts of the flexible base and semi-rigid subbase

modulus on the maximum tensile stress at the bottom of asphalt surface course, the thickness of the flexible base varied from 10, 12, to 15cm. Similarly, its moduli varied from 200, 300, 400, 500, 600, to 700MPa. The moduli of lime-flyash stabilized subbase in pavement structure in Figure 2 varied from 1000, 1500, 2000, 2500, to 3000MPa. The maximum tensile stresses at the bottom of AC-25, are presented in Figures 3, 4 and 5 respectively.

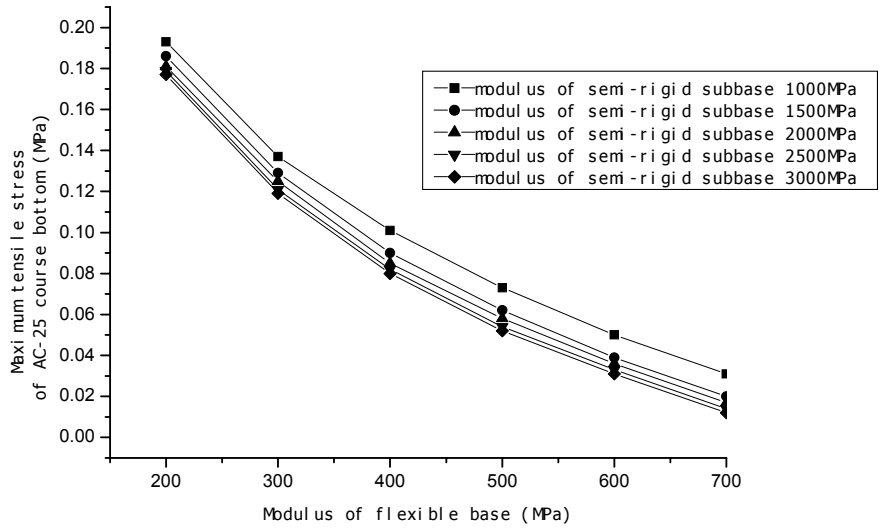

FIG.3. Maximum tensile stress at the bottom of AC-25 with varying flexible base modulus (h_3=10cm).

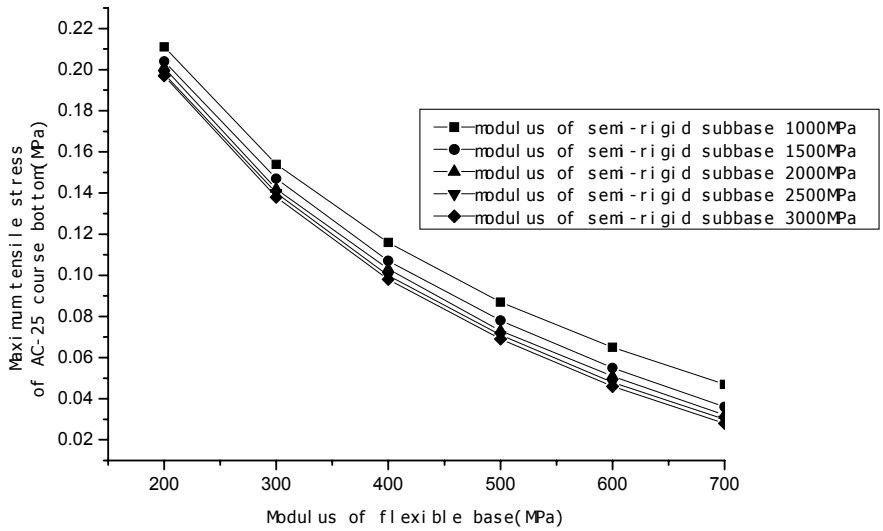

FIG.4. Maximum tensile stress at the bottom of AC-25 with varying flexible base modulus (h_3=12cm).

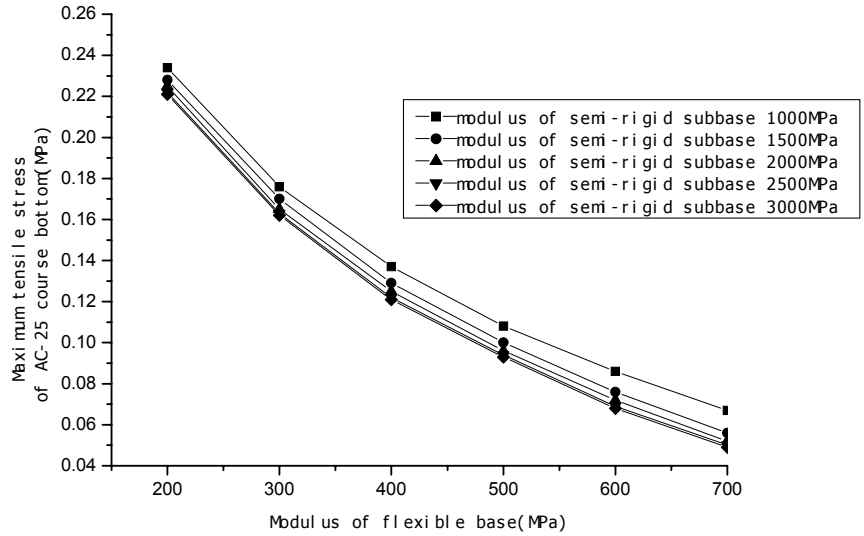

FIG.5. Maximum tensile stress at the bottom of AC-25 with varying flexible base modulus (h_3=15cm).

Figures 3, 4 and 5, indicate that the impacts of semi-rigid subbase modulus on the maximum tensile stresses at the bottom of the asphalt surface course vary insignificantly in pavement structures in Figure 1 when the modulus of flexible base is smaller. With the increasing of modulus of the flexible base, the impact of the semi-rigid subbase modulus becomes more significant. It was observed that when the modulus of the flexible base was higher than 400MPa, the varying slope of the maximum tensile stresses at the bottom of the asphalt surface course was less evident. When the modulus of semi-rigid subbase was lowered, the impact of the semi-rigid subbase modulus on the maximum tensile stresses at the bottom of the asphalt surface course was higher. When the modulus of the semi-rigid subbase was higher than 1500MPa, the varying of maximum tensile stresses at the bottom of the asphalt surface course was minimal. Thus, to reduce the maximum tensile stresses at the bottom of asphalt surface course, the modulus of flexible base should be more than 400MPa; the modulus of semi-rigid subbase should be more than 1500MPa.

CONCLUSIONS

Reflective cracking is a major concern for the cement/lime/flyash stabilized base in China. Although a flexible base can and has been utilized as a sandwich layer to reduce reflecting cracks from a stabilized base, higher tensile stress could be produced at the bottom of an asphalt surface course when subjected to a heavy truck traffic load, which may lead to fatigue cracking. In this study, the nonlinear, finite element technique was utilized to support the experimental pavement in the Tonghua Highway in the Jilin province. The main goal is to establish optimum structure design parameters to reduce the maximum

tensile stresses at the bottom of the asphalt surface course. Based on the analyses, the observations and conclusions are as follows:

(1) When the modulus of the flexible base was higher than 400MPa, evidence of the varying slope of maximum tensile stresses at the bottom of the asphalt surface course was lower.

(2) When the modulus of the semi-rigid subbase was higher than 1500MPa, the varying of maximum tensile stresses at the bottom of the asphalt surface course was very small.

(3) For the pavement structure in Figure 2, the optimal design parameters are that the modulus of the flexible base should be more than 400MPa. Similarly, the modulus of the semi-rigid subbase should be more than 1500MPa.

ABSTRACT

A seismic hybrid simulation between four universities was introduced in this work using a platform named NetSLab. The platform is capable of transferring control and feedback signals among distributed laboratories or computers connected by the Internet. A multi-span bridge was loaded to simulate the responses corresponding to different earthquake hazard levels, in which two FRP retrofitted RC columns were tested physically, and the other three columns were simulated numerically. The results demonstrate that NetSLab has adequate for applications, and the bridge with retrofitted RC columns has adequate seismic behavior under earthquake excitation.

Keywords: hybrid simulation; NetSLab; multi-span bridge; columns; retrofitted

INTRODUCTION

In order to be able to execute testing of large scale specimens to give better insight of structures under earthquake excitation, the concept of hybrid simulation is developed. The prototype structure is divided into substructures, each of which can be tested or calculated at a different site; all substructures are conducted concurrently to form uniform testing. At present, some research efforts have been madeExamples include: NEES in USA connected several universities with high performance networks to explore the benefits of integrating laboratory resources (NEES, 2003; Stojadinovic *et al.*, 2006; Takahashi *et al.*, 2006) and ISEE in Taiwan area developed a testing platform named PNSE based on database approach and TCP/IP approach (Wang *et al.*, 2005). Furthermore, there are several plans such as ED-Net in Japan and KOCED in Korea (Park, *et al.*, 2003; Takashi *et al.*, 2005). In China, a networked testing platform, named NetSLab, has been developed, which solved the technologies of data transmission and collaborative control on the Internet. A series of simulations and tests were executed by the researcher (Fan *et al.*, 2009). A five-column bridge is chosen as the prototype structure in this paper for the demonstrative hybrid simulation.

PROTOTYPE BRIDGE AND SCALED SPECIMENS

The Russian river bridge, as shown in Figure 1, is selected as the prototype structure.

The superstructure is assumed to be a box section with a depth of 1.6m and width of 8m for a 2 lane highway bridge. There are two columns that serve as physical substructures, which consist of CFRP retrofitted RC columns at Harbin Institute of Technology laboratory (HIT Lab) and GFRP retrofitted RC columns at Hunan University laboratory (HNU Lab). The height scale of the two specimens is chosen to be 1/6 based on the available equipment and physical size of each laboratory. Table 1 gives a summary on the parameters of specimens of a multi-span bridge. Figure 2 shows the elevation view of the specimens C-5.

HYBRID SIMULATION METHOD BASED ON NETSLAB

Hybrid simulation is root in pseudo-dynamic testing, which integrates a physical model and a numerical model into a hybrid model. Based on the network, it integrates several single laboratories into a powerful and distinctive networked structural laboratory, which can enhance testing capability and share resources.

NetSLab (Networked Structural Laboratories)

NetSLab is a testing platform based on the concept of Client/Server that links several remotely distributed laboratories by Internet. The frame of NetSLab is

illustrated in Figure 3. Controller organizes the procedure, carries out the analysis, and controls the progress and data communication among all participants. There is only one Controller per testing for the current study. Testers carry out the detailed task for each step to create new results according to previous results. There may be multiple testers in one testing. The testers are further categorized into two types: Actual-Tester, who operates the equipment in each laboratory to generate actual results, and Virtual-Testers, who uses computation to provide analytical data. Remote-Viewer monitors the process and shares the results online without any interference of the test processing. Each component will communicate with NetSLab based on TCP/IP protocol (Xiao *et al.*, 2005; Wang *et al.*, 2007).

The control algorithm is shown in Figure 4. Based on the input information about the testing model, Controller first reads an earthquake record, then calculates the displacement and sends it to Actual-Tester for operating the actuator, and to Virtual-Tester if it is involved. After the actuator achieves the target displacement, Actual-Tester sends the measured restoring force to Controller. Meantime, the calculated restoring force based on selected numerical models by Virtual-Tester is also sent to Controller, and Controller then calculates the displacement for next step.

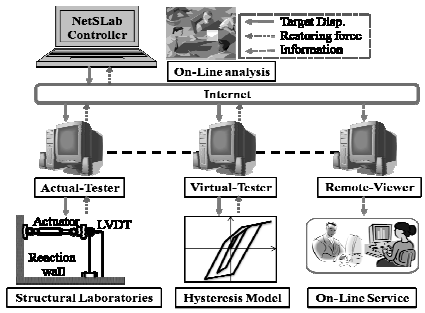

Figure 3. Frame of NetSLab

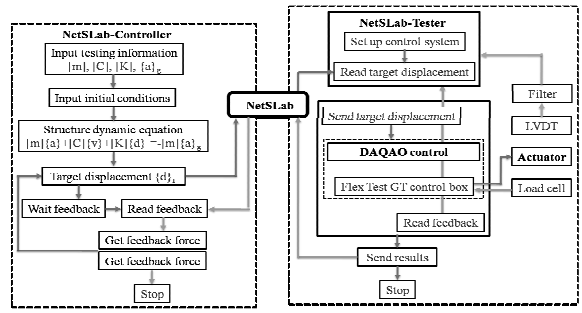

Figure 4. Control algorithm of NetSLab

Bridge testing framework

The hybrid simulation frame of a multi-span bridge is illustrated in Figure 5. The superstructure is assumed to have infinite stiffness and the mass is supported by five columns, then the bridge is modeled as SDOF system in longitudinal direction. The superstructure-to-column connection of C-1 and C-5 are rigid connections and the other three is a hinge connection. The columns C-1 and C-5 are designed as physical substructures and tested in HIT Lab (named PDT-C1) and HNU Lab (named PDT-C2), as shown in Figure 6 (b)(c). The columns C-2, C-3 and C-4 are designed as numerical substructures and are calculated in computers at University of Southern California, Tsinghua University and Hunan University.

(a) Testing frame of bridge **(b) PDT-C1 in HIT** **(c) PDT-C2 in HNU**

Figure 5. Hybrid simulation frame of multi-span bridge

Selection of earthquake excitation

The EL-Centro (S-N) wave, including the max peak ground accelerations from the 1940 Imperial Valley earthquake, is selected for the testing. The bridge is tested by subjecting to increasingly higher seismic demands which represent frequent level earthquakes, design level earthquake and the rare level earthquake. The time step is 0.02s and the step number is 300. The input information of earthquake ground motions is illustrated in Table 2.

Table 2. Input of EL-Centro earthquake ground motions

Seismic fortification intensity	Hazard levels	Scaling factor	Peak value
7° frequent	63%	0.206	0.07g
7° design	10%	0.647	0.22g
8° rare	2%~3%	1.176	0.4g

TESTING RESULTS AND ANALYSIS

The running interfaces of Controller and Actual-Tester are illustrated in Figure 6. It includes the input of acceleration record, displacement and time curve, hysteresis curve, schematic diagram of structure vibration and information in each testing step, et al. The smooth running of NetSLab is validated by the testing.

Figure 7 shows the hysteresis curve of the specimens. PDT-C1 is a RC short column retrofitted with CFRP to prevent brittle shearing damage. PDT-C2 is a RC column retrofitted with GFRP to prevent flexure or premature shear damage. From Figure 7, we can see the failure modes of PDT-C1 and PDT-C2 are all ductility bend failure in the testing. Before yielding, the hysteretic loop is long-narrow and shuttle-shape; the pinching phenomenon is very significant and the changing of stiffness is very limited. But after yielding, the displacement increases significantly and the restoring force changes from line to curve. Furthermore, the hysteretic loop becomes satiety and changes to S-shape. Pinching phenomenon and stiffness decrease very significantly, which proves that FRP has strong confining effects on core concrete.

CONCLUSIONS

Hybrid simulation is an experimentally based method for investigating the seismic response of a structure. An Internet-based platform, called NetSLab, has been utilized in this work for the execution of networked collaborative hybrid simulation among distributed structural laboratories. A multi-span bridge with five columns is chosen as the prototype structure to evaluate the performance of NetSLab. The physical substructures testing sites include the HIT Lab and HNU Lab, and the numerical substructures testing sites include Tsinghua. USC and HNU. The

successful application of hybrid simulation among four universities proves the feasibility of NetSLab. The efficient control and feedback of data is also validated by the testing, and the results also prove that the developed testing system NetSLab is adequate for bridges under earthquake excitation.

ABSTRACT

In order to investigate the behavior of geosynthetic-reinforced soil (GRS), a series of laboratory experiments were conducted on GRS samples made up of granular soil and a nonwoven geotextile. The resilient deflection, resilient modulus, California Bearing Ratio (CBR) and unconfined compressive strength of the GRS mass were the parameters examined to evaluate the performance of the GRS samples. The focus of the tests was to determine the effects of the vertical spacing of the reinforcement and the relative compaction of the granular soil on the performance of the GRS mass. Based on the test results, it was concluded that the compressive strength of geotextile-reinforced soil increases significantly with the decrease in reinforcement spacing or with the increase in the degree of the relative compaction of fill. Furthermore, the well-compacted granular soil reinforced with closely spaced geotextile not only has a higher compressive strength compared to that with widely spaced reinforcement, but also exhibits both ductile and flexible failure mode making it a desirable composite material for the construction of supporting structures. In addition, it was found that the standard laboratory soil resilient modulus and CBR test methods are unsuitable for geotextile-reinforced soil because sliding occurs along the geotextile-soil interface under test loading due to the lack of adequate anchorage of the geotextile in the small sample.

INTRODUCTION

Geosynthetic-Reinforced Soil (GRS) is different from Mechanically Stabilized Earth (MSE) conventionally used in retaining structures (Barrent et al. 2007; Adams et al. 2007a). MSE structures rely on the use of widely spaced metallic or high strength geosynthetics as tie-backs or “quasi-tiebacks” and heavy concrete facial blocks or panels to stabilize the backfill. GRS structures on the other hand rely on the closely spaced geosynthetic reinforcements and the well compacted granular fill with minimal facial elements to create an inherently strong reinforced soil composite (Barrent et al. 2007). A GRS mass is internally stable, but a MSE mass is

not by itself stable. GRS is superior to MSE in resisting both static and dynamic loads (Barrent et al. 2007).

The high bearing capacity of GRS and the small deformation under service loads, led to the use of GRS structures as bridge abutments in recent years (Helwany et al. 2007). GRS bridge abutments are easier to construct and more economical than their conventional reinforced concrete abutments counterparts. The cost saving and ease of construction are - due to the much shorter construction period, lesser excavation, cheaper materials (geotextile and granular soil), and the elimination of piles even when constructed over a weak foundation (Lee et al. 2004). In addition, there is an improved transition from abutment to bridge, unlike the "bump" often experienced at the ends of a bridge resting on conventional concrete abutments. In United States of America, GRS bridge-supporting structures are, therefore, considered a significant advancement in developing technologies to rapidly construct bridges as part of the Federal Highway Administration's "Bridge of the Future" program (Adams et al. 2007a).

Lee and Wu (2004) reviewed some typical observations of several full-scale GRS abutment and pier models.. Adams et al. (2007b) carried out an experimental study on small models of GRS piers, and found that the performance of GRS structure was significantly affected by the reinforcement spacing, but was not affected by reinforcement strength within a working load of 200 kPa. Hu et al. (2008) conducted laboratory tests to investigate the deformation behavior of geogrid-reinforced silty sand. Numerical analysis of GRS structures were also proposed by some researchers, such as Helwany et al. (2007), Wu et al. (2006) and Hatami et al. (2006).

The widely accepted views on the reinforcement mechanism can be categorized as "membrane effect", "confinement effect" and "stress-spreading effect" (Sharma et al. 2009 and Bao 2004). Bao (2004) divided the reinforcement mechanism into "direct reinforcement effect" induced by soil-geosynthetic interaction， and "indirect reinforcement effect" resulting from the composite soil (quasi-rigid mass) formed by the reinforcement material and the adjacent thin soil layer. This idea serves as a guide to understanding GRS properties. However, the performance of GRS mass is mostly unclear until now.

In order to help understand the behavior of GRS mass subjected to vertical loading, the author carried out an experimental laboratory investigation using GRS samples maked up of a granular soil and a nonwoven geotextile reinforcement. Tests of resilient modulus, California Bearing Ratio (CBR) and unconfined compression were conducted on several GRS samples with varying reinforcement spacing/number of

reinforcement inclusions and relative degrees of compaction of the soil At the same time, the same tests were also conducted on a control sample of the granular soil without reinforcement for comparison.

MATERIALS USED FOR THE EXPERIMENTS

The soil used in all tests was a mixture of a crushed stone and clay with a maximum dry density of 21.3 kN/m^3 at the optimum water content of 7.08 %. The particle size distribution of the crushed stone is shown in Figure 1. The clay consists of grains smaller than 0.075 mm in diameter. The ratio of crushed stone to clay was 85:15 by mass. The reinforcement layers were a nonwoven geotextile with a unit mass of 174 g/m^2 and a tensile strength of 3.5 kN/m at 103.2 % tensile strain.

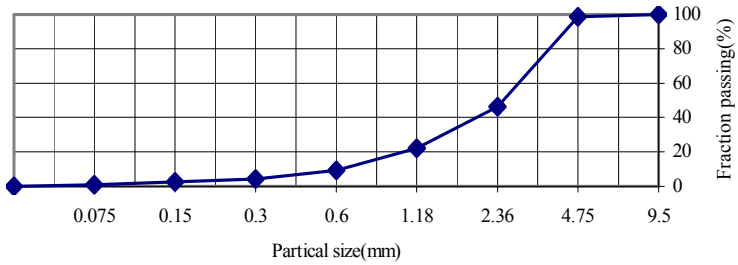

Figure 1. Particle size distribution of crushed stone

TEST SAMPLES AND REINFORCEMENT ARRANGEMENT

According to the Chinese standard test methods for highway engineering (Ministry of Transport of P.R. China 2007, 1994), all samples used in the study were cylindrical specimens made by compressing them in rigid molds. The CBR and resilient modulus test samples had a diameter of 15.2 cm and a height of 12 cm. The soil in the samples was respectively compacted to 92 %, 96 % or 100 % of the maximum dry density at the optimum water content of 7.08 %. The reinforcement arrangements are shown in Figure 2, where *n* is the number of reinforcement layers.

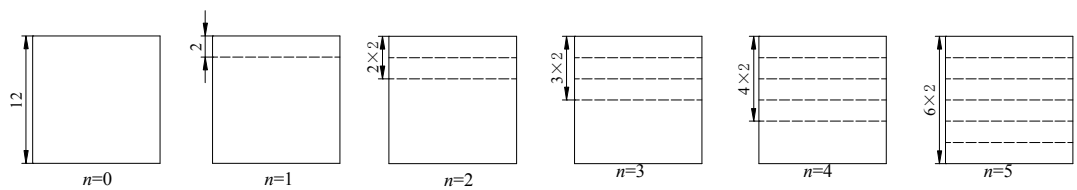

Figure 2. Reinforcement arrangement for CBR and resilient tests (size unit: cm)

For the unconfined compression (UC) tests, samples with a diameter and height of 15 cm were made at 96 % and 100 % relative compaction, at a water content of 7.08 %.

The reinforcement arrangements are shown in Figure 3.

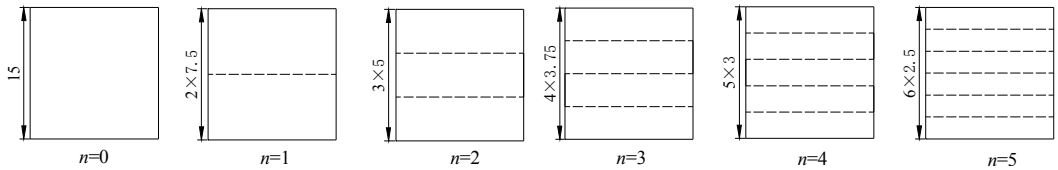

Figure 3. Reinforcement arrangement for UC tests (size unit: cm)

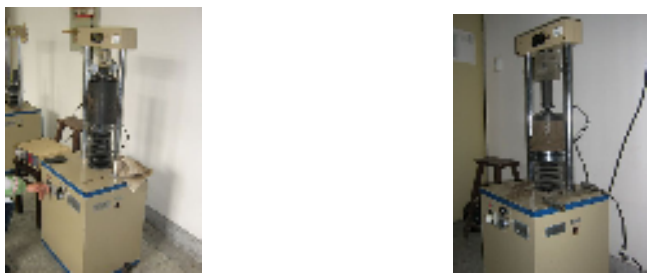
TEST PROCEDURE

All of the laboratory tests were conducted as per standard methods noted above. Figure 4 shows the experimental set-up. Testing load was applied at a constant rate of 1.2 mm/min through a rigid 5 cm circular plate for the CBR and resilient tests and through a 15 cm circular plate for the unconfined compression tests.

TEST RESULTS AND ANALYSIS

Resilient Modulus Tests: The resilient modulus test results are shown in Figure 5 to Figure 9where K is the relative compaction of soil, p is the pressure applied, l is the resilient deflection and E is the resilient modulus.



a) Resilient/CBR test b) Unconfined compression test

Figure 4. Experimental set-up

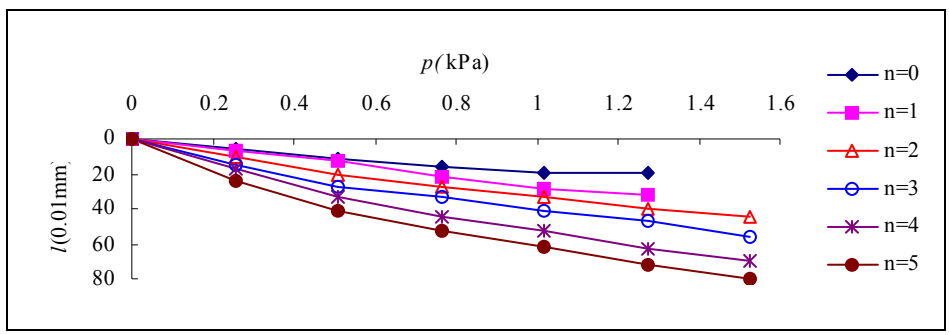


Figure 5. Pressure-resilient deflection curves at K=92 %

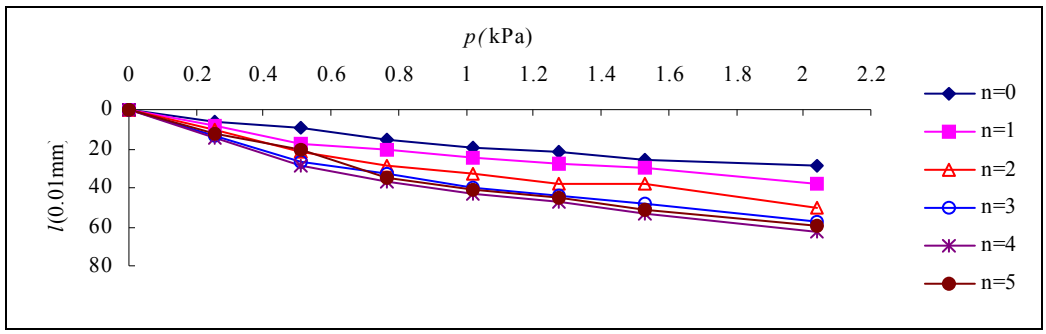

Figure 6. Pressure-resilient deflection curves at *K*=96 %

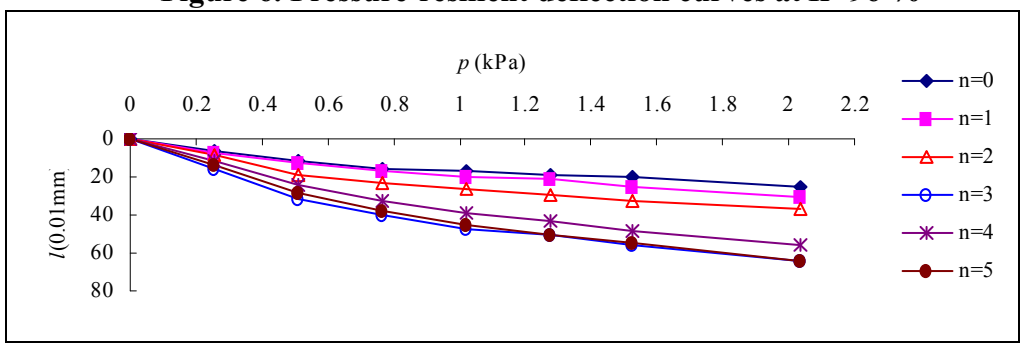

Figure 7. Pressure-resilient deflection curves at *K*=100 %

For a given pressure, the resilient deflection of the reinforced soil increases with n for a relative compaction (K) of 92% (see Figure 5). Similar trends are observed for K=96 % and K=100 % except for reinforcement inclusions exceeding 3 layers (see Figure 6 and Figure 7). The pressure-resilient deflection curves for samples with 3, 4 or 5 reinforcement layers (n =3 to 5) are very similar in magnitude and shape for K=96 % or K=100 %. Coinciding with the effect and trend of K or n on the resilient deflection noted above, the resilient modulus (E) decreases as n increases at K=92 %, or at $K \geqslant 96$ % for $n \leqslant 3$. For K=96 % or K=100 %, E has nearly the same magnitude for n equals to 3, 4 or 5 (see Figure 8).

The above test results imply that the geotextile inclusions reduce the stiffness of the reinforced soil making the soil softer. This outcome is due to the small size of the samples, in which the geotextile cannot be anchored strongly to avoid sliding along the geotextile-soil interface when the sample was centrally loaded during the resilient tests. In the actual GRS structures, such sliding cannot occur under working load (Adams et al. 2007a). Therefore, the standard laboratory method for evaluating resilient modulus prescribed in JTG E40-2007 is not suitable for geotextile-reinforced soil. For this reason, a test method using larger dimensional GRS mass and larger loading plate, such as the field plate load is suggested for geotextile-reinforced soil.

Figure 9 shows the relationship between the resilient modulus and the relative

compaction of the soil. For the soil without geotextile reinforcement, E varies directly with K, which agrees with a lot of experimental data previously presented. For the soil reinforced with 1 or 2 geotextile inclusions, E also increases with K, but the rate of increase from K=96 % to 100 % is greater than that from K=92 % to 96 %, indicating that the higher the degree of compaction, the more reinforcing benefit the GRS mass will experience.

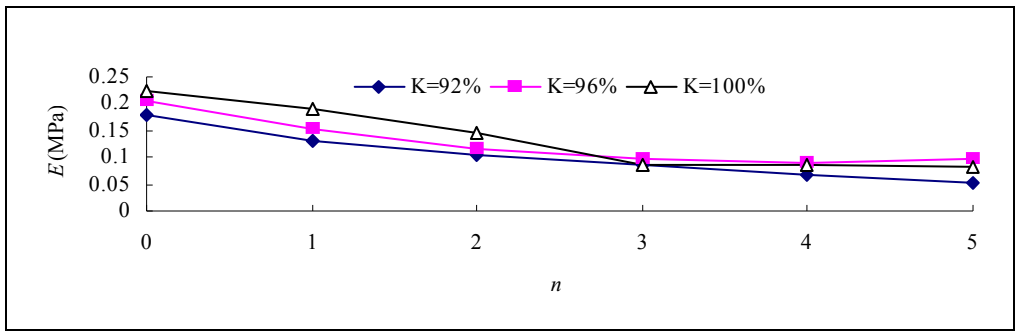

Figure 8. Relationship between resilient modulus and number of reinforcement layers

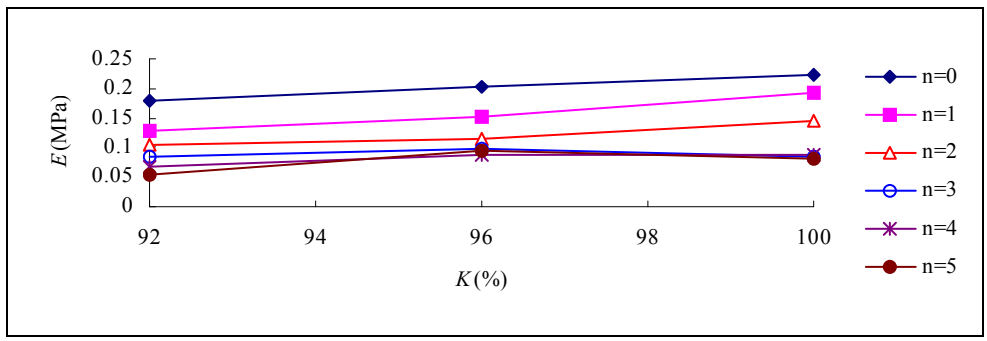

Figure 9 Relationship between resilient modulus and relative compaction of soil

It can be seen from Figure 8 and Figure 9 that the resilient modulus of the reinforced soil samples with n=3, 4 and 5 are approximately equal. This is because nearly no deformation took place in the lower half part of the sample under a lower level of stress due to the small loading plate diameter and lower pressure applied. Based on this observation, it can conclude that the geotextile reinforcement layers placed within the lower half of the sample results in almost no improvement to the properties of the reinforced soil.

CBR Tests: Similar to the resilient modulus, the CBR of the geotextile-reinforced soil is affected by K, and slightly by n. Generally, CBR increases with K, but fluctuates with n (see Figure 10) due to the same reason for the resilient modulus discussed above. Therefore the CBR test carried out in laboratory with a small sample is not a rational method for geotextile-reinforced soil.

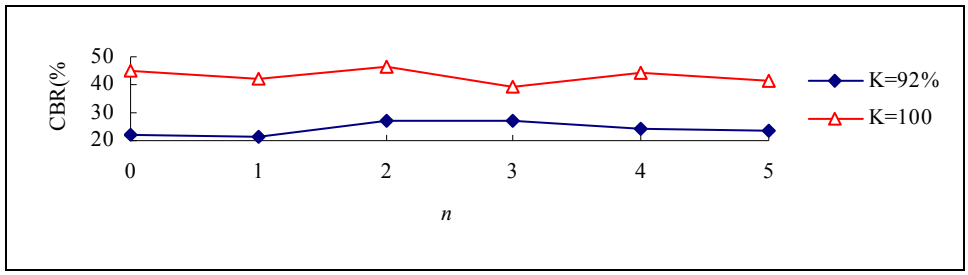

Figure 10. Relationship between CBR and number of reinforcement layers

Unconfined Compression Tests: The relationships between compressive stress and strain of the samples with and without geotextile reinforcement are presented in Figure 11 to Figure 14, where q is the compressive stress and ε is the vertical strain.

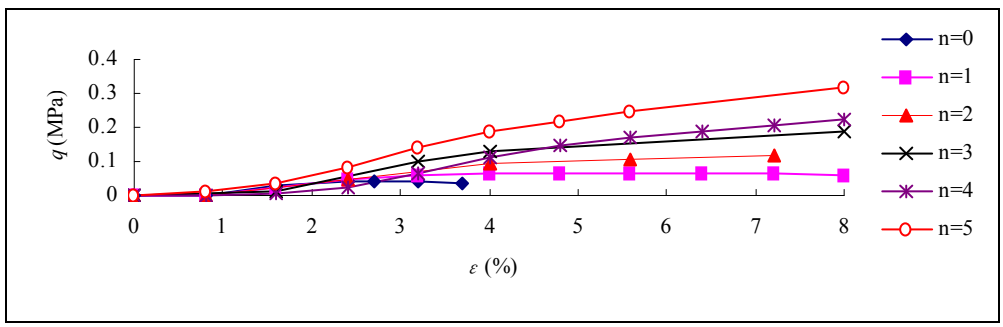

Figure 11. Compressive stress-strain curves while $\varepsilon \leqslant 8$ % at K=96 %

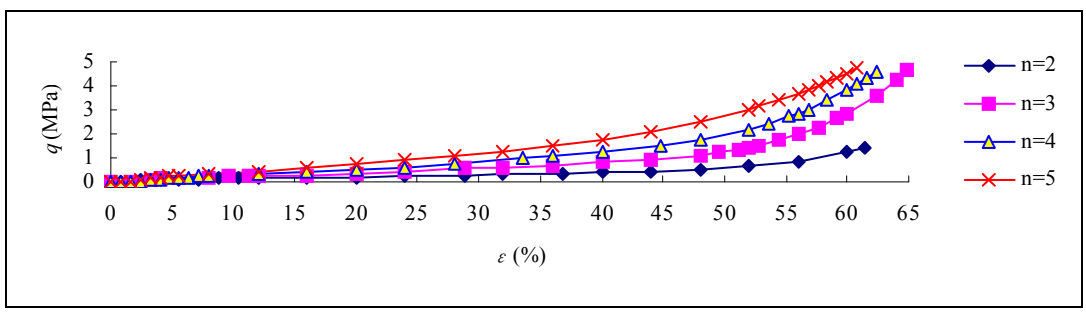

Figure 12. Compressive stress-strain curves at K=96 %

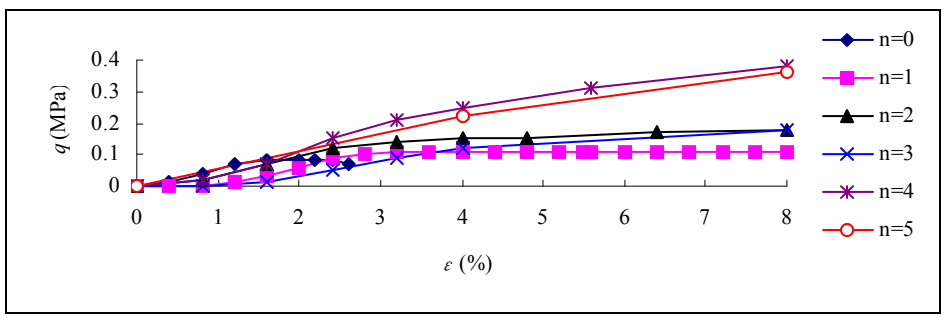

Figure 13. Compressive stress-strain curves while $\varepsilon \leqslant 8$ % at K=100 %

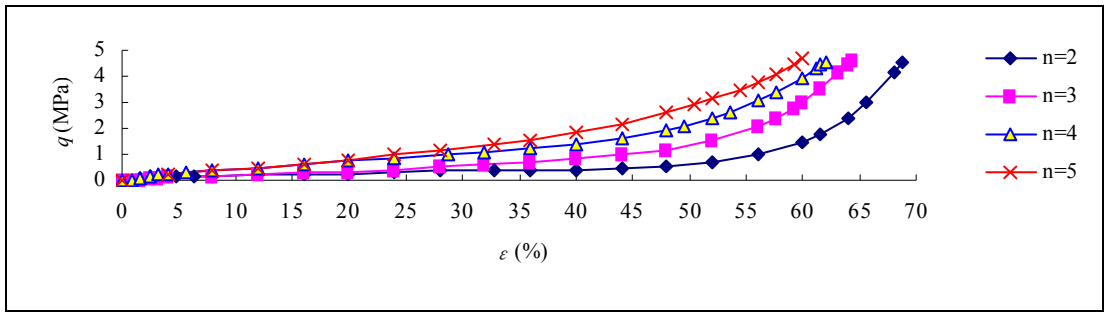

Figure 14. Compressive stress-strain curves at *K*=100 %

A summary of the results of the ultimate compressive strength, q_u, and the corresponding vertical strain, ε_u, for sample with varying reinforcement inclusions (n) are presented in Table 1. It should be noted that the values of q_u in Table 1 represent the maximum stress for the samples without and with one geotextile inclusion (n=0, 1), or the approximate compressive stress of the point of maximum curvature on q- ε curve for sample with more than one reinforcement inclusions (n= 2, 3, 4 or 5)-see Figure 12 and Figure 14.

Table 1. Ultimate compressive strength and the corresponding strain

n	*K*=96%		*K*=100%	
	ε_u (%)	q_u (MPa)	ε_u (%)	q_u (MPa)
0	2.4	0.04	1.6	0.08
1	5.6	0.06	3.6	0.11
2	56.7	0.80	61.0	1.60
3	56.5	2.06	55.0	1.96
4	52.0	2.20	51.0	2.25
5	50.3	2.81	48.7	2.73

As can be seen in Figure 11 to Figure14, the geotextile inclusions have a significant effect on compressive behavior of the reinforced soil when the compressive strain exceeds a critical value of about 4 % at *K*=96 % and 8% at *K*=100 % for the reinforced soil used in this study.

The important results are as follows:

1. The samples without reinforcement and with only one reinforcement layer placed at mid height demonstrated a fragile failure, and as a result these samples have a lower ultimate compressive strength occurring at a relative small strain (see Table. 1). This indicates that the granular soil reinforced with widely spaced geotextile is fragile and weak and therefore unsuitable for

retaining support structures.

2. On the contrary, the samples with 2-5 geotextile reinforcement layers (i.e. reinforcement spacing of 7.5-2.5 cm) exhibited a highly ductile and flexible behavior when subjected to vertical stress, even though the geotextile is very weak (ultimate tensile strength of 3.5 kN/m). The more closely the spacing of the geotextile reinforcements, the better performance of the reinforced soil. It was observed that even if the vertical strain exceeded 60%, except for some grains dropping from the vertical surface of the sample during loading (see Figure 15), samples with 3 or more geotextile reinforcement layers still maintained the form of a highly compacted mass. This experimental result agrees with recommendations proposed by Lee and Wu (2004) and observation presented by Adams (2007b). Therefore, GRS, well-compacted granular soil reinforced with closely spaced geosynthetic, is a desirable composite material for constructing supporting structures.

Figure 15. Picture of reinforced soil at the end of test

CONCLUSIONS

The following conclusions can be drawn from the test results of the investigation:

1. The standard laboratory soil resilient modulus and CBR test methods are unsuitable for geotextile-reinforced soil because the geotextile cannot be anchored strongly in the small sample to avoid sliding along the geotextile-soil interface under test loading.
2. The compressive strength of geotextile-reinforced soil increases significantlywith the decrease of reinforcement spacing and with the increase in the degree of relative compaction of the soil.
3. The well-compacted granular soil reinforced with closely spaced geotextile has a higher compressive strength and exhibits a ductile and flexible failure mode. This makes GRS a desirable composite material for the construction of

retaining support structures.

ABSTRACT: Lime-fly ash stabilized material has been commonly used as base course in seasonal frozen region in China for its high strength and good water stability. But the frost damage happens both during the pavement construction and in service life. During the pavement construction, if the lime-fly ash base layer was exposed in winter, the surface of base course could be frozen resulting in severe deterioration. In this situation, it was not uncommon to remove the whole base course and repave it. However, it was not only a waste of money but also a waste of time. In service life, if the lime-fly ash base course was saturated, it could be severely damaged after several freeze-thaw cycles. Therefore, a study of the frost resistance ability of lime-fly ash material would have great significance. Based on the investigation of ten–year lowest temperature in seasonal frozen region in China and the actual in-service temperature of semi-rigid base, the frost resistance test method of lime-fly ash stabilized mixture was developed. The test was conducted on lime-fly ash mixtures with different mixing ratio. The frost resistance index was determined according to the retained strength ratio. The relationship between water absorption, density and frost resistance index was discussed as well.

Keywords: lime-fly ash, stabilized material, road base, frost resistance test method, frost resistance index.

In China, most of the expressway use lime-fly ash stabilized aggregate as base course due to it's high strength, good water stability and environment-friendliness. Table 1 shows the properties of lime-fly ash mixture.

Table 1. Properties of Lime-fly Ash Stabilized Crushed Stone

items	values
180d compressive strength（MPa）	5.8~7.5
180d tensile strength（MPa）	1.3~1.6
Compressive resilient modulus（MPa）	1300~1700

tensile resilient modulus（MPa）	4500~6000
coefficient of shrinkage（10^{-6}）	20~35
strain of drying shrinkage（10^{-6}）	350~750

However, in seasonal frozen region, the lime-fly ash stabilized material's performance could be severely impacted by low temperature and freeze-thaw cycles. The frost damage could happen both during the pavement construction and in service life. During the pavement construction, if the lime-fly ash base layer is exposed, the surface of base course could be frozen in winter, resulting in severe deterioration. In this situation, it is not uncommon to remove the whole base course and repave it. It is not only a waste of money but also a waste of time. In service life, if the lime-fly ash base course is saturated, it could be severely damaged after several freeze-thaw cycles. So in the design procedure of lime-fly ash stabilized aggregate base, the frost resistance index should be considered.

1. Test Parameter

Currently, there is no well-accepted frost resistance index and corresponding experiment method for lime-fly ash stabilized mixture. Some research has been done to solve this problem. However, as different test methods were used, the results can not be cross-checked with each other. It is necessary to establish a consistent frost resistance test methods and propose parameters to evaluate the frost resistance ability of lime-fly ash stabilized mixture.

1.1 Freezing-thawing temperature and time

Test temperature in frost resistance test method should be the same as the in-place temperature of lime-fly ash stabilized base course in winter. Based on investigation of experiment road, the temperature at top of the base course was from -15°C to -18°C, was and -13°C to -16°C at the bottom. The difference of temperature between pavement surface and the top of base course was 2°C to 3°C. Based on these data and the concrete freeze-thaw test method (freezing temperature is -20°C) in "Testing methods of concrete", freezing temperature of frost resistance test for lime-fly ash stabilized mixture was determined to be -18 ± 1°C. Because the specimen melts faster in water, thawing temperature was determined to be close to room temperature, 20±1°C, which also simulates realistic temperature in water.

The time required to freeze and thaw the samples was determined first. The cost, including the on-site laboratory's test equipments, were considered along with the realistic environment that the lime-fly ash stabilized base course experienced in winter. Only large-scale scientific research institutes and engineering laboratories are equipped with air-cooled refrigeration equipments. Many on-site laboratories could only use compact refrigeration equipment. Considering the effectiveness of freezing equipment and the number of samples frozen, it was determined to use nine test specimens, 16 hours of freezing and 8 hours of thawing time, resulting in 24 hours for one freeze-thaw cycle.

1.2 Curing Age and Freeze-thaw Cycles

1.2.1 Curing age

"Technical code for construction of highway roadbed" specifies that construction of lime-fly ash stabilized base should be suspended one and a half month before the first freezing period. The strength of lime-fly ash stabilized mixture is a function of curing temperature and age. Considering the actual and required curing temperature (20℃), 28 days curing age was selected to evaluate frost resistance property during pavement construction. To determine the suitable age for testing the in-service frost resistance, compressive strength test was conducted to study the relationship between strength and age of the mixture. The study results are shown in Figure 1. It could be seen that after 180 days, the increase of strength slowed down significantly. Therefore, 180 days was selected as the standard curing time.

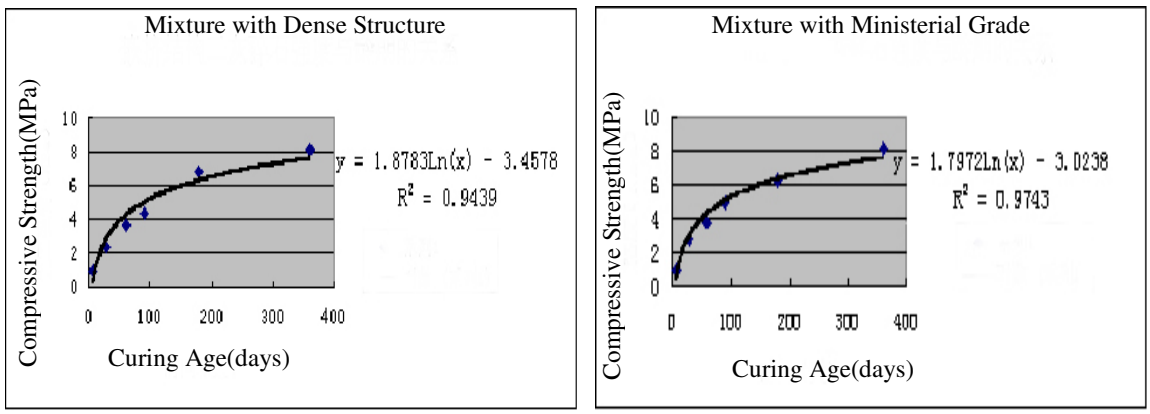

Figure 1 Relationship between Strength and Age of Lime-fly Ash Stabilized Mixture

1.2.2 freeze-thaw cycles

According to freeze-thaw cycle test results of lime-fly ash stabilized mixture specimens with 28 days curing age after 10 cycles, the strength and material loss after the first 5 cycles was not significant. However, after 10 cycles they became significant. Therefore, the retained strength after 5 freeze-thaw cycles was selected to evaluate frost resistance during construction. For 180 days curing age mixture, the retained strength after 10 freeze-thaw cycles was selected to evaluate frost resistance.

2. Test Method

Samples were prepared with optimum moisture content to obtain the maximum dry density. Cylinder samples with diameter of 150mm and height-diameter ratio of 1:1 were used in the test. Samples with 28 and 180 days curing time were used for 5 and 10 freeze-thaw cycles respectively.

Test procedures consist of the following steps:

(1) Before the end of curing time, samples were saturated for 24h at room temperature.

(2) Determine the dry weight. Measure the hight of the samples H_1 to an

accuracy of 0.1mm with a square caliper.

(3) The samples were divided into two groups with 9 samples each group. The first group of specimens were then compressed at a uniform rate with a speed of 1mm/min till failure. Record the maximum compressive load P(N).

(4) The second group was frozen for 16h±1h at -18℃±1℃ using constant temperature refrigerator(or kitchen refrigerator).

(5) The samples prepared by step (4) were weighed and the height, H2, was measured to an accuracy of 0.1mm with a square caliper. Then the specimens were placed into water at 20℃ for 8h±1h.

(6) The samples prepared by step (5) have experienced one freeze-thaw cycle. The weight was determined and steps (4) to (6) were repated.

(7)After 5 or 10 required freeze-thaw cycles the samples were saturated for 24h, the dry weights were determined and the heights of the samples were measured.

(8) Placed the samples on the elevating table of road materials strength tester, The specimens were then compressed at a consatnt rate with a speed of 1mm/min till failure. Recorded the maximum compressive load P(N).

(9)The unconfined compressive strength were calculated using equation (1)

$$Rc\ (R_{DC}) = P/A = 0.000057P \quad (1)$$

In this formula:

Rc, R_{DC}=Sample's unconfined compressive strength before or after freeze-thaw cycles, N;

P=Peak load, N;

A=Cross section area of sample, mm^2.

(10) Standard deviation, Cv, should not be more than 20%.

3. Frost Resistance Evaluation

Frost resistance is the capability of resisting freezing and thawing in the water-saturated state. During the construction period in spring and autumn and in-service in winter, the materials are subject to moisture and subsequently freezing and thawing at low temperature. The expansion of ice in pores generates tension and as the temperature increases, the pressure gradually disappears before the next freeze-thaw cycle. The internal pore water froze to cause frost heave. The pressure is related to the moisture content, freezing speed, and the structure of the pores. After repeated freeze-thaw cycles, cracks occur and freeze-thaw resistance of the material can be determined.

3.1 Frost resistance evaluation indicator

Lime-fly ash stabilized aggregate mixtures with different gradation were tested for 5 and 10 freeze-thaw cycles after 28 and 180 days, respectively. The mix design and aggregate gradation are shown in Table 2.

Table 2. The Mix Design and Gradation of Lime-fly Ash Stabilized Aggregate and Sand Gravel

Serial number	The proportion lime: flyash: macadam	Maximum particle diameter (mm)	Aggregate gradation (%)								
			37.5	31.5	19.0	9.5	4.75	2.36	1.18	0.6	0.075

Frost resistance analysis of lime-fly ash stabilized mixture:

- Strength and mass loss of 28-day samples were significant after 5 freeze-thaw cycles. Therefore, the retained strength ratio after 5 freeze-thaw cycles could be used as frost resistance index.

$$BDR=R_{DC}/R_C \times 100\% \quad (2)$$

In Equation (2), BDR is freeze-thaw Retained strength percentage of semi-rigid material.

- For 180-day curing age samples, the retained strength ratio after 10 freeze-thaw cycles could be used as the indicator to evaluate frost resistance performance. Based on the test results shown in Table 3 and Table 4, the frost resistance index of lime-fly ash stabilized mixture are shown in Table 5.

Table 5. Frost Resistant Index of Lime-fly Ash Stabilized Mixture

Test conditions \ Freezing zone	Middle, light freezing zone
28-day age and 5 freeze-thaw cycles	≥ 40%
180-day age and 10 freeze-thaw cycles	≥ 65%

3.2 Relationship between frost resistance index or water absorption and the test cycles.

3.2.1 Relationship between frost resistance index and the number of freeze-thaw cycles.

Figure 2 shows the results of freeze-thaw test after 28 day curing age. The linear regression with a negative slope indicated that the mixture strength decreased with the development of the freeze-thaw damage resulting from the decrease of mixture density. After 5 freeze-thaw cycles, the frost resistance index was between 50% to 70%, which meant that the retained strength was 50% to 70% of the original strength before freeze-thaw test.

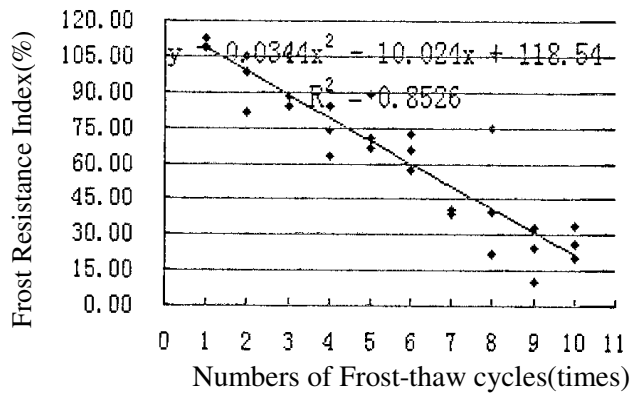

Figure.2 Plot of Frost Resistance Index versus Number of Freeze-thaw cycles

3.2.2 Relationship between water absorption and the number of freeze-thaw cycles

Figure 3 shows the relationship between water absorption and the number of freeze-thaw cycles. It can be seen that water absorption increased with the increase of the test cycles. It could be due to the increase of the internal voids and the decrease of the density, which caused the decrease of the strength. The curve also

showed that the water absorption increased significantly after 5 test cycles.

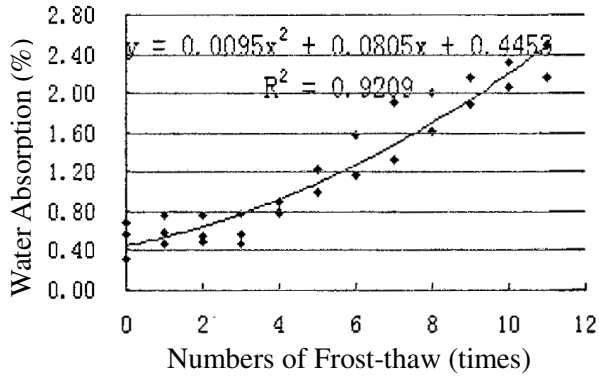

Figure 3. Water Absorption over Test Cycles

3.2.3 Relationship between water absorption and frost resistance coefficient

Figure 4 shows the relationship between frost resistance index and water absorption.

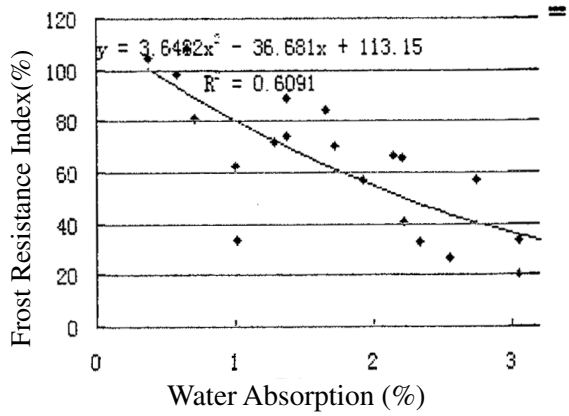

Fig.4 Frost Resistance Index versus Water Absorption

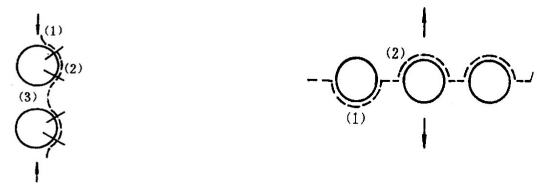
The frost resistance index decreased with the increase of water absorption. This indicated that the mixture's frost resistance capacity is affected by the specimen's density. The lower was the density, the lower was the capacity. The inflection points of relationship curve are located at 1.5% to 2% of water absorption and frost resistance index of 50% to 60%. These diagrams show that the water absorption is representative of the durability. Therefore water absorption is used as indicator to frost resistance design.

4. Analysis of Freeze-thaw Test on Semi-rigid Base

As can be seen from the test results, water absorption gradually increases after the freeze-thaw damage occurs. From the microscopic perspective, lime-flyash stabilized materials contain large pores, capillary pores and the gel pore, among which the free water contained in large pores dominates. When the temperature drops below freezing temperature, the gel and aggregate will contract and water will be frozen, which results in volume expansion. When the internal pores increase, water

absorption gradually increases and density gradually decreases.

The strength of lime-flyash stabilized materials mainly forms by the space grid structure, the gel and some fibrous or rod-like crystals. The induced stress which results from freezing, is similar to the damage mode under uniaxial compression load, as shown in figure 5(a). And the penetration pressure from thawing is similar to the damage mode under uniaxial tension load, as shown in figure 5(b).



(a) (b)

Fig5. The Damage Mode of the Semi-rigid Material on the Effect of the Frost Thawing

With the increase of age, the pozzolanic reaction is further developed, which results in the structure mentioned above. Therefore, the strength and frost resistance of lime-flyash stabilized material continues to increase. For lime and fly ash stabilized mixture, frost resistance will be improved as the early strength increases.

5. Conclusions

This research established a freeze-thaw test method simulating the in-service condition of the lime-fly ash stabilized base course. Experiment was conducted using this method. By analyzing the test results, the frost resistance index was defined and adopted as an indicator of the mixture's frost resistance capacity. The relationship among water absorption, density and frost resistance index was discussed as well.

ABSTRACT

In this paper, a computer-aided method is applied to the detection of horizontal and vertical alignment error during highway construction. The design criterion of highway centerline point corresponding to the detection point of highway midline is put forward. The step-swinging compression method is used to find the corresponding design centerline point. Based on this criterion and the step-swinging approach compression method, highway plane alignment deviation could be divided into transverse deviation and longitudinal deviation along the route. Both the encoding of the types of highway curve and the interval discrimination of the curve of plane alignment are discussed in the step-swinging approach compression method and computer aided calculation of highway plane alignment. Based on these studies, the computer-aided error detection of horizontal and vertical alignment in highway construction is established and used in the project Highway Survey and Design Software Development Integrated in Hunan Province China. Software examples and other examples provided in this paper show that this method is feasible.

Keywords: Road engineering, highway detection, horizontal and vertical alignment error during highway construction, the step-swinging approach compression method

INTRODUCTION

In recent years, relevant foreign literature has focused on existing selected flat vertical alignment optimizing fitting model, flat vertical alignment computer-aided calculation (CAD) (M.Easa, 1999), using GPS system for highway alignment detection (Thomas G. Davis., 1999), etc, for the research of highway alignment detection. It is difficult to find relevant research literature of highway alignment detection for domestic highways (Shao Weihan and Chris Rizos., 1999). The detection of horizontal and vertical alignment error during highway construction is not only important in highway alignment detection, but also important in highway construction quality detection. The usual practice is: detecting highway construction plane and elevation measurements; checking centerline milestones in accordance with the related linear design parameters of the highway plane and longitudinal alignment; calculating the deviation of plane and longitudinal alignment for each centerline milestone to calculate the standard deviation through the statistical

analysis, which then can be used as the precision index for measuring highway flat vertical line construction (WAN Wen-rui. 2002). The above detecting method of solving deviation of plane and longitudinal alignment can't solve the key problem of assessing the deviation of plane alignment (M.Easa , 1999).

THE PROCESS OF COMPUTER-AIDED HORIZONTAL AND VERTICAL ALIGNMENT ERROR DETECTION DURING HIGHWAY CONSTRUCTION

Computer-aided horizontal and vertical alignment error detection during highway construction can be carried out according to the following process:

(1) Detect the control point of the existing highway construction and control network to ensure that the control points of the plane and elevation measurement are accurate and reliable.

(2) Sample at the scene of highway pile-middle lofting $l_i^{'}$, get the coordinate of detection point of the highway midline (x_i, y_i, $H_i^{'}$, $l_i^{'}$).

(3) Search for the milestone (l_i) which has the shortest horizontal distance from the detection point of highway midline by the coordinates of the detection point of the highway midline (x_i, y_i, $H_i^{'}$, $l_i^{'}$) on the platform of detection software with the step-swinging approach compression method, and then calculate the design coordinates of horizontal and vertical alignment (X_i, Y_i, H_i, l_i).

(4) Calculate the horizontal deviation of the horizontal alignment (d_i), the azimuth angle of horizontal deviation (α_{di}), vertical deviation (Δl_i), the deviation between design line and completion line or construction line on the vertical section (ΔH_i). The formulae are as follows:

$$d_i = \sqrt{(x_i - X_i)^2 + (y_i - Y_i)^2}$$

$$\alpha_{d_i} = Arc\sin((x_i - X_i)/\sqrt{(x_i - X_i)^2 + (y_i - Y_i)^2})$$

$$\Delta l_i = l_i^{'} - l_i$$

$$\Delta H_i = H_i - H_i^{'} + \Delta h_i, \qquad i = 1,2,3,...,n$$

Where Δh_i is the difference of height between highway midline point and roadbed design elevation , which can be used to correct ΔH_i.

(5) Grant d_i, Δl_i, ΔH_i for deviation statistics according to the highway construction contract section, and ignore the affect of the errors of elevation control points and the three-dimensional detection to the construction deviation. Thus there may be a reflection of the centerline of highway contract tenders lofting plane and elevation accuracy of the standard deviation σ_j, σ_H:

$$\sigma_{dj} = \pm\frac{1}{\sqrt{N}}\sqrt{\sum_{i_0}^{i_n} d_i^{\,2}}\ ;\quad \sigma_{\Delta lj} = \pm\frac{1}{\sqrt{N}}\sqrt{\sum_{i_0}^{i_n} \Delta l_i^{\,2}}\ ;$$

$$\sigma_j = \pm\sqrt{\sigma_{dj}^{\,2} + \sigma_{\Delta lj}^{\,2}}\ ;\quad \sigma_{Hj} = \pm\frac{1}{\sqrt{N}}\sqrt{\sum_{i_0}^{i_n} \Delta H_i^{\,2}}\ ,\quad j = 1,2,3,...,N$$

Where i_0, i_n are from the middle initial contract tenders of the highway to termination points of the serial number of points in the section j.

(6) Count σ_j, σ_{Hj} of each contract section by weighted statistics using the length of the contract section during highway construction (D_j), and then get the accuracy of the road lofting plane and elevation of the whole highway midline (σ, σ_H):

$$\sigma = \pm\sqrt{(\sum_{j=1}^{N} D_j \sigma_j^{\,2}) / \sum_{j=1}^{N} D_j}\ ; \qquad \sigma_H = \pm\sqrt{(\sum_{j=1}^{N} D_j \sigma_{Hj}^{\,2}) / \sum_{j=1}^{N} D_j}$$

CONFIRMATION OF THE DESIGN MIDLINE POINT AND CORRELATIVE ALGORITHM

We can get the coordinates of the detection point of the highway midline (x_i, y_i, $H_i^{'}$, $l_i^{'}$), (i=1, 2,…, n) by detecting the on-scene samples. The corresponding coordinates of the highway design centerline point (X_i, Y_i, H_i, l_i) can be searched and confirmed by a certain algorithm on the three-dimensional coordinate software platform of highway horizontal and vertical alignment.

A. Determination criterion of design midline point

It appears easy to observe measurement error due to the impact of construction when the highway is completed or under construction. In addition, the actual design line of roads failed to fit the highway midline entirely. It comes to bias. Therefore, the sample testing from the scene by the middle of the highway coordinates (x_i, y_i, $H_i^{'}$, $l_i^{'}$), can not directly be obtained from the corresponding point of the centerline highway design route mark of mile l_i and (X_i, Y_i, H_i, l_i) coordinates, thus it is not possible to calculate the deviation of the centerline, as well as to inform (X_i, Y_i, H_i, l_i) the construction lofting precision.

As shown in Figure 1, the horizontal alignment deviations $\sqrt{d_i^{\,2} + \Delta l_i^{\,2}}$ can be decomposed into a line perpendicular direction of the deviation along the horizontal line d_i and the direction of vertical deviation Δl_i. From the $\sqrt{d_i^{\,2} + \Delta l_i^{\,2}}$, d_i and Δl_i constitute three differential right triangles, we can see the highway centerline and the corresponding point of the design of the highway centerline connection point d_i (horizontal deviation) in the middle lane highway design point of the middle line. Thus, d_i compares with the same road midline of the corresponding point and non-point design of the centerline of Highway Connection $d_i^{'}$, it makes:

$$d_i = \min$$

Therefore, d_i =min is a criterion for detect point of the centerline with the corresponding point of highway design. With highway centerline of highway design with the corresponding point midline point criterion, a theoretical basis is established when the design of the centerline on a highway mark of mile points plane coordinate and automatically searching.

Figure1. Graphic of the deviation of highway's plane line

B. Principle of the step-swinging approach compression method

Swing by step approach compression method and the centerline of highway correspondence highway design midline point mark of mile plane coordinate and the principles are as follows:

A highway centerline of point $J_i(x_i, y_i)$, corresponds to the search mark of mile l highway design point of the centerline $Z_l(X_l, Y_l)$. (X_l, Y_l) can be calculated from the horizontal alignment obtained mark of mile l. Let searching mark of mile l be l_0, search for the pile step away from ΔS (> 0), and $l = l_0 + \Delta S$.

The horizontal alignment error can be calculated as follows:

$$d_{l_0-J_i} = \sqrt{(X_{l_0} - x_i)^2 + (Y_{l_0} - y_i)^2}\ ; d_{l-J_i} = \sqrt{(X_l - x_i)^2 + (Y_l - y_i)^2}$$

$$\Delta d = d_{l-J_i} - d_{l_0-J_i}$$

If $\Delta d = d_{l-J_i} - d_{l_0-J_i} < 0$ that $d_{l-J_i} < d_{l_0-J_i}$, assume that $l = l + \Delta S$. Continue to iterative approach, the cycle of $\Delta d = d_{(l+\Delta S)-J_i} - d_{l-J_i}$, till $d_{(l+\Delta S)-J_i} > d_{l-J_i}$, d_{l-J_i} and l as a second stage iterative cycle of the initial relative value;

Here, $l = l - 0.1\Delta S$ (step reduced to 0.1ΔS, and reverse search), $\Delta d = d_{(l-0.1\Delta S)-J_i} - d_{l-J_i}$

If $\Delta d = d_{(l-0.1\Delta S)-J_i} - d_{l-J_i} < 0$, suppose that $l = l - 0.1\Delta S$, Continue to iterative approach, the cycle of $\Delta d = d_{(l-0.1\Delta S)-J_i} - d_{l-J_i}$, until $d_{(l-0.1\Delta S)-J_i} > d_{l-J_i}$, d_{l-J_i} and l as the third stage iterative cycle of the initial relative value;

Let $l = l + 0.01\Delta S$ (step reduced to 0.01ΔS, and reverse search), and the steps are similar to the cycle of iterative calculation above.

Step-final stage of search for one millimeter, and with one more step on the opposite direction of the search, cycle iterative approach till $d_{(l\pm 0.001)-J_i} > d_{l-J_i}$, and d_{l-J_i} =min.

Let $d_i = d_{l-J_i}$, which is the distance between the highway centerline as the detection point $J_i(x_i, y_i)$ and point $Z_{li}(X_i, Y_i)$ highway design centerline of horizontal alignment error. Corresponding highway design centerline point mark of mile $l_i = l$, highway design plane coordinate $(X_i, Y_i) = Z_l(X_l, Y_l)$ centerline point. α_{di} can be obtained by coordinating reverse calculation.

EXAMPLES

This paper uses highway construction deviation of computer-aided detection method for calculating the highway construction of horizontal and vertical alignment error. The methods are feasible in two situations. One is algorithm-curve in a variety of types and another is various types of embankment design elevation of superelevation rotational pattern under all circumstances. Table 1, Table 2, and Table 3 took "Highway integrated setting software"--vertical and horizontal alignment deviation of relevant as an example.

CONCLUSIONS

A. This paper proposes a criterion of centerline point design, that's d_i =min, and the step-swinging approach compression method in which the highway horizontal alignment deviation is divided into transverse deviation and longitudinal deviation along the route.

B. The vertical alignment deviation ΔH_i should be amended in highway construction automatic calculation according to the different types of roadbed design elevation, the super-elevation rotational pattern and stages.

C. The method of computer-aided error detection of horizontal and vertical alignment in highway construction based on the step-swinging approach compression and the criterion d_i =min was successfully adopted in the project Highway Survey and Design Software Development Integrated in Hunan Province China. Software examples and other examples provided in this paper show that this method is feasible.

ABSTRACT

After discussion about definition and constitution and properties of fitting normal error, one new method is put forward, that suggests the fitting normal error represents the error of fitting the horizontal alignment in old-highway. In addition, the accuracy indexes of fitting horizontal alignment in old-highway based on fitting normal error is established. The algorithms of swinging approach on compressible size step can be used to calculate the fitting normal error. From the way and basic norm of decision about fitting normal error' sign discussed, It is practicable that the quantity of fitting the horizontal alignment in old-highway is controlled by the accuracy index of fitting the horizontal alignment in field and interior work. Finally, an example of estimate for accuracy of fitting horizontal alignment in reform design of the State Highway G321 is offered.

Keywords: Fitting horizontal alignment in old-highway, Fitting normal error, Fitting accuracy, Algorithm of swinging approach on compressible size step

INTRODUCTION

It is very common to redesign and reform old-highways through measuring the horizontal and vertical section lines (Chen et al. 2005; Thomas et al.1999). They also need fitting. Furthermore, the vertical section lines are on the basic of the horizontal alignment. From redesigning and reform old-highway horizontal alignment angle, work of horizontal alignment has more load and higher level skill demand, which makes the horizontal alignment be the key of fitting the horizontal alignment in old-highway (Liu Su 2004). In recent decade years, researches on the horizontal alignment in old-highway, such as at home and abroad, are not much on the discussion about the fitting accuracy (Easa.1999; Muthusubramanyam.2003; Shao et al.1999; Steve Lam et al. 2003), but more about the algorithm of the computer auto fitting normal error (China Ministry of Communications 1999). There is a fitting error in the comparison between the fitting horizontal alignment function

and the original horizontal alignment in old-highway, caused by the effect of the measure error, crossing line point of intersection operational error and curve element configure error, which affects the quality of the fitting plan lines in old-highway (Survey Adjustment Group in School of Geodesy and Geomatics of Wuhan University 2003). So it's necessary to make a reach on the fitting normal error of the horizontal alignment and fitting accuracy in the old-highway reform plan and on the criterion of corresponding technology, too (He Yi 1998). The method of accuracy of fitting horizontal alignment in old-highway is discussed with the example of fitting the horizontal alignment in the redesigning and reform of the State Highway G321 based on the fitting accuracy of the horizontal alignment in this paper.

FITTING NORMAL ERROR OF PLANE LINE IN OLD-HIGHWAY

A. The definition of fitting normal error of the horizontal alignment in old-highway

According to an interval, which is from the end-point i-1th of horizontal curve to the end-point i^{th} of horizontal curve, it is divided into N parts. Supposed that the function of i^{th} section fitting the horizontal alignment of old-highway as follows:

$$F_i = \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} f_{xi}(l, R_i, Ls_{i1}, Ls_{i2}) \\ f_{yi}(l, R_i, Ls_{i1}, Ls_{i2}) \end{pmatrix} (i = 1,2,...,N) \quad (1)$$

Where, x and y are in the coordinates of one point on this horizontal alignment (including the straight line and horizontal curve), l is the mark of mile, R_i is the radius of curve, Ls_{i1} and Ls_{i2} are the length of the first and second transition curve respectively.

One section of plane of road is divided into two equal parts by a midline, in which number of points is n_1. Based on the control of the high grate plane, the coordinate of fitting reference point by measuring divided point will be calculated as follows:

$$(X_k, Y_k) \quad (k = 1,2,...n_i)$$

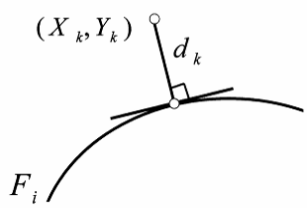

Figure 1 Diagrammatic sketch of fitting normal error

Seek the function of shortest distance to the fitting horizontal alignment in Fig.1:

$$d_k \quad (k = 1,2,..., n_i)$$

Where d_k is on the direction of the centerline normal of interpreter point to the fitting centerline, and d_k is regarded as the fitting normal error from point (X_k, Y_k) to the

curve (see Fig 1). The fitting normal error of the horizontal alignment d is the token of the fitting error.

B. **The structure and the property of the fitting normal error of the plane line in old-highway**

Supposed that the fitting normal error of the horizontal alignment d in old-highway is formed by sum of Δ_p, ε_1 and ε_2 where Δ_p represented the fitting error of the controlling point; ε_1 represented the fitting error of the crossing line, and ε_2 is the curve fitting error. Namely,

$$d = \Delta_p + \varepsilon_1 + \varepsilon_2 \tag{2}$$

Δ_p is caused by three factors, such as accident error, measuring error of old-highway constructing period, the error of equal divisions made in reform design period and the measuring error of the coordinate. ε_1 is the fitting system error, which is caused by the system warp for point of intersection of beeline threading . Where ε_2 is the fitting system error, caused by ΔR, ΔLs the stating system error of curve radius R and the length of transition curve.

The fitting criterion of the method of least square shall be satisfied in the fitting horizontal alignment in old-highway, as

$$\sum_{k=1}^{n_i} d_k^2 = \min \tag{3}$$

And the one fitting it is called unbiased fit, that is,

$$E(d) = E(\Delta_p) + E(\varepsilon_1) + E(\varepsilon_2) = 0 \tag{4}$$

Since Δ_p is an accident error, so it can be concluded that $E(\Delta_p) = 0$, that is $E(\varepsilon_1) + E(\varepsilon_2) = 0$ can be concluded from (4). If $\varepsilon_1 = \varepsilon_2 = 0$, the fitting horizontal alignment in old-highway will satisfy the fitting criterion of method of least square (3), which is an unbiased fit. On the contrary, if $\varepsilon_1 + \varepsilon_2 \neq 0$, then the fitting horizontal alignment in old-highway won't satisfy the criterion of method of least square, when it is a biased fit. As a result, Fig.2 shows the biasness and linearity of the straight segment and curve segment fit. The statistical properties of ration of the fitting normal error of the horizontal alignment in old-highway show the fitting quality of the horizontal alignment.

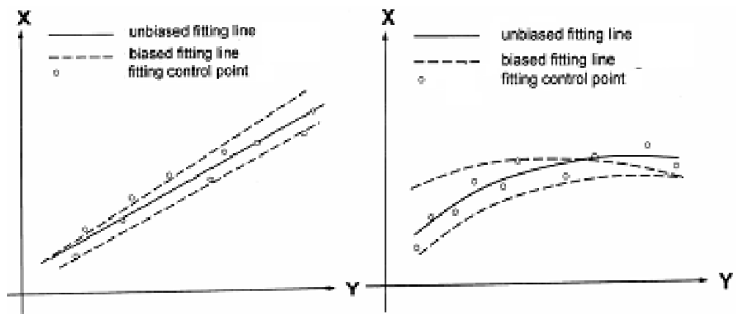

Figure 2 Diagrammatic sketch of fitting straight line and curve

The fitting normal error d is affected by the fitting accident error and the leading fitting system error.

Δ_p comes from the fitting field work, while ε_1 and ε_2 come from the fitting interior work. As usual, the fitting field works contents two major subjects. One is the fitting reference point conformed by the equal divided highway. Another is the measure of fitting reference point coordinate. In order to conform the equal divided highway error of the fitting, it is necessary to make reference point becomes the major point to decide the value of Δ_p, and it is based on premise that measuring error in the old-highway construct period and the measuring error of fitting control coordinate during the redesigning and reform period satisfy enough accuracy. There are two major works during interior work of fitting horizontal alignment, which are the threading point of intersection and state curve elements (curve radius, transition curve). ε_1 and ε_2 are the major errors which cause the biasness of the fitting normal error *d*. If Δ_p satisfies enough accuracy, the magnitudes and signs of ε_1 and ε_2 decide the magnitude and direction of d and it's systematic rather than random.

C. Arithmetic of *d* the fitting normal error of the horizontal alignment in old-highway

Arithmetic of computing *d* is the key to the arithmetic of the fitting index of horizontal alignment in old-highway. Considering constrains above, the paper put forward the algorithm of swinging approach on compressible size step is used to get solve:

Let (X_k, Y_k) $(k = 1,2,...,n_i)$ be the fitting reference point coordinate of the horizontal alignment in old-highway i^{th} section, corresponds to (x_l, y_l) coordinate of point in the midline in the fitting horizontal alignment function F_i of searching mark l. And point (x_l, y_l) can be obtained by calculating of the fitting horizontal alignment coordinate function (Liu Su 2004). If the original number of the searching mark l is l_0 and the searching length is the distance ΔS (>0), and $l = l_0 + \Delta S$, also, then there will be an error from fitting reference point (X_k, Y_k) to the midline point of the fitting function (x_{l_0}, y_{l_0}) and (x_l, y_l) as follows;

$$d_{l_0-k} = \sqrt{(x_{l_0} - X_k)^2 + (y_{l_0} - Y_k)^2} \; ; \; d_{l-k} = \sqrt{(x_l - X_k)^2 + (y_l - Y_k)^2}$$

And the difference of biasness likes this: $\Delta d = d_{l-k} - d_{l_0-k}$

If Δd <0, then $d_{l-k} < d_{l_0-k}$, and if $l = l + \Delta S$ and $\Delta d = d_{(l+\Delta S)-k} - d_{l-k}$ is kept iterative approach to calculate circularly, till $d_{(l+\Delta S)-k} > d_{l-k}$, d_{l-k} and l are taken as the second comparative original number of iterative circle calculate and $l = l - 0.1\Delta S$ is assumed (the length is reduced to $0.1\Delta S$ with reverse searching), $\Delta d = d_{(l-0.1\Delta S)-k} - d_{l-k}$ will be solved.

If Δd <0, $l = l - 0.1\Delta S$ and is kept iterative to

calculate $\Delta d = d_{(l-0.1\Delta S)-k} - d_{l-k}$ repeatedly, till $d_{(l-0.1\Delta S)-k} > d_{l-k}$, d_{l-k} and l are taken as the third comparative original number of iterative circle calculate and $l = l + 0.01\Delta S$ is assumed (the length is reduced to $0.1\Delta S$ with reverse searching), and the same steps continued……

The length of last part is 1mm, opposing to the last step and iterative circularly till $d_{(l\pm 0.001)-k} > d_{l-k}, d_{l-k} = \min$ will be obtained.

$d_k = d_{l-k}$ is taken as fitting normal error of horizontal alignment in old-highway , and it is caused by the departure of the fitting reference point (X_k, Y_k) ($k = 1,2,...,n_i$).The responding mile mark of the fitting horizontal alignment in old-highway is l, and the plane coordinate is (x_l, y_l) .

D.* Judgment of sign to fitting normal error *d

Since the increasing direction of fitting midline mark regarded as the progress direction, the distance which fitting reference point departure around the midline is the determinant benchmark of the sign of the normal error d. In order to facilitate judge the sign of fitting normal error, the right is positive, to the left is negative. To confirm the sign of d needs to calculate the coordinate azimuth angle α_d that from (x_l, y_l) , the respond fitting midline point to the fitting reference point, then compares it with the tangent azimuth angle of the fitting midline point (x_l, y_l) in this horizontal alignment segment. Table 1 shows the Correlate data about some normal errors of N42 fitting horizontal alignment in one partition of State Highway G321.

Table 1 Correlate data about some normal errors of N42 fitting horizontal alignment in one partition of State Highway G321

Channel mark	Tangent azimuth angle	Normal azimuth angle	Normal error
191676	323°48′	53°48′	-0.269
191696	323°46′	53°46′	-0.34
191716	323°38′	53°38′	-0.365
191736	322°05′	52°05′	-0.278
191756	318°46′	48°46′	-0.204
191776	316°07′	226°07′	0.081
191796	311°18′	221°18′	0.237

191836	303°25′	213°25′	0.101

THE FITTING ACCURACY INDEX AND CONTROL OF THE HORIZONTAL ALIGNMENT IN OLD-HIGHWAY

According to the structure and quality of the fitting normal error of the horizontal alignment in old-highway, the accuracy index- mean-square deviation, which can show the affect degree of the accident error and system error, shall be taken to measure the fitting quality of the horizontal alignment.

Considered the maneuverability, the mean-square deviation shall be replaced

by formal approximation of estimative error in fitting as the fitting accuracy index of the horizontal alignment.

If d_k ($k = 1,2,...,n_i$), the fitting normal error of the plane line i is taken, there will be a fitting accuracy index of the plane line *i* as follows:

$$m_i = \sqrt{\sum_{k=1}^{n_i} d_k d_k \Big/ n_i} \quad (i = 1,2,...,N) \tag{5}$$

The fitting accuracy index of the horizontal alignment in old-highway like this:

$$m = \sqrt{(\sum_{k=1}^{n_1} d_k d_k + \sum_{k=1}^{n_2} d_k d_k + ... + \sum_{k=1}^{n_N} d_k d_k) \Big/ (n_1 + n_2 + ... + n_N)} = \sqrt{\sum_{i=1}^{N} n_i \cdot m_i^2 \Big/ \sum_{i=1}^{N} n_i} \tag{6}$$

THE EXAMLLE OF THE ACCURACY EVALUATION OF FITTING HORIZONTAL ALIGNMENT IN ONE SEGMENT OF G321

One project in one partition of State Highway G321 is a technology reform basing on the original second highway with whole length of 120 km. It is right to recover the horizontal alignment in old-highway, the 1st class plane control lead based on state coordinate system to equal divide the old-highway and measure the coordinate, because the horizontal alignment in old-highway is complex and the design data about the original line is not compete. So it is quite important to separating of the horizontal alignment in old-highway during threading point of intersection and using line software, such as AutoCAD. In order to get generalized results, the paper chooses total 67 partitions from K170+000 to K207+309.55 in the old partition, divided by interval, which is from the *i*-1th end-point of horizontal curve to the i^{th} end-point of horizontal curve. And the fitting accuracy of the horizontal alignment of every segment is obtained, on the base of the fitting normal error of 18000 calculated fitting reference points. As a result, Fig.3 is a chart of accuracy distribution of fitting horizontal alignment in one partition of every partition .If the fitting accuracy limited error is 0.500m,then the 24th, 27th, 33rd, 34th, 35th, 40th fitting accuracy of horizontal alignment are lower in the Chart, which is 0.748m; 1.273m; 1.987m; 1.061m; 1.797m; 0.743m.The fitting accuracy of the horizontal alignment in old-highway from K170+000 to K207+309.55 will be 0.190m, which will satisfy the fitting accuracy limited error after refitting the six horizontal alignment and correcting . Fig.4 is a chart of accuracy distribution of fitting horizontal alignment after correction.

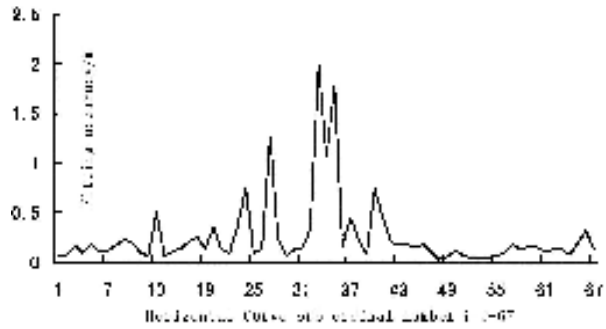

Figure 3 Chart of accuracy distribution of fitting plane linear in one partition of State Highway G321

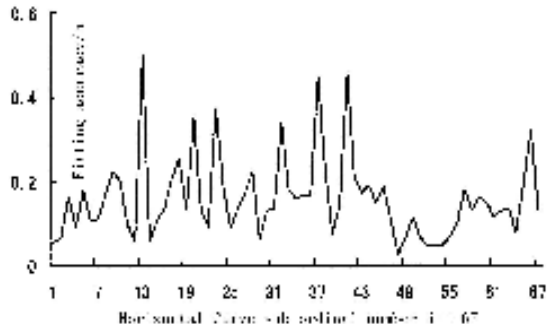

Figure 4 Chart of accuracy distribution of fitting plane linear after correction

CONCLUSIONS

The fitting error of horizontal alignment in old-highway can be signaled by the fitting normal error of horizontal alignment. Furthermore, the normal error is caused by three factors, such as accident error, measuring error of old-highway constructing period, the error of equal divisions made in reform design period and the measuring error of the coordinate formed, which are the result of the effect of accident error and system error. The fitting normal error of horizontal alignment in old-highway can be got from the computer, and algorithm of swinging approach on compressible size step. Finally, judgment of sign of fitting normal error can be got by comparing the fitting azimuthally angle and king pile tangent to confirm the deflection of the normal. Since increasing direction of fitting midline is mark of highway, turning to left is positive, while turning to right negative.

In addition, the accuracy index can be used to show the fitting quality of the pale lines in old-highway. According on the fact that the fitting accuracy index of the partition horizontal alignment can reflect the fitting quality of the horizontal alignment of partition in old-highway; the fitting accuracy index of the horizontal alignment in whole old-highway can reflect the fitting whole quality of the horizontal alignment in the old-highway basing on the fitting accuracy of the partition horizontal alignment

Furthermore, the fitting quality of the horizontal alignment in old-highway can be controlled in field and interior. The example of accuracy estimation of fitting horizontal alignment in one partition of State Highway G321 can prove that the estimated method of fitting accuracy of the horizontal alignment in old-highway, which bases on the normal error, works. The study about the limited error of the fitting horizontal alignment in old-highway and the related technology criterion still has a long way to go.

Abstract: Effects of the layer interface condition on fatigue behavior of asphalt pavements with semi-rigid bases were evaluated in this study by means of viscoelastic three-dimensional finite element analyses. The Coulomb friction model was adopted to simulate the behavior of the layer interface. Effects of the position of the frictional interface, temperature, and friction coefficient were investigated. The results show that fatigue cracking is unlikely to occur in AC layers for a properly designed asphalt pavement with semi-rigid bases if all layer interfaces are fully bonded. A frictional interface can result in large horizontal tensile stress at the bottom of the AC layer that forms the interface. Depending on the position of the frictional interface, fatigue cracking may initiate at the bottom of HMA or at the bottom of an intermediate AC layer. With the increase of the Coulomb friction coefficient, the tensile stress at the bottom of the corresponding AC layer can be significantly reduced, especially at high temperatures.

Keywords: viscoelasticity; three-dimensional finite element method; Coulomb friction model; fatigue cracking; friction coefficient.

1. Introduction

Fatigue cracking has long been recognized as one of the major distress types of asphalt pavements. In China, semi-rigid materials (e.g., cement treated or lime-flyash treated aggregates) are widely used as base materials for asphalt pavements. Semi-rigid bases possess high elastic modulus values and provide a good load carrying capacity to the pavement structure. Thus, tensile stress and tensile strain at the bottom of the asphalt concrete (AC) layer can be efficiently reduced, which results in less fatigue cracking. However, severer fatigue cracking in AC layers is still observed in some asphalt pavements with semi-rigid bases. The reason for the occurrence of AC fatigue cracking could be that fatigue cracking first takes place in semi-rigid bases under repeated traffic loading, reducing the semi-rigid bases to materials like granular bases, which leads to large tensile stress and strain at the bottom of the AC layer and subsequently fatigue cracking in AC layers develops. Studies have shown interlayer conditions have significant influences on asphalt pavement responses (Romanoschi et al. 2001; AlHakim 2002). Filed experiences also suggest that poor interlayer conditions may play an important role in the fatigue cracking of asphalt pavements with semi-rigid bases. It is the purpose of this paper to investigate this issue by performing mechanistic analysis of relevant pavement responses. Traditionally, asphalt pavement responses are analyzed using linear-elastic layered theory, which may not be capable of reflecting the real behavior of asphalt pavements since asphalt concretes are typical viscoelastic materials. In this study, effects of interlayer conditions on the fatigue behavior of asphalt pavements are investigated by conducting three dimensional (3D) finite element (FE) analyses in which asphalt concretes are

modeled as viscoelastic materials.

2. Finite element model and material properties

A typical asphalt pavement with a semi-rigid base, as illustrated in Figure 1, was selected for analysis in this study. Asphalt concretes were treated as viscoelastic materials while the semi-rigid base, granular base, and subgrade were treated as linear elastic materials whose elastic moduli and Poisson's ratios are listed in Figure 1. According to Boltzmann superposition principle, a viscoelastic material has the following constitutive relationship:

$$\sigma(\xi) = \int_0^{\xi} E(\xi - \tau) \frac{\partial \varepsilon}{\partial \tau} d\tau \qquad (1)$$

where σ and ε are stress and strain respectively, E is the relaxation modulus of the viscoelastic material, τ is integral variable, and ξ is reduced time. The following relationship exists between reduced time ξ and physical time t:

$$\xi = \int_0^t \frac{dt}{\alpha_T} \qquad (2)$$

where α_T is time-temperature shift factor. Time-temperature shift factors reflect the effects of temperature on a material's mechanical properties. Once the time-temperature shift factors are known, the mechanical properties of asphalt mixtures at various temperatures can be determined from those at the reference temperature. As can be seen from equation 1, the relaxation modulus is the basic parameter to characterize the viscoelastic material's mechanical property. However, determination of the relaxation modulus directly from laboratory testing requires complex operations and expensive equipment and often involve large errors. In this study, the viscoelastic properties of asphalt mixtures were obtained by conducting complex modulus tests at various conditions and then converting the complex modulus results to relaxation moduli. Complex modulus tests of SMA13, Superpave20, and Superpave25 were performed at five temperatures (4, 15, 25, 40 and 50℃). At each temperature, complex moduli were determined at seven frequencies (25, 20, 10, 5, 1, 0.5 and 0.1Hz). Details about the complex modulus tests and results were documented elsewhere (Zhao et al. 2006). Interconversion from the complex modulus to the relaxation modulus is based on theoretical formulations presented by Schapery (Schapery et al. 1999). Details on the numerical analyses of Interconversion and results can be found elsewhere (Zhao et al. 2007). The resulting relaxation moduli are represented using the Prony series as follows:

$$E(t) = E_{\infty} + \sum_{m=1}^{M} E_m \exp(-t/\rho_m) \qquad (3)$$

where ρ_m is relaxation time, $\rho_m = \frac{\eta_m}{E_m}$; E_{∞} and E_m are spring moduli, and η_m is the viscosity of the dashpot. The parameters of the Prony series and time-temperature shift factors at a reference temperature of 25℃ for various asphalt mixtures are presented in Table 1 and Figure 2 respectively (Zhao et al. 2006, 2007).

SMA13	4.0cm	Viscoelastic	μ =0.3
Superpave20	6.0cm	Viscoelastic	μ =0.3
Superpave25	8.0cm	Viscoelastic	μ =0.3
Semi-rigid base	40.0cm	E= 2000 MPa	μ =0.25
Granular subbase	20.0cm	E = 250 MPa	μ =0.35
Subgrade	E= 60 MPa	μ =0.4	

Figure 1 Asphalt pavement structure

A dual-tire assembly with a center-to-center distance of 32cm was used in this study. Each tire has a contact area of 18.9 ×18.9cm^2. The intensity of the load is assumed to vary with time according to a haversine function as follows (Huang 1993):

$$L(t) = q\sin^2(\frac{\pi}{2} + \frac{\pi \times t}{d}) \qquad (4)$$

where d is the duration of load and q is the amplitude of load. In this study, a haversine load with a duration of 0.1s and a peak load of 0.7MPa was adopted to simulate the applied traffic loading. The commercial software ABAQUS was used to create a three-dimensional finite element model for the pavement, as shown in Figure 1, and relevant user subroutines were developed for analyses. Due to the double symmetry of geometry, boundary conditions, and load configuration about the x and y axes, only a quarter model was analyzed. The dimensions of the FE model were 3.0m×3.0m×5.0m in the X, Y and Z directions respectively. Eight-node linear brick elements with reduced integration were selected to discrete the model and the resultant mesh contains 24,098 elements and 26,208 nodes. In addition to the symmetric boundary conditions, roller support and fixed support were adopted on vertical boundaries and the bottom of the model, respectively. Such boundary conditions have been successfully used by Zaghloul et al. (1993) and Kuo et al. (1995).

Two interlayer condition models, the Coulomb friction model and elastic stick model, are commonly used in pavement analysis. Yoo et al. (2006) compared pavement responses calculated using the two models and measured field responses. The results did not show the superiority of one model over the other. Thus the Coulomb friction model was used in this study for its simplicity. The Coulomb friction model assumes no relative motion occurs between the surfaces defining the interface if shear stress is less than the critical stress, $\tau_{\max}$, which is proportional to the normal pressure at the interface as presented in equation 5:

$$\tau_{\max} = \mu p \qquad (5)$$

where p is the normal stress at the interface and μ is the friction coefficient. In this study, a wide array of friction coefficients ranging from 0.0 to 1.0 with an interval of 0.2 were used to evaluate the effects of different layer interface conditions.

3. Analysis results and discussion

Horizontal tensile stresses at the bottom of the AC layers, which are the critical responses for fatigue cracking in China's asphalt pavement design method, were calculated at three different temperatures (10, 25 and 40℃). At each temperature, analyses were performed for four different cases of layer interface conditions as shown below:

- Case 1: All layer interfaces were fully bonded.
- Case 2: The Coulomb friction model was adopted at the SMA13-Superpave20 interface and other interfaces were fully bonded.
- Case 3: The Coulomb friction model was adopted at the Superpave20-Superpave25 interface and other interfaces were fully bonded.

- Case 4: The Coulomb friction model was adopted at the Superpave25-base interface and other interfaces were fully bonded.

If the Coulomb friction model was used for a layer interface, responses were calculated at various friction coefficients (0.0, 0.2, 0.4, 0.6, 0.8 and 1.0). Results obtained from Case 1 formed the basis for comparisons. Figure 3 shows the variations of horizontal tensile stresses with loading time at the bottom of the Superpave25 layer for Case 1. Positive and negative values indicate tensile and compressive stresses respectively. To illustrate the effectiveness of the semi-rigid base in reducing fatigue cracking, results were obtained by replacing the semi-rigid base in Figure 1 with a granular base (E=300MPa), which can also be regarded as a severely cracked or deteriorated semi-rigid base, are also presented in Figure 3. The semi-rigid base and granular base are respectively labeled as 'SRB' and 'GB' in the figure.

As shown in Figure 3, except for the case of the semi-rigid base at 40℃, tensile stresses developed at the bottom of the Superpave25 layer during loading phase and the tensile stresses gradually changed to compressive stresses during unloading phase. This is due to the fact that the pavement deflects downwards during the loading phase and elastic layers (base, subbase, etc.) tend to rebound to its original shape instantaneously during the unloading phase, while AC layers rebound gradually due to their creep behavior, which causes compressive stress at the bottom of the AC layer (Wang et al. 2006). Figure 3 shows that peak tensile stress occurred before the 0.05s loading time at which peak load took place. Tensile stress is influenced by both the applied load and stress relaxation characteristics of asphalt mixtures. Once the effects of stress relaxation exceed those of the applied load, tensile stress starts to decline, which causes a peak tensile stress time prior to 0.05s. At higher temperatures, the effects of stress relaxation become more evident and thus peak tensile stress happens at an earlier loading time. For example, the peak tensile stress time for the case of the semi-rigid base at 10℃ was 0.0465s and it was advanced to 0.033s at 25℃.

As expected, the use of the semi-rigid base in asphalt pavement greatly reduced the potential of fatigue cracking in AC layers. Compared to asphalt pavement with the granular base, the maximum tensile stresses at the bottom of the Superpave25 layer were reduced by 69% and 91% at 10℃ and 25℃, respectively, when a semi-rigid base was used. The bottom of the Superpave25 layer was even subjected to horizontal compressive stress at 40℃ for the case of the semi-rigid base. The results indicate that for a properly designed asphalt pavement with semi-rigid bases, fatigue cracking is unlikely to occur at the AC layers if the semi-rigid bases are in good condition and all layer interfaces are fully bonded. Following analyses were performed only on the asphalt pavement with semi-rigid bases, as shown in Figure 1.

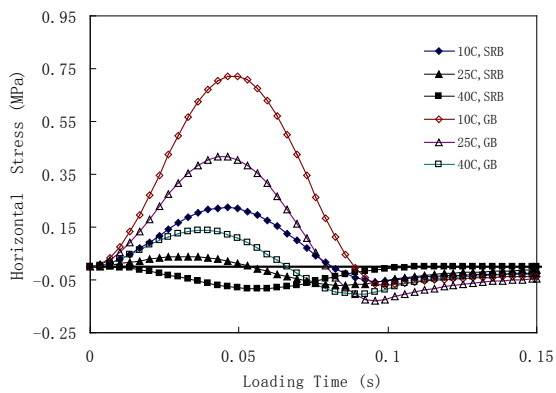

Figure 3. Tensile stresses at the bottom of Superpave25 layer (case 1)

Figures 4, 5, and 6 present the horizontal tensile stresses at the bottom of the Superpave25 layer for various interface condition cases and temperatures. Only the results calculated using a friction coefficient of 0.6 are presented in these figures. As shown in these figures, with the use of the friction condition at a layer interface, if the bottom of the Superpave25 layer was subjected to horizontal tensile stress during the loading phase, the horizontal stress gradually changed to compressive stress as time continued, similar to what happened in Case 1. The use of the friction condition at the SMA13-Superpave20 or Superpave20-Superpave25 interface did not adversely affect the tensile stress at the bottom of the Superpave25 layer. Compared to Case 1's results, the tensile stress at the bottom of the Superpave25 layer became less for Case 2's interlayer condition and Case 3's interlayer condition resulted in compressive stress during the loading phase. However, the use of the friction condition at the Superpave25-base interface significantly increased the tensile stress at the bottom of the Superpave25 layer. The tensile stresses increased by 1.9 and 6.1 times for Case 4 compared to Case 1's results at 10 and 25℃, respectively. At 40℃, the horizontal stress varied from compressive stress for Case 1 to tensile stress with a maximum value of 0.12MPa for Case 4.

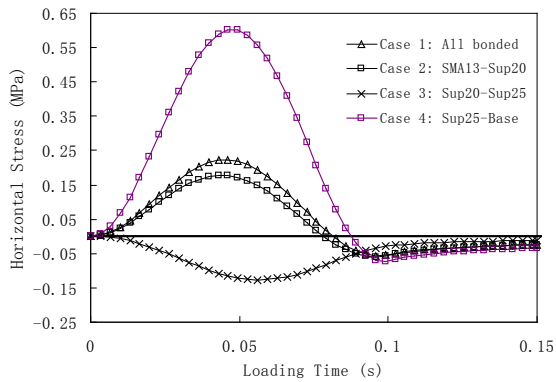

Figure 4. Horizontal stresses at the bottom of Superpave25 layer (10℃, μ=0.6)

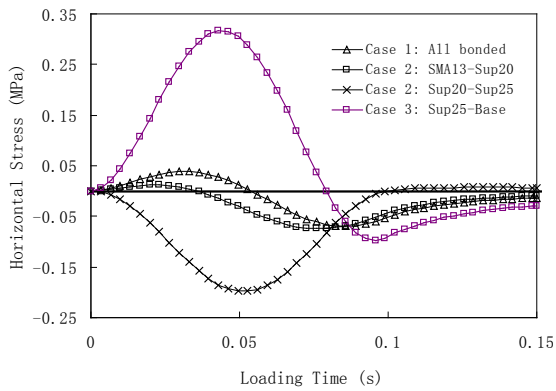

Figure 5. Horizontal stresses at the bottom of Superpave25 layer (25℃, μ=0.6)

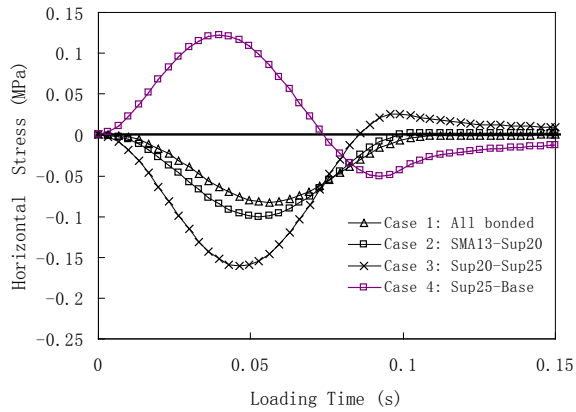

Figure 6. Horizontal stresses at the bottom of Superpave25 layer (40℃, μ =0.6)

Table 1 lists the maximum tensile stresses at the bottom of the Superpave25 layer obtained at various friction coefficients. For comparison purposes, the results from pavements with granular bases and Case 1's interlayer condition are also presented in the table. As shown in Table 1, the variations of the friction coefficient for Case 2 and Case 3's interlayer conditions had little influence on the maximum tensile stress while the maximum tensile stress decreased significantly as the friction coefficient increased for Case 4, especially at high temperatures. For example, the tensile stress decreased by 15.2% as the friction coefficient increased from 0.0 to 1.0 for Case 4 at 40℃. It can be observed from Table 1 that the maximum tensile stresses obtained from Case 4 were close to those obtained from pavements with granular bases and Case 1's interlayer condition. This observation indicates that fatigue cracking could develop at the bottom of HMA in asphalt pavements with semi-rigid bases if the AC-base interface is not fully bonded.

Table 1. Maximum horizontal tensile stress at the bottom of Superpave25 layer (MPa)

Note. C = compressive stress; *tensile stress occurs during unloading phase.

Although a friction model at the SMA13-Superpave20 or Superpave20-Superpave25

interface did not increase the tensile stress at the bottom of the Superpave25 layer, it had an adverse effect on the tensile stress at the bottom of the AC layer which formed the frictional interface, shown in Figures 7 and 8. Figures 7 and 8 respectively presents the horizontal stress at the bottom of the SMA13 layer for Case 2 and at the bottom of the Superpave20 layer for Case 3 with a friction coefficient of 0.6. For comparison purposes, results from Case 1 are also presented in the figures. For Case 1's interface condition, the bottom of the SMA13 or Superpave20 layer was subjected to compressive stress during the loading phase and the compressive stress changed to tensile stress with the inclusion of a friction model at the corresponding interface. The maximum tensile stress at the bottom of the Superpave20 layer reached 0.48, 0.24, and 0.11MPa at 10, 25 and 40℃, respectively. Such large tensile stresses were likely to initiate fatigue cracking at the bottom of the Supepave20 layer.

Tables 2 and 3 list the maximum tensile stresses calculated at different friction coefficients. As shown in these tables, the tensile stress at the bottom of an AC layer was somewhat influenced by the variation of the friction coefficient of the corresponding interface, especially at high temperatures. Analyses of other results indicated that variation of the friction coefficient at one interface had little influence on the tensile stress at the bottom of other AC layers.

4. Conclusions

Base on the results presented, the following conclusions can be drawn regarding the fatigue behavior of asphalt pavements with semi-rigid bases:

- Fatigue cracking is unlikely to occur in AC layers for a properly designed asphalt pavement with semi-rigid bases if the semi-rigid bases are in good condition and all layer interfaces are fully bonded.
- A frictional interface can result in large horizontal tensile stress at the bottom of the corresponding AC layer, and consequently fatigue cracking in the AC layer.
- Depending on the position of the frictional interface, fatigue cracking may initiate at the bottom of HMA or at the bottom of an intermediate AC layer.
- With the increase of the Coulomb friction coefficient, the tensile stress at the bottom of the corresponding AC layer could be significantly reduced, especially at high temperatures. However, the influence of the friction coefficient variation on tensile stress in other AC layers is negligible.

Damage Model Analysis of SBS Modified Asphalt Mixture

Ying Ronghua, Chen Xiao, Wu Ting and Zhang Zhiyong
(School of Traffic and Transportation Engineering, Changsha University of Science & Technology)

Abstract: The visco-elastic models and the damage models, which are coupled to the visco-elastic continuum damage model, are used for analyzing the uniaxial tension tests of the SBS modified asphalt mixture. The fatigue damage characteristics of the SBS modified asphalt mixture and damage effect have been considered in terms of energy and a fatigue damage model. The models and testing results correlate well with each other. The model can predict the fatigue life of the SBS modified asphalt mixture under different tensile strain levels.

Key words: modified asphalt mixture; tension tests; visco-elastic; damage factors; fatigue damage

Research in years suggests that asphalt mixture is a complex thermal rheological material. Its deformation is related to force state, temperature and loading rate. In practical engineering, the suitable temperature range of the asphalt pavement is -25 ~ 75℃. Therefore, it is necessary to understand the stress - strain relations of asphalt mixture at different temperatures. As asphalt pavement undertakes repeated external loading, it is also needed to recognize the fatigue properties of asphalt mixture. Currently, the main theoretical research model of asphalt mixture is the visco-elastic model, which can better reflect the strain rate effect of creep, relaxation and elastic modulus but can not explain the stress relaxation phenomenon. The damage constitutive model that reflects the reduction of effective area through the changing of damage parameters are able to reflect stress - strain curves in the whole process but not the strain-rate effect of material deformation. Previous asphalt mixture fatigue models are mostly regularity formula aimed at specific problems, which are applicable under certain conditions. However, its physical meaning is not clear.

In this study, uniaxial tensile tests of the equal strain rate loading control and strain control fatigue tests with triangular waveform on the SBS modified asphalt mixture are carried out with the electro-hydraulic servo test system of MTS810 at different temperatures. Then the two constitutive models are correlated with the data of uniaxial tensile test to establish a viscoelastic continuum damage constitutive model. According to the fatigue test interpreted with the energy principle, a fatigue damage model considering the tensile strain level is proposed . Because the damage effects of materials are taken into account, the model predictions match well with the experimental results and reflect the stress and strain levels in the SBS modified asphalt mixture.

1 Experimental study

1.1 Experimental materials

The SBS modified asphalt of AH-70 of Caltex is used in the test. The aggregate is a limestone and its mechanical properties are presented in Table 1,. The mineral powder is the limestone powder. The AC-13 gradation recommended in standards is adopted. It is shown in Table 2. The asphalt-aggregate ratio is 5% determined by the Marshall method.

Table 1 Test result of limestone

Crushing value/%	Sturdiness/%	Abrasion value/%	Compressive strength	Adhesion	Absorption/%
18.8	3.0	19.5	Grade 1	Grade 4	≤0.73

1.2 Specimen fabrication

Taking similar conditions between a lab compaction method and the field compaction method as a criterion, wheel-grind compaction is consistent with field condition and is therefore selected as the lab compaction method. After the SBS modified asphalt mixture is compacted using the wheel-grind compaction method, the sample is cut into trabecular specimens by a rock cutting machine. The specimen size is 45 mm × 45 mm × 250 mm (Lv, 2001). In order to eliminate the error in the preparation process, the specimens are processed repeatedly to meet the requirement that the ends of specimens of a total of 30 are horizontal.

Table2 Gradation composition

Gradation type	The percentage passing the following sieve pore/%									
	16.0	13.2	9.5	4.75	2.36	1.18	0.6	0.3	0.15	0.075
AC-13	100	97.5	79	58	44.5	32.5	24.0	17.0	12.0	6.0

1.3 Loading mode

In uniaxial tensile tests it is loaded at four temperatures -15, -5,5, and 15 ℃ under equal strain rate, and the loading rate is ε = 10-31 / s. Each specimen is loaded to the residual strength stage. Three specimens are tested at each temperature. In the uniaxial cyclic loading test, the triangular waveform loading is adopted for the tensile strain levels of 0.30%, 0.40% and 0.45% according to the strain control mode. The test temperature is -5℃, load rate $\dot{\varepsilon}$ = 10-31 / s, and the fatigue criterion is that the strength is decreased to 50% of the initial strength (JTG F40-2004). In order to eliminate the influence of eccentricity, specimens are preloaded at a small stress level and is recovered.

1.4 Testing system

The electro-hydraulic servo test system of MTS810 is used to carry out the experimental study. The load range of MTS810 is ±10 t (± represents tension and compression respectively), and it is automatic in the entire testing process through the computer control. In addition, MTS has a corollary temperature control system-the Tenny environment box with temperature control accuracy of ± 0.1 ℃.

1.5 Data acquisition and processing

Results of this study are acquired by the computer system which is the corollary equipment of MTS loading system with the interval time of 0.1s. Data are transmitted through electrical signals. Because of the effects of impedance and drifting, the collected data often fluctuate around the true values. So the Origin 6.0 filter (FFT) is used to filter collected data to attain the approximate real smooth curve (Figure 1). At higher temperatures, the deformation of SBS modified asphalt mixture is shown as an increasing curve, shown in Figure 1. The creep phenomenon of the material is obvious in Figure 1. At lower temperatures, the deformation of SBS modified asphalt mixture is shown as rising, linear and brittle until fracture of materials happens. It is also discovered that the failure strength decreases when the temperature increases.

Figure 2 shows the peak stress curve related to cycle number under different strains in the uniaxial cyclic loading tests. Shown in Figure 2, the peak stress also increases when the level of strain increases . The fatigue life varies with different strain levels.

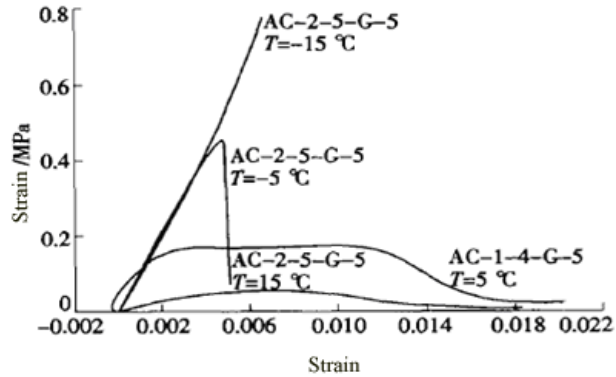

Figure1Stress-strain curves at different temperatures

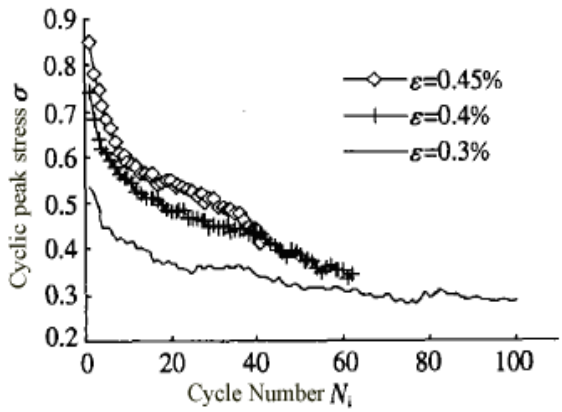

Figure2 Cyclic peak stress curves with cycle number changing

2 Establishment and Analysis of constitutive model

2.1 Establishment of viscoelastic damage constitutive model under uniaxial tension

2.1.1 Visco-elastic constitutive model of asphalt mixture

There are many constitutive models used to describe asphalt mixture by applying visco-elastic constitutive models, which include the Burgers, Kelvin, Maxwell and the generalized Maxwell models. The Maxwell model can be adopted to describe the main features of the viscoelastic creep and relaxation behavior of asphalt mixture. The Maxwell model reflects a viscoelastic fluid model. A large number of tests proved that asphalt mixture is a viscoelastic fluid material. Moreover, the Maxwell model is relatively simple. In this study the Maxwell model is selected to describe the viscoelastic behavior of SBS modified asphalt mixture. The constitutive equations of Maxwell model are as follows (Yang, 1992).

$$\sigma + \frac{\eta}{E}\dot{\sigma} = \eta\dot{\varepsilon} \tag{1}$$

By the Boltzmann superposition principle:

$$\sigma(t) = \varepsilon_0 G(t) + \int_0^t G(t-\xi)\frac{d\varepsilon(\xi)}{d\xi}d\xi \tag{2}$$

Where: G(t)-the relaxation function of the Maxwell model, G(t)=Eexp(-tE/η);when t=0, $\varepsilon_0 = 0$.

2.1.2 Determination of continuum damage factors

Compacted SBS modified asphalt mixture specimens have a lot of internal defects (voids, cracks and crushing). In essence, these micro-defects are discrete. As a simple approximation, in the continuum damage mechanics, all micro-defects are distributed. The impact to material caused by distributed micro-defects is expressed by one or several internal continuous field function of damage variables. The damage and fracture research results about rocks, cement concrete materials show that Weibull distribution is suitable for describing damage and fracture process of such materials, so the Weibull function will be used to describe the distribution of these defects (Yu and Feng, 1997).

$$\phi(\varepsilon) = \frac{m}{\alpha}(\varepsilon-\gamma)^{m-1}\exp\left[-\frac{(\varepsilon-\gamma)^m}{\alpha}\right] \tag{3}$$

While the damage factor D is determined by the number of defects, and $\frac{dD}{d\varepsilon} = \phi(\varepsilon)$, so

$$D = \int_\gamma^\varepsilon (x-\gamma)^{m-1}\exp\left[-\frac{(x-\gamma)^m}{\alpha}\right]dx = 1-\exp\left[-\frac{(\varepsilon-\gamma)^m}{\alpha}\right] \tag{4}$$

In this formula location parameter γ is equivalent to the damage threshold. Because there are voids when the asphalt mixture is shaped, it is considered that γ=0, and the damage value of asphalt mixture can be defined by Weibull function with two parameters: $D = 1-\exp\left(-\varepsilon^m/\alpha\right)$.

2.1.3 Visco-elastic continuum damage model

When specimens are subjected to tension, the deformation is always associated with defects. The viscoelastic damage constitutive model can be set up under the uniaxial tension (Yu and Qian, 1993).

$$\sigma(t) = (1-D)\left[\varepsilon_0 G(t) + \int_0^t G(t-\xi)\frac{d\varepsilon(\xi)}{d\xi}d\xi\right] = \exp\left[-\frac{\varepsilon(t)^m}{\alpha}\right]\left[\int_0^t E\exp\left[\frac{E(\xi-t)}{\eta}\right]\frac{d\varepsilon(\xi)}{d\xi}d\xi\right] \tag{5}$$

To the loading at equal strain rate, when $\frac{d\varepsilon(t)}{dt} = \varepsilon = \frac{\varepsilon(t)}{t}$:

$$\sigma(t) = \exp\left[-\frac{\varepsilon(t)^m}{\alpha}\right]\frac{\varepsilon(t)}{t}\eta\left[1-\exp\left[-\frac{Et}{\eta}\right]\right] \tag{6}$$

If $G'(t)$ is defined as a tensile modulus when the damage is considered in direct tension test, the tensile modulus is obtained by moving the strain to the left of the formula:

$$G'(t)=\frac{\sigma(t)}{\varepsilon(t)}=\exp\left[-\frac{\varepsilon(t)^m}{\alpha}\right]\frac{\eta}{t}\left[1-\exp\left[\frac{Et}{\eta}\right]\right] \tag{7}$$

From Formula 7, we can see that even if the damage of materials is not considered, its tensile modulus is also gradually decreasing. If using the reduction of original damage modulus as the damage value of the material, the viscous flow deformation in the material deformation used as a part of damage is included to the damage values of materials that are not used to reflect damage changes of the material.

2.1.4 Comparison of theoretical model predictions with test results

According to the time-temperature equivalence principle, a master curve of 15℃of tensile modulus is obtained by using Arrhenius shift factors to the tensile modulus of SBS modified asphalt mixture curves shown in Figure 1 at different temperatures. The displacement factor is:

$$\alpha_T=\exp\left[-\frac{\delta H}{R}\left[\frac{1}{T}-\frac{1}{T_0}\right]\right] \tag{8}$$

Where: δH is the activation energy of the material. For this material, δH =133938.5; R is the universal constant (8.314). T is temperature, and T_0 is the reference temperature, which are absolute temperatures.

Table3 The shift factor at different temperatures with the reference temperature of 15℃

Reference temperature/℃	-15	-5	5	15
The shift factor α_T	0.001497	0.015384	0.133702	1

Using fitting function DamageEvisco of the Nonlinear Curve Fitting in Origin6.0, as shown in Figure 3, each parameter of the visco-elastic damage model at 15℃ is obtained: m = 0.09604, α = 0.71774, η = 8548.89 MPa • s, E = 407.138 MPa, R2 = 0.977.

Comparing the tensile modulus curve at 15℃ with the original curve, Figure 3 shows that the results of theoretical calculations are well fitted with the experimental results. The consistency indicates relevance of the model for the tensile modulus.

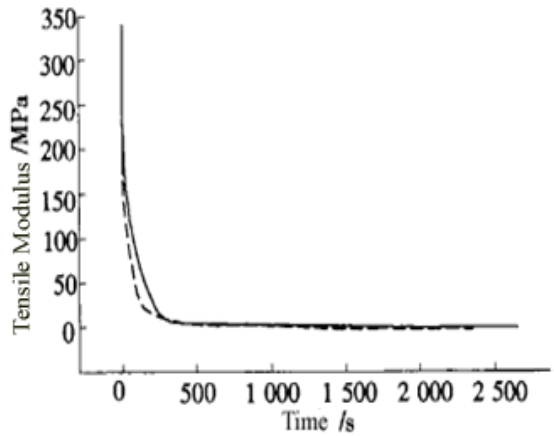

Figure3 the main curve of tensile modulus and the fitting curve of asphalt mixture at 15℃

2.2Establishment of fatigue damage model under uniaxial cyclic tension

It is necessary for asphalt pavement to withstand traffic loads and repeated variation of temperature in the long-term process. So it is more practically significant to do research on the fatigue characteristics of asphalt mixture. In the existing fatigue damage models, there is Chaboche model, Wang model, Lemaitre model and so on. In essence, a variety of models are just regular formula to the specific problem. They are applicable under certain conditions, but its physical meaning is not clear. The process of fatigue damage in fact is an irreversible process of energy consumption. Therefore, the plastic strain energy consumed in each cycle of the damage course (known as the cyclic hysteresis energy) can be adopted as the state parameter to define the damage function, so that the obtained damage model has clear physical significance. The energies dissipated in each strain cycle can be determined by the areas of the hysteretic loop of stress-strain curve. The energies consumed in each cycle of stress are the areas of hysteresis loop of this cycle, that is:

$$\Delta W_i = \int_0^T \sigma(t)\varepsilon(t)dt \qquad (9)$$

Where: T-a cycle period.

In the whole process of fatigue life, the accumulative dissipated energy is the sum of all hysteresis energy, that is:

$$W_F = \sum_l^{N_F} \Delta W_i \qquad (10)$$

Where: N_F is the fatigue life; W_F is the total energy consumption when achieving the fatigue failure.

In the previous energy model, the majority uses the cyclic hysteresis energy ΔW_i as a state parameter. The evolution of damage is manifested as the accumulation of cyclic hysteresis energy, and it is often assumed that the hysteresis energy ΔW_i in each cycle is constant. The test results show that the cyclic hysteresis energy under different strain levels changes with the cycle number Ni (shown in Figure 4), and it is related to the level of tensile strain that is the maximal tensile strain. The equation can be assumed:

$$\Delta W_i = aN_i^b \varepsilon^c \qquad (11)$$

Where: a, b, c-material parameters; N_i- the cycle number; ε- the level of tensile strain that is the maximal tensile strain.

The Formula11 is transformed into the logarithmic form to obtain a bivariate polynomial of first power, and the equation can be obtained by the regression of multivariate function:

$$\Delta W_i = 0.095 N_i^{-0.16891} \varepsilon^{0.97686} \qquad (12)$$

Where: N=201, R^2=0.885. The curves of the equation after regression are shown in Figure 4.

A large number of test studies have shown that the relationship between the total absorbed energy of SBS modified asphalt mixture and fatigue life at different strain levels satisfy the formula:

$$W_F = a_f N_F^{b_f} \qquad (13)$$

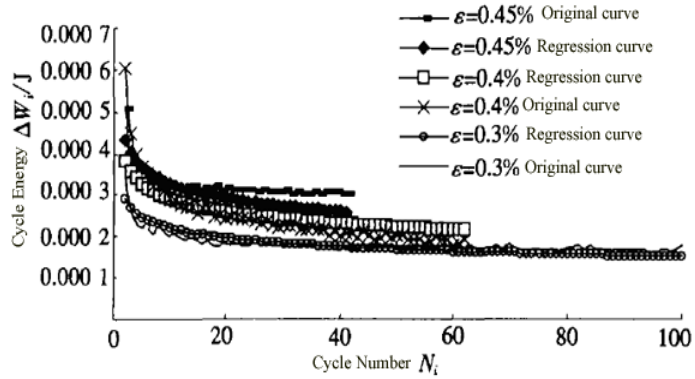

Figure4 The relationship between cycle energy and cycle number

Table4 Fatigue life of asphalt mixture under uniaxial tension and the accumulative dissipated energy

Tensile strain rate/%	Temperature/℃	Fatigue life/times	Accumulative dissipated energy
0.30	-5	42	0.013824
0.40	-5	62	0.016098
0.50	-5	100	0.018387

Through the regression of the data listed in Table 4, in which N = 3, R2= 0.9935, it is obtained:

$$W_F = 0.0043 N_F^{0.318} \tag{14}$$

From the viewpoint of energy, it can be defined that the damage in a cycle is equal to the ratio of the hysteresis cycle to the accumulative dissipated energy, that is:

$$D_i = \Delta W_i \Big/ W_F \tag{15}$$

The cumulative damage after cycling of N times is as follows:

$$D_N = \int D_i dN \tag{16}$$

The Formula (14) and formula (15) are substituted into the Formula (16):

$$D_N = \frac{a\varepsilon^c N^{b+1}}{a_f (1+b) N_F^{b_f}} = \frac{26.583\varepsilon^{0.977} N^{0.831}}{N_F^{0.318}} \tag{17}$$

Formula (17) is the energy expression of fatigue damage function D of the SBS modified asphalt mixtures under uniaxial tension considering both strain level and cycle number. When N = 0, D0 = 0; when N = NF, substitution of the strain level can be used to obtain the damage value related to the strain level. The test results are substituted into the formula to obtain the damage value of 1, which shows that the derivation formula is reasonable and correct. At the same time, prediction formula of the fatigue life related to the strain level can also be obtained through Formula (17).

3 Conclusion

1) The characteristics of the visco-elastic models and the damage models, which are coupled to visco-elastic continuum damage model, are analyzed by a large number uniaxial tension tests of SBS modified asphalt mixture. The model can reflect not only the strain-rate effect but also the stress relaxation phenomena. It also can obtain stress response at different temperatures based on

the Arrhenius shift factor.

2) Through the cyclic tensile test, the fatigue damage characteristics of the SBS modified asphalt mixture and damage effect have been considered in terms of energy and a fatigue damage model with the consideration of tensile strain level. The model can be used to predict the fatigue life under different tensile strain levels.

3) Damage value related to the strain level was obtained by using the fatigue damage model under uniaxial cyclic tension, which verifies that the theoretical value is consistent with the test results.

ABSTRACT

The method for identifying flutter derivatives of deck section model is popularized to full bridge aeroelastic model. The flutter derivatives of aeroelastic model of Hangzhou Bay Bridge are studied comprehensively using the stochastic subspace identification technique. The wind tunnel tests are conducted in smooth and turbulent flows with 3 attack angles and 5 yaw angles. The research results reveal that evident difference exists between section and aeroelastic model flutter derivatives. In turbulent flows, the flutter derivatives stabilities of aeroelastic model are more unsatisfactory. At the same reduced wind speed, with the alteration of attack angles and yaw angles, no monotonous laws for aeroelastic model flutter derivatives can be obviously observed.

INTRODUCTIONS

The bridge engineering is entering a new era characterized by construction of many cross-sea bridges. China has also initiated the along-the-Pacific highway project crossing Bohai Strait, Yangtze River, Hangzhou Bay, Pearl River and Qiongzhou Strait (Xiang, 2000). With the increase of bridge spans, the wind-resistant performances become more important, and the wind loads accompany the whole processes of construction and service. Flutter derivatives identification of bridge is one key aspect in the research of wind-resistant performance of large-span flexible bridges.

The methods for flutter derivatives identification of rigid section model are most studied and have the widest application. However, they can only reflect the bridge deck cross-sectional self-excited characteristics. Flutter derivatives of full-bridge aeroelastic model considering 3-D effect, multi-modal coupling effect as well as a variety of non-linear factors caused by the large added angle of attack, geometric non-linearity and so on. It can give a more reasonable and detailed explanation about the flutter mechanism of 3-D full-bridge structures. For identifying flutter derivatives of full-bridge model, one can measure the structural transfer function affected by aeroelastic characteristics, perform parametric optimal estimation using the least square method with a good applicability (Zasso, 1996). The stochastic subspace technique (Qin, 2004; Chen, 2006) can identify flutter derivatives directly based on signals acquired in turbulent flow field. Traditional identification of flutter derivatives study mainly concern the single orthogonal

direction to the span and consider this direction as the most dangerous state, while less study is undertaken concerning skew wind conditions. The flutter study of Hong Kong Tsing Ma Bridge section model under skew wind conditions shows that (Zhu, 2002): for different attack angles, critical flutter speed changes non-monotonically with yaw angle, and the minimum flutter critical wind speed often arises under skew wind conditions. The actual strong winds often deviate from the orthogonal direction to the span.

So far, no literatures have been found concerning flutter derivatives identification of full-bridge aeroelastic model under skew wind conditions in wind tunnel tests. The relevant investigations will be comprehensively performed in this study.

OVERVIEW OF THE WIND TUNNEL TEST OF HANGZHOU BAY BRIDGE

Hangzhou Bay Bridge is situated in coastal area of Zhejiang Province, where is frequently attacked by typhoons. This cable-stayed bridge has two diamond-shaped pylons and the main span is 448m. The wind resistance performance is essential throughout construction and service phases. The wind tunnel test for flutter derivatives identification of full-bridge aeroelastic model of the bridge was conducted, and the test cases include 2 flow fields (smooth and turbulent) with 3 attack angles(-3º,0º,+3º) and 5 yaw angles (0º,10º,20º, 30º,40º). The geometric scale of the full-bridge aeroelastic model is selected to be 1:100, and the aeroelastic model in wind tunnel is shown in Figure. 1.

Figure 1. Full bridge aeroelastic model of Hangzhou Bay Bridge.

DETERMINATION OF MODEL PARAMETERS

The relevant parameters of full bridge aeroelastic model are listed in Table 1, in which the deck section mode parameters are also provided. Parameters such as the first-order symmetric vertical bending frequency f_h and torsion frequency f_α, modal mass m_h, moment inertia I, and so on, obtained from the analysis of actual bridge design data, are also presented in Table 1. And the structure modal damping ratios ξ_h, ξ_α of the actual bridge are assumed to be 1%. It can be seen from Table 1:

For full-bridge aeroelastic model, some difference still exists between the actual and the expected goal values of f_h and f_α even after substantial adjustment tests. This is mainly due to the aeroelastic model involves lots of components and deviations of component's mass, mass distribution, stiffness, and boundary conditions from their ideal values. Frequency and damping ratios errors will affect the flutter critical wind speed, but not the specific values of flutter derivatives. Determination of mode mass of aeroelastic model is less convenient than section model.

Table 1. Design Parameters of Hangzhou Bay Bridge Models.

Parameters	Actual Bridge	Section model		Aeroelastic Model	
		Goal	Actual	Goal	Real
m_h (kg/m)	29740	6.069	6.07	2.974	2.974 Nominal

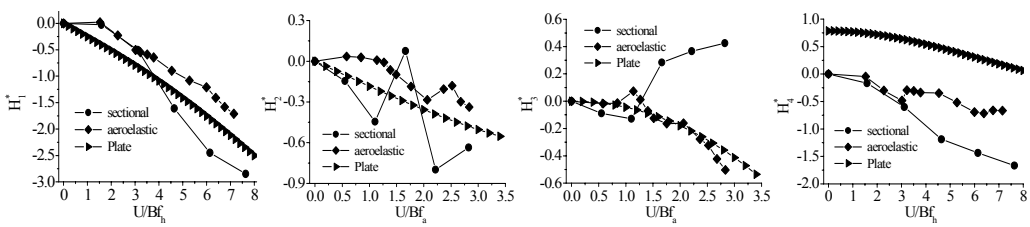
There exists obvious deviation of full-bridge aeroelastic model mode mass calculated by using coordinates expansion technique from expected values, and the main possible reasons may include: (1) the test scheme itself lacks in precision; (2) errors in calculation of actual bridge modal mass; (3) errors in the model fabrication. The modal mass of aeroelastic model was suggested to be directly calculated from the real bridge according to the geometric scale, and the reasonable explanation was presented (Xu, 2006). The vertical bending and torsion modal mass used in the flutter derivatives identification program of this paper, i.e., the nominal values in Table 1, are calculated from those of the real bridge.

FLUTTER DERIVATIVES IDENTIFICATION

Displacement micro sensors are employed at the mid-span of aeroelastic model to acquire signals of vertical, lateral and torsion displacements under conditions of different flow fields, attack angles, yaw angles and wind speeds. And displacement signals here are obtained through ambient excitation in the turbulent flow field and pulse excitation at the mid-span in the smooth flow field, respectively. Flutter derivatives identification through lateral displacement signals shows poor accuracy due to the relatively strong noise compared with the weak signals. In this paper, the stochastic subspace technique is used to identify 8 flutter derivatives, $H_1^* \sim H_4^*$ and $A_1^* \sim A_4^*$, which are related to vertical bending and torsion. Due to limited space, the specific identification method and process are not given here, but the detailed introduction can be found in other relevant literatures.

Section model and aeroelastic model in the smooth flow field. Flutter derivatives of section model, aeroelastic model as well as flat plate in smooth flow field with 0º attack angle are shown in Figure 2.



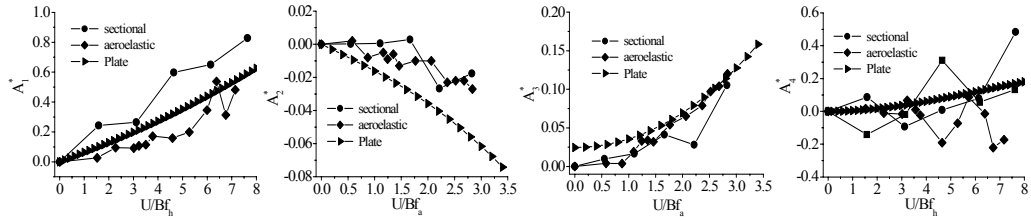


Figure 2. Flutter derivatives in smooth flow.

It can be observed as: (1) Between section and aeroelastic models, H_1^*, H_4^*, A_1^* and A_3^*, are in good agreement, and they have the similar trends to those of flat plate. (2) Monotonic relationship does not exist between section and aeroelastic models with reduced wind speed. (3) At higher reduced wind speed, the flutter derivatives identification accuracy of section and aeroelastic models is relatively poor.

Aeroelastic model in the smooth and turbulent flow field. Flutter derivatives of aeroelastic model in smooth and turbulent flow fields are shown in Figure 3. Small differences exist between identified frequencies with different wind speed at the same wind speed. Therefore the physical wind speed is adopted.

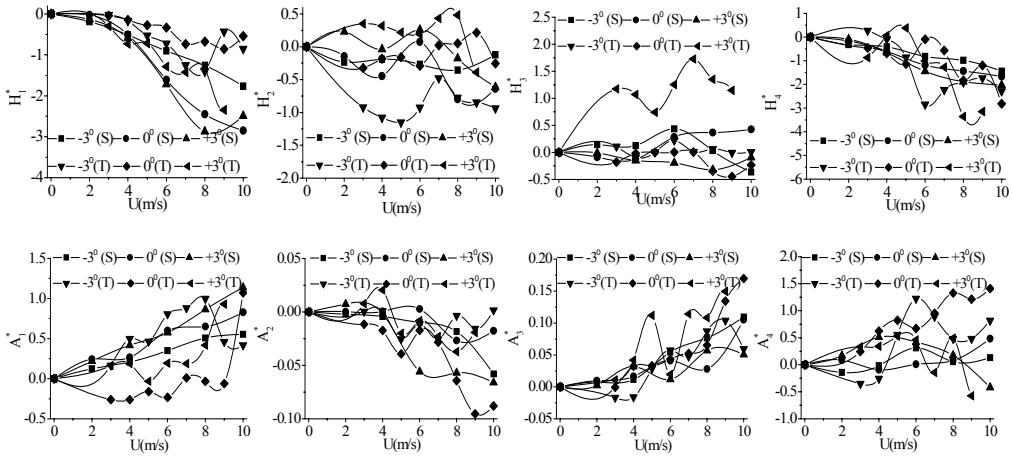

Figure 3. Aeroelastic model flutter derivatives.

From Figure 3, it can be observed as: (1) Flutter derivatives in turbulent flows have poor stability. The possible reason could be that the amplitude is relatively larger and the nonlinearity is more obvious under the condition of pulse excitation in smooth flow field. (2) Significant deviations exist under conditions of different flows and attack angles. Therefore from the perspective of improving flutter derivatives identification stability, the identification had better be undertaken in smooth flow field.

Aeroelastic model with skew winds. Due to the fixed wind direction in the tunnel, skew winds can only be realized by change of the angle between bridge model axis and flow direction. What should be noted is that all the parameters such as the deck width, the modal mass, etc. used to identify flutter derivatives under skew winds are taken as those under 0º yaw angle wind. Flutter derivates of with different yaw angles of

10º,20º,30º,40º are shown in Figure 4.

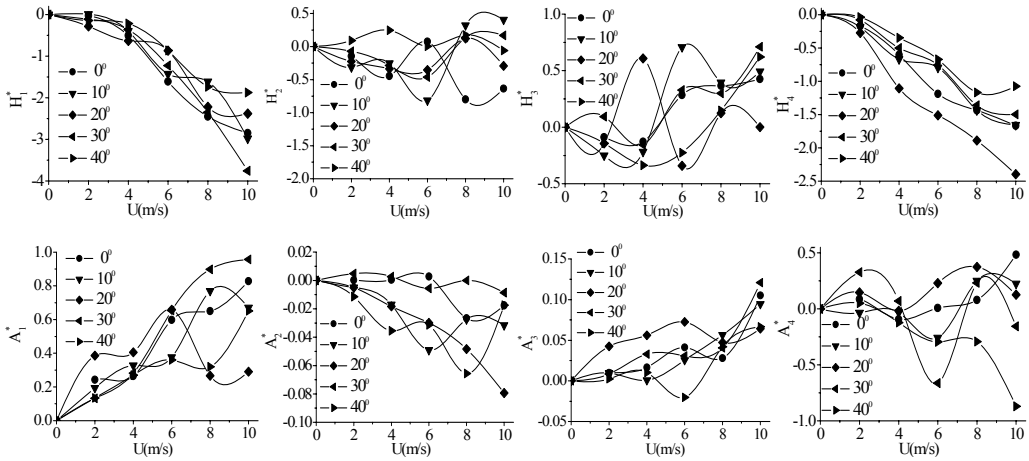

Figure 4. Aeroelastic model flutter derivatives with different yaw angles.

From Figure 4, it can be seen as follows:

(1) No obvious monotonic relation exists between flutter derivatives and yaw angles due to the involvement of complex vibration modes of pylons and cables.

(2) H_1^*, H_4^*, A_1^* and A_3^* have good trends at different yaw angles, and flutter derivatives of section and aeroelastic model with different wind attack angles have similar characteristics. This proves that the identification stability of flutter derivatives is related to their respective characteristics.

(3) Structural modal coupling may happen under different wind loads due to different wind yaw angles, i.e., significant differences exist among the state matrices.

(4) The flutter derivatives under orthogonal wind condition show more stability relatively than those under skew wind condition.

Analysis for stability of identification results.

(1) The deck of Hangzhou Bay Bridge has a streamlined cross-section, and vortex-induced vibrations occur within a very wide range of wind speeds in wind tunnel test, therefore the stability of flutter derivatives of section model is not quite satisfactory.

(2) Stability of flutter derivatives of aeroelastic model is less satisfactory than that of section model. The main reasons include existence of more modes participation in the vibration of aeroelastic model, different effective attack angles, internal modes phase differences, more unfixed modal coupling and more obvious non-linearity.

(3) Obvious difference appears between the flutter derivatives from smooth and turbulent flows, and the former one is more stable. This is mainly due to less modes participation in smooth flows and relatively pure signals for the pulse excitation way. While in turbulent flow field, more modes participation exists, especially those of cables, and the noise-to-signal ratio is relatively high, the identification is thus quite difficult.

(4) Multi-modes participation exists in the vibration of cable-stayed bridges, and it also has a higher degree of modal coupling than those of suspension bridges. It is easy

to understand that the accuracy and stability of flutter derivatives identification of full-bridge aeroelastic model of suspension bridges are more satisfactory, and this point can be verified through wind tunnel test.

(5) The generalized modal mass of the bridge system and the deck width are utilized in flutter derivatives identification of aeroelastic model. The identification results may vary greatly for various bridge types, span arrangement, tower and cable forms, even if the deck cross-section is the same.

(6) The noise, uncertainty of the test equipment system and multi-modes participation may lead to significant deviations of identification results from the theoretical ones, especially at high speed wind when the linear assumptions and small amplitudes can not be met.

CONCLUDING REMARKS

In smooth and turbulent flows, with 3 attack angles and 5 yaw angles, flutter derivatives of full-bridge aeroelastic model of Hangzhou Bay Bridge are identified by the stochastic subspace identification technique. For flutter derivatives, significant difference exists between section and aeroelastic model of Hangzhou Bay Bridge. There is no evident monotonic relationship between flutter derivatives and wind attack and yaw angles. Poor stability appears in flutter derivatives identification of aeroelastic model in turbulent flow field with skew winds. This is mainly due to strong asymmetry of the model and wind system under conditions of different attack and yaw angles. Due to the influence of multi-modal coupling, flutter derivatives of full-bridge aeroelastic model of Hangzhou Bay Bridge are not quite stable. For identification of flutter derivatives of full-bridge aeroelastic model under skew winds, more comprehensive and in-depth studies still need to be done.

ABSTRACT

In order to simulate discontinuum mechanics of asphalt pavement, a new numerical scheme—*Meshfree Manifold Method* is deduced by integrating *Numerical Manifold Method* and *Mesh-free Method*. It is not only appropriate for contact computation but also can eliminate the limitation of regular mesh method. Meanwhile, two useful element models were provided, kernel principles linkage of asphalt mastic and searching for support nodes were discussed. An example was given to show its efficiency in simulating discontinuous deformation of asphalt mixture. This method is promising in solving fracture or large deformation problems.

INTRODUCTION

The commonly used methods to numerate discontinuous mechanics mainly include DEM *(Discrete Element Method)*, DDA (*Discontinuous Displacement Analysis*), and NMM (*Numerical Manifold Method*). Among these methods, DEM is the most successful to be applied for asphalt mixture, it is a mature method in solving the discontinuous problems and large deformation cases. However, because DEM tightly depends on combination of elastic or viscous components to reflect the contact state between particles, it hardly achieves stress distribution of asphalt mastic. This paper introduced NMM simulated the discontinuous deformation of asphalt mixture.

NMM was established by Shi Genhua (1991 and 1997) by using finite covering system in modern manifold, it takes advantage of finite element method , discontinuum kinematics , combines discontinuous and continuous deformation into a uniform mathematical expression. Lin(1995), Ohtsubo(1997) and Lu(2002) also made a great contribution to the development of NMM.

Asphalt mixture is filled with a lot of gaps, cracks, irregular aggregates, asphalt and other materials, so FEM-mesh-based NMM faces difficulties such as volume integration, displacement coordination between materials and mesh deformity caused by large deformation. However, *Meshfree/Meshless Method* (MFM) can provide a way to solve this problem. MFM was developed in 1970's, which mainly includes: SPH(*Smooth Particle Hydrodynamic Method*, Lucy, 1977),

RKPM (*Reproducing Kernel Particle Method*, Liu, 1995), DEM(*Diffuse Element Method*, Nayroles, 1992), EFGM(*the Element-free Galerkin Method*, Belytschko, 1994) and so on. EFG is suggested to be used for its symmetrical coefficient matrix and agreement with variational method.

In theory, *Meshfree Manifold Method* (MMM) is good at dealing with discontinuous problems of asphalt mixture, especially for large deformation, cracks, and material coupling calculation.

GENERALLY MANIFOLD COVERING SYSTEM

In *Numerical Manifold Method*, there are two mesh sets—physical mesh and mathematical mesh (Figure 1). Physical meshes are enclosed by objects' borders, cracks, blocks and the interface between different materials, which define the physical region of integration. Mathematical meshes are also named mathematical covers, which only define the precision of approximate solution. They can be any shapes but must cover the entire physical region.

Mathematical covers are divided by physical meshes into physical covers, and the overlap of physical covers is defined as the element of MANIFOLD. It is the basic unit of NMM and can be any shapes.

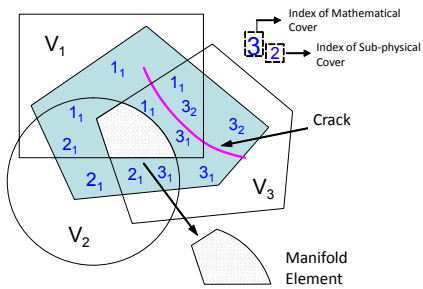

Figure 1. 2D Manifold covering system

VARIATION PRINCIPLE OF MINIMUM POTENTIAL ENERGY

Approximate displacement functions. If $(u_i(x,y,z), v_i(x,y,z), w_i(x,y,z))$ is the displacement function defined on Physical cover U_i, which can be expressed as a series forms as follow:

$$u_i = (u_i(x,y,z) \quad v_i(x,y,z) \quad w_i(x,y,z))^T = S \cdot D_i \tag{1}$$

Where, S is the basic series, D_i is the freedom degree of cover U_i.

Total displacement function. Assuming a point (x,y,z) is covered by q physical covers, the displacement function can be obtained by weighted mean of the q displacement approximation functions as follow,

$$\begin{Bmatrix} u(x,y,z) \\ v(x,y,z) \\ w(x,y,z) \end{Bmatrix} = \sum_{i=1}^{q} N_i(x,y,z) \begin{Bmatrix} u_i(x,y,z) \\ v_i(x,y,z) \\ w_i(x,y,z) \end{Bmatrix} = \sum_{i=1}^{q} N_i(x,y,z) \cdot S \cdot D_i = T \cdot D \tag{2}$$

Where, $N_i(x,y,z)$ is weight function of physical cover.

Global control equations. Assuming there are n physical covers in the

solution domain , according to the principle of minimum potential energy, we have the global control equations as follow,

$$\begin{bmatrix} K_{11} & K_{12} & K_{13} & \cdots & K_{1n} \\ K_{21} & K_{22} & K_{23} & \cdots & K_{2n} \\ K_{31} & K_{32} & K_{33} & \cdots & K_{3n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ K_{n1} & K_{n2} & K_{n3} & \cdots & K_{nn} \end{bmatrix} \begin{Bmatrix} D_1 \\ D_2 \\ D_3 \\ \vdots \\ D_n \end{Bmatrix} = \begin{Bmatrix} F_1 \\ F_2 \\ F_3 \\ \vdots \\ F_n \end{Bmatrix} \tag{3}$$

Where K_{ii} is only determined by the material of physical cover U_i, and $K_{ij}\ (i \neq j)$ is the impact matrix of cover U_j on cover U_i.

COMBINATION WITH MESHLESS METHOD

Approximation scheme on compactly supported domain. In EFG, if n points lie in the neighborhood of evaluation point x, the weighted squared error norm of $u^h(x)$ in those points can be given by MLS (*Moving Least Squares*) as,

$$J = \sum_{i=1}^{n} w_i(x - x_i)\left[u^h(x) - u(x_i)\right]^2 = \sum_{i=1}^{n} w_i(x - x_i)\left[p^T(x_i)a_i(x) - u(x_i)\right]^2 \tag{4}$$

Where, $p^T(x) = \left[p_1(x) \quad p_2(x) \quad \cdots \quad p_m(x)\right]$ is m-times complete basis monomial, $a(x)$ is the coefficient vector, m is the number of basis monomial, and $w_i(x) = w(x - x_i)$ is the weight function of point x_i in point x.

Shape function of Meshfree Manifold Method. Let Eq. (4) obtain the minimum-style, shape function is gotten:

$$N(x) = p^T(x)A^{-1}(x)B(x) \tag{5}$$

Where $A(x) = \sum_{i=1}^{n} w_i(x)\,p(x_i)\,p^T(x_i)$, $B(x) = \left[w_1(x)\,p(x_1) \quad \cdots \quad w_n(x)\,p(x_n)\right]$

Then, substitute Eq. (5) into Eq. (2) and (3), we can obtain the equations of MMM scheme.

AVAILABLE ELEMENT MODELS

For MMM, two useful models are shown in Figure 2. In both models, edge nodes are placed at the mid of each edge, and face nodes and body node are all coincide with their centroid. Although 22-nodes model may be not so accurate, it can simplify the calculation and cut off more than 70% freedom degree.

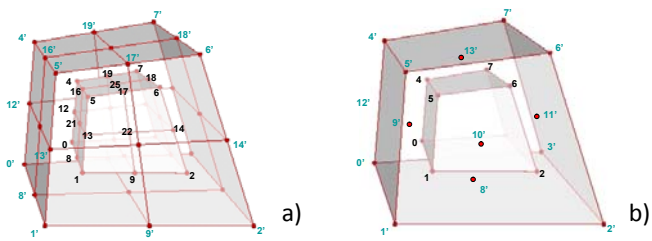

Figure 2. Element models: a)77-nodes model, b)22-nodes model

DEFINITION OF ASPHALT MIXTURE SOLUTION DOMAIN

Linkage of Asphalt mastic. Overlap between asphalt regions usually results in difficulties on numerical integration. While meshfree method can offer facilities for this integration (Figure 3a):

To define each node with two attributes: particle index and material index. All nodes on particle A (such as points *a*, *b*, *c*, *d* and *f*) have a particle id *A*, and all nodes on particle B (such as points *c*, *d*, *e*, *f*, *g* and *h*) have a particle id *B*. So node *c* and *d* have two particle ids, *A* and *B*. In the same way, a node locates in one material body has a single material id; otherwise, it will has more than two material ids. For example, node *b*, *d*, *e* and *g* have asphalt index; and node *a* and *h* have both index of stone and asphalt. Node *f* is an exception, which should be ignored in computation.

Searching for support nodes. If domain size (length, width and height(L_i), or sphere radius(r)) has been assigned, any node x_i who agrees with all the following three rules will be defined as the influence node of evaluation node x_I: a) $|x_I - x_i| \le L_i$ or $|x_I - x_i| \le r$; b) x_I and x_i have the same particle id a_k; c) x_I and x_i have the same material id m_s.

Background integration on asphalt mastic. Like meshfree method, since asphalt mastic connects with each other, integration must be calculated depending on background lattices (like Figure 3b). As shown in Figure 4, the global integration on asphalt region Ω can be translated into weighted summary of all lattice points like Gauss integral. The valid point will be determined by relative position of lattice point to the integration domain. Additionally, if lattices on borders are further refined in the same way, integral precision will increase obviously.

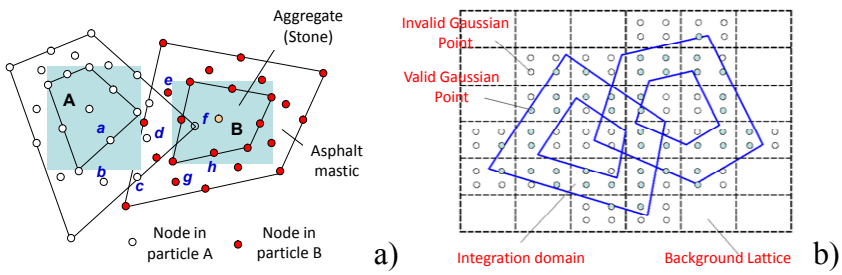

Figure 3. Likage and background integration for asphalt mastic

NUMERICAL EXAMPLES

In order to test the validity of MMM, a simple asphalt mixture model composed of 16 polyhedral particles was used to analyze the influence of aggregate-asphalt modulus ratio to stress distribution (Figure 4a). In this model, the diameters of particles subject to AC-16 gradation . For simplifying calculation, the model is only composed of two different sieve size particles(13.2~16mm, 11granules; 16~19mm, 5 granules). Bottom of the model is fixed, the side is free. A vertical pressure is loaded on the top, the strength varies linearly along with the time (p_{min}=0 at 0*sec*, and p_{max}=10N at 1.0*sec*). Aggregate modulus is assumed as 40Gpa and

Poisson's ratio is 0.25. For comparison, three different modulus of asphalt mastic are selected: i) Ea = 130Mpa; ii) Ea = 650Mpa; iii) Ea = 1300Mpa. Poisson's ratio is always 0.3.

The results are shown as Figure 4b) ~d) and Table1.

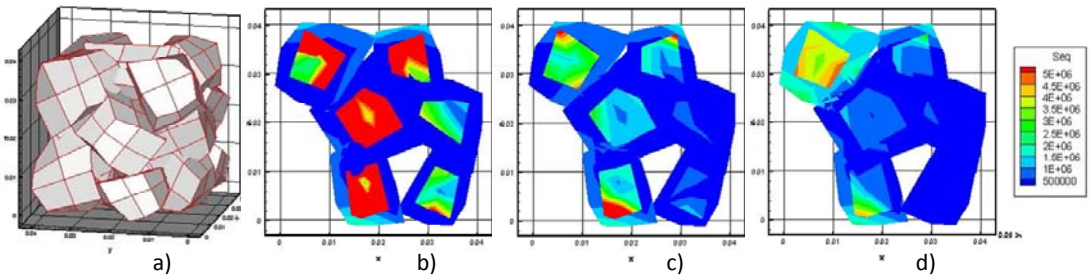

Figure 4. Numerical model (a) and contour of equivalent stress slice when t=0.1s (Ea: b-130Mpa, c-650Mpa, and d-1300Mpa).

As shown in Figure 4, the discontinuous features of asphalt mixture model lead to irregular distribution of inner stress, and it is obvious that stress is more concentrated on aggregate.

For No.3 particle (Table 1), if taking the mean equivalent stress ratio of two materials as evaluation index, the results show that: with the ratio increasing, stress in asphalt mastic increases slightly, while stress in aggregate decreases dramatically. This indicates that: the greater the modulus ratio is, the more stress the aggregate is concentrated on; smaller modulus ratio can help stress distributes more evenly. This conclusion is very useful in practice: in order to give full play to ultimate strength of aggregate and asphalt, we should keep the modulus ratio at a reasonable level to achieve stress coordination between aggregate and asphalt.

Table 1. Relation of Mean Stress And Modular Ratio for No.3 Granule

Aggregate-asphalt modulus ratio Es/Ea		40GPa /130MPa	40GPa /650MPa	40GPa /1300MPa
Equivalent stress of aggregate /MPa	Max	17.9151	3.8091	1.8774
	Min	0.3286	0.2720	0.2604
	Mean $\bar{\sigma}_s$	7.6104	1.5779	0.8231
Equivalent stress of asphalt mastic /MPa	Max	0.8664	1.6105	3.0732
	Min	0.0845	0.0477	0.0776
	Mean $\bar{\sigma}_a$	0.2766	0.3239	0.4002
Stress ratio $\bar{\sigma}_s / \bar{\sigma}_a$		27.51	4.87	2.06

Additionally, although reducing the aggregate-asphalt modulus ratio can make the inner stress distribution more uniform, while, average stress among different particles are definitely different (Figure 4b~d). So it can be discovered that re-distribution of stress is the integrated result caused by the strength (or stiffness) balance from particles inside and outside.

CONCLUSION

a) Based on the combination with *Numerical Manifold Method* and *Meshfree Method*, an efficient numerical method— *Meshfree Manifold Method* was deduced, which provides a good method to simulate discontinuous mechanics of asphalt mixture. And it is promising in simulating the process of crack or large deformation.

At the same time, numerical example given in this paper shows that:

b) The stress distribution of asphalt mixture is closely related to the modulus ratio of aggregate and asphalt mastic. The greater the modulus ratio is, the more stress the aggregate is concentrated on. Although reducing modules ratio can make stress distribution more balance inside the particles, unbalance between the particles.

c) In order to take advantage of ultimate strength of material, it is necessary to keep the mechanical status of aggregate and asphalt mastic harmony by adjusting modulus ratio.

ABSTRACT

The inspection and assessment are necessary because it can provide the necessary scientific foundation for the maintenance, rehabilitation and technical reconstruction of existing suspension bridges. Most stiffening girders of suspension bridges are steel truss girders or steel box girders. The safety evaluation of steel beams is to evaluate the ultimate state of the structure so as to avoid disastrous accidents during serving. In this paper, through field investigation of the defects and static and dynamic load tests of the bridge, combined with the finite element analysis, a safety evaluation method is developed and adopted to evaluate the load-carrying capacity of the Qingcheng suspension bridge. In the procedure the coefficient of considering load-carrying capacity and effect of fatigue and rust of the steel is adopted. The evaluation method of this paper can provide reference for safety evaluation and reinforcement construction of existing suspension bridges.

Introduction

At present, the main methods of evaluating the load-carrying capacity or the safety of the bridges are as follows: assessment based on appearance investigation, assessment based on calculation according to the design code, the load test, the assessment by expert system, and assessment based on theory of time-dependent reliability (Shi 2001). The Evaluation Method of Load-Carrying Capacity of the Highway Existing Bridge (on trial) had been enacted by the China Communications Ministry in 1988. However, it only applies to existing reinforced concrete bridge and pre-stressed concrete bridges. Currently, there isn't any code for safety evaluation of steel bridges in China (Lei, 2000). In addition, most of the assessments according to design code are inclined to be conservative and aren't accurate to reflect the mechanic behavior after the structure deteriorates. Currently, a more reasonable way is to combine the calculation results with the load test data to evaluate the load-carrying capacity of bridges. In this paper, with consideration of the characteristics of the fatigue and rusting of existing steel bridges and combining the static and dynamic load tests with the finite element analysis, the assessment of a suspension bridge with double flexible cable is carried out. This can be carried on

in two steps as follows: Carry load tests on the bridge, and then judge the possible damage according to the experimental results or determine load-carrying capacity and evaluate the safety of the bridge.

Field investigation of the defects and static and dynamic load tests of the bridge

Brief introduction of the bridge. The Qingcheng Bridge is over the Yellow River and is about three kilometers away from the Daxia reservoir in China. It has already been in use for 20 years. The structural form is a flexible suspension with a double cable (see Figure 1). The main span is 180m and the bridge approach on each side is composed of 4×16m simple supported bridges. The height of the reinforced concrete cable tower is 18.5m. The rise-span ratio is 1/12 and both the upper and lower cables are all steel wire rope composed of 6φ45mm. The diameter of the upper suspender is 25mm and of the lower one is 45mm. The stiffening girder is composed of longitudinal and transverse beams which are made of 16Mn I-steel.

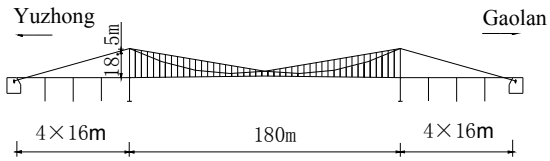

Figure 1. Sketch of Qingcheng Bridge (unit: m)

Field investigation of the defects. Some longitudinal and transverse beams of the stiffening girder have corrosion. A few clamps slipped along the cable. The suspenders do not bear the loads uniformly because some suspenders unload and others overload. The concrete protection course of the cable tower has some damage and stripping. The crack of the R.C. cable tower is serious, especially in the bottom parts. The width of some cracks even reaches 3.4mm. After years of service, the deck elevation has changed a lot with the following characteristics: The maximum settlement exists in the middle of the main span and the value is 1.054m, it reaches 0.58% of the span length. From the beginning to now the camber changed from 1m to 0, some place in the middle span even lower than the horizontal line.

Static and dynamic tests of bridge. Static tests are carried on by design load (a car weight 20t) and six loading conditions are considered (see Table 1). The distance from the center of the front wheel to that of the rear wheel is 4m; the front axle Load is 7t, and that of the rear is 13t. During the load test, the car is forward Gaolan. The control sections are edge of bearing (section I), l/8(section II), l/4(section III), 3l/8(section IV), middle span (section V), middle of 24# cross beam(section VI) and bottom of cable tower. Dynamic tests take a car weight 20t as a vibration source to measure the dynamic response and natural frequency and impact factor for further assessment.

COMPARISON OF RESULTS

Finite element analysis model. This part is about the three-dimensional finite element analysis of the suspension in which the program ANSYS is used. The

cable and suspender are simulated by the three-dimensional tension-only nonlinearity link element (link 10). The cable tower and the longitudinal and transverse beams of the stiffening girder are simulated by the three-dimensional beam element (beam 44). The deck is simulated by the shell element (shell63). The total bridge is divided into 6492 elements and 4550 nodes. It is considered that the nonlinearity effect is caused by large displacement with small stain, gravity stiffness and initial stress of cable.

Table 1. Loading conditions and control sections

Loading conditions	Distance from the rear axle to centre line of bridge span	Distance from the control section to centre line of bridge span
1	89m (the car is near Yuzhong)	89m (section I, near Yuzhong)
2	68 m (the car is near Gaolan)	68 m (section II, near Gaolan)
3	4 m (the car is near Yuzhong)	4 m (section III, near Yuzhong)
4	29 m (the car is near Yuzhong)	22 m (section IV, near Yuzhong)
5	1 m (the car is cross the centre line)	0m (section V)
6	6m (the car is near Gaolan)	6m(section VI, near Gaolan)

Table 2. Comparison of Results

Loading conditions	Item(stress /MPa or displacement/m)	Theory value	Test value	Checkin-g factor
1	Shear stress of the stiffening stringer on section I	27.5	20.8	0.756
2	Nomal stress of longitudinal beam bottom on section II	162.6	125.6	0.772
3	Nomal stress of longitudinal beam bottom on section III	169.6	130.6	0.770
4	Nomal stress of longitudinal beam top on section IV	26.9	19.2	0.738
5	Vertical displacement of longitudinal beam on section V	0.524	0.387	0.738
	Vertical displacement of the cable on section V	0.512	0.362	0.707
	The max normal stress on bottom section of cable tower	0.376	0.378	1.005
	Longitudinal displacement at top of cable tower	0.004	0.004	1.000
6	Normal stress in the bottom of the stiffening cross beam (24#) on section VI	58.9	46.5	0.790

Table 3. Frequency/Hz

Vertical vibration/ n	Vibration mode	Frequency of theoretical value	Frequency of test value
1	Vertical symmetric bending	0.3398	0.3549
2	Vertical Antisymmetric bending	0.4676	0.4867

Comparison of results calculated by finite element analysis and experimental data. Table 2 shows the theoretical value and the test value of the deflection (stain) of control sections in each loading condition. The checking factor, the ratio of experimental data to the theoretical value, is less than 1.0; so it can be concluded that the total rigidity of bridge superstructure is good and the bridge is working in a

normal state. The first two vertical vibration modes and frequencies are tested in the dynamic test (see Table 3). The experimental frequencies are all higher than theoretical values, which verifies that the rigidity of the bridge is good. Therefore, the suspension system is working in a normal state. However, the checking factor of stress on the bottom section of the cable tower is 1.005. Considering the results of gap observation and the longitudinal displacement of top cable tower, it can be concluded that the load-carrying capacity of the cable tower is lower because of the development of a crack. The checking factor is not enough to determine the load-carrying capacity of the bridge(Song, 2002). Therefore in the following parts of the paper, an expression for safety evaluation using the coefficient of load-carrying capacity andconsidering the fatigue and rust of steel is proposed and adopted to evaluate the load-carrying capacity of the Qingcheng Bridge.

EVALUATION OF LOAD-CARRYING CAPACITY

Currently, in China there isn't any code for load-carrying capacity evaluation of existing highway suspension or steel bridges. Some countries have a code on load-carrying capacity evaluation (BD21/01, Eurocode No.3). In report (Lichtenstein Consulting Engineers, Inc. 2001), it is proposed that the expression of load-carrying capacity should be

$$R.F = \frac{R_u - \gamma_D D}{\gamma_L L(1+\mu)} \tag{1}$$

Where $R.F$ is the coefficient of load-carrying capacity; R_u is the actual ultimate strength of section evaluated; γ_D is the factor for dead loads; γ_L is the factor for live loads; μ is the impact factor for live loads; D is the dead loads effect of section evaluated;L is the live loads effect of section evaluated. If $R.F \geq 1$, the load-carrying capacity can meet the requirement, otherwise, it can't.

During the evaluation, the rust effect can't be neglected because of the generally existing rust in steel bridges. Using the factors, γ_1 and γ_2 to modify the design value of the bending strength R, it yields $R_u = \gamma_1\gamma_2 \cdot R$

From Eq. (1) we have

$$R.F = \frac{\gamma_1\gamma_2 R - \gamma_D D}{\gamma_L L(1+\mu)} \tag{2}$$

Considering the bending resistance failure on normal section, R=310MPa, the information of dead loads is definite when testing the bridge, so γ_D=1.0. According to the code *JTG D60-2004*, γ_L= 1.4. From the experimental data, the impact factor μ=0.1. There is some rust in the longitudinal and transverse beams of the stiffening girder, but the loss ratio of section area is less than 5%,and the

mechanic performance has no conspicuous changes (Hui, 1992, Eung, and Ram, 2003); it can be seen that $\gamma_2 = 1.0$.

Currently, the study on the fatigue of highway steel bridges is relatively deficient. In the book (Pan, 1983), a method is proposed to calculate the fatigue reduction factor γ_1.

$$\gamma_1 = \frac{1}{(a\beta \pm b) - (a\beta \mp b)\rho} \qquad (3)$$

Where $a = \frac{R}{2\varepsilon_r K\sigma_\rho}$, $b = \frac{R}{2K\sigma_b}$

Where ε_r is the factor of underload causing the increase of fatigue strength due to underload; K is the coefficient of uniformity of fatigue strength; σ_b is the ultimate strength of material; ρ is the coefficient of cyclic and $\rho = \frac{\sigma_{\min}}{\sigma_{\max}}$; β is the coefficient of stress concentration, that is, $\beta = \frac{fatigue\ \ strength\ of\ \ basic\ \ material}{fatigue\ \ strength\ of\ \ conjunction\ \ material}$; σ_ρ is the fatigue strength corresponding to the number of cycles which can be got from the fatigue graphs (Pan, 1983,1999).

The basic material of the bridge-stiffening girder is 16Mn I-steel, adopting a high strength bolt as the conjunction. Therefore, ε_r=1.4, K=0.83, σ_b=520MPa, β=1.83. From the experimental data, ρ=-0.25. Through traffic volume investigation and record of stress history, it can be seen that the number of cycles is about 400,000 (bridge works 20 years). Consider the fatigue graphs of 16Mn I-steel. It can be seen that σ_ρ=365MPa. Recall from Eq.(3) and substitute the parameters by the values above, the value of the fatigue reduction factor γ_1 in the current state is equal to 0. 905.

From Eq.(2), it can be seen that the value $R.F$ of the longitudinal beams in the middle span bridge section is 1.313, and the value $R.F$ of the longitudinal beams in the $l/8$ section is 1.410. It can be concluded that the bridge in its current state still has the ability to serve under design load after considering the fatigue and rust of the deck system.

CONCLUSIONS

With consideration of the characteristics of the fatigue and rusting of existing steel bridges and combining the static and dynamic load tests with the finite element analysis, the assessment of a suspension bridge with double flexible cable is carried

out in this paper. Firstly, from load test data combined with the finite element analysis, it can be concluded that the cable tower should be strengthened due to the large horizontal displacement of the cable tower top; Due to the large settlement and light torsion of the deck the suspension system needs to be adjusted. Secondly, compare the experimental data with the theoretical value; it can be seen that the total rigidity of the bridge superstructure is good and the bridge is working in its normal state. Thirdly, the checking factors and the coefficient of load-carrying capacity of stiffening girder show that the stiffening girder can satisfy the requirements and need not be strengthened. The evaluation method of this paper can provide references for safety evaluation and reinforcement construction of existing suspension bridges.

Abstract: Based on the nonlinear theory, through changing the design parameters, the stability of model curve rigid frame bridges with long-span during cantilever construction was analyzed; The results show that the central angle of the curve dominated the stability coefficient; The nonlinear stability coefficient of bridge is 35% of eigenvalue flexure. Data was collected for a large number of long-span rigid frame bridge which have been built. Through comparison and classifying, the results indicate that the types of piers and its design parameters (the central angle of curve , slenderness ratio of piers, and the main pier types, the number of tie-girder) are related to the stability coefficient. The simple and creditable formulas can be taken as reference in designs.

Introduction

Long-span curve bridges with high piers are continuous rigid frames in general, which are built by the method of sub-segmental cantilever construction. During the construction stage, the T- rigid frames suffer less constrain; their inter-force and deformation are very complex (He and Xiang, 2003). The gravity centers of each section of the curve's supper-structure are not in one line, so that the piers are under eccentric compression. Torque, rotation angle and lateral displacements of piers and beams were formed by gravity. These characteristics make major long-span curved bridge design and construction more complex than a straight bridge (Wang and He, 2005, 2006). In this paper, based on non-linear mechanics, through analysis the stability of long-span high-pier curved bridges, the relationship of stability and curved bridge design parameters was pointed out, which provided the basis for the large span continuous rigid frame bridge design, construction and monitoring.

Methods of non-linear analysis

To solve the non-1inear mechanics problems, the incremental method is usually used. The structure's critical loads are divided into several increments， each increment load corresponding to the deflection curve can be regarded as the linearity approximation. Such linear treatment can be quite accurate to the original non-linear course. When the structures bear a group of loads, we assume the loads grow in fixed proportion. The critical proportion determines the critical loads. We can determine the critical loads by the critical proportion.

The concrete constitutive uses formula(1):

$$\sigma = k_3 f_c \frac{A(\varepsilon/\varepsilon_0)+(D-1)(\varepsilon/\varepsilon_0)^2}{1+(A-2)(\varepsilon/\varepsilon_0)+D(\varepsilon/\varepsilon_0)^2} \quad (1)$$

Where k_3 =1,A=1.74,D=0.5, ε_0 =0.002, f_c is the axial compression strength of concrete.

Reinforced uses formula(2). $(\sigma_e, \varepsilon_e)$ is the elastic limit point.

$$0 \le \sigma_s \le \sigma_e \quad \varepsilon_s = \sigma_s / E_s ; \quad \sigma_s \ge \sigma_e , \quad \sigma_s = \sigma_e \qquad (2)$$

In the stability analysis, piers are compression members; reinforced bars and concrete are equivalent strain. Therefore, the stability calculations still use integral models, which is a isotropic hardening model with nonlinear constitutive relation.

Nonlinear stability analysis in cantilever construction stage

Taking Xu Shui river bridge in the Shan Xi province as the background, the curve central angle is 38° and the piers are 120m high. During cantilever construction, the loads composed by the weight and construction loads consider geometric and material non-linearity . Since the age of concrete is short, the material elastic modulus was reduced by 10%. The results are shown in table 1. Based on the calculation results, we can indicate that eigenvalue coefficients are the biggest; The stability coefficients which consider the large deformation are slightly reduced; The stability coefficients which only consider nonlinear material will be about 47**%** of the eigenvalue coefficient; In considering the combined large deformation and material nonlinearity, stability coefficients are reduced significantly, about 35**%** of the eigenvalue coefficients .

Table 1 Results of Stability Coefficient under Different Considering Factors

Linear elasticity	Geometric nonlinearity	Material nonlinearity	Dual nonlinearity
7.62	7.37	3.63	2.68

When considering material nonlinearity stability, the stability problem has been transformed for the solving of ultimate load. The carrying capacity of the structure is lost because of pressure and bending effects for piers. It is obvious that the continuous rigid frame bridges are the second type of instability. Material yield has become a major factor in controlling its ultimate bearing capacity.

Non-linear stability analysis for different central angles of curve in cantilever construction stage

The central angles of curve bridges are 0°、22.92°、28.65 °、38.2°、45.82°、57.30°、76.39°、114.59°, the height of the piers are 120m. Considering the weight and construction loads in the largest cantilever construction stage, combined with large deformation and material nonlinearity, the ultimate load coefficients of the T rigid-frames were calculated. They are shown in table 2. The relationship between central angles of the curve and the ultimate load coefficients are shown in Fig.1. The formula of the relationship between load coefficient P_{cr}/P and the curve central angle φ is formula(3)

$$P_{cr}/P = 5.37647 - 0.15255\varphi + 0.00348\varphi^2 - 4.57639\times10^{-5}\varphi^3 - 3.04149\times10^{-7}\varphi^4 \qquad (3)$$

Table 2 Nonlinear Stability Coefficient at Different Central Angle of Bridge

central angle(/°)	0	22.92	28.65	38.2	45.82	57.30	76.39	114.59
Nonlinear coefficients	5.38	3.23	2.99	2.67	2.45	2.25	1.89	1.26

It is obvious that the eigenvalue coefficients and non-linear coefficients at the construction stage are reduced with the larger central angle of the curve; the non-

linear coefficients decreased quickly. Therefore, the relevance between the non-linear coefficient and the central angle is greater.

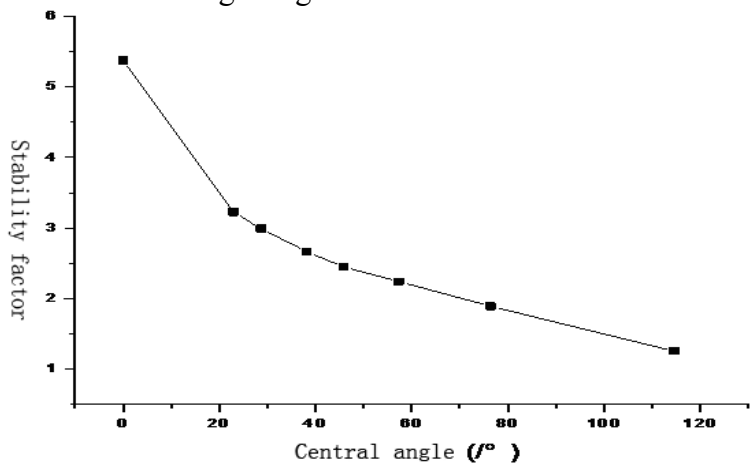

Fig.1 Relationship between nonlinear stability factors and central angles

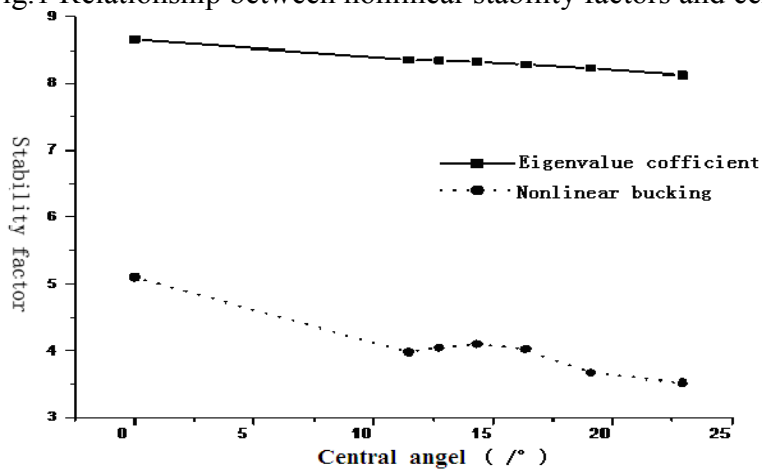

Fig.2 Relationship between stability factors and central angles

Slenderness ratios of bridge piers and their stability

Taking the Xu Shui river bridge in the Shan Xi province as the background, its design parameters were changed so that the central angles of the curves are 114.59°、76.39°、57.30°、45.84°、38.20°、28.65°、22.92°、0° and the slenderness ratios of the bridge piers are 33.15、37.30、41.44、45.59、49.73、53.87、58.02、62.17、66.31. This considers the self-weight and construction loads in the largest cantilever construction phase. When it considered the combination of large deformation and material nonlinearity, the T rigid-frame nonlinear stability coefficients were calculated. The relationship between slenderness ratio of the bridge piers, the curve central angle and the nonlinear stability coefficient is shown in the Fig.3.

Space of coupled double Thin-wall pier on stability

Drawn from the results in Fig 4 . As the double-limb space H is increased, the stability coefficients of main piers λ are increased. The relationship between H and λ can be fit for the formula (4).

$$\lambda = 8.88575 + 1.04663\,H + 0.02373\,H^2 - 0.00242\,H^3 \qquad (4)$$

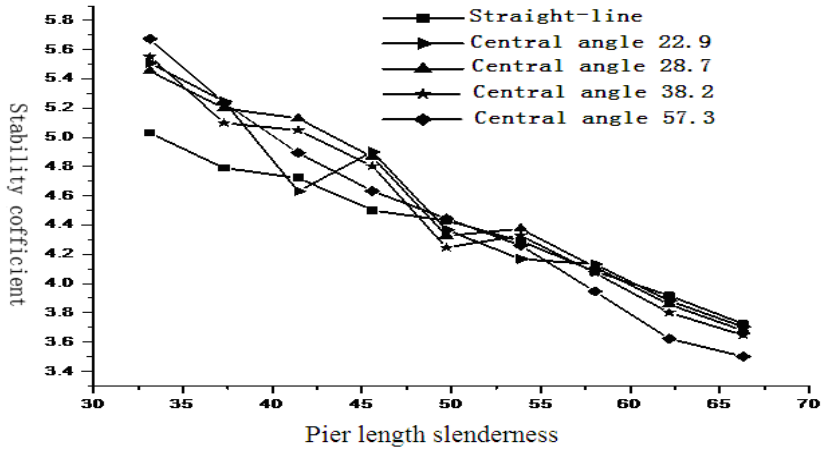

Fig.3 Relationship between slenderness ratio and nonlinear factors

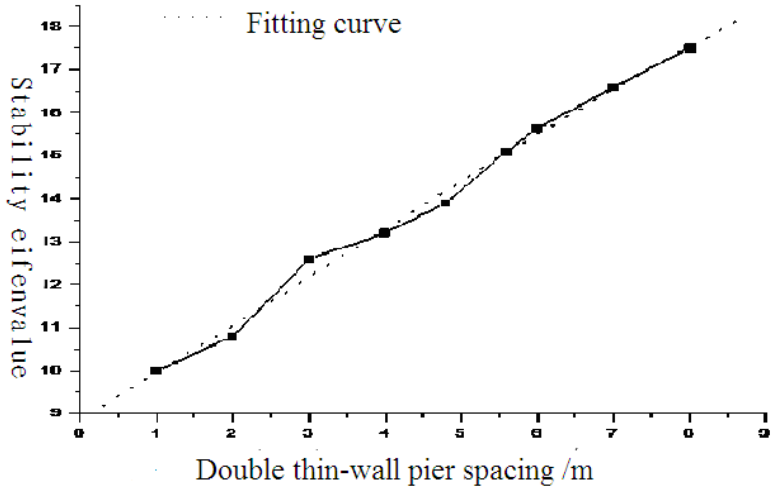

Fig.4 The space *H* and stability coefficient λ

By studying the design parameters and the stiffness of the thin wall on the structures, as well as their stability, through the optimize regression analysis of pier design parameters, we can get the conclusion as follows: With the decrease of the stiffness of the thin wall, the stability coefficient will be reduced; With the decrease of the space of the double-limb thin wall *H*, the stability coefficient λ will be reduced. As we can see, the stability of the bridge is also more sensitive to the space of double-limb piers.

Settings of tie beams on stability

The Long Tan river bridge has the highest piers of continuous rigid frame bridges in the domestic. The results are in table 3(a). In order to strengthen the rigidity of thin-wall hollow piers in longitudinal bridges, one tie beam was set every 60m. In view of this, tie beams increase the stability of the high-piers in longitudinal bridges. Through the spatial analysis, we could see that the first-order instability of the bridge is in transverse, and the stability factor was still large, so we could remove the tie beam when the bridge had been completed. During the construction, we could solve the stability problem by temporary support. To do that, we could not only solve the problem of excessive tensile stress of the tie beam, but also could reduce the

longitudinal stiffness of continuous rigid frame bridges, which is more conducive to the structure of the force.

Table 3(a) Stability Coefficient of Piers 178m High

Number of tie beam	0	1	2
Eigenvalue coefficients for cantilever construction	6.52	8.72	8.66
Eigenvalue coefficients for full-bridge	11.89	11.80	11.78
Nonlinear coefficients for cantilever construction	5.40	5.39	5.29
Nonlinear coefficients for full-bridge	5.32	5.39	5.34

For another long-span continuous rigid frame bridge, the height of the piers is 120m (spans are 110m+200m+110m). The nonlinear stability for thin wall piers is located at 0, 1, 2, 3, and 5 tie beams. The results are in table 3(b). The relationship between the stability factor and the number of tie beams is in Fig.5. As we can see, setting up a tie beam in the cantilever construction stage can improve the stability. However, additional tie beams will lead to the T-rigid frame stability factor being reduced with the increased number of tie beams. As we can see, setting up more tie beams is not favorable for the stability of the structure.

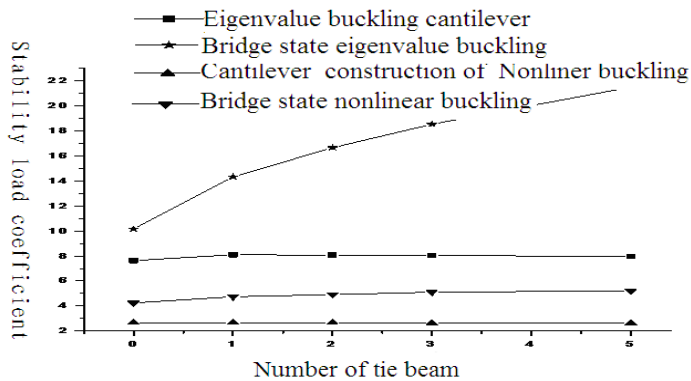

Fig.5 Stability coefficient λ and the number of tie beam

Table 3(b) Stability Coefficient of Piers 120m High

Number of tie beam	0	1	2	3	5
Eigenvalue coefficients for cantilever construction	7.62	8.10	8.06	8.03	7.97
Eigenvalue coefficients for full-bridge	10.15	14.32	16.65	18.53	21.50
Nonlinear coefficients for cantilever construction	2.67	2.68	2.67	2.65	2.63
Nonlinear coefficients for full-bridge	4.25	4.74	4.91	5.10	5.22

Piers setting of continuous rigid frame bridges

Based on the design of piers for dozens of typical high pier long-span continuous rigid frame bridges gathered in our country, through summing up and analyzing, we could see that there was certain regularity for span and the height of main piers, types of pier(double limb or single limb),cross section types(solid or hollow);While the span in above 160m, the main piers were set up for the hollow piers of the thin wall of one pair of limbs,their interval distance was mostly above 8m;While the span was smaller than 160m, the main piers were mostly set up for the solid thin wall with one pair of limbs,their interval was mostly under 8m;The heights of piers were 60～110m, one tie beam was set transversely; The heights were above 110m, 1 or 2 tie

beams were set up; The width of the piers in the transverse bridge was the same as the box beam. For the higher piers , their vertical width was greater ,which is a need of stability for the bridge.

Conclusion

Considering the large deformation and nonlinear material, the stability coefficient of high pier and long-span curve continuous rigid frame bridges is 35% of eigenvalue buckling. With the central angle increase, the stability coefficient will decrease rapidly, and the impact of the central angle is very prominent; There are certain regularities of design parameters and stability of large-span curved bridges. However, the span and pier height are dependent on the geomorphology and traffic requirements. Therefore, selecting the rational design type of the main pier is conducive to the structure internal force and structure stability; For small-span, we can select dual-limb solid thin-wall piers. Most spaces are at 8m below. But, as curved bridges, because of torsion, the thin-wall pier should not be too thin in the construction stage. While the span in above 160m, the distance between limbs is mostly above 8m. The stiffness of the piers was reduced with the increased height. When deformation need has been met, we can select thin-walled hollow single piers with bigger cross-sectional width to enhance the stability of the main piers; The heights of piers were 60～110m, one tie beam was set transversely; The heights were above 110m, 1 or 2 tie beams were set up, which is a need of stability for the bridge in construction and the full-bridge.

A Study on Spatial Correlation and Power Spectrum of Natural Wind at Xihoumen Bridge

LIU Ming，LIAO Haili，LI Mingshui, MA Cunming

Research Center for Wind Engineering, Southwest Jiaotong University, Chengdu, China, 610031, Email: rainmanok@gmail.com

Abstrat: In design of a long-span bridge, gust response of the bridge is very important and must be taken into account. The long-span structure has low natural frequency, small mass and extremely low inherent damping. The spatial correlation and spectrum of the wind in the low-frequency range affect the gust response However, there are very limited field data about spatial correlation of natural wind and wind spectrum. In the wind-resistance design, the decay factor is set to be 7, which affects the wind-resistance design of a long span bridge. Therefore, natural wind were measured at Xihoumen Bridge and the wind speed spectrum and spatial correlation are calculated. The results show that the spatial correlation of the natural wind is lower than that specified in the wind-resistance design specification of China in the low-frequency ranges. The most appropriate wind spectrum and decay factors fitting to the field measurements are recommended. This means that there is a possibility of being able to modify the design specification of long span bridge concerning gust response. The calculated results provide credible technical guide to construction of Xihoumen Bridge and ensure wind resistance safety.

Keyword: *Field measurement, Wind spectrum , Spatial correlation, Decay factor*

1.Introduction

With the emergence of high-strength materials and the development of design and construction technology, the development of long-span bridges has become more and more rapid. Because of large flexibility, relatively small mass and extremely low inherent damping, long-span suspension bridges are susceptible to vibrate caused by wind. Hence the effect of wind-induced responses has to be taken into account in the design of long-span suspension bridges. The power spectral density (PSD) and spatial correlation of wind-speed are important factors which affect the gust response of structures.

Xihoumen Bridge, located in the Xihoumen bay of ZhouShan City of China, is one of the longest span suspension bridges .It has a total length of 2713m including the main span of 1650m, and two side spans of 578m and 485m, respetively. The bridge is 36m wide with four traffic lanes, with a height clearance of 64.6m above water level. In order to investigate wind characteristics and to provide reliable field measurement data, anemometers were installed on the bridge deck 3.5m above the

deck and about 68m above the sea level. Field measurements at this bridge were conducted from October 2007 to March 2009.

These calculated results can provide credible technical guidance to construction of Xihoumen Bridge with ensured wind-resistance safety. The results can be used as references to the other bridges.

2. Field measurement

This paper presents full-scale data measured at the Xihoumen Bridge with focus on a power spectral density (PSD) and spatial correlation of wind-speed fluctuation, which are important factors of the wind-resistance design of a long-span bridge.

Four 3D anemometers are installed on the bridge deck (approximately 68m above sea level), The layout of anemometers at Xihoumen Bridge is shown in Fig1.Using data of any two anemometers, spatial correlation can be analyzed as a function of distance (T.Miyata et al., 2002). The average PSD quantities can be obtained using the data of the four anemometers.

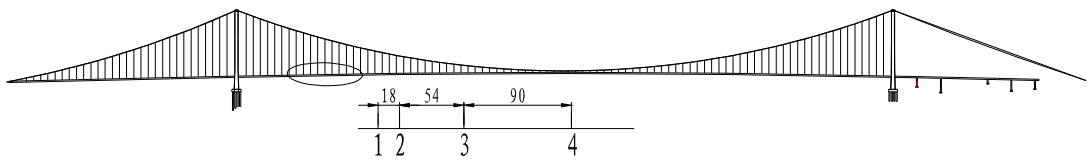

Fig1. Layout of anemometer at Xihoumen Bridge

3. Characteristics of wind

Fig. 2 and Fig.3 show the measured results of wind speed with four 3-D ultrasonic anemometers during a strong wind. As shown, the 10-min average wind speeds of the four anemometers are very similar. The 10-min mean wind speeds range from 1m/s to 19.4m/s. The longitudinal turbulent intensity (I_u) is from 0.04 to 0.25, and the longitudinal gust factor (G_u) is from 1.72 to 2.90. The average quantity of 10-min mean wind speed is 9.83m/s.

The mean values of I_u, I_v and I_w are 0.15, 0.114 and 0.05, respectively, and the ratio among them is I_u:I_v:I_w =1:0.75:0.35, which shows that the result from this field measurement is different from the recommended values by wind-resistance design specification of China. And the mean values of G_u,G_v and Gw are 2.32, 0.27 and 0.10, respectively.

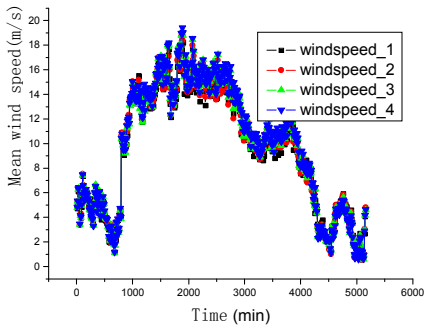

Fig2. 10-min average wind speed

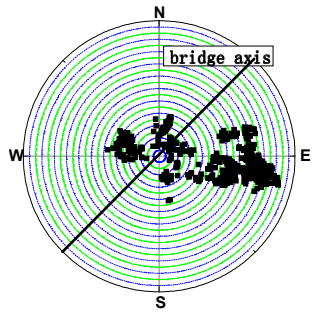

Fig3. 10-min average azimuth

2 Power spectral density

Power spectral density can describe the energy distribution of fluctuating wind velocity in frequency domain. Davenport has fitted some longitudinal wind velocity spectrum based on the field data measured in different regions and at different heights all over the world. Following that some researchers presented some empirical expressions based on Davenport's spectrum. Among many proposed spectra, the Kaimal spectrum and Panofsky spectrum have been recommended by wind-resistance design specification of China.

The field measured power spectral density of wind velocity was calculated using the Fast Fourier Transform technique (FFT) on transforming the turbulence velocity fluctuation time series data. Segment average and Hanning data windows were employed to smooth the spectrum. The parameters such as mean square value of longitudinal velocity fluctuation and longitudinal mean velocity are chosen to normalize the power spectral density and frequency.

Fitting the measured spectrum to theoretic spectrum (Pang, 2006), the following expressions can be used to describe the wind characteristics at Xihoumen Bridge during this strong wind:

Longitudinal wind spectrum: $$\frac{nS_u(n)}{\sigma_u^2} = \frac{6.79f}{(1+13.16f)^{5/3}} \quad (1)$$

Lateral wind spectrum: $$\frac{nS_u(n)}{\sigma_u^2} = \frac{4.18f}{(1+7.91f)^{5/3}} \quad (2)$$

Vertical wind spectrum: $$\frac{nS_w(n)}{\sigma_w^2} = \frac{0.38f}{(1+0.41f)^2} \quad (3)$$

Where S_u (n), S_v (n), S_w (n) are longitudinal, lateral and vertical power spectral density, respectively, n is the frequency; $f=nz/U$, and z is the height.

The comparison of longitudinal and vertical wind velocity spectrum with fitted spectrum has shown in Fig.4. It is shown that the fitted spectrum can describe the wind characteristics at Xihoumen Bridge very well.

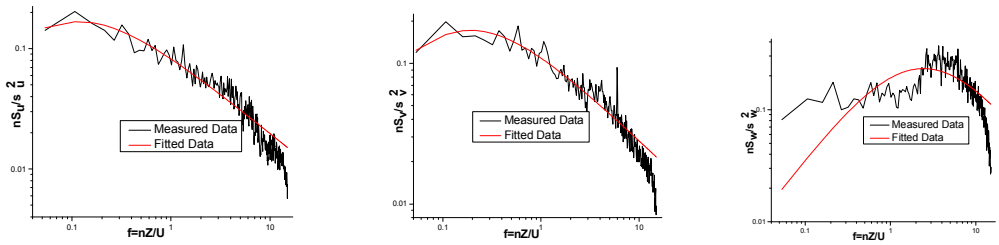

Fig4. Power spectrum of measured data at Xihoumen Bridge

3 Spatial correlation of winds

To determine the spatial correlation of wind, co-coherence of wind records are calculated, which is defined by the following equation (R. Toriumi et al., 2002):

$$Co-coherence=\frac{S_{uu}^{C}(,x1,x2,f)}{\sqrt{S_{uu}(x1,f)S_{uu}(x_2,f)}}=\exp(-k\frac{f\Delta y}{U}) \qquad (4)$$

Where $S_{uu}(x_1,f)$、$S_{uu}(x_2,f)$ is the spectrum of wind-speed fluctuation (u) at x_1 and x_2. $S^{C}_{uu}(x_1,x_2f)$ is the real part of cross-spectrum of u between x_1 and x_2, k is the decay factor, f is the frequency, $\Delta y=(|x_1-x_2|)$ is the transverse distance and U is the mean wind speed.

Co-coherence of data at Xihoumen Bridge calculated with Eq.(4) is shown in Fig.5. It is shown that no matter the distance is large or small, the coherence is unity when the frequency is zero. In addition, there is a tendency for the coherence to decrease with the increase of the distance between measurement points.

The decay factors are shown in Fig.8.and Table 1. It is seen that the decay factors range widely. While the distance is 18m, the decay factors are similar to the recommended values in wind-resistance design specification of China. Others are smaller than the recommended ones. There is a tendency for the decay factors to decrease with the increase of distance.

It also can be fund from Fig.6 that the decay factors have a weakly increasing trend with the increase of mean wind speed.

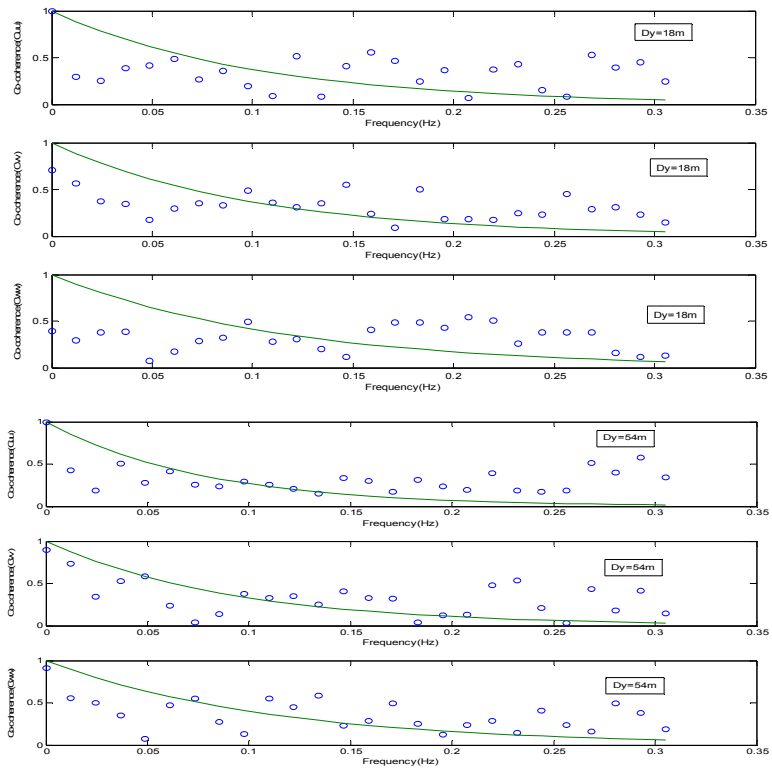

Fig.5 Co-coherence of measured wind data at Xihoumen Bridge

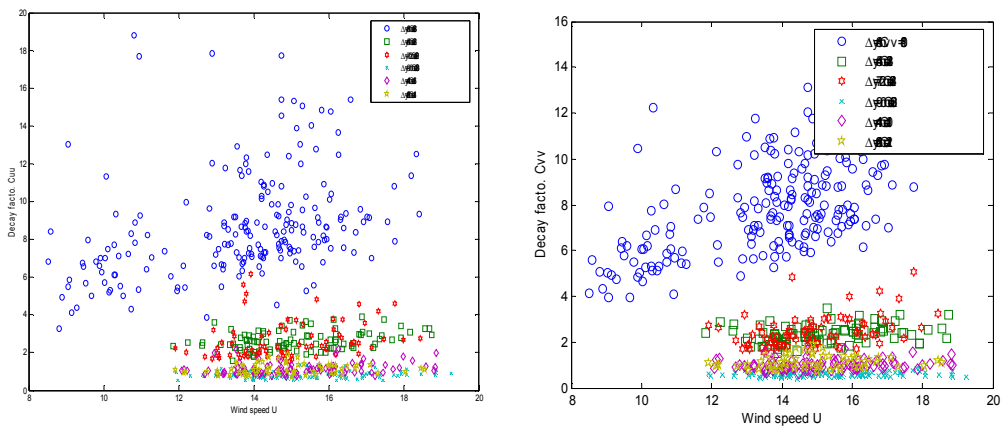

Fig.6 Decay factors at Xihoumen Bridge

Table 1. Decay factors at Xihoumen Bridge

Distance(m)	C_{uu}	C_{vv}	C_{ww}
18	8.68	8.01	9.19
54	2.63	2.34	2.85
72	2.69	2.46	2.56
90	0.84	0.62	1.21
144	1.16	1.01	1.23

162	1.14	1.12	1.16

4.Conclusions

This paper presents part of results from field measurements at the Xihoumen Bridge, Wind power spectral density and spatial correlation were analyzed and discussed. Some conclusions from this study are summarized as follows.

(1) Power spectral density were analyzed by fitting the PSD to Kaimal spectrum and Panofsky spectrum. The modified expressions can describe the wind characteristics at Xihoumen Bridge during this strong wind very well.

(2) It is seen that the decay factors range widely. While the distance is 18m, the decay factor is similar to the recommended values in wind-resistance design specification of China. But However other factors have lower values than the recommended ones. There is a tendency for the decay factors to decrease with the increase of the distance. The results show that the coherence is close to unity when the frequency is zero.

(3) These results come from the field data during only one strong wind. So a continuous and long-term field measurement should be carried out. More data should be collected to understand the general characteristics of natural wind at Xihoumen Bridge.

ABSTRACT

Self-anchored cable-stayed suspension Bridges ，as a new type of bridge is rarely investigated. Based on simulating turbulent wind fields, the effects of some factors such as geometrical nonlinearity, lateral aerodynamic memory effect, and fluctuating wind on main cables on buffeting response of the Dalian Harbor Sea-routine Bridge, a self-anchored cable-stayed suspension with 800m main span, are analyzed and the characteristics of buffeting response for the new type of bridge are summarized. It is worthy of concern in results that fluctuating winds on the cables causes the vibration of main cables and brings coupling vibration of the stiffing girder, which makes a greater effect on the girder of a self-anchored cable-stayed suspension bridge than those on the girder of a general suspension bridge.

Keywords: Self-anchored cable-stayed suspension bridge; Buffeting; wind field

1. INTRODUCTION

The 1360m long Dalian Harbor Sea-routine Bridge,as shown in Figure 1.,is a combined system bridge containing both self-anchored suspension bridges and cable-stayed bridges. It serves as a part of the Across Sea Highway of Dalian City in Northeast China and provides the vital linkage between the urban area and the economic development area. The bridge deck consists of a pre-stressed concrete box girder within the cable-stayed bridge and a steel box girder within the suspension bridge,which to a larger degree reduces investment and improves the mechanical properties of the structure. Moreover,the total 8 hangers were arranged at the connecting zone so as to improve the fatigue of the side hanger cables. Differing from traditional cable-stayed suspension bridges, the main cables of the Dalian Harbor Sea-routine Bridge are anchored at the ends of the stiffening girder,so it is

named as a self-anchored cable-stayed suspension bridge. As a result, the horizontal components of the main cables' force are transferred to the girder, which will reduce the stiffness of the girder due to P-Δ effects (Huang et al.,2007); The wind-reduced vibration of the new type of cable supported system will be more serious. The Dalian Harbor Sea-routine Bridge is located at the entrance of Dalian Bay. The bridge site is mainly affected by tropical cyclones, or typhoons, that generally occurre between May and August. Therefore, the aerodynamic behavior of the Dalian Harbor Sea-routine Bridge is of great concern, not only to the bridge itself, but also to the new type of combined system.

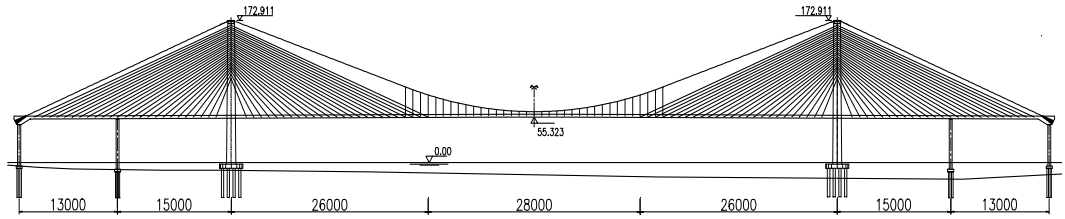

Figure 1. Layout of Dalian Harbor Sea-routine Bridge（unit: cm）.

In the current study, buffeting response of the Dalian Harbor Sea-routine Bridge is performed and the effects of some factors such as geometrical nonlinearity, lateral aerodynamic memory effect and fluctuating wind on main cables on buffeting response have been analyzed. Some characteristics regarding buffeting response and several suggestions being favorable to guide the anti-wind design of the new type of system are obtained.

2. SIMULATION OF WIND FLUCTUATIONS

The turbulent wind field is a random variable related to time and spatial position and it has been recognized that the along-wind turbulence “u” and vertical turbulence “w” can be considered as stationary Gaussian random processes with zero means. Therefore, they can be generated using the techniques for digital simulation of multidimensional random processes. According to a theory developed by Shinozuka, the sample of random process F(t) can be expressed as (Cao et al.,1998)

$$f_j(t) = \sum_{m=1}^{j} \sum_{l=1}^{N} \left| H_{jm}(w_{ml}) \right| \sqrt{2\Delta w} \cos[w_{ml} t + \theta_{jm}(w_{ml}) + \phi_{ml}], j = 1,2,\cdots,n \qquad (1)$$

Where N is the sum of sampling frequencies; $\Delta\omega = \omega_{up} / N$, ω_{up} is the maximum circular frequency(i.e.,when $\omega > \omega_{up}$, $S(\omega) = 0$); ϕ_{ml} is a random phase angle with indexes; $\theta_{jm}(w)$ is the argument of $H_{jm}(w)$; $H_{jm}(w_{ml})$ is a element of Cholesky decomposed matrix of cross spectral density matrix.

The Eqs.(1) is adopted to simulate the wind fields of the Dalian Harbor Sea-routine Bridge and some parameters related to the simulation are given, such as bridge deck elevation of 60m, terrain roughness length of 0.01m, mean wind velocity of 40m/s, the maximum circular frequency of 4πrad/s,time interval of 0.025s,the total 195 nodes along the girder and the tower as well as the main cables,10 min duration. The comparison between the simulated correlation function as well as power spectra at midspan and goal results are shown in Figure 2 and Figure 3 and it can be indicated that the simulated fluctuating wind velocities are available.

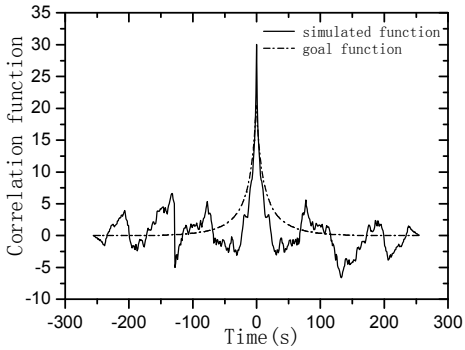

Figure 2. Horizontal fluctuating velocity correlation functions at mid-span.

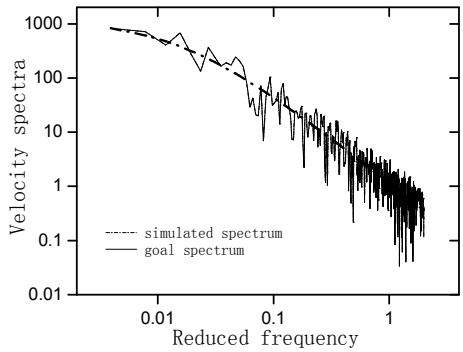

Figure 3. Horizontal fluctuating velocity power spectra at mid-span.

3. CALCULATION OF AERODYNAMIC FORCES

3.1. CALCULATION OF BUFFETING FORCES

A.G.Davenport gave the buffeting force expressions in the time domain based on quasi-steady theory(Chen et al.,2000), as follows

$$\left.\begin{aligned} D_b(x,t) &= \frac{1}{2}\rho U^2 B[2C_D(\alpha_s)\frac{u}{U}+C_D^{'}(\alpha_s)\frac{w}{U}] \\ L_b(x,t) &= -\frac{1}{2}\rho U^2 B\{2C_L(\alpha_s)\frac{u}{U}+[C_L^{'}(\alpha_s)+C_D(\alpha_s)]\frac{w}{U}\} \\ M_b(x,t) &= \frac{1}{2}\rho U^2 B^2[2C_M(\alpha_s)\frac{u}{U}+C_M^{'}(\alpha_s)\frac{w}{U}] \end{aligned}\right\} \quad (2)$$

Where u and w are horizontal and vertical fluctuating wind velocity,respectively; C_D, C_L and C_M are drag, lift and moment coefficients with mean static wind attack of α_s ,respectively,which can be obtained from wind tunnel test ; $C_D^{'}=dC_D/d\alpha$, $C_L^{'}=dC_L/d\alpha$ and $C_M^{'}=dC_M/d\alpha$.

Based on the above the simulated fluctuating wind velocity,the buffeting forces acting on the overall bridge can be obtained.

3.2. CALCULATION OF SELF-EXCITED FORCES

Scanlan put forward, firstly, the mathematical model of self-excited forces expressed with aerodynamic derivatives in the frequency domain based on the linear hypothesis(Xiang, 1994). This assumption, however, is not appropriate for long-span bridges, where nonlinearity due to either geometric or aeroelastic effects must be considered. As an alternative method, buffeting response of long-span bridges under wind turbulence can be analyzed in the time domain. An efficient calculating method involving impulse response functions of self-excited forces for long-span bridges developed by Y. K. Lin (Liu et al.,1996)) is adopted in this study.

4. INFLUENCE FACTORS ANALYSIS OF BUFFETING RESPONSE

4.1. INFLUENCE OF GEOMETRIC NONLINEARITY

It is well known that long span bridges should take geometric nonlinearity into account. The comparison, considering geometric nonlinearity or not, of vertical, lateral and torsional displacements at midspan of the girder are shown in Figure 4. It can be seen that the effects considering nonlinearity on the vertical displacements of buffeting response may be neglected, but on the lateral and torsional displacements the effects are considerable and all results are smaller than those only considering linearity. The reasons of which are that the P-Δ effects reduced the stiffness of the girder. For the cable supported bridges, however, the main members of the supporting loads are the main cables and hangers as well as the stays. The lateral displacements enlarged the axial forces of those members and therefore gave more contributions to the overall stiffness of the structure due to the effect of stress stiffening.

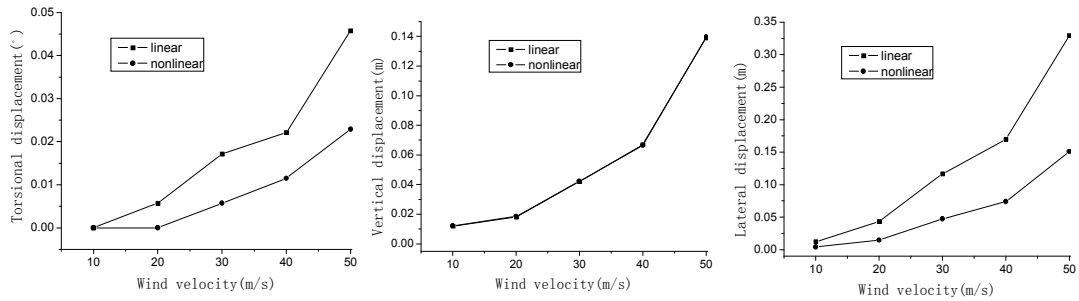

Figure 4. Comparison of displacements at midspan considering nonlinear factors or not.

4.2. INFLUENCE OF LATERAL AERODYNAMIC MEMORY EFFECT

The effects of lateral motion on sel-excited forces are in general not considered because aerodynamic derivatives related to the lateral freedom degree can not be obtained due to extensive use of a double freedom section model in wind tunnel tests so far, which will affect the precision of the buffeting response and accurate evaluation of structural fatigue life. Hence,the lateral aerodynamic derivatives

according to expression given by Y. K. Lin (1996) are used to analyze the buffeting response here. It can be observed from Figure 5 that lateral aerodynamic memory effect has little effect on vertical displacements, whereas influence on torsional displacements, especially on lateral displacements, has a considerable effect and the tendency becomes greater with the addition of wind velocity. So the long span self-anchored cable-stayed suspension bridge should consider the effects of lateral aerodynamic memory effect on the buffeting response.

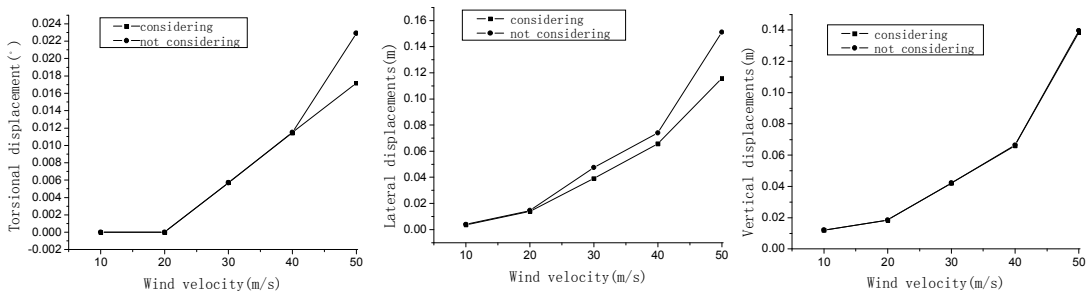

Figure 5. Comparison of displacements at midspan considering lateral aerodynamic memory effect or not.

4.3. INFLUENCE OF FLUCTUATING WIND ON MAIN CABLES

Buffeting response analysis of bridges donsn't generally take the influence of fluctuating wind on main cables into account. One of the reasons lies in the limitation of the method of simulating wind fields; the other is that some researchers think subjectively that the influence is but little, but the actual conditions have not been known clearly so far due to lack of specific materials. Based on the above simulated turbulent wind fields containing the main cables, the results of the buffeting response at midspan of the Dalian Harbor Sea-routine Bridge are shown in Figure 6.

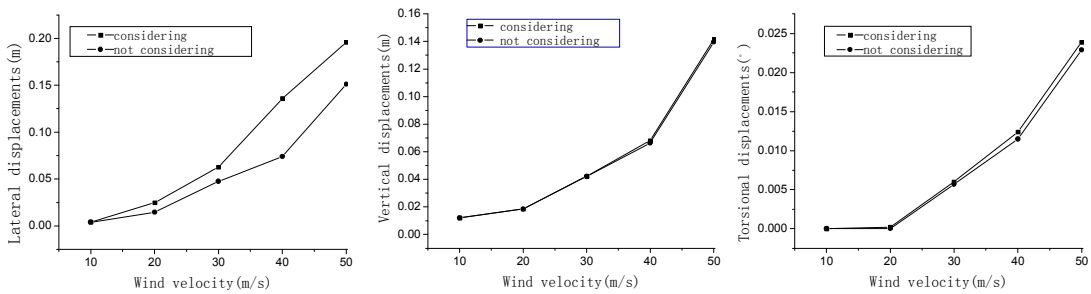

Figure 6. Comparison of displacements at midspan considering fluctuating wind on cables or not.

The fluctuating wind on the main cables makes a considerable effect on the lateral displacements of the girder at the midspan.Effects on torsional displacements can also not be ignored, which are different from those of Jiangyin Bridge,a long span suspension bridge with 1385m main span. The reasons for the greater effects lie in that, on the one hand, the cables of self-anchored cable-stayed suspension bridges are denser than those of suspension bridges, which results in greater fluctuating wind loads, and on the other hand the gravity stiffness is smaller because loads supported by the main cables are only a part of the overall loads of the bridge, which made the main cables liable to vibration under fluctuating wind loads and further enlarged the vibration of the girder due to the coupling effects between main cables and the girder. In other words, the main cables and the girder are connected through, not only hangers, but also anchor block at the ends of the girder. It is therefore worthy of concern the effects of fluctuating wind on the main cables on the girder of self-anchored cable-stayed suspension bridges.

5.CONCLUSIONS

The paper analyzes the buffeting response of self-anchored cable-stayed suspension bridges such as the Dalian Harbor Sea-routine Bridge. The theoretical analysis reveals that the effects of geometrical nonlinearity and lateral aerodynamic memory effect on the girder of the new type of cable supported bridge can not be ignored; the former reduces the lateral and torsional displacement of the girder at midspan and the tendency becomes more obvious with the addition of wind velocity whereas the latter reduces the torsional displacement and especially the lateral displacement at the same position. It is worthy of concern that the fluctuating wind on the main cables makes a greater effect on torsional displacement of the girder than those of general suspension bridges.

Abstract

The method of stiffness reduction had been adopted to consider nonelastic characteristics of reinforced concrete in concrete structure standard of the United States and Canada. Concrete structure design code of China also accepted the method of stiffness reduction as a supplementary way to solve the second-order effects problem when necessary. However, bridge code of China still uses amplified coefficient of eccentricity to consider nonlinear characteristics of reinforced concrete. In view of the absence of investigation in the stiffness reduction of reinforced concrete bridge pier, this paper adopts the numerical integral method to computerize simulation and analyze the regulation of the stiffness change for rectangular section reinforced concrete bridge pier under different axial compression ratio and different forces of horizontal earthquake action, which is verified according to the test result. As a result, a stiffness reduction factor is proposed to consider nonlinear characteristics of reinforced concrete bridge pier.

Keywords: Reinforced concrete bridge pier, numerical integral method, nonlinear characteristics, stiffness reduction factor

1. Preface

Reinforced concrete bridge pier represents characters of material and geometric nonlinearity under ultimate limit state. The material nonlinearity is affected mainly by nonlinear elastic constitutive relation of components material, components cracking and slippage of reinforced bar. The geometric nonlinearity displayed mainly at additional internal force and additional displacement caused by axial force acting on deflection components or vertical load acting on lateral displacement structure, which is second-order effects. The stiffness reduction method had been adopted to consider nonelastic characteristics of reinforced concrete in concrete structure standard of the United States and Canada. Concrete structure design code of China also accepted the stiffness reduction method as a supplementary way to solve the second-order effects when necessary. However, bridge code of China still uses the amplified coefficient of eccentricity to consider nonelastic characteristics of

reinforced concrete. In view of the absence of investigation in the stiffness reduction of reinforced concrete bridge pier, this adopts the numerical integral method to computerize simulation and analyze the stiffness change regulation. In particular, for rectangular section reinforced concrete bridge pier under different axial compression ratio and different forces of horizontal earthquake action in test model of literature [4], and it is verified by the test results. Finally, a stiffness reduction factor is proposed to take account of the above-mentioned two nonlinear characteristics of reinforced concrete bridge pier.

2. Analysis principle

The moment-curvature relation computer program is compiled by numerical integral method to computerize simulation the rectangular section member, which is analyzed under different axial compression ratio and different forces of horizontal earthquake action.

2.1. Basic assumptions of the program

To computerize simulation nonlinear full range analysis of rectangular section reinforced concrete bridge pier with biaxial bending and compression, the computer program is based on following assumptions:

1). The average strain accords with the assumption of plane section in the whole force analysis process.

2). The strength of concrete is neglected in tensile area, and the stress-strain relationship of concrete in compressive region references the kent-park model [5], as shown in Figure 1.

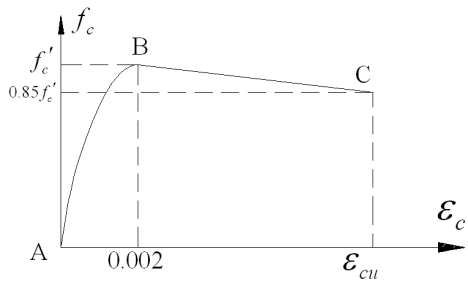

Figure 1. Stress-strain curve of concrete.

In Figure 1, the characteristics of the curve are as follows:

$$\sigma_c = \begin{cases} AB: f_c'[2\varepsilon_c / 0.002 - (\varepsilon_c / 0.002)^2], \\ \qquad (\varepsilon_c \le 0.002) \\ BC: f_c'[1 - 0.15(\varepsilon_c - 0.002)/(\varepsilon_{cu} - 0.002)], \\ \qquad (0.002 \le \varepsilon_c \le \varepsilon_{cu}) \end{cases} \quad (1)$$

Where, f_c' is the prism compressive strength of concrete, and ε_{cu} is the ultimate compression strain of concrete, which is 0.004255. Considering eccentrical compression and primary axial compression model have influence on descent segment, this adjusts the slope of the descent segment to be 0.15.

3). Stress-strain curve of longitudinal reinforcement is assumed to perfect plastic elastic material and takes the double broken line model shown in Figure 2.

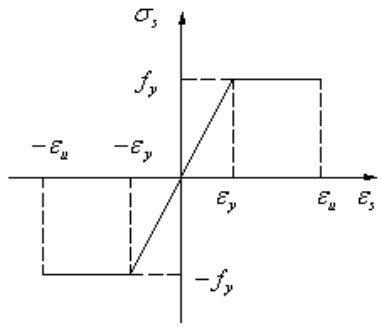

Figure 2. Stress-strain curve of reinforcing bar.

4). The spalling of cover concrete is not considered.

5). Dividing the section into numbers of small rectangle units and approximate thinking its resultant force located in the centroid of units.

6). Concrete shrinkage and creep effect in compressive region is ignored.

2.2. Programming principle

The moment-curvature relation of rectangular section reinforced concrete bridge pier with biaxial bending and compression is gotten by adding curvature step by step under axial force N and loading angle α. α is shown in Figure 3 and its positive direction is anticlockwise. The specific method is as follows:

1). Preliminary selection distance R and angle θ are shown in Figure 4. Thus, the distance between each reinforcing bar of the section and neutral axis, as well as the distance between each concrete elements centroid and neutral axis can be calculated from:

$$r_i = R - (x_i^{'} \cos\theta + y_i^{'} \sin\theta) \qquad (2)$$

Where x_i', y_i' are coordinates of point i.

2). To determine section initial curvature Φ_0.

Based on plane section assumption, concrete stress σ_{ci} of point i and reinforcing bar stress σ_{sj} of point j are obtained according to strain equation $\varepsilon_i = \Phi_0 r_i$ of point i and stress-strain relationship of concrete and reinforcing bar. Therefore, the section internal force N', $M_{\mathrm{x}}^{'}$ and $M_{\mathrm{y}}^{'}$ are gotten by the equilibrium condition of force.

3). Comparing obtained force N' with N, as well as the resistance loading angle β ($\beta = arctg(M_{\mathrm{x}}^{'} / M_{\mathrm{y}}^{'})$) with the given loading angle α to see whether they satisfy the requirement error. If they do not satisfy the above-mentioned two requirement error, then change the location parameter of neutral axis and the normal angle, and recalculate until they satisfy the requirement error. Therefore, M' is the corresponding

M value of the reinforced concrete bridge pier with biaxial bending and compression when the value of curvature Φ is given.

4). Adding curvature Φ in proportion, and repeating steps 1~3, seeking the corresponding value of M. Obtaining the value of Φ_u and M_u when the maximum compressive strain of the edge in compressive region arrives the instability strain of compression reinforcement.

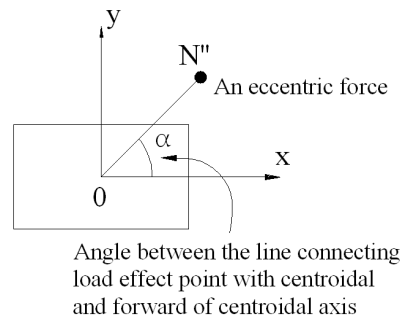

Figure 3. Definition of loading angle α .

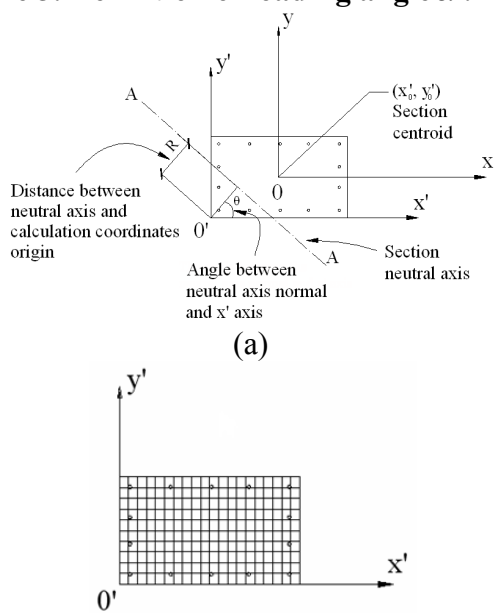

Figure 4. Calculated models.

3. Program verification

3.1. Verification of the moment-curvature relation

To verify the reliability of the computer program, the nonlinear program of the normal section bearing capacity of the rectangular section reinforced concrete bridge pier is applied to simulate and analyze the test model in the literature. The theoretical value and the test value are shown in Figure 5~8.

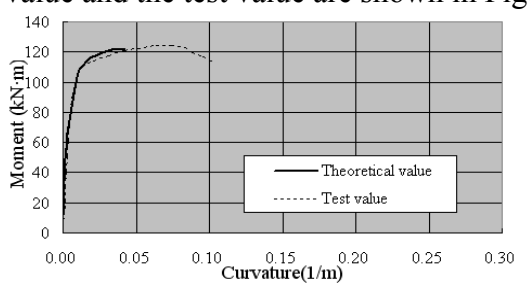

Figure 5. Moment-curvature relation of 1# bridge pier.

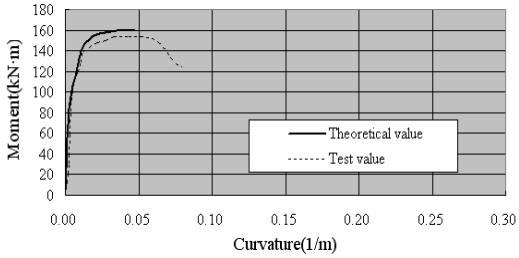

Figure 6. Moment-curvature relation of 2# bridge pier.

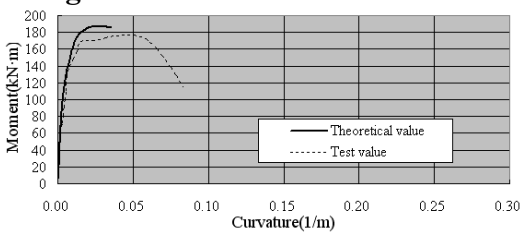

Figure 7. Moment-curvature relation of 3# bridge pier.

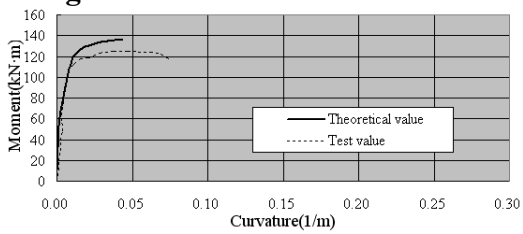

Figure 8. Moment-curvature relation of 4# bridge pier.

We can see that the theoretical value of the moment-curvature relation agree well with the test value of the moment-
curvature relation from Figure 5~8.

3.2. Verification of horizontal displacement of the theoretical value and the test value.

Based on the test model in the literature and taking 1# bridge pier for example. It can be divided into five equal portions along the height and its axial compression ratio is 0.1, then choosing eight degree of earthquake resistance protection seismic and the second kind of ground. Thus, the standard value of horizontal earthquake action is 20.97kN and the moment of each section is obtained. According to the moment-curvature relation computer program in this paper, the curvature of each section can be gotten by the moment of each section. Then the horizontal displacement of the top of the bridge pier is calculated from the curvature distribution along height of the bridge pier.

The moment considered second-order effects of each section are gotten on the basis of the horizontal displacement of the top of the bridge pier, so as to determine the curvature considered second-order effects of each section, then the final horizontal displacement of the top of the bridge pier as shown in Table 1 is calculated from the curvature distribution along the height of the bridge pier, which has considered the second-order effects.

Table1. Summary of results for horizontal displacement.

Speci-men	Axial Compressi-on Ratio	Calculated Value (mm)	Test Value (mm)	Percent Difference
1	0.1	7.69	7.58	+1.45%
2	0.175	19.85	17.73	+11.96%
3	0.25	52.22	57.86	-9.75%
4	0.125	29.45	23.58	+24.89%

We can obtain that the horizontal displacement of the theoretical coincides quite well with the horizontal displacement of the test.

4. The analysis procedures for determining the stiffness reduction factor of rectangular section reinforced concrete bridge pier

4.1. Calculation procedures

1). Determining the geometric parameters, sectional reinforcement and concrete strength of the example according with current standard.
2). Selecting different axial compression ratio of the example to calculate the moment-curvature relation.
3). Determining the force of horizontal earthquake action and dividing the example into five equal portions along the height.
4). Determining the horizontal displacement according to structural mechanics method and the moment of each section considered second-order effects.
5). Obtaining the curvature of each section according to the moment-curvature relation.
6). Obtaining the stiffness reduction factor on the basis of bending energy equivalent principle.

4.2. Calculation the stiffness reduction factor

The internal force of each elements and the displacement of each nodes are calculated from the moment-curvature relation. Figure 9 represents the final deformation of some the bridge pier segment, which has totally n nodes and is divided into $n-1$ elements. The average bending stiffness $(\overline{EI})_i$ of the i element is calculated from the moment of the element and the rotation angle of the element nodes. Supposing the average moment of the i element is $\overline{M_i}$, and the relative rotation of two ends of the element is $\Delta\varphi_i$ and the length of the element is Δs_i, then the average curvature can be written as:

$$\overline{k}_i = \frac{\Delta\varphi_i}{\Delta s_i} \qquad (3)$$

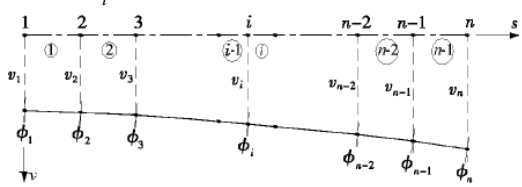

Figure 9. The final deformation of some bridge pier segment

By the moment-curvature relation, the average bending stiffness $(\overline{EI})_i$ of the i element can be written as: $(\overline{EI})_i = \dfrac{\overline{M_i}}{\overline{k_i}}$ (4)

The whole equivalent bending stiffness of the bridge pier segment can be calculated from the bending energy equivalent principle of the investigated bridge pier segment. Therefore, the equivalent bending stiffness reduction factor α_e is obtained.

Bending deformation energy of some bridge pier segment can be written as:

$$E_b = \frac{1}{2}\sum_{i=1}^{n}\overline{M}_i\Delta\varphi_i = \frac{1}{2}\sum_{i=1}^{n}(\overline{EI})_i\overline{k}_i^2\Delta s_i \quad (5)$$

Supposing the bending stiffness of some uniform-section elastic pole is $(EI)^*$, which has the same bending deformation energy with the original bridge pier segment in the same forming process condition. It can be written as follow:

$$E_b = \frac{1}{2}\sum_{i=1}^{n}(EI)^*\overline{k}_i^2\Delta s_i \quad (6)$$

$(EI)^*$ can be calculated from formula (5)~(6), then the equivalent bending stiffness reduction factor α_e can be shown as the following:

$$\alpha_e = \frac{(EI)^*}{EI} = \frac{\sum_{i=1}^{n}(\overline{EI})_i\overline{k}_i^2\Delta s_i}{EI\sum_{i=1}^{n}\overline{k}_i^2\Delta s_i} \quad (7)$$

5. Calculation examples analysis for determining the stiffness reduction factor of rectangular section reinforced concrete bridge pier

5.1. Basic parameters of the examples

The data of the test model in literature [4] is taken to use computer to computerize simulation under different axial compression ratio and different forces of horizontal earthquake action. The cubic compressive strength of concrete is 35.0 N/mm^2 and the elastic modulus of concrete is 40GPa. The main reinforcing bar is Φ10 of HRB335, whose yield strength is 375.0 N/mm^2 and elastic modulus is 200GPa. Other parameters are shown in Table 2.

Table2. Some parameters of the examples.

Specimen	Axial Compression Ratio	Bridge Pier Height (m)
1	0.1	3.0
2	0.175	3.3
3	0.25	3.6
4	0.125	3.9

5.2. Calculation results analysis for the example

Based on the formula (7), the stiffness reduction factors of rectangular section reinforced concrete bridge pier are finished into Table 3.

Table3. Stiffness reduction factors.

Specimen	Axial Compression Ratio	Stiffness Reduction Factor
1	0.1	0.39
2	0.175	0.35
3	0.25	0.24
4	0.125	0.28

6. Conclusion

Through theoretical analysis of the test results, we can obtain that the theoretical results agree well with the test results. The axial compression ratio has influence on stiffness reduction factor. The suggestion stiffness reduction factor of rectangular section reinforced concrete bridge pier is 0.3, which is an average value.

Abstract: As cracking is one of the leading and most critical types of deterioration for reinforced concrete (RC) bridges, how to properly assess cracking condition is of great importance for effective concrete bridge management. However the current assessment techniques are subjective, time-consuming, and rely mostly on human visual inspection. In order to improve the effectiveness of cracking condition assessment, a fuzzy neural network (FNN) system was developed in this study, as an alternative to traditional assessment methods. Based on the comprehensive analysis of RC bridge cracking，this paper also set up the assessment criteria for RC bridges for both flexural cracking and shear cracking, and gives the form of membership function for each criterion. Finally the system was verified using statistical crack samples of several RC bridges.

Keywords: RC bridges; Cracking Assessment; criteria; fuzzy-neural networks

1 Introduction

Cracking can be of various sizes and can occur anywhere on concrete surface, and may also lead to severe deterioration, such as rebar corrosion, to reinforced concrete (RC) bridges if they are wide and/or deep enough. Elzafraney (Elzafraney 2005)has analyzed microcracks quantitatively for RC bridge deck; the causes of transverse RC deck cracking have been summarized by classifying them into three categories and the effects of design factors were studied with a finite-element method(Hadidi 2005., Saadeghvaziri 2005). The influence factors of cracking, however, are too complicated to be analyzed precisely.

Furthermore, as cracking is one of the leading and most critical types of deterioration for RC bridges, how to properly assess cracking severity is of great importance for effective concrete bridge management. In order to evaluate cracking effectively, and due to the fact that the current assessment techniques are subjective, time-consuming, and rely mostly on human visual inspection, many studies have been conducted in this field. AbdelRazig and Chang(AbdelRazig and Chang 2000) constructed a model applying digital image processing and neural network techniques for constructed facilities surface quality assessment; condition state evaluation systems of concrete slabs and existing RC bridges were developed using neuro-fuzzy hybrid system, that considering cracking with the maximum crack width and crack condition(Kawamura 2003). In many cases cracking is only roughly considered as a kind of defect with no more attention being paid(Brito 1996, Zhao 2002).

Based on the comprehensive analysis of RC bridge cracking，in this study, the assessment criterion system of simple supported RC bridges was set up for both flexural cracking and shear cracking, and the membership functions were specified for each criterion. Next, the fuzzy-neural network system was developed to assess the crack condition of RC bridges. Finally the system was verified using statistical crack samples of several RC bridges.

2 Assessment criteria

Actually cracking on a RC beam surface can be classified under the following major categories: flexural cracking which is induced by flexural stresses; shear cracking which often occurs in the regions between a supported point of a beam (or slab) and its 1/4 span, induced by shear stresses; shrinkage cracking due to drying and thermal shrinkage; and the longitudinal horizontal cracking caused by reinforced bar corrosion. As for existing concrete bridges which have serviced for a certain period, the shrinkage due to drying and thermal has completed, and the shrinkage cracking could be ignored since they are always stable. The longitudinal horizontal cracking always means severe rebar corrosion and can be considered as a key factor in the analysis and assessment of rebar corrosion. So for in-service RC bridges attentions should be paid to flexural cracking and shear cracking when studying cracking.

The influence factors for condition state assessment of flexural cracking and shear cracking were sorted into two types: indirect and direct. The indirect factors include age, traffic volumes, the heaviest traffic load, environment, the structure type, concrete grade etc., while the direct factors are the cracking shape, space, location, degree of orientation, width, depth, length, and crack number. Of course it is impossible to consider all the factors to evaluate the cracking for RC bridges. So the assessment criteria must be extracted from all the factors before the assessment process goes on.

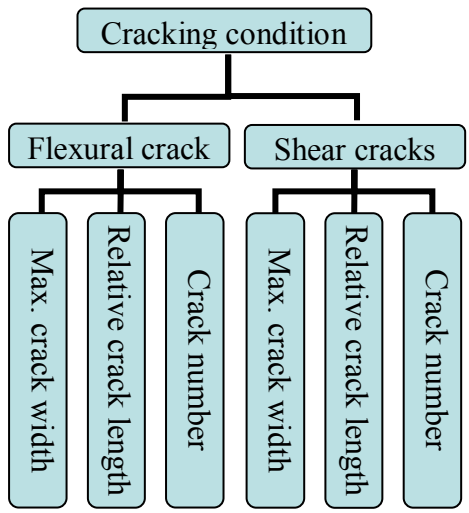

Fig. 1. The criteriA for cracking condition

Based on an overall analysis, Fig.1 presents the criteria for simple supported RC bridge cracking condition state assessment. Here the relative crack length is the ratio of the widest crack length to the beam height or of its vertical reflection height to the beam height for shear cracking. And in terms of these criteria the cracking condition

has 5 rates with larger number indicating more severe condition, as shown in Table 1.

Table 1 Definitions for crack condition states

Cracking condition	Definition
1 (Excellent)	No visible cracks
2 (Good)	The max. crack width is less than the acceptable value
3 (Moderate)	The max. crack width is larger than the acceptable value, but its relative length is small
4(Severe)	The max. crack width is larger than the acceptable value, and its relative length is medium
5(Dangerous)	The max. crack width is larger than the acceptable value, and its relative length is large

The final general assessment result for a simple supported RC bridge depends on the more severe cracking condition between the flexural cracking and the shear cracking.

3 Fuzzy neural network (FNN)

Here the neural network techniques were combined with fuzzy logical system to develop the FNN system in which membership functions and fuzzy rules were described with the neural network implicit language. Fig.2 indicates the topological configuration for a multi-layer FNN with application of the error back propagation (BP) method. Details about FNN could be found in references(Kawamura 2003, Zhao 2002).

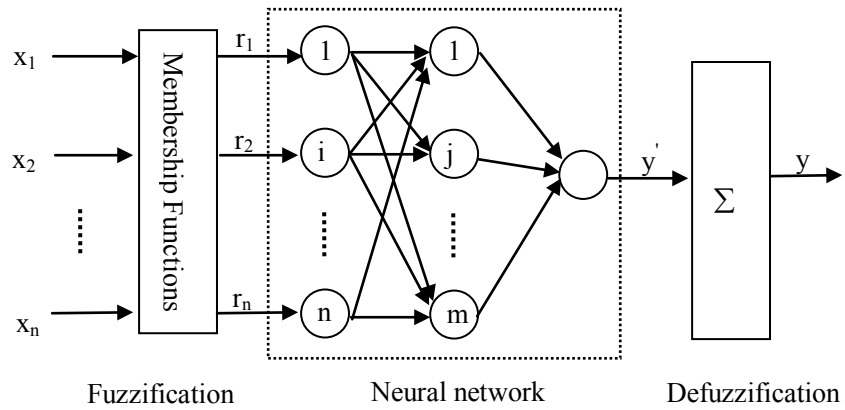

Fig.2. Configuration for the fuzzy-neural network

3.1 Fuzzification and defuzzification

With the pre-processing of inputs and the post-processing of outputs FNN is able to integrate fuz-zy concepts into the input-output system. For in-stance, if a variable space was divided into five independent subsets, named as A、B、C、D and E, respectively,

Then a n dimensional input vector X_n could be extended into a 5n dimensional vector, written as：

$$X_{5n}=\left[U_{A(x_1)}(x_1),U_{B(x_1)}(x_1),\cdots\cdots;U_{D(x_n)}(x_n),U_{E(x_n)}(x_n)\right]^T \qquad (1)$$

where $\left\{U_{A(x_i)}(x_i), U_{B(x_i)}(x_i), \cdots\cdots, U_{E(x_i)}(x_i) \mid (i=1,2,\cdots,n)\right\}$ are the grades of membership function of x_i corresponding to each fuzzy subsets..

And the centroid-average method was used to defuzzify the system outputs,, expressed as：

$$y = \sum_{k=1}^{M} (k \times y_k^{'}) / \sum_{k=1}^{M} y_k^{'} \qquad (2)$$

where y is the defuzzified output, M is the number of possible values for a certain variable, k is the value given to the variable and $y_k^{'}$ is the system output corresponding to k.

3.2 Membership function

The form of membership functions is crucial for fuzzy inference, but now its choice can only rely on experiences without any theoretical proof. For those qualitative problems such as cracking condition, the monodrome function is enough. While for those quantitative criteria such as the max. crack width, the monodrome function may be too simple and may also lead to wrong results since the cut-off points of data space cannot be defined properly. In the present study sigmoid functions were applied. A sigmoid function is given as:

$$F(X) = \left[1 + e^{-X}\right]^{-1} \qquad (3)$$

$$X = Wx + \theta \qquad (4)$$

where X is the weighted sum of input variables, W is the weight vector and θ is the threshold vector(Kawamura 2003a).

(1) Membership function for relative crack length

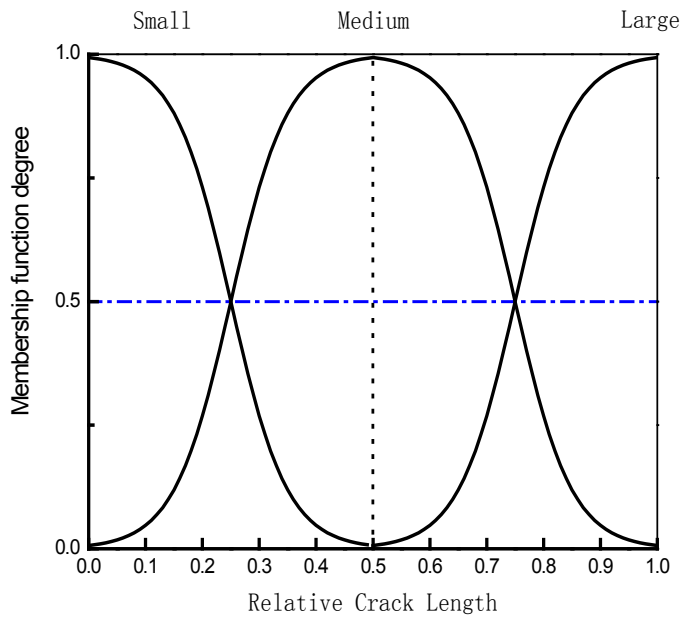

Fig.3. Membership function for relative crack length

The relative crack length is the ratio of the widest crack length to the beam height or of its vertical reflection height to the beam height for shear cracking. And its evaluation space was set with 3 fuzzy subset: Small, Medium and Large, as shown in Fig.3.

(2) Membership function for max. crack width

The max. crack width can be obtained easily., and its limited value was set to be 1mm. If the measured value is larger than 1 mm, it means this width belongs to the "huge" subset and its grade of membership function equals to that of 1mm. The membership function for the max. crack width was shown in Fig. 4.

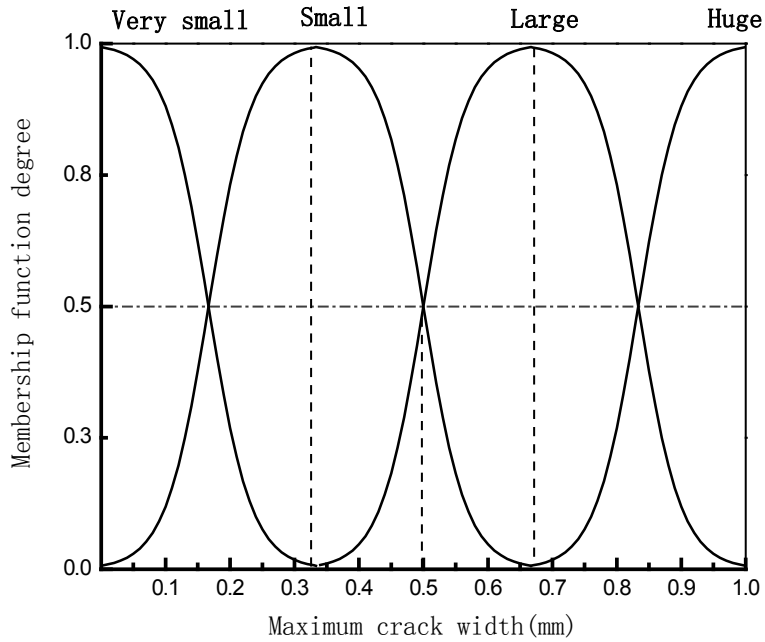

Fig.4. Membership function for max. crack width

(3) Membership function for crack number condition

Even located in the same region different cracks may bring different influences upon the structure due to their differences in length and width. So the influences of cracking length and width must be considered when the criterion, the number of crack, is evaluated. The following formula describes the cracking number condition with considering the cracking length and its width.

$$\text{points of crack number condition} = \sum_{i=1}^{3}\sum_{j=1}^{3}\omega_{ij}N_{ij} \qquad (5)$$

where N_{ij} is the number of crack in each interval designated in Table 2, and ω_{ij} are the corresponding weights which can be decided according to Table 2. "-" means in these cases the cracking is negligible. And the cracks whose widths are less than 0.05mm are omitted due to they are invisible and insignificant.

The maximum value for crack number condition points was set to be 15 since it means there were at least 10 wide and long cracks, which might not be achieved because the structure would have failed before it occurred. Fig.5 presents the form of membership function for crack number condition.

Table2 Weights for cracks

Width / Relative length	>0.3mm	0.15~0.3mm	<0.15mm
>0.8	1.5	1.2	—
0.3~0.8	1.3	1.0	0.7
<0.3	—	0.8	0.5

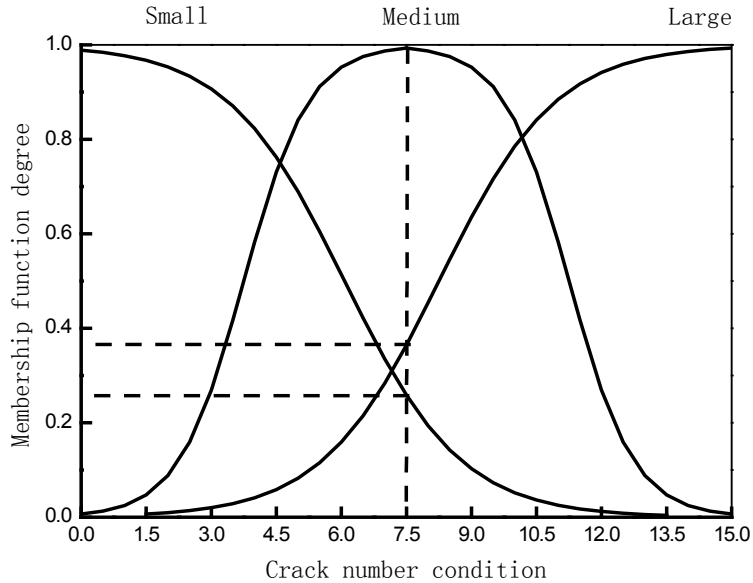

Fig.5. Membership function for crack number condition

(4) Machine learning for membership functions

The aforementioned initial forms of membership functions may not be effective enough to practical applications. Fortunately, however, they could be modified by altering the weights and the thresholds in the process of neural network machine learning. Fig.6 indicates the form alteration of the corresponding membership function with the weight and the threshold altered using machine learning.

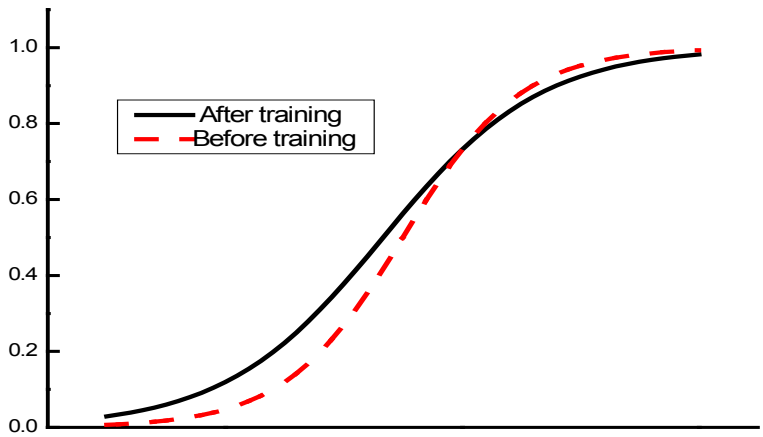

Fig.6. Machine learning for membership functions

4 Illustrative examples

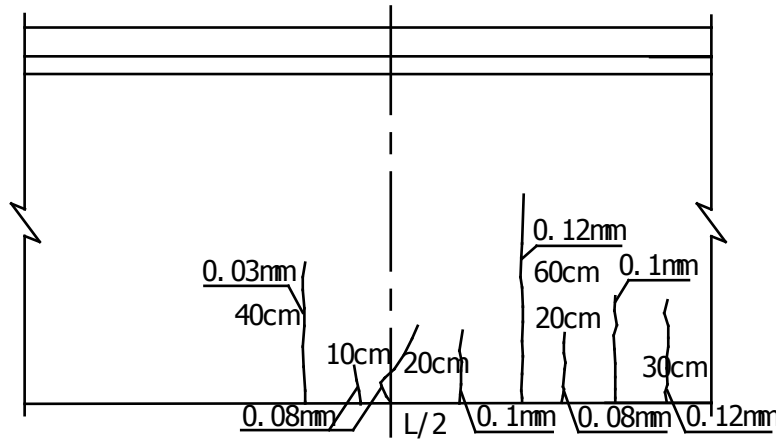

Fig.7. Flexural cracks on the central art of a T shape RC beam

Fig.7 indicates the flexural cracks on the central part of a T shape RC beam with the height of 110cm. With removing the cracks narrower than 0.05mm the input-output sample could be formed as: (0.54 0.12 4.4 1). After fuzzification the extended sample was given as: (0.000 0.985 0.015 0.802 0.198 0.000 0.000 0.506 0.459 0.036 1 0 0 0 0). By collecting data from 4 simple supported RC bridges in Jiangxi province, the People's Republic of China, 42 input-output pairs were obtained. In order to make FNN learn about the past enough to predict properly to the future, the 3-way cross validation was implemented in this study. 42 samples were randomly divided into 3 mutually exclusive subsets, namely, A, B and C, with each subset 14 samples. Each time, use one subset as the testing set and the other two as the training sets. And repeat 3 times.

Table 3 Comparison of FNN outputs with the target values with subset C being tested

Samples	Target values for dataset C	Outputs of FNN system for dataset C being tested
29	(1.0 0.0 0.0 0.0 0.0)	(0.9997 0.0002 0.0002 0.0000 0.0000)

36	(1.0 0.0 0.0 0.0 0.0)	(0.9997 0.0001 0.0001 0.0000 0.0000)
37	(1.0 0.0 0.0 0.0 0.0)	(0.9997 0.0001 0.0001 0.0000 0.0000)
38	(1.0 0.0 0.0 0.0 0.0)	(0.9996 0.0002 0.0002 0.0000 0.0000)
39	(1.0 0.0 0.0 0.0 0.0)	(0.9996 0.0002 0.0002 0.0000 0.0000)
40	(1.0 0.0 0.0 0.0 0.0)	(0.9996 0.0002 0.0002 0.0000 0.0000)
41	(0.0 0.5 0.5 0.0 0.0)	(0.0000 0.4226 0.4426 0.0000 0.1348)
42	(0.0 0.5 0.5 0.0 0.0)	(0.0001 0.4985 0.5001 0.0000 0.0014)

The final multi-layer FNN configuration was determined as 3-10-10-21-5-1 with the learning rate and the momentum factor both 0.25 and the acceptable error 0.01.

The simulation results of FNN were exhibited in Table 3, Figs. 8 and 9 with subset C, A and B being tested, respectively. As mentioned earlier, in the present study, the BP method was applied as a learning method, and the resubstitution method was applied to the system as a training method. Comparison of the system outputs in Table 3, Figs.8 and 9 with the target values reveals that the total agreement ratios are 78.5%, 85.7% and 100% for A, B and C being tested, respectively. In the case subset A being tested 3 outputs show totally deviation from the target values because of the lack of training samples whose target values are 4 to 5. While when B was tested two outputs deviate from the target values. If the testing sample No. 10 in subset B (its system output is 3.007 and its corresponding target value is 2~3) were not taken into consideration as a deviating sample, then the total agree ratio for this case could be 92.9%. Therefore, FNN system could achieve the expected agree ratio if the number of available samples with various cracking condition used for learning is enough.

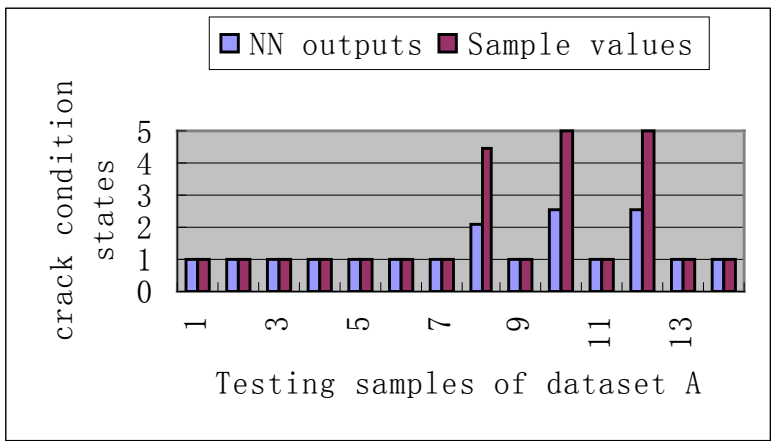

Fig.8. Comparison of the simulation results with the target values for dataset A being tested

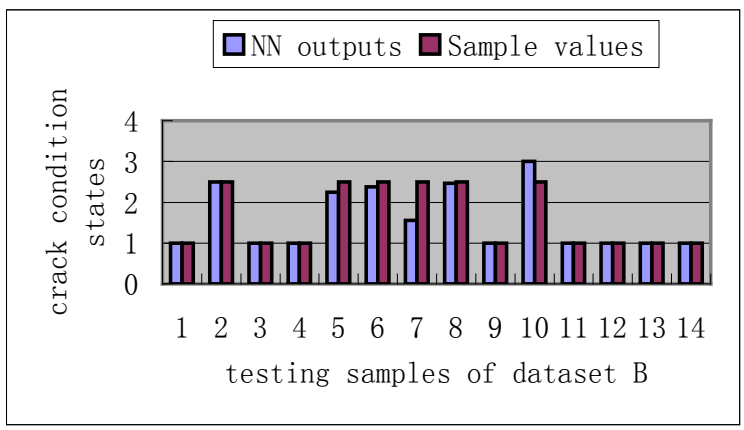

Fig.9. Comparison of the simulation results with the target values for dataset B being tested

5 Conclusion

Based on the comprehensive analysis of RC bridge cracking，in this study, the assessment criterion system of simple supported RC bridges was set up for both flexural cracking and shear cracking, and the membership functions were specified for each criterion. Then the fuzzy-neural network system, which is introduced into engineering applications as an alternative to traditional methods, was developed to assess the crack condition of RC bridges. Finally the system was verified using statistical crack samples of several RC bridges.

However, since the reliability of the system depends on the distribution of training samples used for learning, the performance of the FNN system should be improved by using a larger number of samples with various cracking conditions.

ABSTRACT

In order to improve soft clay subsoil effectively in practice, the vacuum well-point dewatering and preloading method was used to test in Songhuajiang River flood land. Based on the field data observed in practice and effective stress theory of K.Terzaghi, the mechanism of improving soft ground by the vacuum well-point dewatering and preloading and the change of effective stress and effective reinforcement depth were studied. The experiment results showed that pore water pressure decreased quickly in sand drain but slowly in soil. Decrease of groundwater lever had great influence on preloading effectiveness .The effect of water closing was harmful to soil consolidation. With vacuum well-point dewatering and preloading, not only consolidation degree and speed increased but also the stability of side slope and the soil were improved. It is concluded that using vacuum well-point dewatering and preloading would speed up consolidation in the bank area of Songhuajiang River and similar areas.

Key words:
Vacuum well-point dewatering and preloading ； Effective stress；Pore water pressure；Effective reinforcement depth； Groundwater lever

In recent years more roads, bridges and structures were built in the bank area of Songhuajiang River. One tall building which has three basement stories was constructed in li-min development area located in Songhuajiang River north bank. The ground base is typical Songhuajiang flood land. The subgrade soil has large natural water-content, high compressibility, low bearing capacity, bad water permeability and high groundwater lever. In order to increase stability of ground base and consolidation degree of soil and improve shear strength of ground, It is effective to use vacuum well-point dewatering and preloading method to speed up consolidation and reduece erection time. Based on the observation of field test, the mechanism of improving soft ground by the vacuum well-point dewatering and preloading and the reinforcement effects were studied in this paper.

1 Introduction to construction method:

Physico-mechanical index of subgrade soil is shown in table 1.

There were two sets of light Vacuum Well Point established on both sides of testing soil at the same time withW-4 Mechanical Vacuum Pump configured. Arrangement of field test was shown in Fig 1.

Table 1 Physico-mechanical index of subgrade soil

Level number	name	lever depth /m	water content /%	void ratio e	plasticity index $/I_P$	liquidity index $/I_L$	modulus of compressibility /MP_a	permeability coefficient 10^{-6}/cm·s^{-1}
2	fine sand	3.5	26	0.76	—	—	11.05	9.57
3	grayish brown silty clay	3.6	30.8	0.88	12.3	0.967	5.28	1.45
4	grayish black muddy clay(containing fine sand)	7.6	38.5	1.12	13.6	1.574	3.08	4.90

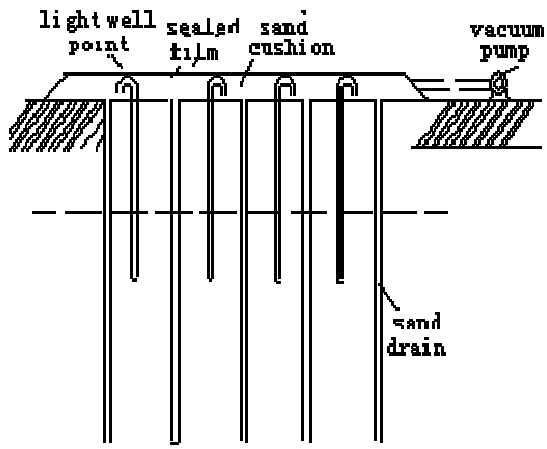

Fig. 1 Field test on soft clay ground well-point dewatering and preloading under combined-method of vacuum

The well point had a buried depth of 7m. Dewatering lasted for 90 days in an aimed and planned way. It was 0.3m sand cushion on the top of ground and a layer of 40mm earth work fabric as flowing layer with 5% slope. A bag of sand-well were strike to a depth of 12m. After well-point dewatering equipment buried, dewatering began. To cut off water source recharge from Songhuajiang River, a grouting isolated land was set on lateral side of dewatering area. Sealing system was consisted of double-layerPVC film . The vacuum degree increased at first 3 days and then decreased to reach a constant of 80 kPa since pumping. Because ofthe promissory construction conditions, the practical dewatering process was only carried out in 80d. In order to check the quality of reinforcing ground soil and pre-dominate the consolidation and settlement of each soil layer during strengthening, ground surface settlement, layered sedimentation, lateral displacement, pore water pressure and vacuum degree were monitored at the construction process. Base on the observation data of pore water pressure, vacuum-pumping and dewatering stopped when soil consolidation degree forereached 95%.

2 Mechanism analysis of foundation soil

The vacuum well-point dewatering and preloading technique is the combined-method of vacuum and dewatering preloading, which has drainage consolidation, dewatering and vacuum preloading function at the meantime pumping by vacuum device and decreasing groundwater lever by means of well-point dewatering equipment. In the loading, the pore water pressure depressed and effective stress increased while total stress is invariable. Based on the action of vacuum and dewatering preloading, the variation of pore water pressure and increase of effective stress have specific regular

pattern. Mechanism of improving ground by the combined two methods of vacuum dewatering and preloading was analyzed through the variation of effective stress and analysis of stress path.

2.1 **Stress path of the vacuum well-point dewatering and preloading technique**

The variation of effective stress of ground soil in the course of combined-preloading of vacuum dewatering and loading was analyzed with K.Terzaghi theory. The distribution of soil stress before vacuum pumping and dewatering were shown in Fig.2.

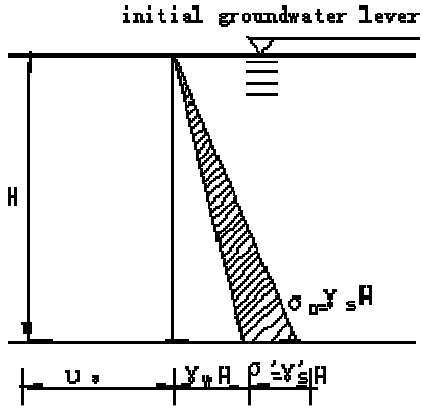

Fig.2 Distribution of effective stress before vacuum-pumping and dewatering

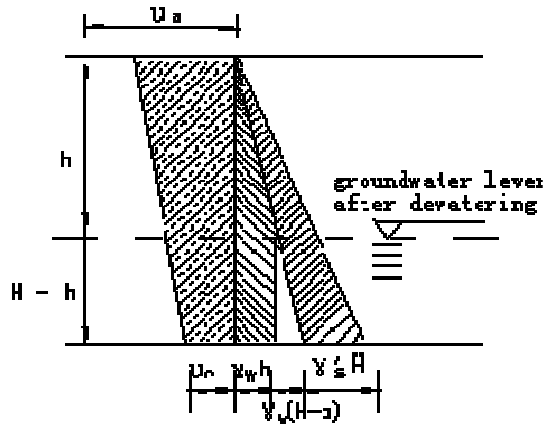

Fig.3 Distribution of effective stress after combined preloading

γ_s and γ_s' is the gravity density and flotation gravity density of ground soil respectively. $_w$ is the gravity density of water. Fig.2 showed that initial static pore water pressure $u_0 = \gamma_w z$ in which z is the depth of ground level calculated. Initial total stress of soil is $\sigma_0 = \gamma_s H$. In some position of soil the effective stress is σ', and gravity pressure of water is μ; each point in soil is subjected to atmospheric pressure μ_a before vacuum pumping and dewatering.

According to K.Terzaghi effective stress theory, the effective stress during reinforcement is equal to

$$\sigma' = \sigma_0 - \mu_0 + \mu_1 + \mu_2$$

μ_1 is suction pressure formed in pore space of soil when vacuum preloading; μ_2 is vacuum degree varied with depth. While stopping vacuum and dewatering preloading, soil body under groundwater lever is in over consolidation. Distribution of effective stress of soil after combined preloading was showen in Fig.3.

Static water pressure and effective stress of Z point after combined preloading were expressed as following equations:

$$\begin{cases} \begin{cases} u = 0 \ , & (z \le h); \\ \sigma' = \gamma_s{}' z + \mu_1 + \mu_2 = \gamma_s{}' z + \gamma_w z + \mu_2 = \gamma_s z + u_2, & (z \le h); \end{cases} \\ \begin{cases} u = \gamma_w (H - h), & (z > h); \\ \sigma' = \gamma_s{}' z + \mu_1 + \mu_2 = \gamma'_s z + \gamma_w h + u_2, & (z > h). \end{cases} \end{cases}$$

The varied process of effective stress can be analyzed by reinforced stress path for soil, shown in Fig.4. Any unit stress condition is K_0before reinforcing, and total stress path (TSP) is fixed. Effective stress path (ESP) is AB line ($\varepsilon_v = \varepsilon_h$) after combined preloading. Whereas in site some cracks parallel to borderline line in reinforced soil body can be observed, which is due to the whole soil body was subjected to isotropic consolidation pressure produced by vacuum and dewatering preloading and shrinkage of soil body occurred. So horizontal displacement was turned into inside when soil subsided, At the same time the maximum horizontal displacement occurred in surface of soil edge. Therefore, effective additional stress caused by vacuum and dewatering preloading made soil effective stress downward departure from K_0 line, then ESP line was AD line.

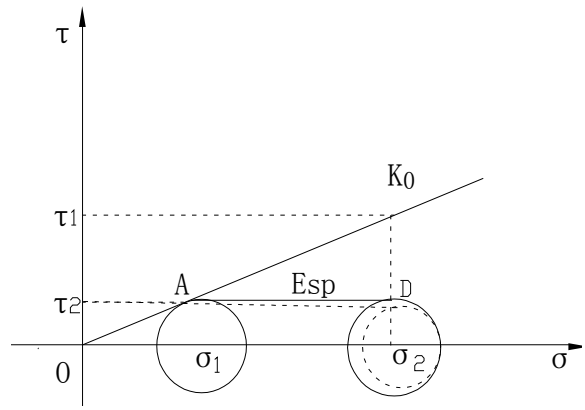

Fig.4 Stress path for soil in vacuum watering test area

2.2 **effective depth of vacuum and dewatering preloading**

Fig.5 and Fig.6 showed the actual observation records. After 5 days draining，the vacuum degree reached a constant of 80 kPa. Through practical monitoring, vacuum degree in 12m sack sand-drain degreased 25% because of resistance of sand drain, which verified that sand drain can transfer vacuum degree and draining. Vacuum degree had a quick attenuation under sand drain, and reinforced effect was non-ideal； Most settlement occurred in sand drain after draining. It could be concluded that effective depth was consistent with depth of sand drain.

Effective depth is reinforced by the combined two methods of vacuum dewatering and preloading Firstly, gas in sand cushion was drawn-off after the surface of foundation produced vacuum, and then atmospheric pressure in sand cushion and sand drain fall down one after the other. Differential pressure in soil and cushion and sand drain made soil body become consolidation. Onthe other hand, continuous air suction and drawing water of vacuum preloading made a descent on groundwater lever.

Otherwise, groundwater drained by well point brought on a sharp decline of original phreatic line again. Therefore, it is logical that vertical gravity stress in soil layer was changed; initial stability conditions and corresponding stress distribution were destroyed. Internal stress of soil had a new stabilization.

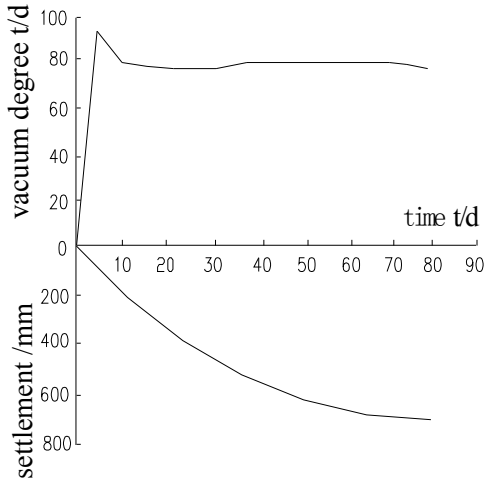

Fig 5 Curve of P-T-S (vacuum degree,settlememt,time)

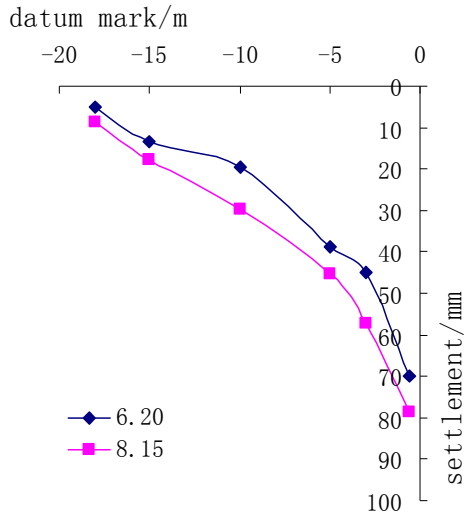

Fig.6 Curves of laminar settlement in reinforced area by vacuum dewatering

Sedimentation measured on June 20th could be acquired from curves of laminar settlement shown in Fig.6: the total settlement was 70 mm within 0~18 m, and the settlement was 18 mm approximately which was 26% of total sedimentation within 12~18m under sand drain based on the field observation record and other literatures, it is the vacuum preloading method that is useful to increase effective stress down depth in soil under sand drain, but reinforced effect was determined by dewatering preloading. Beyond sand drain strengthening action was inconspicuous for a sharp decent of vacuum degree under sand drain by combined-method of vacuum and dewatering preloading, Although reinforced effect was influenced by vacuum preloading, drainage consolidation caused by dewatering preloading was the definitive factor of reinforced effect. The influenced depth and reinforced effect produced by the combined two preloading methods were better than by single vacuum preloading obviously.

3 Groundwater lever

The groundwater lever had a great influence on reinforced effect of soil by preloading. Decreasing degree of groundwater is related with action intensity of sucking vacuum, property of foundation, supply of water source and well point equipment and so on.

During vacuum preloading, vacuum pressure on reinforced area reduced pore water pressure, so pore water in soil was absorbed by differential pressure and produced seepage to ground surface. If the pressure of sand drain was smaller than pressure of soil at the same depth, pore water could leak through liquid to sand drain. Two-way seepage of pore water led to a descent of groundwater lever. While pressure was balanced, the line of groundwater lever reached a stable level. In this research, groundwater lever was decreased by 1.5m measured by water level gauge after

vacuum pumping was carried for 20d, and subsequent descending speed was very slow. The groundwater level was fallen down continuously and quickly in the procedure of preloading of the combined-method for soil which had higher sand-carrying capacity; 25d later, descending level reduced by 7.3m. Descending groundwater level not only decreased static pressure and increased effective stress of soil, but also made fully use of top vacuum preloading.

The pore water pressure measured before testis directly proportional to the depth of soil. Descending speed of pore water pressure in sand drain was faster than in soil body during construction due to the permeability of sand drain is greater than soil body. All the transitive effect of vacuum pressure in soil body filled in pore water was non-ideal.

5 CONCLUSION

1) It is seen that the combined-method of vacuum and well point dewatering preloading is useful to strengthen soil and increase the consolidation speed and degree; besides, the combined two methods not only improved the stabilization of side slope and foundation, but also unlikely produced extrusion on around soil.

2) Several factors, such as climate conditions, groundwater level and surrounding influent stream, have great influences on the decreasing speed and degree of groundwater level, as well as reinforced effect. Therefore some steps should be modified to eliminate external detrimental factors to accelerate soil consolidation. It is effective to adopt the combined-method of vacuum and dewatering preloading to improve soft foundation. Anticipated effect could be reached in two and half months.

3) When vacuum degree reached 80 kP_a, the soil body generated inboard horizontal deformation. At the same time, cracks occurred around boundary apparently. It should be paid attention that a rather large lateral deformation will affect surround buildings.

ABSTRACT

Nine square concrete-filled steel tube (CFT) columns with different axial load level (0.165~0.517), slenderness ratio (10.82~32.88), and constraining factor (0.61 ~1.51) were tested under a constant axial load and cyclically varying lateral loads. The experimental results showed that the hysteresis curves of the test columns are plump in shape without significant pinch phenomenon, which means that the stiffness and strength of the columns deteriorated slowly and the columns have a good ability of energy dissipation. Based on the analysis of the experimental data, the expressions of maximum strength Q_u and ultimate deformation δ_u of square CFT column are proposed. Park damage index is employed for CFT columns seismic damage evaluation. According to the test data, the value of parameter β is determined.

INTRODUCTION

With the advantages of high load-bearing capacity, excellent seismic behavior, good fire-resistance and easy for construction, CFT is greatly used in bridge construction practice. CFT includes circular CFT and square CFT. In comparison, square CFT has higher flexural strength, simpler joint details and is easier for connection on site (Han,2004). Thus, researchers and engineers are paying more attention on square CFT structure and its seismic behavior. Studies by many researchers had shown that parameters such as axial load level, slenderness ratio, steel ratio and strengths of materials have different effects on the seismic behavior of the columns (Amit et al,2002). However, the research on this aspect is still insufficient and the conclusions made by the different researchers do not concur. On the other hand, the study of the accumulated damage model of square CFT is also insufficient. In this paper, nine square CFT columns were tested under combined constant axial load and cyclic lateral load in order to investigate the hysteresis behavior

of the columns. According to the analysis of experimental results, the damage accumulation model of the square concrete-filled steel tube based on the deformation and energy dissipation was established.

EXPERIMENTAL PROGRAM

Nine specimens were designed for the test. The dimensions and parameters of the test specimens are shown in Table 1. In table 1 B, t and L are the width of the cross-section of specimen, the thickness of steel tube and the length of specimen respectively. λ is the slenderness ratio of the specimen, which is defined by CECS159:2004. $\xi = f_y A_s / f_c A_c$ is the constraining factor of the column. Where A_s is the cross- section area of steel tube and A_c is the cross-section area of concrete. $n_0 = N/N_0$ is the axial load level of the specimen, where N is the applied axial load. $N_0 = A_c f_c + A_s f_y$ is the nominal axial load capacity of the specimen.

Specimen design and construction. The square steel tubes were made from four sheets of steel plate by welding and the grade of steel plate was Chinese Standard Q235. The properties of steel plate were measured by conducting the test according to the Chinese Standard Metal Tension Test Method (GB/T228-87). The measured steel yield strength (f_y) was listed in table 1. The target grade of concrete used was Chinese standard C40. During the preparation of the specimens, three 150*mm* concrete cubes were cast and cured in condition similar to the specimens. The concrete cubes were tested according to the Chinese standard Test Method for the Mechanics Properties on Ordinary Concrete (GBJ81-85) and it was found that the concrete cubic compressive strength (f_{cu}) equaled 36.5 N/mm^2. The concrete compression strength (f_c=0.8 f_{cu}) was 29.2 N/mm^2.

Test set-up and load procedure. Figure. 1 shows the schematic of the test set-up. The axial load was applied with a 3,200 *kN* hydraulic jack on top of the specimen. The lateral load was applied with a hydraulic jack fixed to the reaction wall, and the maximum moving distance of the jack was 500 *mm*.

The axial load was applied and maintained constant until the failure of the specimen. According to the Chinese standard Specification of Testing Methods for Earth-

quake Resistant Building（JGJ101-96）, the lateral load was applied under load-displacement control condition. Before the yield of the specimen, the lateral load was controlled by load and applied step by step. Every one-third of the specimen lateral yield load was applied in one cycle at each of the lateral load level. After the specimen yielded, the lateral load was controlled by displacement. The integral multiple of the yield level lateral displacement was taken to control the applied lateral load and three cycles were imposed at each displacement level until the specimen lateral load resistance had deteriorated to 85% of the lateral load capacity.

TEST RESULT AND ANALYSIS

From the experimental observation, all the specimens had the same failure mode. The column stiffness had not deteriorated significantly from initial loading to yield of the compression flange of the steel tube. With the increase of lateral displacement, the bulge at the bottom of the steel tube compression flange took place, but was flatten when unloaded and during reverse loading, the flange at the opposite face begins to bulge. The location of the bulge of the steel tube was at 40~70mm above the bottom of the column. The lateral stiffness of the column began to decrease, but the lateral load was still increasing. The bulge grew with load cycling and increasing lateral displacement. The lateral load of the column began to decrease when the compression side of the web of the steel tube bulged. Several specimens cracked at the welded corner before it failed.

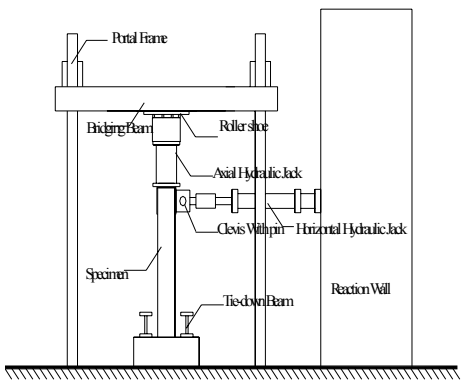

Figure.1 Schematic of the test

The lateral load-lateral displacement responses of some specimens are shown in Figure 2. These figure show that the hysteretic loop of the specimens are plump in shape and have no significant pinch phenomenon, which indicate that the

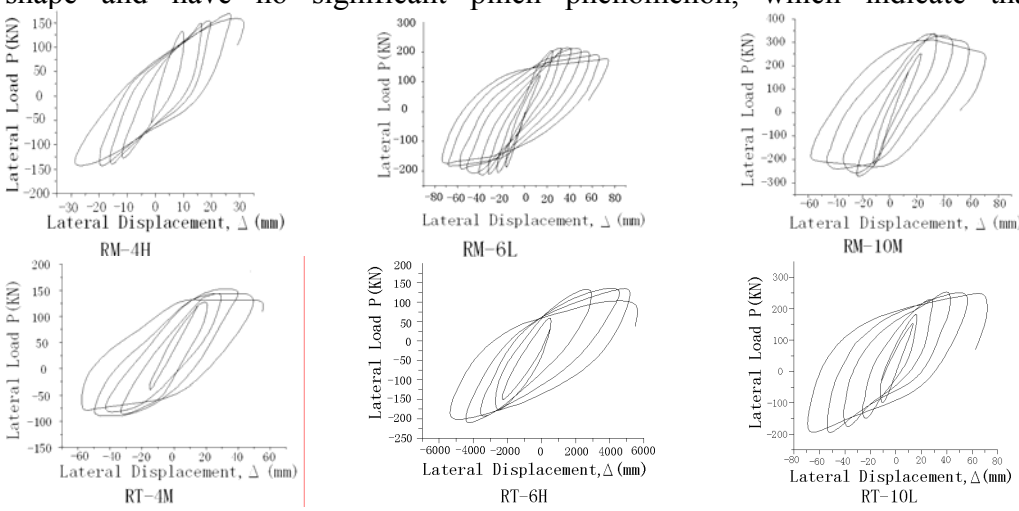

Fig.2. Lateral load-lateral displacement (P- Δ) response

square concrete-filled steel tube column has better hysteretic behavior and greater energy-dissipation characteristics.

The maximum horizontal strength Q_u and ultimate deformation δ_u of the specimens are listed in table 2.

Table 2. Test Result of the Specimens.

specimen	RS-4L	RS-6M	RS-10H	RM-6L	RM-10M	RM-4H	RT-10L	RT-4M	RT-6H
Q_u（KN）	398	566	737	210	290	151	215	120	166
δ_u(mm)	23.76	31.63	32.4	67.81	58.16	27.48	67.81	56.98	52.57

SEISMIC DAMAGE MODEL

Park model (Park et al,1985), accepted for most engineers in seismic engineeringfield is used for square CFT columns in this paper. Seismic structural damage is expressed by Park model as a linear combination of the damage caused by excessive deformation and that contributed by absorbed hysteretic energy. The damage index is given by

$$D = \frac{\delta_M}{\delta_U} + \beta \frac{\int dE}{Q_Y \delta_U} \tag{5}$$

In which δ_M is the maximum deformation under earthquake; δ_u is the ultimate deformation under monotonic loading; Q_y is the calculated yield strength; dE is incremental absorbed hysteretic energy; β is a non-negative parameter.

According to reference ZHANG-sumei(2005), the yield strength Q_y is given by

$$\boldsymbol{Q_y = (0.8 - 0.24 n_0) Q_u} \tag{6}$$

In which Q_u is the maximum strength of CFT column subjected to reversed loading. The following is proposed for evaluating Q_u based on the analysis of the experimental data

$$\boldsymbol{Q_u = (2.72 \lambda^{-0.2} - 8.33 \times 10^{-3} \lambda n_0^3) \frac{M_u}{L}} \tag{7}$$

Where M_u is the ultimate moment of square CFT column, which can be evaluated by CECS159:2004. L is the length of column.

Based on reference ZHANG-sumei (2005) and the analysis of the experimental data, the ultimate deformation under monotonic loading δ_u can be evaluated by following:

For $0 \le n_0 \le 0.5$

$$\boldsymbol{\delta_u = \left[\left(115 n_0^2 - 53.9 n_0\right) \lambda^{-0.75} - 2.08 \times 10^{-3} \lambda + 1.17\right] \frac{Q_y L^3}{EI} - \frac{0.15 Q_u}{K_d}} \tag{8}$$

Or for $0.5 \le n_0$

$$\delta_u = (1.8\lambda^{-0.75} - 5.21\times10^{-4}\lambda + 0.292)\frac{Q_y L^3}{EI} - \frac{0.15Q_u}{K_d} \quad (9)$$

In which the stiffness in the elastic stage, EI, is given by CECS159:2004; K_d is the stiffness of descending stage of lateral load verses lateral displacement curve，which can be expressed

$$K_d = \left[-0.1\left(\frac{\lambda}{50}\right)^{1.4} n_0^{0.4}\xi^{-0.3}\right]\frac{L^3}{3EI} \quad (10)$$

The evaluated yield strength Q_y and the ultimate deformation δ_u of the specimens are listed in table 3.

DETERMINATION OF β

The load-deformation curve for each test is integrated up to the failure point to get absorbed hysteretic energy E_h, which is listed in table 3. Then, at the point of failure, D=1.0, the corresponding value of β is evaluated by Eq 5. The β of all specimens is listed in table 3. The average of β, 0.03, is proposed for evaluating damage index of square CFT column. In fact, parameter β has a correlation with axial load level n_0, slenderness ratio λ and constraining factor ξ. Reasonable β expression will need more test data.

Table 3 . Evaluated Data of the Specimens

specimen	Q_Y（KN）	Q_u（KN）	δ_u(mm)	E_h（KN.mm）	β
RS-4L	276.96	366.19	27.12	107011.41	0.0087

RT-6H	120.23	173.54	73.87	82931.62	0.031

CONCLUSION

Square CFT column has high lateral load bearing capacity and high lateral stiffness under combined lateral load and axial load. Even though the flange of the steel tube has bulged, the lateral load is still increasing and the stiffness has no significant deterioration.

The hysteretic curves of the specimens are plump in shapes, and have no significant pinch phenomenon, which indicate that square concrete-filled steel tube column has high energy dissipation capacity.

Based on the analysis of the experimental data, the expressions of maximum strength Q_u and ultimate deformation δ_u of CFT column are proposed.

Park damage index is employed for CFT columns seismic damage evaluating. According to the test data, the value of parameter β is determined.

ABSTRACT

Based on analysis of the influence degrees of structure types at early damages of cement pavements in large-grade highways, combined structure type of cement stabilized crushed stone drainage base and semi-rigid base is proposed. Base on function analysis of drainage base, design principles and indices of the cement stabilized crushed stone mixture are determined. And then, the type of coarse framework, distributing of cement slurry, and the component of grading are determined according to new characters of material design method which including the optimum vibrating compaction techniques and the dynamic stress press-in test having confined pressure and the volume design method in grading components. Finally, the method for determining the reasonable consistency of cement stabilized crushed stone mixture is presented, which adopts porosity diversity and strength as evaluation criterion. The void-framework cement stabilized crushed stone mixture demanding drainage base function will be consequently designed.

INTRODUCTION

Cement concrete pavement has the advantages of high strength, good capacity of supporting and separating loads, heavier rigidity, better stability and durability, no rutting and less maintenance cost, so it has been extensively used in the high-grade highway in China, especially in the overload heavy-traffic pavements. However, the early damages also appear in concrete pavement, such as surface cracking, broken slab, deformation, blow-up and mud-pumping (Grogan 1994). By analysis, water is one of the most important factors (Hall 1994). The water goes into the surface of base through the cracks and turn into mud, with fine aggregate under heavy traffic loads, eroding the base and then bursting out from cracks, a phenomenon called mud-pumping. The phenomena of mud-pumping weaken the support at the edge and separates cement concrete pavement from the base, then

accelerates the destructive process of cement concrete pavement. Use of the cement stabilized crushed stone permeable base can weaken the water pressure, balance the load-carrying capability and avoid the damages on the pavement.

MIXTURE DESIGN INDICES ON THE FUNCTION ANALYSIS

Function Analysis

In order to relieve the cement concrete pavement damage, cement stabilized crushed stone base should have the following functions:

(1) Function of Drainage: Good function of drainage can relief the dynamic water pressure caused by heavy traffic with high-speed, which reliefs not only the washing and pumping of semi-rigid base, but also the empty and break of concrete slab.

(2) Good Function to Resist Permanent Deformation: In order to ensure the structural integrity and prevent concrete slab separating from base, cement stabilized crushed stone permeable base should have less residual deformation.

(3) Enough Strength: As the base, cement stabilized crushed stone should have enough strength to support traffic loading and give support to increase fatigue life of cement concrete pavement.

Design Indices

Besides using VV to reflect drainage ability and compressive strength to represent mechanical strength, permanent deformation is taken into account based on the function analysis. Specific mixture design indices are as follows:

(1) VV≥15%;

(2) 7d compressive strength≥3MPa;

(3) Cumulative permanent deformation under 25KN.

MIXTURE DESIGN CHARACTERS

Optimal Molding Techniques

Contrast tests between vibrating and static stress compaction indicate that vibrating compaction can obviously improve compressive strength and be close to rolling methods in site (Tian et al. 2006). Thus, by ensuring the uniformity of cement mortar and keeping the integrity of aggregates, vibrating compaction method is adopted in which optimum techniques are as follows: vibrating force 7KN, vibrating frequency 30Hz, amplitude of vibration 0.694mm, time of vibration 1min.

Dynamic Stress Press-in Test

The strength of stone mixture roots in the function of inner frictional angle, and lateral confinement σ_3 should be considered to evaluate the resistance deformation ability. Thus on the basis of classical C.B.R method, dynamic stress press-in test has been put forward, which bears dynamic semi-sine wave load using MTS machine with frequent 0.1 HZ and slot time 0.9 seconds by steps, each steps

having 100 times.

Volumetric Design Method

The volumetric design method (see Equation 1) is used to design the cement stabilized crushed stone (Zheng and Hu 2004).

$$q_c + q_f = 100$$
$$q_c \times (VCA_{DRC} - V_v) / (100 \times \rho_{f(s)c}) = q_f / \rho_{tf} \quad (1)$$

Where, q_c = weight percent of coarse aggregate, %;
q_f = weight percent of cement mortar, %;
VCR_{DRC} = impaction void volume of coarse aggregate, %;
VV = Volume of air voids, %;
$\rho_{f(s)c}$ = impaction density of coarse aggregate, g/cm^3;
ρ_{tf} = density of cement mortar， g/cm^3.

DESIGN STEPS

（1）design of coarse aggregate skeleton and cement mortar
（2）volumetric design of the mixture
（3）determination of the reasonable mixture consistency

DESIGN EXAMPLES

Raw Materials

Selected Aggregate is Jilin Province limestone (Table 1) and cement is ordinary Portland cement with cement mark 42.5, which meet the demand of specifications.

Table1. Sifting and Density Values of Coarse Aggregate.

seize /mm		31.5	26.5	19.0	16.0	13.2	9.5	4.75
Passing rate/%	1#	100	95.6	48.7	15.9	1.2	0.3	0.2
	2#	——	——	100	98	79.5	32	0.2
density g/cm^3			2.734	2.730	2.740	2.736	2.751	2.750

Design of Coarse Aggregate Skeleton

According to technical specifications of drainage base recommended in China and successful experiences abroad, five kinds of coarse aggregate skeletons are selected for experimentation using CBR test and dynamic test in order to determine the gradation of coarse aggregate skeleton with higher strength and smaller permanent deformation. Gradation 1 and gradation 2 are the medians in Technical Specifications, gradation 3 and 4 are trend of cement stabilized crushed stone derived from better experiment gradation. Gradation5 is the median of AASHTO NO.67 gradation value. Specific gradations are shown by Figure 1, and the test results are

summarized in Table 2.

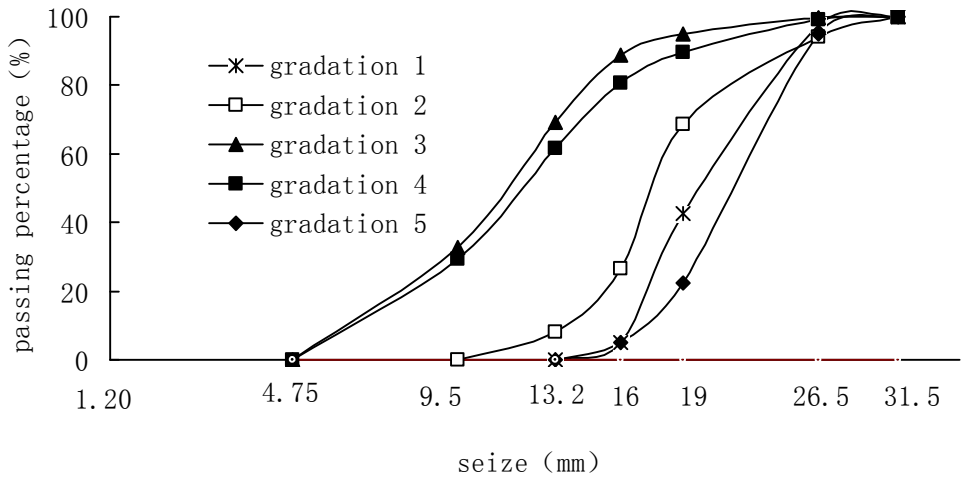

Figure1. Graduations of Coarse Aggregate Skeleton.

Table2. CBR and Cumulative Permanent Deformation of Coarse Aggregate Skeleton.

item \ number	1	2	3	4	5
impaction density (g/cm^3)	1.735	1.770	1.732	1.730	1.651
impaction void /%	36.7	35.5	36.9	36.7	40.0
CBR values/%	125.6	121.3	45.3	163	178.8
5kN permanent deformation /mm	0.80	0.59	1.34	0.78	1.15
10kN permanent deformation /mm	1.09	0.79	1.39	1.43	1.05
15kN permanent deformation /mm	1.47	1.45	1.62	1.60	1.21
20kN permanent deformation /mm	2.26	1.98	2.78	2.01	1.52
25kN permanent deformation /mm	2.95	2.34	3.58	2.18	2.46
cumulated permanent deformation /mm	8.56	7.15	10.72	8.00	7.39

CBR and the cumulative permanent deformation are regarded as the main values to evaluate the mechanical properties of the aggregate skeletons. CBR can reflect the ability to resist load, dynamic load test can reflect material's ability in resisting permanent deformation at different stage by the accumulated permanent deformation under different stress state stages. So it is used as the main index to evaluate the ability of resisting deformation. From Table 2, CBR and cumulative permanent deformation have the same assessment of outcomes. Higher the CBR

value, smaller the corresponding value of accumulated permanent deformation. Therefore, based on the data coming gained from two kinds of tests, frame 4 and 5 are determined as the optimum framework structures.

Design of Cement Mortar

Taking into account the characteristics of the northern cold regions, cement mortar is composed by ordinary Portland cement, sand, slag, water and water reducer. Cement mortar is designed with orthogonal method, in which water-cement ratio, the amount of sand, slag dosage, dosage of water reducer are considered. Each factor considers four levels using the corresponding L16 (4^5) orthogonal test table. Combination of specific tests and test results are shown in Table 3. By using a direct comparison of test data, the efficacy of factor analysis, variance analysis and so on, comprehensive considering standards of 7d, 28d compressive strength, flexural strength and mobility, number 5 is fixed on the best ratio of mortar as cement stabilized gravel mixture.

Table3. The Specific Test Combinations and Test Results.

Number	w/c	Sand (%)	Filler (%)	Water Reducer (%)	7d BS (MPa)	7d CS (MPa)	28d BS (MPa)	28d CS (MPa)	Fluidity (cm)
1	0.42	0	0	0	10.33	56.9	10.60	67.2	>25

15	0.51	20	10	0.9	6.80	49.0	7.25	60.4	24.5
16	0.51	30	0	0.6	6.65	38.2	7.92	54.4	>25

NOTE：BS represents Bending Strength, CS represents Compressive Strength.

Designed to Determine the Volume of Mixture Gradation

Assuming that VV= 20%, using the method described above, the quantity of coarse aggregate skeleton is determined as 85% and cement mortar is 15%, in which

percent of the cement is 10.8%.The compressive strength of the mixture has reached 11.2 MPa, which is much higher than the strength requirements of base. In economic terms, the increase of cement dosage will bring substantial increase in cost. Comprehensively considering the strength of cement stabilized crushed stone and economic factors. And number 5 cement mortar is adjusted. The adjusted mass ratio is, water: cement: slag: water reducer = 0.45:1:0.93:0.01.

DETERMINATION OF REASONABLE CONSISTENCY

Evaluation Standards of Reasonable Consistency

Uniformity of air voids: The difference between upper and lower percentage of voids in a specimen should be less than 5% , which serves as the standard to evaluate the uniformity of voids. The method of measuring the voids is as follows: the cylindrical (Φ15×15cm) specimen is cut into two parts from the mi ddle, forming upper part and lower part. The air voids of each part are measured. Then the void difference (△VV) can be calculated by Eq.1-2. When △VV is positive number, it means the upper VV is larger than the lower part. The negative △VV means larger VV in the lower part. The smaller ｜△VV｜ means more equal void and good permeable performance.

$$\triangle VV = VV_{up} - VV_{down} \quad (2)$$

Strength: 7d unconfined compressive strength≥3MPa is the standard to evaluate the strength of the mixture.

Definite Method of Reasonable Consistency

Comparing different water-cement ratios with △VV and the strength (see Figure 2), the scope of water-cement ratio demanding the uniform voids and strength is determined. When water-cement ratio is ≤0.39, the △VV is <5% and when water-cement ratio is ›0.31, then 7d compressive strength is≥3MPa, so the water-cement ratio should be between 0.32 and 0.39. Considering strength, binding conditions and uniformity of void inside the sample specimen, the best water-cement ratio is determined as 0.36.

CONCLUSION

Based on the above analysis, conclusions are as follow:

(1) According to function requirements of drainage base, three design indices are determined for cement stabilized crushed stone mixture.
(2) Adopting the new methods of best vibrating compaction and dynamic stress press-in test, coarse aggregate skeleton type, cement mortar and graduation of cement mixture are determined.
(3) The method of determining optimum water-cement ratio is put forward.

ABSTRACT

The hot mix asphalt (HMA) pavements absorb heat from the sun causing increased temperature of the pavements and the cities as the albedo of the HMA surface is only 0.05-0.15. High temperature may incrase the potential of rutting and urban heat island (UHI). Decrease of the pavementsurface temperature can be achieved by using heat reflection coating. In this research, an easy construction and cheap heat reflection coating material is developed. Using the coating, the surface temperature is 11.4℃ lower than the common HMA surface. Other performance such as anti-skid, moisture resistance, adhesive force and rigidity are tested. The results show that the coating satisfies the requirements. The cost of the coating is much cheaper than the other heat reflection coating.

Key words: heat reflection coating, lower temperature effect, anti-skid experiment

Introduction

Hot mix asphalt pavement is commonly used to pave highway and city streets. In early period, a lot of damages such as cracking, rutting and moisture damage appear. Rutting is one of the major reasons to cause rehabilitation or reconstruction. The research done by Sheng (2001) showed that over 80% of the pavement reconstruction is caused by deep rutting.

High temperature increases the rutting potential. As we known, the HMA is a temperature sensitive material. At high temperatures, the anti-shear performance decrease. HMA pavements tend to be absorptive with an albedo of approximately 5-15% (Berzt, 1998). In summer, the pavement surface temperature is 15-25℃ higher than the air temperature.

Conventional method to solve the rutting is to improve the high-temperature performance by using high quality asphalt and aggregate or appropriate gap-graded aggregate gradation. All these are passive to accept the high temperature. At the same time, these high quality aggregate and asphalt increase the construction cost, thereby,

decrease the economical effectiveness of the roadway system. The gap-graded gradation is difficult for construction. Even taking these methods, the problem of rutting is still not fully solved.

Can we solve the problem more directly? One important reason that causes the high temperature of the pavements has been ignored – the low albedo of the HMA surface. For a surface under the sun with insulated underneath structure, the equilibrium surface temperature, T_s is obtained from

$$(1-\alpha)I = \varepsilon\sigma(T_s^4 - T_{sky}^4) + h_c(T_s - T_a)$$

α	solar-reflectivity or albedo of the surface
I	total solar radiation incident on the surface, W/m^2
ε	emissivity of the surface
σ	Stefan-Boltzmann constant, 5.6685×10-8 Wm^{-2}K^{-4}
T_s	equilibrium surface temperature, K
T_{sky}	the effective radiant sky temperature, K
h_c	convection coefficient, Wm^{-2}K^{-1}
T_a	air temperature, K

From the formula (Berzt, 1998), increase the albedo of the pavement surface, we can get lower T_s, which indicates a a lower temperature of HMA. The study done by Sheng (2001) showed the dynamic stability (DS) increase exponentially with the decrease of temperature. It proves that rutting can be controlled by increasing albedo.

There are some possible ways to increase the pavement surface albedo. One technique for light-colored pavement is to use white or light colored aggregate in an asphalt binder. Light colored aggregates that are suitable for asphalt include high silica gravel, quartz, white stone, white marble and some types of granite (Rosenfeld, 1995). But the cost is high if local source for such aggregates is not available. Another possible method to improve the albedo is using heat reflection coat. It is widely used in building roof and oil deposit. The heat reflection for pavements is developed by Japan. It can decrease the temperature about 10℃. But the cost is as high as \$40-53/m^2 (Kinouchi, 2001).

Another benefit of increasing the pavement albedo in cities is to mitigate urban heat island (UHI) effect. Summer urban heat islands with daytime average air temperature 2.5 higher than surrounding rural areas are found throughout the world (Akbari, 1990). The urban heat islands caused an increase of 1.5-3.0% in peak cooling demand for each 0.5℃ increment (Akbari, 1993). In big cities such as Chicago and L.A., asphalt pavement consumes more than 20% of the surface area. It is considered that dark pavements and the surface of the building is one of the major heat sources causing the urban heat island, as it absorbs more heat from the

sun. If we can decrease the pavement surface temperature, UHI in big cities can be mitigated effectively.

2. Coat design

According to conversation of energy and heat conduction, the surface temperature is lower when the albedo is higher. The objective of this study is to design a coat with high albedo without glaring for the consideration of driving safety. A pavement coating is developed to satisfy both high albedo and low brightness with innovative technology. The function of this technology is based on a thin paint coating on the surface of the conventional dark asphalt pavement, which gives relative high reflectivity for the near infrared region and low reflectivity for the visible range. This results in increased albedo while maintaining the dark colored pavement surface.

The coat is composed of basic resin materials, pigment, functional filler and auxiliary materials. The scattering rate is used to represent the albedo. The scattering rate m is obtained from: $m=n_p/n_r$

Where n_p is the refraction coefficient of pigment, n_r is the refraction coefficient of basic resin materials. The high m can be obtained by using pigment with high refraction coefficient and basic resin materials with low refraction coefficient. Usually the colophony is used as basic materials. However, considering its high cost and pollution to environment, the silane-acrylate emulsion can be used as basic materials.

The refraction coefficient is affected by the diameter of the particles. The smaller the particles are, the higher the refraction coefficient is. Therefore the small fine hollow glass pigments are chosen. The fine glass particles are included in the paint to add additional effects on reducing thermal conduction and heating of the coat. TiO_2 is used as the color pigment. Five different cases are provided to compare.

3 Test methods

3.1 Temperature reduction experiment

As an important property, the temperature reduction effect is tested. In this study, the indoor simulation solar radiation system (Liang, 2005) is taken to test the effect of the coating. The lamp-house is iodine-tungsten light which has similar spectrum with the sun. The radiation intensity is 788 W/m^2 and the radiation time is 7 hours. The temperature is tested by sensor fixed in the surface. To compare with the Japanese coating, five coating materials and the Japanese coating are painted on 30×30 cm specimens to test the effect of temperature reduction.

3.2 Anti-skid performance

After applying the paint coating, the pavement surface can be slippery and dangerous to drivers. The anti-skid performance must be tested. In this study, the BPN is used to evaluate the skid resistance of the painted surface. The paint coating surface is tested with and without water application. In this study, six surface coating materials including the five developed in this study and one Japanese coating were tested.

3.3 Coat performance

The coating materials should be adhesive to the pavement surface with the application of rains and wheels. The adhesive force, rigidity and water-endurance are tested.

3.3.1 Adhesive force

The adhesion between the coating and the underneath material (HMA) is the necessary condition to increase albedo. Van de Walls force and hydrogen bond provides main part of the adhesive force. It is an important index for the coating. In this research, the experiment follows the method GB/T9286-88.

3.3.2 Rigidity

Rigidity is an important index to evaluate the service life of the coating material. The rigidity is tested by pencil method. Different rigidity pencil is used to distinguish the rigidity of the coat. Use a pencil to draw on the paint coating. If it can write without groove, the rigidity of the coating material equals the rigidity of the pencil.

3.3.3 Water-endurance

Considering the actual condition, the coating can be easily eroded by rain. An experiment is designed to simulate such condition. The coating material is painted on a test board first, and 1/3 of the test board is put in 40℃ flowing water. The time for the coating material to be peeled off from the board surface is then recorded.

4 Results

4.1 Temperature reduction test

The temperature reduction test results are presented in Figure 1. From Figure 1, the surface temperature of specimens with coating are lower than the specimen without coating, which proves that using coating can decrease the temperature effectively. Different coating materials also showed different effect in temperature deduction. Case 1, 2, 3, 4, 5 decrease 3.6℃, 8.5℃, 9.8℃, 11.4℃ and 9.7℃ respectively. Case 4 is the most effective one in all tested groups, which lowers the temperature 11.4℃. The Japanese coat decrease 6.3℃ and is less effective than the

case 4 coating.

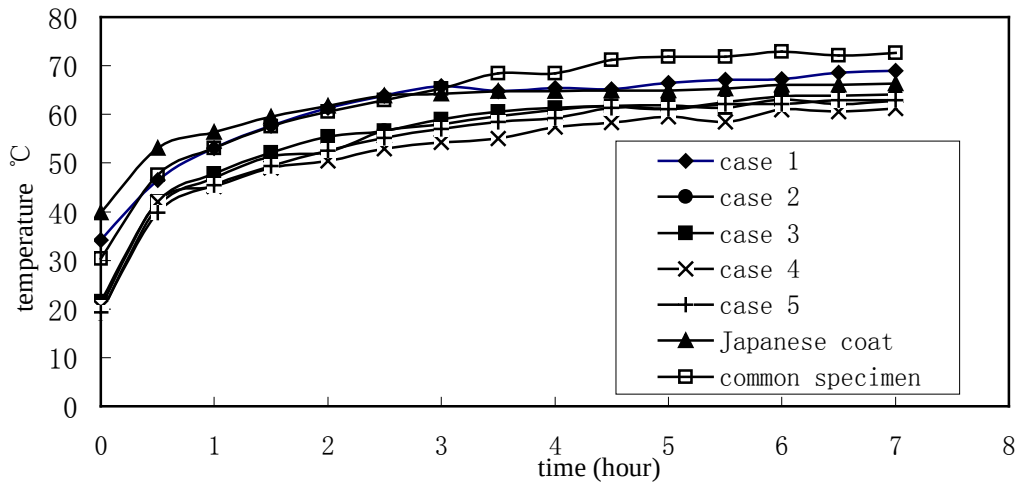

Figure 1 the results for lower temperature for different cases

4.2 Anti-skid performance

Following the method described above, the results are showed in table 1. From table 1, compared with the conventional HMA, the paint coating decreases the anti-skid performance largely. But most of them can still satisfy the minimum BPN requirement of 45. Case 5 does not satisfy the requirements. The Japanese coating has relative better anti-skid performance.

Table 1 the results for anti-skid performance

Specimens	Without water BPN	Water BPN
Without coat	84	64
Case 1	61.8	47.9
Case 2	71.1	51.4
Case 3	78.1	47.9
Case 4	64.4	49.9
Case 5	70.7	40
Japanese coat	69.4	51.6

4.3 Coating performance

The results of coating performance are showed in table 2. From the table 2, the different cases have similar adhesive, rigidity and water-endurance performance. It is because all the coats have the same basic resin materials. The coats developed have good adhesive and rigidity. Case 4 have the best water-endurance performance.

Table 2 the results for coat performance

Project	Case 1	Case 2	Case 3	Case 4	Case 5
Adhesive (%)	100	100	100	100	100
Rigidity	4H	4H	4H	4H	4H
Anti-water(h)	360	360	360	400	360

5 Cost and economical analysis

The Japanese coating chooses colophony or resin as the basic materials and fine hollow ceramic as functional pigments. The colophony is expensive which lead to the high cost of the coating material. In this study, silane-acrylate emulsion is chosen as the basic materials, which is cheap and no pollution to environment. Considering the construction technology and materials price, the cost of the coating is about $\$1/m^2$, which is much cheaper than the product provided by Japan.

Although the price is low, the working life of the coating developed is short. This is because the basic material is water-soluble. Compared with the colophony materials, the coating cannot be used for long time. According to field observation, the life of the coating is 2 months. Since the typical high temperature season is 1-2 months, such coating material can be applied to the highway and urban roads before the high temperature season every year.. When the season is over, the coating will break off. The overall economical value of such coatings is still higher than the Japanese coating with has longer working life (15 years) but much higher initial price. .

Conclusions

1) The heat reflection coating developed in this research can effectively reduce the pavement surface temperature. The surface with Case 4 coating is 11.4℃ lower than the reference specimen. Compared with the Japanese coating, the developed cases have better effect.

2) After applying the paint coating, the anti-skid performance decrease largely. But all cases except case 5 can satisfy the specification requirements.

3) Through the coating performance test, the coatings developed have similar adhesive force, rigidity and water-endurance performance.

4) The developed coating has better economy effect than the Japanese coating. The costing is much cheaper than the Japanese coat because the using silane-acrylate emulsion instead of colophony.

ABSTRACT

In the construction of a Large Span Pre-stressed Box-girder Concrete Continuous Rigid Frame Bridge with High Piers, the joint plan of the bridge depends on the construction conditions and design status. In this study, several joint plans were analyzed using the nonlinear finite element method for finding an optimum joint plan. In the analysis, the space beam elements were used to simulate the piles, the piers and the beams, and the link element to simulate pre-stressed reinforcement. The technology of element life and death was used to simulate the construction process. The non-line effects associated with big distortion, concrete shrinkage, and creep were considered in the simulation. Aiming at the high temperature joint of the bridge, a new technique, namely ‘loading anti-jacking force’, was proposed based on the analysis of the impaction related to the high temperature joint of the structure. In addition, the formula of the anti-jacking force was given originally. This research demonstrated that the non-linear finite element method is effective in engineering practice. This research can provide references for the design, the construction, and the monitoring of similar bridges.

INTRODUCTION

Because of its light, low-cost, mature technology, adaptability , and other advantages, LPBCCRFBHP (the Large Span Pre-stressed Box-girder Concrete Continuous Rigid Frame Bridge with High Piers) is favored by many bridge builders, especially in the application on mountain highway construction. The

LPBCCRFBHPs commonly use cantilever concreting construction technique. There are two main problems involved in the design and construction of LPBCCRFBHP: the bending deflection of the box-girder is oversize and the box-girder cracks (Wu Xiaoguang et al. 2001). The cantilever concreting construction can be used to adjust the elevation of formwork erection, the pre-stressed effective means, etc., resulting in avoiding or reducing the occurrence of the above two issues in the box-girder segmental (Cai Sujun et al. 2007). Therefore, to fulfill the design requirements and to ensure the state of stress and beam-line, the joint construction section of the bridge is one of the key concerns. In the actual construction, the joint actual temperature is often higher than the design temperature because of the limitation of machine equipment, and the rushing of construction progress. Hence, , the joint construction programs need to be adjusted according to the actual conditions, especially the actual temperatures at joint sections.

In this study, the Yesan River Bridge, which is designed as a LPBCCRFBHP, was analyzed in order to choose an optimum plan of the tentative joint program. The Yesan River Bridge is a grand bridge in Yichang-Enshi expressway in the Hubei province of China, which is a part of the Shanghai-Chengdu National Highway. The superstructure of the main bridge is a three-span Pre-stressed concrete Continuous Rigid box-girder Frame Bridge (as shown in Figure 1). The No. 3, 4 piers of the main bridge were the thin-walled high piers, with heights of 120.0m and 86.5m respectively . Two side span folds and a central span fold were designed all over the bridge and the length of each fold was 2.0m.

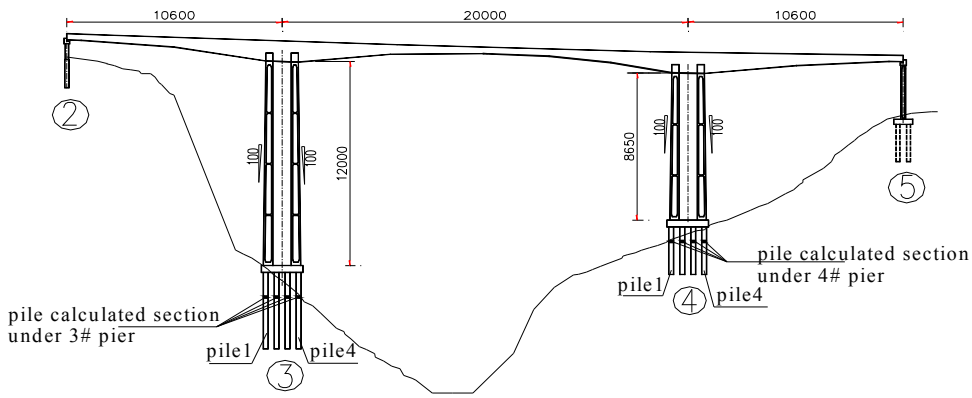

Figure 1. The sketch of the superstructure of the main Yesan River Bridge.

DICISION OF NEW JOINT SCHEME

THE JOINT SCHEME

The cantilever concreting construction was used in the Yesan River Bridge. The full-bridge joint order is both sides first, and then the middle. Because the 3 # T pier structure has completed the largest section of the cantilever construction, and 4 # T pier structure of the cantilever construction is a month later than 3 # T pier structure, there is enough time to destroy the center cradle of the pier 3# structure. According to the construction site, the following joint plans were put forward:

Plan one: Don't dismantle the cradle; the section of three folds all use the cradle to fold directly. Put pressure on the side span to adjust linear and the stress.

Plan two: As shown in Figure 2, after the 3# pier central span cradle is demolisted, the 3# pier side span folds. Then the 4# pier central span cradle transfers to 3# pier T structure to carry on the 4# pier side span fold. And pier 4# T structure of central span cradle will be back to joint section dismantling principal truss of the cradle, using the bottom of the cradle and the side form carrying on the central span joint construction.

Plan three: As shown in Figure 2, after removing the central span cradle of 3# bridge pier, we put the 3# bridge pier side span together, and then put the cradle of 4# bridge pier central span forward. The cradle truss of the 4# pier mid-span can be removed after the bottom-cradle, side die and inner die of 4# pier mid-span have been hanging at the largest cantilever segment of 3# T and 4# T piers mid-span. Then start to construct the joint paragraph of the 4# bridge pier side span and central span in turn.

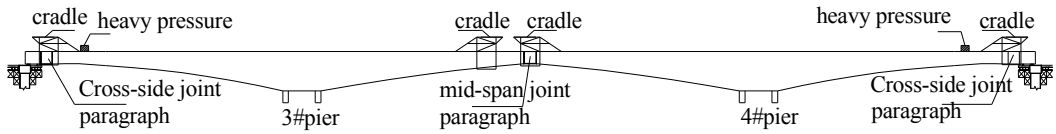

Figure 2. The schematic of the joint program.

In the simulation, non-linear space beam elements were used to simulate pile, pier and main beam, and member-units to simulate the pre-stressed reinforcements. The model of the structure's spatial analysis was established to analyze the designed joint program and the options above. The calculation model is shown in Figure 3.

Figure 3. The model of structures calculation anal ysis.

ANALYSIS OF THE RESULTS

The originally designed joint program and the three new options above were analyzed. The main beam deformation and the difference of stress after 1500 days after the completion of the bridge are shown in the Figure 4.

The results shown in Figure 4 demonstrate that there is only a small difference between the first program (side span's matching weights is 45 t) and the designed program about the bending deflection of each side span section. The largest bending deflection deviation in the central span is the lower 27 mm. The largest stress deviation of the section on edge is about 0.4 mpa, and that on the lower edge is about -0.3 mpa. The difference in the linear and forcement is so large that it can't be

adjusted in joint construction. For these, the first joint program is not feasible. The second program is coherent with the first program in the condition that the side span's matching weights is 45 t in the first program, but because of the cradle's removing around the joint paragraph of the central span, it will bring some security risk in the process of construction. In addition, the main truss of the cradle is removed after the side span of the pier. # The 4 T configuration gets joint in the second program; this will affect the process of the joint of the central span. In the third program, the process of the joint is in the condition that 4# T pier side span's matching weights is 55 t, the largest deviation of the linear and stress is respectively 4.6 mm and 0.05 mpa at last. After the joint of the main Yesan River Bridge, the side span's joint error of the pier # 3 T configuration, the side span's joint error of the pier # 4 T configuration, and central span's joint error are 11 mm, 8 mm, and 10 mm respectively. While the allowed maximum deviation of the linear is 20 mm in the process of the joint, these factors indicate the availability of the third joint program. Hence the third program was adopted in the construction of main Yesan River Bridge.

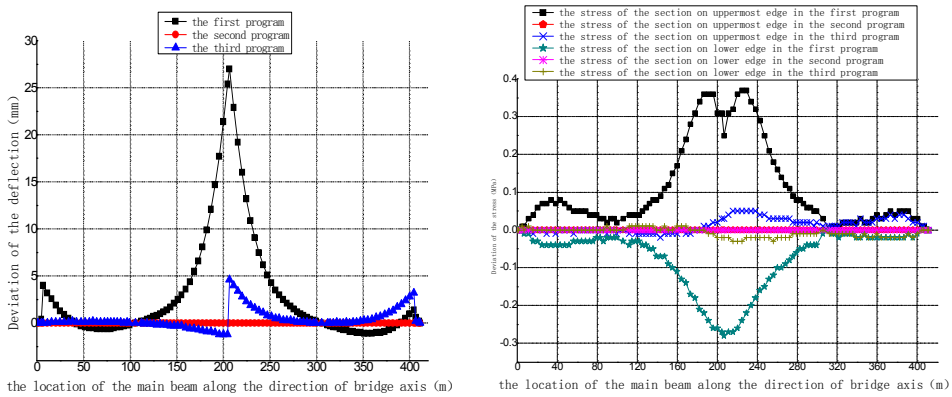

Figure 4. Comparison of the three new joint programs and the original designed joint program (deviation of the deflection = the deflection of the original designed joint program - the deflection in the first(second, third) program).

JOINT AT HIGH TEMPERATURE

THE DETERMINATION OF REASONABLE JOINT TIME AT HIGH TEMPERATURE

The pre-stressed concrete continuous rigid frame bridge is the multiple statically indeterminate structure. If the joint temperature is a little high, the new deposited concrete in the joint paragraph will shrink in the process of hardness with the dropping of the temperature, at the same time the deposited beam of the both ends of the colong kou will shrink with the dropping of the temperature. (Hu Wenxue et al. 2007) Hence, the cracks will appear between the joint paragraph and the deposited beam of both ends and the connectivity of the jointed beams can't be ensured. The dropping of the temperature will also induce a greater secondary inner force, which will superpose with the inner force produced by the shrinking of the concrete (Zhou

Guangwei et al. 2006). In addition, the dropping of the temperature will induce the shrinkage of high piers, especially for height-difference piers. Under the same dropping temperature condition, the difference of volume contraction is higher as the height difference of piers is higher. The effect of this reason is similar with non-uniform settlement of the foundation.

About the upstream of the Yesan River Bridge, the original design was to make the joint in 15+5℃. Due to the effect of the progress, the upstream of the Yesan River Bridge is scheduled to start the joint of the main span on August 2. In August, the air temperature around the Yesan River Bridge is about 19-37℃ (the lowest-highest temperature). Through the surveying, the average temperature of the box beam concrete was found to be higher than 19℃, as the observed temperature data shown in Table 1. As shown in Table 1, the lowest data of the main beam's average temperature was around 26℃ and appeared in the early morning in the range of 3 to 6 o'clock. At this period of time, the air temperature and beam body temperature didn't have large change, so we chose 5 pm to start the rigid lock work.

Table 1. The temperature from July 31 to August 1 about the Yesan River Bridge's right pieces atmosphere（℃）.

time	the maximum temperature of the box beam's concrete	The average temperature of the box beam's concrete	air temperature
31-Jul 06:00	26.58	26.24	19.3
31-Jul 08:00	27.23	26.28	20.3

1-Aug 03:00	27.82	26.32	18.9
1-Aug 05:00	26.38	26.19	19.0

THE EFFECT OF JOINT TO THE STRUCTURE AT HIGH TEMPERATURE

The average temperature of main beam concrete is -2.1℃ in cold weather through our observation, so from the 26℃ (when the central span get joint) to cold winter (about -2.1℃), the temperature's change is 28℃ on the dropping side. Such a change will cause a large affect to the removement of the bridge pier and inner force of the structure. In the simulation, two extreme beam temperatures (about -2℃ and 32℃) were used while the central span get joint is 26 ℃.

DISPLACEMENT OF HIGH PIERS

Based on the simulation for the joint process of the Yesan River Bridge under extreme beam temperatures, some conclusion could be drawn : the effect of different

joint temperatures is large due to the displacement of the pier-top and the vertical displacement of the middle of central span. If the central span get joint in designed temperature (15℃), when the structure as an integrity achieves the extremely high temperature or low temperature, the position displacement of the pier-top is roughly the same, but the deformation of the central position of the central span in the condition of dropping temperature is twice than the rising temperature. If the central span get joint at high temperatures (26℃), when the whole structure's temperature achieves the maximum temperature, the deflection and settlement of the pier-top are not very large, but when the whole structure's temperature achieves the minimum temperature (-2℃), the deflection of the pier-top can reach to 3.1 cm, the settlement of the pier-top is about 3 cm, too; besides, the absolute elevation of the central position dropped 7.2cm. It's worth to figure out that the settlements of the two high pier-tops are different to each other. There is additional stress in the structure due to the large deflection of the pier-top and the non-uniform settlement of the high pier-tops.

THE INTERNAL FORCE OF THE STRUCTURE

When the joint process of the Yesan River Bridge is at high temperatures and under the extreme beam temperatures, the simulation demonstrated that the force of high piers is slightly influenced by the beam temperature when the central span was jointed at different temperatures. When starting the joint in the same temperature, the effect of the temperature is large due to the structure's stress, especially to the stress of pile while the pile appeared prodigious tensile stress. For example, in the pile-bottom section of pile 1 of pier 4#, the tensile stress reach to 2.19 MPa, so is 1.20 MPa in the pile-bottom section of pile 2 of pier # 4's leg. Such a large tensile stress together with the live load will make the stress in the section of pile-bottom ascend the limitation of the concrete's stress and induce cracks.

COUNTERMEASURE OF THE JOINT WHILE TEMPERATURE IS HIGH

Some effective measure (Biao Wu 2006) was adopted when the joint temperature is high, for example, loading anti-jacking force. The effect of temperature and the shrinkage and creep of concrete on the linear and force of structure can be eliminated by loading anti-jacking force on 3# pier and 4# pier before the mid-span was jointed. Imposed anti-jacking force diagram is in Figure 5：

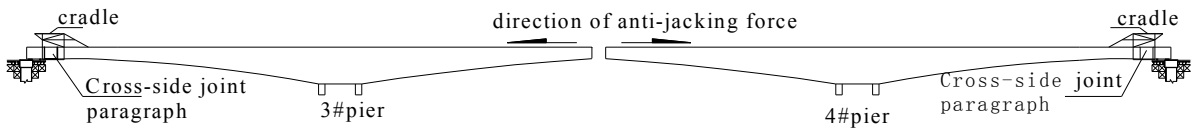

Figure 5. Impose anti-jacking force.

TO DETERMINE THE SIZE OF THE ANTI-JACKING FORCE

The purpose of the anti-jacking force is primarily to offset temperature and concrete shrinkage and creep of the linear structure and the impact of stress. The

anti-jacking force required to meet the following formula：

$$\{u\}_{F+\Delta T}^{\text{High temperature closure}} - \{u\}^{\text{Design temperature closure}} \le [\delta_u]$$
$$\{\sigma\}_{F+\Delta T}^{\text{High temperature closure}} - \{\sigma\}^{\text{Design temperature closure}} \le [\delta_\sigma] \quad \cdots\cdots(1)$$

where u is the horizontal displacement of the nodes of the main beam; σ is a structural stress; F, ΔT are the anti- jacking force and the temperature difference between the temperature of the high temperature joint and the design temperature joint; $[\delta_u]$, $[\delta_\sigma]$ are the given displacement and stress for the anti-jacking force optimized. According to the experience of monitoring and control many continuous rigid frame bridges, $\delta_u^{\max}$ check 0.005m, $\delta_\sigma^{\max}$ get 1.0MPa。

Through optimizing calculation, it must impose 26 t anti-jacking forces at the top of mid-span on 3# pier T structure in advance, and 28 t on 4 # pier. However, the anti- jacking force must be imposed symmetrically. 27 t anti-jacking force on the joint of the bridge in the central span was optimal to eliminate the adverse effects during high temperature joint. The deviations of the pier top are very close while the 27t anti-jacking force is imposed during the high temperature joint and the design temperature joint. The stresses at the bottom of the pile have a large difference up to 0.63 MPa, which is mainly caused by high-rise pier. However, it is still a degree of optimization that imposes 27 t anti-jacking force compared to not imposing any force during the high temperature joint.

LOADING ANTI-JACKING FORCE

Anti-jacking force was symmetrically imposed on the box beam of the lower reaches of the web on the axillary stems. For the Yesan River Bridge, a 27 t anti-jacking force was imposed on the web on the lower and upper reaches. Each jack on the lower reaches and the upper reaches are 13.5 t. Figure 6 shows a photograph while imposing the anti-jacking force.

Figure 6. Imposing anti-jacking force.

CONCLUSION

Based on the actual construction conditions of Yesan River Bridge, comparative analysis of four joint plans were conducted through a non-linear finite element method in this research. A new joint plan was nailed down and applied to joint the right pieces of the Yesan River Bridge.

Extreme temperatures of the continuous rigid frame bridge and a series of joint temperatures were considered in the simulation. The results demonstrate that the joint temperature has a great influence on the deviation of the pier-top and the vertical deviation of mid-span of central span section. If the central span is jointed under design temperature, the pier-top-change rate is roughly equal when the whole structure reaches an extreme high or an extreme low temperature, but the deformation that caused by temperature cooling is 2 times of that caused by temperature rising. Considering varied joint temperature of the mid-span, a high pier bridge stress is slightly affected by the joint temperature, whereas the force of main beam and the pile are highly affected by the joint temperature. Under a same joint temperature, the stress of the various key cross-section of the structure is greater impacted by temperature changes, and the pile is affected most.

Through loading anti-jacking force to joint continuous rigid frame bridge under high temperature conditions, the pier-top deviation and pier-top-pile cross-section of the tension can be greatly reduced to meet the design requirements; the value of anti-jacking force is identified by the deviation of the pier top and the force of the structure together.

Research on Structural Design of Interlocking Concrete Block Pavement for Rural Road

Ma Songlin[1], Hou Xiangshen[1] , Wu Dayong[1]

[1]School of Transportation Science and Engineering, Harbin Institute of Technology, Add.：202 Haihe Road, Nangang District, Harbin 150090, P.R. China; Tel.：86-451-86282120; Fax ： 86-451-86283779; E-mail: masonglin@hit.edu.cn

ABSTRACT

In China thousands of kilometers of rural roads need to be paved. In order to reduce the construction and maintenance costs, the interlocking concrete block pavement can be used in low traffic rural road. The structural design criteria of interlocking concrete block pavement with different types of base causes was researched. The results indicated that the design criteria is different for different base course. The methods of the criteria calculating and structure design were given.

KEYWORDS

Rural road; Interlocking concrete block pavement; structural design

INTRODUCTION

Interlocking concrete block pavement is a pavement which is aligned tightly with high strength concrete block and has property of integrity due to joint transferring shear force. Interlocking concrete block pavement is seldom used in driveway pavement in China at present. There are many merits of this kind of pavement such as strength and durability of structure, low construction costs and the convenience of maintenance, especially no need of heavy machine during construction of the pavement. These merits meet the requirement of rural road construction in China; therefore the study of interlocking block pavement in rural road construction was carried out.

FAILURE STYLES OF INTERLOCKING BLOCK CONCRETE PAVEMENT

There are 6 kinds of failure in interlocking concrete block pavement (B.Shackle, 1985). ① Loose and separation of blocks. Under vehicular load, there is a trend of separation in blocks. Especially in the condition of slope, due to the vibration of vehicles, blocks are slid along direction of slope and joints are separated in blocks at the top of slope so that interlocking of pavement is lost. The paver shape or laying pattern was selected to prevent the failure. ② Breaking or striping of block edge. Because paver is rotate under vehicular load, the breaking or striping of edge is easy to occur. To prevent this failure the block should be manufactured in chamfering edge of surface. ③ Break or abrasion of block. Two reasons can result in break of paver. One is cavity beneath of paver because the surface of base course is not even, another is low bending strength of paver. Controlling construction quality is to prevent the former and controlling manufacture quality of paver is to prevent the latter. Abrasion is due to insufficient rigid of aggregate in block or not suitable dosage or grade of cement. ④ Permanent deformation and sag of pavement. Permanent deformation and sag usually occur in pavement. The large permanent deformation not only deteriorates

service level of pavement, but also results in seeper. Water leak along the joints of blocks can destroy the bearing capacity of pavement structure. Therefore permanent deformation is adopted as the criterion of structural design occur because of insufficient compaction of base or sub-base can results in sag of pavement. ⑤Shear failure. Shear failure occur in pavement with unbounded base such as granular. The reasons of shear failure are low strength basement and high loading. ⑥ Fatigue cracking of base course. Fatigue damage will be happened in interlocking block pavement with semi-rigid base course under repetitive loading. This kind of damage is similar to asphalt pavement. Fatigue cracking of base is main factor in damage of base and destructing of pavement structure. Therefore bending stress at the bottom of base is used as criterion of structural design of interlocking block pavement with semi-rigid base course.

ANALYSIS OF STRUCTURAL DESIGN CRITERIA

According to the analysis of mentioned failure styles of interlocking block pavement, the former three kinds of failure are not related to structural design. For rural road the shear damage is hardly happened due to overloading vehicles. Therefore in structural design the exceeding permanent deformation and fatigue cracking of semi-rigid base must be controlled.

Interlocking block pavement is flexible pavement consisting rigid units. If base course is unbound granular, the permanent deformation will accumulate in pavement under repetitive vehicle loading. When the depth of permanent deformation rises to some value, the service capacity of pavement will be extremely influenced. Therefore the depth of tolerance permanent deformation in design period is adopted as structural design criterion of interlocking block pavement. Namely DR (depth of permanent deformation calculated) $\leq$ [DR] (tolerance permanent deformation)

The fatigue bending stress of base course usually adopts as criterion in the design of flexible pavement with semi-rigid base course in order to control cracking of base course. But cracking of base course of interlocking block pavement take place, the service capacity of the pavement is not destroyed. The fatigue life of the pavement should be divided into two stages. In former stage fatigue life is predicted through bending stress of semi-rigid base course. In latter stage fatigue life is predicted according to calculating tolerance permanent deformation through elastic modulus of cracked stabilized coarse aggregate base (equivalent modulus of compacted granular). The structural design of interlocking pavement should be separated into two stages. For interlocking block pavement with stabilized fine aggregate base, when cracking of base take place, the load carrying capacity of the pavement will decrease rapidly, the fatigue bending stress of base course is used as criterion of structural design only(Yao Zukang,2003).

CALCULATION OF STRUCTURAL DESIGN CRITERIA OF INTERLOCKING BLOCK PAVEMENT WITH SEMI-RIGID BASE COURSE

When a base course is stabilized coarse aggregate, the two stage design method should be used. In former stage fatigue life is decided by fatigue bending stress of base course bottom, whereas in latter stage fatigue life is determined by permanent deformation of a cracked stabilize coarse aggregate.

The formulation of tolerance bending stress of base course bottom in interlocking block pavement with semi-rigid base course is following:

$$[\sigma] = 3.0 \cdot \frac{\sigma_S}{K_d \cdot N_m^{0.1}} \quad (1)$$

Where

$[\sigma]$—tolerance bending stress of half rigid base bottom (Mpa);

σ_s—maximum strength of half rigid base (Mpa);

Nm—cumulative number of standard axle load;

Kd—coefficient of dynamic load ， Kd=1.05。

CALCULATION OF PERMANENT DEFORMATION OF INTERLOCKING BLOCK PAVEMENT WITH GRANULAR BASE

The formulation of permanent deformation of interlocking block pavement usually is achieved with regress analysis method according to results of site test.

In accordance with the research of relevant test in Tongji University, the formulation of permanent deformation of interlocking block pavement with granular base as follows (Sun Linjun,1996):

$$D_R = 1.9 \cdot C \cdot l \cdot e^{-11h} N_m^{0.265} \quad (2)$$

Where

h —thickness of block (cm);

l —deflection of pavement under vehicle loading once （mm）;

Nm—cumulative number of axle load related to l ;

C —when h=8，10，12cm，C=1.17，1.25，1.34 respectively。

Therefore structural design of interlocking block pavement with granular base is carried out with the formulation when cumulative number of standard axle load and tolerance permanent deformation are determined, deflection of pavement can be calculated through FEM of pavement simultaneously.

In order to analyze the relationship between the fatigue life of two stages, structural model of interlocking block pavement with different block thickness and different modulus of sub-grade are used to calculate the respective numbers of axle load of two stage fatigue life: Nm-σ(first stage) and Nm-l (second stage). The result of calculation is shown in **Figure 1**. it can be seen that the ratio of Nm-σ and （Nm-σ+Nm-l）is limited in minor range when base thickness is same although different block thickness and different modulus of sub-grade.

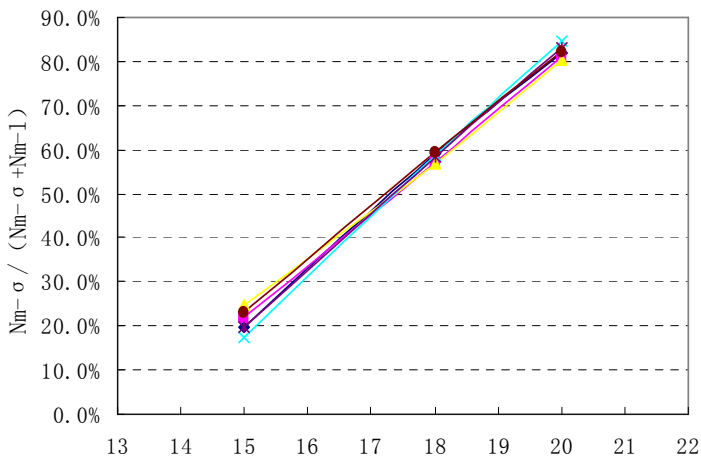

Figure 1. Relationship between base thickness and N_m- /（N_m- +N_m-$_l$）

In pavement structural design Nm-σ/（Nm-σ+Nm-l）in table 1 can be determined according to assumed base thickness.

Table 1. Ratio of N_m- /（N_m- +N_m-l）in structural design pavement

Thickness of base (cm)	15	16	17	18	19	20
N_m-σ/(N_m-σ+N_m-l）(%)	30	43	55	65	75	85

In structural design of interlocking block pavement the calculation of both stage must meet the requirement of design criteria, if the calculated permanent deformation in second stage is much less than tolerance permanent deformation, a new calculation should be carried out with reduced ratio of Nm-σ/(Nm-σ+Nm-l).

CONCLUSION

Through the analysis of failure styles of interlocking block pavement, the permanent deformation and fatigue cracking of semi-rigid base course were adopted as design criteria to control pavement failure for rural road. Where base is granular material, the depth of permanent deformation is used as criterion of structural design. Where base course is stabilized coarse aggregate, structural design is divided into two stages, in first stage the bending stress of semi-rigid base course is used as design criterion, whereas in second stage the permanent deformation of granular base course assumed to be same thickness with semi-rigid base course is used as design criterion.

The Analysis of Dowel and Tie Bars Effects on Curling up in Concrete Pavement Slabs

Xinkai Li[1], Songlin Ma[1], Xiangshen Hou[1]

[1]School of Tranportation Science and Engineering, Harbin Institute of Technology, P.O. Box 150090, City, Harbin, P.R.China; PH (86) 451- 86282120; FAX (86) 451-86282116; email: lxkhit@126.com

ABSTRACT

The effects of dowels and tie bars on curling in concrete pavement slabs is still not clear in design. Therefore, a 3D finite element model (FEM) of the multi-slabs resting on elastic foundations is developed to investigate this effects, and the design plan of dowels and tie bars in FEM are determined according to cement concrete pavement design specification in China, and in FEM beam element is employed to simulate the dowels and tie bars. From the calculated results, the tie bars effects on slab curling is little, and dowels effects is very obvious at slab joints where the stress will increase and curling up will decrease, but for the whole slab the effects of dowels is not obvious.

INTRODUCTION

A concrete slab will tend to curl when it is subjected to a temperature gradient extending vertically through the slab thickness. The tendency to curl induces stresses in the pavement as the pavement is restrained by its weight, the interface between slab and foundation, and the dowels and tie bars from adjacent slabs. The thermally induced stress caused by such interaction can be a significant factor in contributing to early pavement cracking.

Therefore, over the years, the problem of curling stresses received attention from many researchers. From the Westergaard's solution in 1927 to now, many models were developed, especially the finite element models. Those researchers developed techniques for dealing with the problems of slab's self weight, partials contact, nonlinear temperature gradient, and the combined effect of thermal and traffic loads (B. Chubane et al. 1995; Brucea.S. 2002; E. Masad et al. 1996). However, the effects of dowels and tie bars on curling stresses didn't attract attentions of researchers and it is not very clear for the curling stress in jointed concrete pavement (Gergis W. et al. 2001; I.E. Harik et al. 1994).

In this article, 3D finite element modeling is used to examine the effects of dowel and tie bars on curling stresses in jointed concrete pavements. The basic feature in the model is a detailed modeling of dowel and tie bars. The dowel and tie bars using beam elements are embedded in concrete using solid brick elements. After a brief description of the features of the 3D FEM, the curling stress and displacement of multi-slabs with dowel and tie bars are compared with the results with no dowel and tie bars. Then the influence of dowels, tie bars is discussed. The role of dowel bars in activating magnitude of stresses and reducing magnitude

of displacement at joints due to uniform negative temperature differential is discussed and the effects of tie bars on slab curling is analyzed also.

THE FEM OF MULTI-SLABS CURLING

The Parameters in FEM

The multi-slabs resting on elastic foundation are modeled through finite element procedure ABAQUS and the sizes of each slab are 4m×4m×0.2m (length ×width ×height).The interface between slab and fo undation is very complicated and important to concrete pavement and in this FEM the interface is assumed to be frictionless (unbonded). The frictionless interface is simulated through contact elements which can well model the separation of slab and foundation as slab edge curling up. The values of parameters in FEM are listed in **Table 1**.

Table 1. The values of parameters in FEM

Parameters	Elastic Modulus （MPa）	Possion's ratio	Density (Kg/m^3)	Thermal conductivity （W/mK）	Coefficient of Thermal Expansion	Thickness of Slab (cm)
Slab	30000	0.15	2400	6	$5e^{-6}$	20
Foundation	400	0.30	2000	0	0	200
Parameters	Elastic Modulus （MPa）	Possion's ratio	Density (Kg/m^3)	Thermal conductivity （W/mK）	Coefficient of Thermal Expansion	Diameter X Spacing (mm)
Dowel bars	2e5	0.3	7830	10	$5e^{-6}$	28 X 300
Tie bars	2e5	0.3	7830	10	$5e^{-6}$	14 X 800

In FEM the temperature gradient is assumed to be linear along thickness of slab and the " negative gradient " is considered only because slab edge curling up is more often and serious to slab, especially in northeast of China. The term "negative gradient" is used when the temperature of the slab top is smaller than that of the slab bottom. The heat change between slab and foundation is ignored. The temperature differential is assumed to be -1.0℃/cm.

The 3D eight nodes continuum is employed in FEM. Through comparison of different element sizes, the number of elements of slab, 20×20×2 (length × width ×height), is selected. **Figure 1** presents the meshed model.

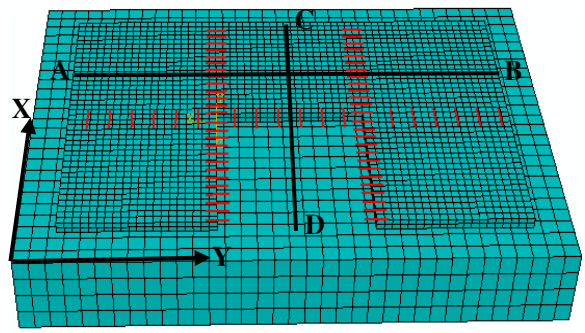

Figure 1. The Finite element model

Verification of FEM

If the self weight of slab is ignored, the close form solution of single slab curling up due to temperature gradient can be derived through slab geometrical relationship. The curling deflection can be calculated by following equation (1) (Masad E. et al. 1996; Yao Zukang 1981). Therefore, this case is selected to validate the FEM.

$$\delta = \frac{\alpha \Delta FL^2}{2h} \qquad (1)$$

Where: δ — The vertical displacement of arbitrary point in slab;

α — Coefficient of thermal expansion of concrete;

ΔF — Temperature gradient along slab thickness;

h — Slab Thickness

L — The distance from arbitrary point to slab center.

It can be known that the self weight of slab is closer to zero the results should be converge to results of Equation (1). In FEM changing the parameters of slab density can realize the self weight of slab to be close to zero. If the slab weight is assumed to be W, and when slab weight is from W to 0.001W in FEM, the calculated results are presented in **Figure 2**.

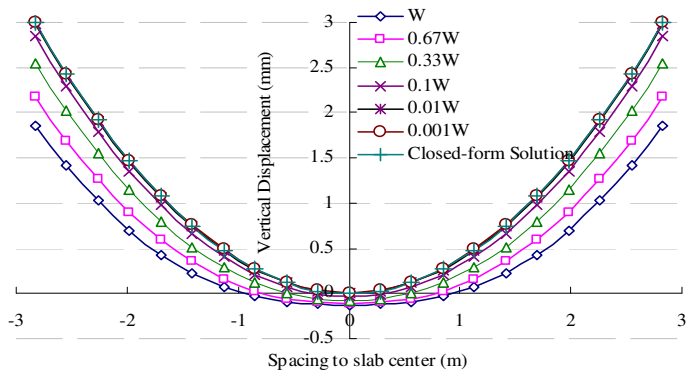

Figure 2. The vertical displacement as different slab self weights

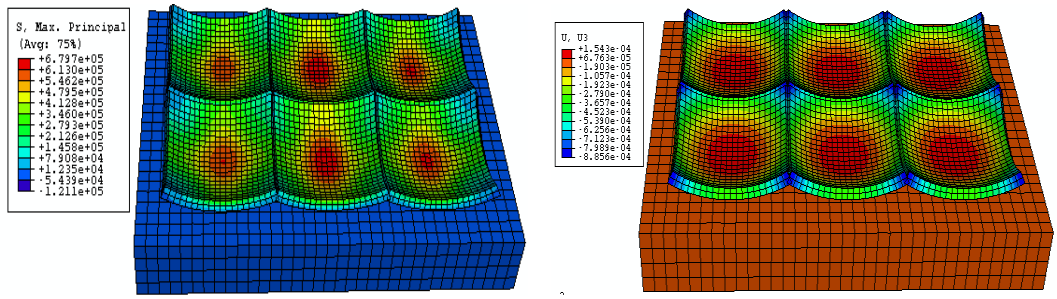
In **Figure 2** with slab self weight decreasing the curling deflection increases. when the self weight is converge to zero the calculated results is very close to close-form solution by Equation (1).Through the comparison of FEM and Closed-form solutions this FEM can be used for calculating the responses of slab.

THE EFFECTS OF DOWEL AND TIE BARS ON SLAB CURLING

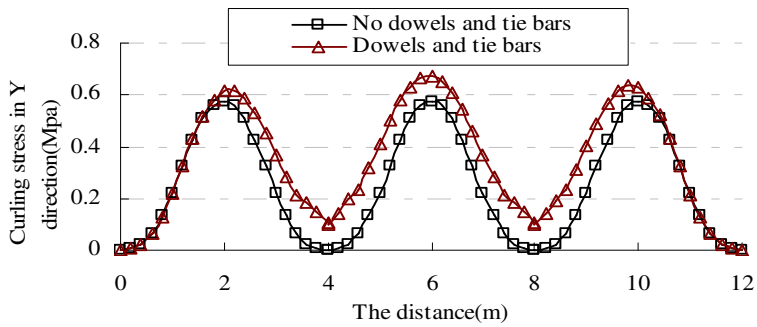
Figure 3(a) illustrates the deflection and maximum principal stress profiles that six concrete slabs take due to the application of negative linear gradients of −20 ℃.



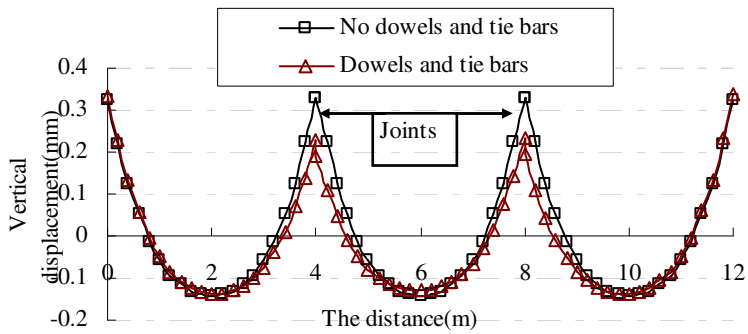
a)Maximum principal stress b）Vertical curling deflection

Figure 3. Deformed slab due to curling

In the case of negative temperature gradient, the slab will be supported over its middle portion while the joints and slab side-edges deflect upward. The stress and displacement along the slab longitudinal centerline AB in **Figure 1** are investigated to explain the effects of dowel bars. The stress and displacement along the slab transverse centerline CD in **Figure 1** are investigated to explain the effects of tie bars.



a) The vertical displacement



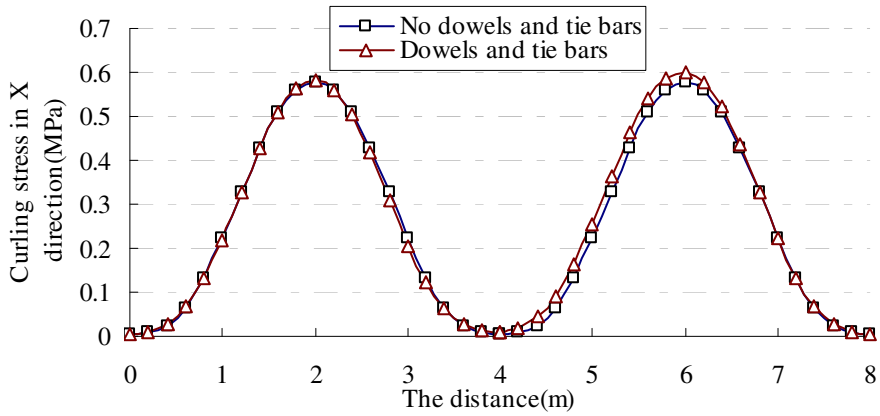
b) The stress in Y direction

Figure.4 The calculated results by FEM along line AB

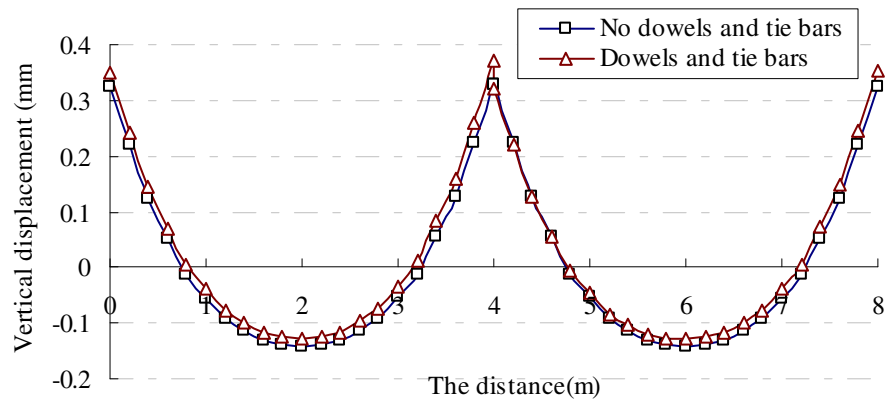
The 3DFEM computed distributions of the stress in Y direction and vertical displacement along line AB are shown in **Figure 4**. From **Figure 4a)** the dowel bars contribute to reduce vertical displacement at joints, but the effects of dowel bars on whole slab curvature are not obvious. From **Figure 4b)** due to the contribution of dowel bars to restrain slab curling the curling stress at joints increases and the curling stress in whole slab increases also.

The transverse centerline CD in **Figure 1** crosses the longitudinal joints

including tie bars, therefore the line CD is selected to illustrate the effects of tie bars on curling. The 3DFEM computed distributions of stress in X direction and Vertical displacement along CD are shown in Figure 5. From Figure 5 it can be found that the effects of tie bars on slab curling is very little and can be ignored.



a) The vertical displacement



b) The stress in Y direction

Figure.4 The calculated results by FEM along line CD

CONCLUTIONS

A 3D finite element model is developed to investigate the effects of dowel and tie bars on curling in concrete pavement slab. After the 3DFE model is validated, the results of dowel and tie bars are compared with the results of no dowel and tie bars. From the comparison indicate that the effects of dowel bars on slab curling is obvious and dowel bars will restrain the curling deflection and increase the stress in whole slab, especially on joint, and the effects of tie bars is not obvious and can be ignored.

Experimental Analysis of Interface Bond Performance of UTW

Yu-qiang Huang[1], De-cheng Feng[1], Xin-kai Li[1], and De-you Feng[1]

[1]School of Transportation Science and Engineering, Harbin Institute of Technology, Harbin 150090, China

ABSTRACT

The interface bond condition between the concrete panels and asphalt pavement influences the stress status of Ultra-Thin Whitetopping (UTW) slabs. Therefore, it's necessary to understand the performance of interface bonding between the thin concrete slabs and old asphalt pavement. Previous researches mostly used straight sniping experiment or wedge split experiment to evaluate the interface bond condition; however, those tests do not represent the actual bonding behavior between UTW slabs and asphalt pavement sufficiently. In this paper PCC-AC composite beams were designed and cast and were subjected to three point loading test. The Crack Mouth Opening Displacement (CMOD) curves and Mid-span deflection-Load curves were collected through the experiments of different bond conditions. By comparison of results obtained from testing beams with different interface conditions, it was proved that this test can be used to evaluate interface bonding conditions of UTW pavements.

Key words: UTW; interface bond.

INTRODUCTION AND BACKGROUND

Ultra-thin whitetopping (UTW) is a rehabilitation technique for distressed asphalt concrete (AC) pavement, usually consisting of constructing a thin layer of concrete slabs (50-100mm) on top of the AC pavement (Charles J. Churilla. 1998). In total, 313 projects comprising of almost one million square yards of UTW in 35 states were constructed through the end of 2002 in the United States (ACPA.2003). Good field performance records indicated that UTW can be an effective rehabilitation technique for deteriorated asphalt pavement.

Previous researches howed that interface bonding between the UTW slabs and the asphalt pavement played a major roles in affecting the UTW performances. Interface bonding reduces stresses in the concrete slabs significantly by making the two layers as a monolithic pavement system.(Sanford et al.1992). The service levels of UTW pavements are largely dependent on the existence and maintenance of sufficient interface bond strength between the concrete and asphalt layer (Chung-Lung Wu et al.2007).

Because of the much smaller size of UTW slabs, when the wheel load travels on one edge of the slab, the other side of the slab tends to move up, which would cause tensile stresses on the interface. In the meanwhile, the interface under the loads is under compression (Figure.1). Interface bond strength between the asphalt layer and UTW is one of the most important factor in affecting UTW pavement performance.

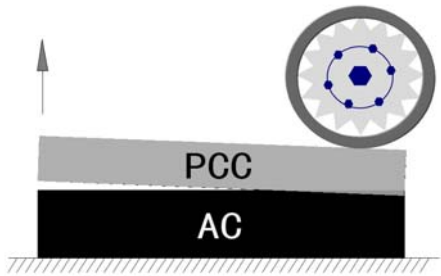

Figure.1. Performance of UTW with wheel load

EXPERIMENTAL PROGRAM

Many test methods have been used for evaluating interface bond strength, including straight pull experiment, straight snips experiment, three points bending resistance experiment, four points bending resistance experiment and wedge split experiment (SONG Yu. 2005).

In the straight pull experiment setup, specimens need to be perforated for fixing, which will result in strength reduction. As a result, asphalt concrete will be damaged easily at the perforated locations. Therefore, , straight pull experiment is not applicable for asphalt concrete specimen.

The principal theory of three point-bending resistance experiment and four-point bending resistance experiment is to simulate the layer structure of pavement. Load is placed at the center of the specimen and the interface movemenst caused by the deflection are then calculated. However, neither of two test methods can simulate the interface contact between UTW and asphalt realistically since the test result is mostly impacted by level friction. The same situation is also relevant to straight snips experiment.

In the wedge split experiment, a rectangular slot is cut at one side of the specimen along the interface. Loading is then applied at the rectangular slot to split the specimen in order to evaluate the resistance to shearing. However, the cracking behavior of interface contact is not the same as that of UTW.

In order to simulate the interface bonding behavior between UTW and asphalt pavement more realistically, a new test method was developed in this study. As presented in Figure 2, the test procedure include the following:

- Make PCC-AC composite beam in the size of 400×100×100mm
- Conduct three point bending resistance experiment
- Take the measurements and record of load, span centre deflection and cracking process of the PCC-AC composite beam
- Study cracking behavior under different interface bonding conditions.
- The distance between pivot and joint face is 150mm.

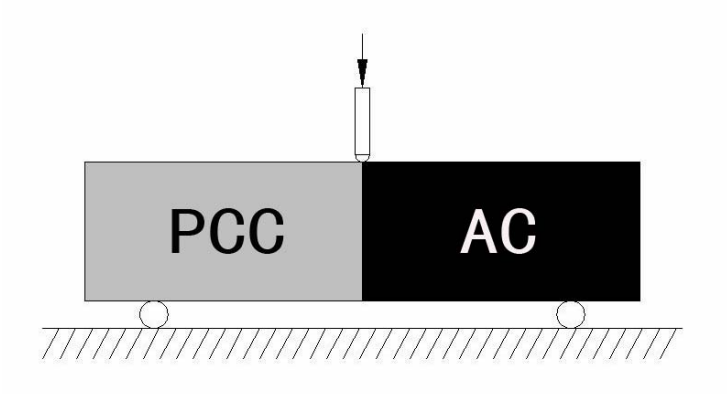

Figure.2. Graphic of PCC-AC composite beam test

MATERIAL

There are two gradations for asphalt mixture：AC-13I and AC-20I. No. 90 petroleum asphalt for pavement is used in this experiment. The performance of the asphalt mixture has been verified to meet specification requirements.

Typical mixing proportions for concrete were used for UTW. The water-cement ratio is 0.30, with a 28-day flexural strength 6.56Mpa, also meeting requirement.

INTERFACE TREATMENTS

The contact surface of asphalt layer was processed to create four different surface conditions to simulate interface bonding behaviors under different surface conditions (Table.1).

Table.1. Surface treatments

Surface treatments	Original	Tack coat with macadam	Milled	Notched
Fig				

EXPERIMENT PROCESS

The asphalt concrete specimens are cast in vibration compaction. It is concreted for 28 days before subjected to the three points loading experiment using a MTS machine. Before loading, the wire-type displacement transducer is attached to one side of the composite beam to measure the cracking course. (Figure.3)

Figure.3. Experiment process

EXPERIMENT RESULTS

Table.2. Experiment results

Surface treatments	Crack position	Cracking surface condition	Crack	cracking surface

Original	Bonding interface	smooth		
Tack coat with macadam	Bonding interface	smooth		
Milled	AC (close to interface)	rough		
Notched	AC (close to interface)	rough		

COMPARISONS OF THE AC-13I AND AC-20I SPECIMENS

As shown in Figure 4, for the original asphalt surface, the loads increase rapidly in both tests of AC-13I and AC-20I. The peak load values appear at the point where width of crack is about 1mm. After that, the values drop quickly. The specimens lost the ability to carry loads when the width of crack is about 4mm. The limiting load of AC-20I specimen is higher than that of AC-13I specimen because the average grain size of AC-20I is coarser and its surface pore is larger than AC-13I. As a result, more cement mortar entered the structure of AC-20I ,which resulted in enhanced interface bonding.

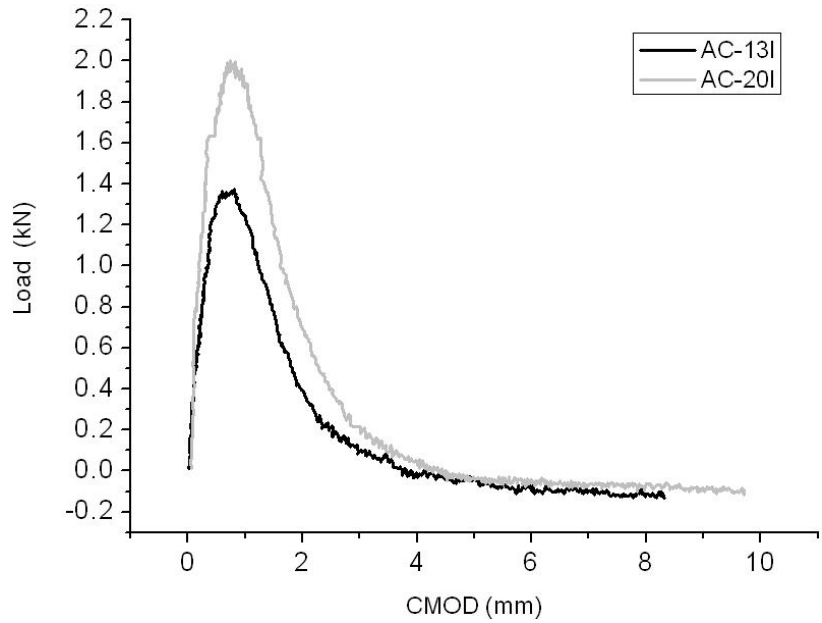

Figure.4. CMOD-Load curve of original surface

In the condition of tack coat with macadam (Figure.5), crack appears at the tack coat and the cracking surface is smooth. The concrete connect tightly with the macadam. The limiting load of AC-20I specimen is higher than AC-13I specimen, appears when the crack width is about 3.5mm. This is mainly caused by the rougher surface and larger surface pore of AC-20I . As a result, the bonding area of AC-20I is larger and lead to a stronger interface bonding.

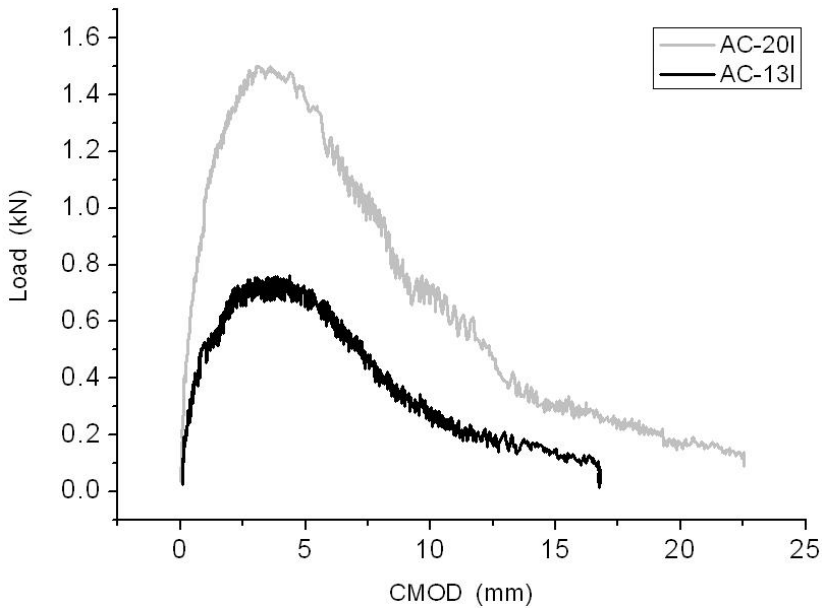

Figure.5. CMOD-Load curve of tack coat with macadam

CONTRAST BETWEEN DIFFERENT SURFACE TREATMENTS

In the condition of AC-20I specimen, CMOD-Load curve fig (Figure.6) and midspan deflection-Load curve fig(Figure.7) with different Surface disposes as follow:

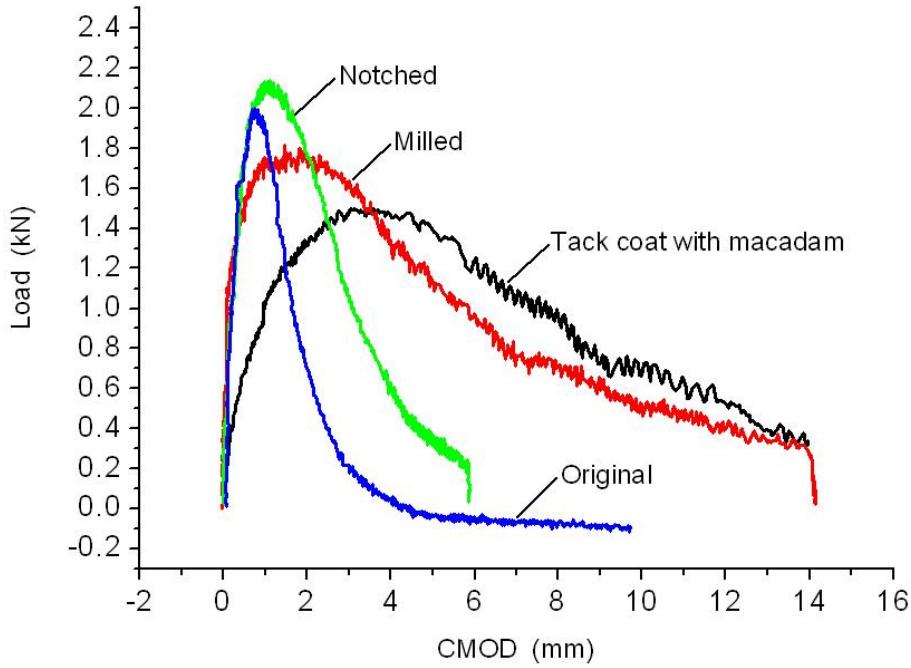

Figure.6. CMOD-Load curve

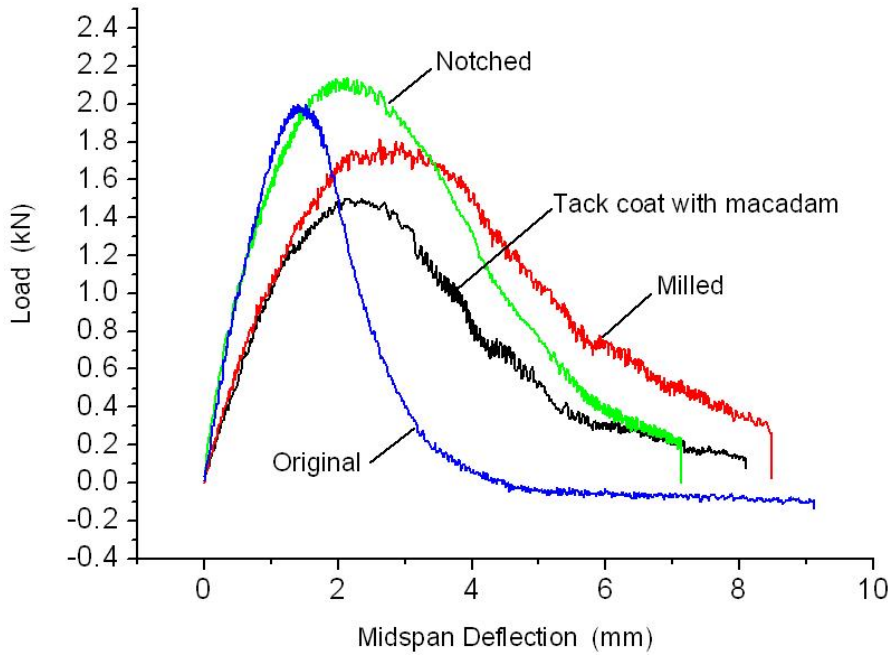

Figure.7. Midspan deflection-Load curve

Interface treatments increase the breaking energy of the specimen and reduce the break speed for the higher interface bonding strength. In the case of specimens with original interface, the load peak value appears very early and the break speed of interface is very fast. Interface contact conditions have a major effect on the stress condition of the pavement structure (JI XIAO-ping et al.2007).

For specimens with milled and notched surfaces, the failure occured in the asphalt concrete. Those crack curves represent the failure performance of asphalt concrete but not the interface. In these two cases, the bonding strength is higher than the tensile strength of asphalt mixture.

For specimens treated by tack coat with macadam failures occurred at the interface. Its interface failure speed is higher than those that with original surface. The interface bond strength depends on the strength of tack coat. When the bond strength of tack coat exceeds the tensile strength of asphalt mixture, the specimens will fail in the asphalt mixture.

CONCLUSIONS

Through comparisons of different tests for evaluating interface behavior, such as straight sniping or wedge split test, the three point composite beam test is designed. Different interfaces are considered for this experiment. Through the experimental analysis the following conclusions can be drawn.

1) Three point beam test is capable of evaluating the interface bond conditions through experiment results.

2) From test results observed, the bigger surface pore and roughness of AC will increase the bond area of interface of AC and PCC, which result in a stronger bonding.

3) Treating asphalt concrete surface with different modes can improve the interface bonding strength, especially the interface with milled and notched surfaces.

ABSTRACT

It's generally accepted that there is good correlations between International Roughness Index (IRI) and body ride comfort. However, the study in this paper has discovered that the road displacement frequency power spectrum densities are not quite corresponding to the IRI. This paper establishes the body-vehicle vibration model of 3 degree of freedom as the model to calculates a_w as evaluation parameter, and analyze systemically the relationship between IRI and human body ride comfort. It has been concluded that the IRI can't reflect the differences of the road roughness and a_w is a better parameter of the ride comfort.

KEYWORDS

Body-vehicle Vibration Model, Road Evenness, IRI, Body Acceleration, PSD

FOREWORD

To convert the different road evenness indexes, the World Bank organized the international study group which included the experts of Brazil, England, U.S., France, and others in 1982. Through many researches and testing, the International Roughness Index (*IRI) was developed* to evaluate the road evenness level (Li, 2002).

The IRI adopts mathematics model to simulate quarter vehicle, running at the road profile with a velocity of 80km/h. IRI is the displacement accumulation of the vehicle suspension, and the effect of vibration frequency is not taken into account. However, body ride comfort is directly related to vibration frequency (Zhao, 2000).

For the description of the road evenness, GB7031-86 is adopted, and denotes the road evenness with road displacement dimensional frequency *PSD,* its detailed form is in Formula (1) (GB7031-86, 1986).

$$G_d(n) = G_d(n_0)\left(\frac{n}{n_0}\right)^{-w} \quad (1)$$

Where n is the dimensional frequency, namely the reciprocal of the wavelength, (number of the wave in one meter), m^{-1};

n_0 is reference dimensional frequency, $n_0 = 0.1 m^{-1}$;

$G_d(n_0)$ is the PSD of the road displacement under the reference dimensional frequency, namely road roughness coefficient, $m^2/m^{-1}=m^3$;

w is the waviness parameter, which decides the frequency structure of the PSD of the road; normally assumed to be 2. It means that the scope of PSD is uniform.

From analysis of real road profile of some road sections, it is observed that w isn't a constant. The value ranges from 1.6 to 2.4, with an average value of 2.0. Figure 1 shows the PSD of three real road profiles.

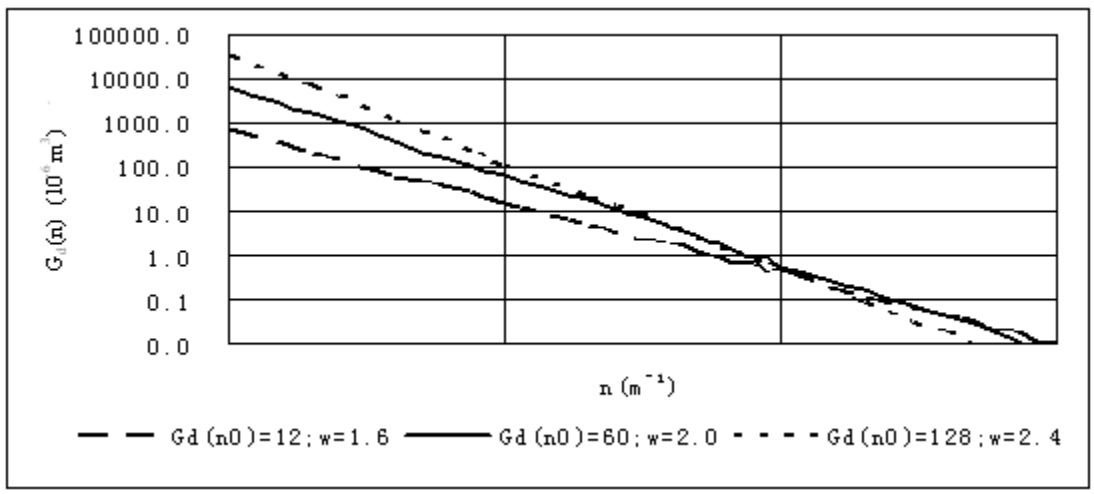

Figure 1. The relationship between PSD and n

The result in Figure 1 also shows that frequency characteristics of PSD is not constant.. IRI can't denote the ride comfort of the passenger.

EVALUATION OF THE HUMAN BODY RIDE COMFORT

Currently, the most popular evaluation standard for the human body vibration is ISO 2631-1:1997(E) ***ISO2631-1 Mechanical Vibration and Shock Evaluation of Human Exposure to Whole-Body Vibration-Part1: General Requirements*** which is issued I 1997. The standard presents a frequency response range between 0.5~80Hz, and within this frequency range the human body has different sensitivity degrees to different frequencies. To the vertical vibration, the frequency weighted function is close to the Formula (2).

$$w(f)=\begin{cases}0.5 & (0.5\le f\le 2)\\ \dfrac{f}{4} & (2<f\le 4)\\ 1 & (4<f\le 12.5)\\ \dfrac{12.5}{f} & (12.5<f\le 80)\end{cases} \tag{2}$$

Filtered through the frequency weighted function ($w(f)$), the real acceleration function $a(t)$ can be converted into frequency weighted acceleration function $a_w(t)$, which is related to human body ride comfort. In the whole time of vibration analysis, it can calculate the total effect of the vertical vibration to the human body according to the next formula:

$$a_w=\left[\frac{1}{T}\int_0^T a_w^2(t)dt\right]^{\frac{1}{2}} \tag{3}$$

In ***General Requirements*** a_w is the standard of comfort level of the passenger. The detailed standard values are shown in Table 1.

Table 1 correlation between a_w and the human subjective feelings

a_w (m/s^2)	human subjective feelings
<0.315	comfortable
0.315~0.63	A little uncomfortable
0.5~1.0	uncomfortable
0.8~1.6	quite uncomfortable
1.25~2.5	Very uncomfortable
>2.0	Most uncomfortable

BODY-VEHICLE VIBRATION MODEL OF 3 DOF

To compare a_w with IRI, the body-vehicle vibration system is predigested to a 3 DOF model (Tao, 2004).

Premises of the model

(1) the tire and the road are in full contact with no separation
(2) the roll and pitch t vibrations are small and were not considered; only the vertical vibration is calculated
(3) the stiffness of the suspension, the tire and the chair are linear; the damp of the suspension and the chair are also linear to the comparative velocity; the damp of the tire is small and was not considered
(4) the human body is at the top of the vehicle axle, and is fixed

(5) there are rigid joints between the vehicle and the suspension

According to the premises, the predigested vibration model is shown in Figure 2:

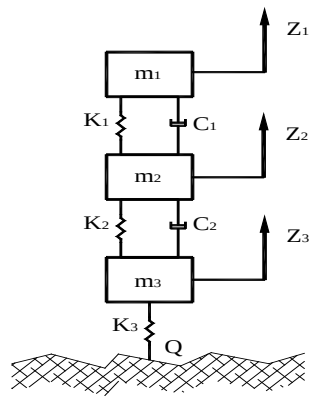

Figure 2.Human body-vehicle vibration model

c_1 is half of the damp of the chair (the vehicle is symmetrical between left and right, so the parameters of the model, such as m_1、 k_1 and c_1 is the half),

c_2 is the damp of the suspension, z_1 is the vertical displacement of the chair

z_2 is the displacement of the vehicle, z_3 is the displacement of the tyre

and Q is the road roughness.

Parameters of the Model

As presented by Pan Li, 2004, the following parameters of the human-chair system are used:

m_1=32.5kg; m_2=345kg; m_3=40kg; k_1=4950N/m; k_2=20000N/m; k_3=192000N/m; c_1=130N·s/m； c_2=1500N·s/m。

Establishment of the Vibration Differential Equation

The vibration differential equation of the model of 3 degree of freedom is:

$$\begin{cases} m_3 z_3'' + k_3(z_3 - Q) = c_2(z_2' - z_3') + k_2(z_2 - z_3) \\ m_2 z_2'' + c_2(z_2' - z_3') + k_2(z_2 - z_3) = c_3(z_1' - z_2') \\ \qquad + k_3(z_1 - z_2) \\ m_3 z_1'' + c_1(z_1' - z_2') + k_1(z_1 - z_2) = 0 \end{cases} \tag{4}$$

The road roughness Q is a discrete highness sequence ($[h_1, h_2, ...h_i...]$), so Equation (4) can be revolved with numerical method. First, it is necessary to reduce the derivative order of Equation (4). According to the definition of Formula (5), the Equation (4) can be converted to Equation (6):

$$\begin{aligned} u_1(t) &= z(t) = (z_1, z_2, z_3) \\ u_2(t) &= z'(t) = (z_1', z_2', z_3') \end{aligned} \tag{5}$$

$$u' = \frac{d}{dt}\begin{pmatrix} u_1 \\ u_2 \end{pmatrix} = \begin{pmatrix} 0 & I \\ -M^{-1} \otimes K & -M^{-1} \otimes C \end{pmatrix} \otimes \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} + \begin{pmatrix} 0 \\ M^{-1} \otimes Q' \end{pmatrix} + \begin{pmatrix} 0 \\ M^{-1} \otimes Q \end{pmatrix} = \frac{d}{dt}(u_1, u_2) \tag{6}$$

This conversion increases the number of Equation (4), but it reduces the derivative order of Equation (4). With Runge-Kutta numerical method, the variable z_1、 z_2、 z_3 and z_1'、 z_2'、 z_3' can be resolved.

To solve for differential coefficient, the human body acceleration (a_{ti}), can be resolved from z_1'. The acceleration in frequency field can be available according to Flourier transform. Weighed in frequency field with the function $w(f)$ and transformed with Flourier contrary transform, frequency weighed acceleration sequence a_{wti} is available. Therefore, the human body total weighted root mean square acceleration is calculated as:

$$a_w = \left[\frac{1}{N} \sum_0^N a_{wti}^2) \right]^{\frac{1}{2}} \tag{7}$$

In the formula, the letter 'N' is the number of the disperse point in the stochastic sequence of the weighed acceleration.

COMPARISON AND ANALYSIS BETWEEN IRI AND HUMAN BODY ACCELERATION

Frequency parameter *w* decides frequency structure of PSD, and the human body ride comfort has different susceptivities for different frequency structures. In order to compare IRI and weighted root mean square acceleration, this paper separately calculates the values of IRI and a_w when the frequency parameters are either the same or different.

Frequency parameters are the same

The factors that affect human body ride comfort are vibration frequency and acceleration slope. When the frequencies are the same, the frequency structures of PSD are the same, there is one-to-one relationship between IRI and a_w.

Based on the real road profile, the results of IRI and a_w (when w=2), are shown in Table 2 and Figure 3.

Table 2 The value of IRI and a_w when w=2

$G_d(n_0)\times 10^{-6}\mathrm{m}^2/\mathrm{m}^{-1}$ $n_0=\mathrm{m}^{-1}$	*IRI* (m/km)	a_w ($\mathrm{m/s}^2$)
8	1.5	0.11
17	2.2	0.15
33	3.0	0.20
60	4.2	0.27
123	6.1	0.41
239	8.7	0.58

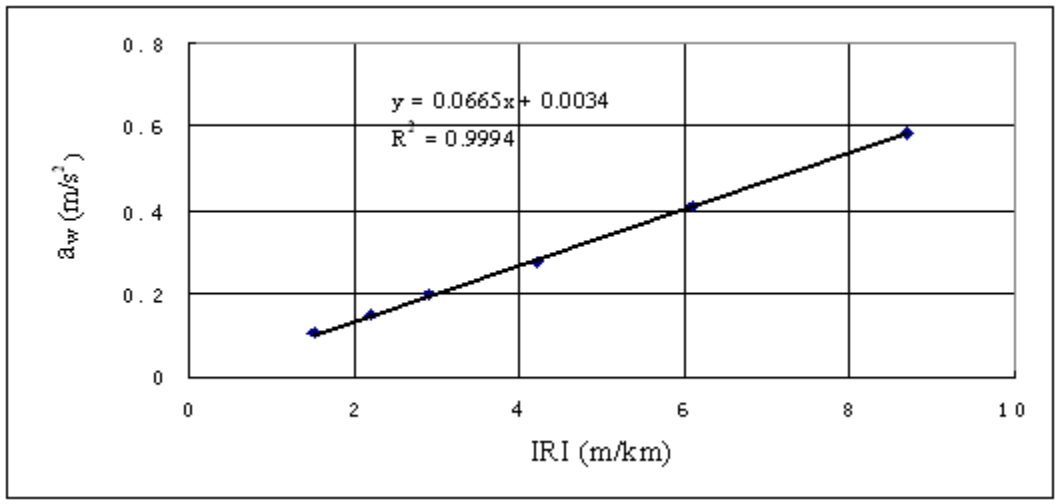

Figure 3. The relationship between a_w and IRI when w=2.

As shown in Figure 3, IRI and a_w have linear correlation when the frequency parameters are the same and the frequency structure is constant. In this case, IRI can reflect the human ride comfort.

Frequency parameters are not the same

The analysis of the real road profile shows that the frequency parameters are always different. When the frequency structures of the PSD are different, there isn't one-to-one relationship between IRI and a_w. For each IRI value, there can be some different a_w values. Choosing five different road sections with the same IRI (IRI=3.0) and five different frequency parameters (w=1.6，1.8，2.0，2.2 and 2.4), this paper calculates the five values of a_w. The results are shown in Table 3 and Figure 4.

Table 3 The different a_w with the same *IRI*

w	$G_d(n_0)\times 10^{-6}$	a_w

(f=1)	(m^2/m^{-1})	(m/s^2)
1.6	18	0.140
1.8	23	0.166
2.0	32	0.199
2.2	37	0.224
2.4	45	0.247

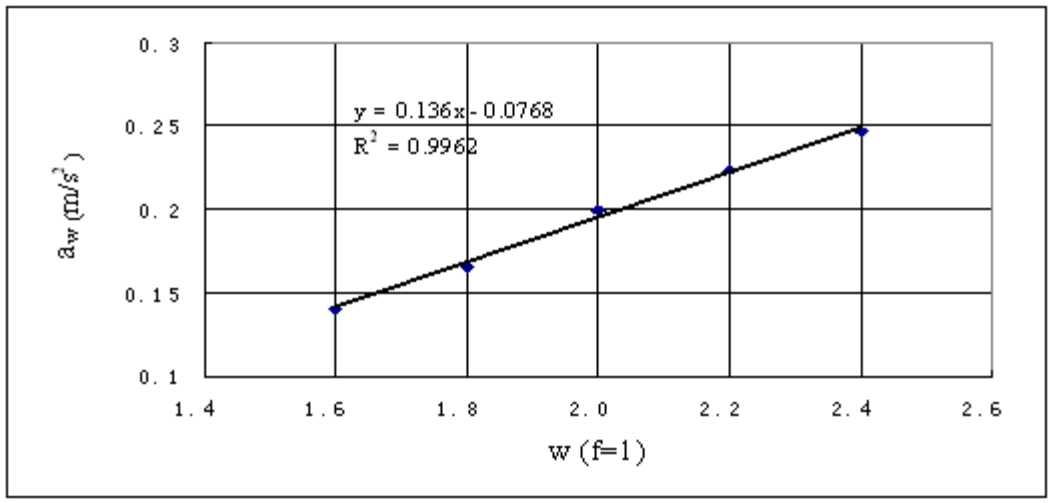

Figure 4. Relationship between a_w *and w* when IRI are same

From the results, there are different values of a_w to the same *IRI*. When the frequency parameters are different, IRI can not reflect the ride comfort of the passenger.

CONCLUSION

This paper establishes the human body-vehicle vibration model of 3 degree of freedom and vibration differential equations, calculates the *IRI* and human acceleration based on the *PSD* of the road, and analyzes the correlation of *IRI* and human acceleration. The results show that *IRI* can not reflect the ride comfort of the passengers because the frequency parameters are not the same.

ABSTRACT

In this study a new anti-rutting agent (ARK-1) was introduced to analyze effect on pavement performance of asphalt mixture. Taken three gradations of AC-13 mixture with ARK-1 and without ARK-1 as investigation objects, high-temperature and water stability as well as cracking resistance at low-temperature were measured respectively. The results of tests show that the ARK-1 is feasible to improve pavement performance of asphalt mixture and its influence on high-temperature stability of asphalt mixture is obviously superior to that on water stability and cracking resistance at low-temperature. A project example of Louding freeway between stations 35+450 and 36+450 was proved that the costs of pavement with the ARK-1 would be more economical than that of pavement with SBS-modified asphalt binder.

INTRODUCTION

Largely northwest regions of China belong to arid or semi-arid climate, where the air temperature in July and August is more than 30℃ usually, and surface temperature of asphalt pavement may be up to more than 50℃ due to absorbing energy more than releasing energy of conduct, convection and radiation. As a result, rutting will be rapidly occured and developed at high temperature under heavy truck traffics. Therefore it is necessary to effectively and economically improve high-temperature stability of asphalt mixture.

In recent years there are many researches to improve high-temperature performance of asphalt mixture, shown in previous work by the authors (Wu and Xu, 2005; Wang *et al*., 2007; Xiao *et al.*, 2007; Xu *et al.*, 2004). Many studies were uneconomical or ineffective, or difficult to construction technique. A new anti-rutting agent (ARK-1) mixed with asphalt mixture, was studyed in laboratory. In order to verify ARK-1 effect on rutting resistance, comparing studies between ARK-1 and SBS-modified asphalt binder were done in Luoding freeway which was constructed in July 2005.

MATERIALS AND EXPERIMENTAL METHODS

Asphalt Binder/Aggregate Tests

Asphalt binder used in this study was AH-90 produced by the Lanlian oil refinery. All of aggregates were crashed sandstone collected from a stone quarry at Anning area in Lanzhou city where sandstone has higher intensity and hardness for pavement construction. Mineral powder used in tests could be obtained after the sandstones were levigated.

Three gradations of AC-13 including upper limit, middle value and modified lower limit (hereinafter referred to "lower limit") were analyzed in this study and gradation compositions of mixture were listed in Table 1.

Table 1. Gradation compositions of mixture

Items	Mesh passing (%)									
Sieve size (mm)	16	13.2	9.5	4.75	2.36	1.18	0.6	0.3	0.15	0.075
Upper limit	100	100	85	68	50	38	28	20	15	8
Middle value	100	95	76	53	37	26	19	15	10	6
Lower limit	100	90	68	47	29	25	22	10	8	6

ARK-1 Tests

ARK-1 is a kind of black solid-state particles which contains more than 95 % fiber polymers and less than 5 % fillings. Its density is about 0.91 ~ 0.98 g/cm^3 and its size is about 2 ~ 4 mm by using sieving test and its melting index (MI) is more than 0.1 g/10mins to ensure enough melt flow rate at 190 ℃ and under 50kN load pressures during mixing procedure. Softening point of ARK-1 is between 150 ℃ and 170 ℃.

Controlling the homogeneity and storage of mixture with ARK-1 is much simpler than that of mixture with SBS or SBR. When mineral aggregates are heated up to 170 ~180℃, the amount of ARK-1 is directly entered into heated mineral aggregates and mixed continuously till all ARK-1 is completey melted in heated mineral aggregates. Compared with common asphalt mixture, ARK-1 mixture has the same method for controlling quality, storage and transportation except that the whole mixing procedure of ARK-1 mixture takes about four minutes longer than that of no ARK-1 mixture does.

Wheel Tracking Tests

The specimens were mixed in the optimal asphalt contents and compacted by the Plate Compactor. Demansion of specimen is 300×300×50mm (three specimens per parallel control test) with 0%, 0.3 %, 0.4 % and 0.5 % ARK-1 (weight ratio of ARK-1 to aggregate). Slab of the compactor may pass on 24 times to and fro and 9 kN load pressures during compacting. In this study wheel tracking instrument was made by Changsha Yaxing Digital-control Co., Ltd.. And all wheel tracking tests were conducted at 60 ℃ (0.5 ℃ accuracy) and 0.7 MPa (0.05 MPa accuracy) to measure Dynamic Stability(DS) and rutting depth.

Water Stability and Cracking Resistance Tests

MARSHALL-Immersion Test and Indirect Tension Test under freeze-thaw (AASHTO T283) in this study were carried out to evaluate water stability of asphalt

mixture with ARK-1. The residual stability, indirect tensile strength and test strength ratio (TSR) of asphalt mixture at 25℃ (0.5℃ accuracy) were measured to determine if different ARK-1 contents would be beneficial for water stability.

Cracking resistance of asphalt mixture at low-temperature was conducted to measure flexural-tensile strength, stiffness modulus and flexural-tensile strain under 50mm/min of loading rate by using bending experiment.

RESULTS AND DISCUSSION

Results of the Marshall Tests

Marshall Stability and Flow Value of three gradations of AC-13 varying with ARK-1 contents are presented in Figure 1. The Marshall stability is gradually increasing and the flow value is gradually reducing with the increasing ARK-1 contents. Based on chemical analysis, heated ARK-1 can formed to some silky plastic fibre, which can reinforce interactions and improve adhesion ability among asphalt binder, aggregate skeleton and mineral power. The Marshall stability is obviously increased when ARK-1 contents are more than 0.3%.

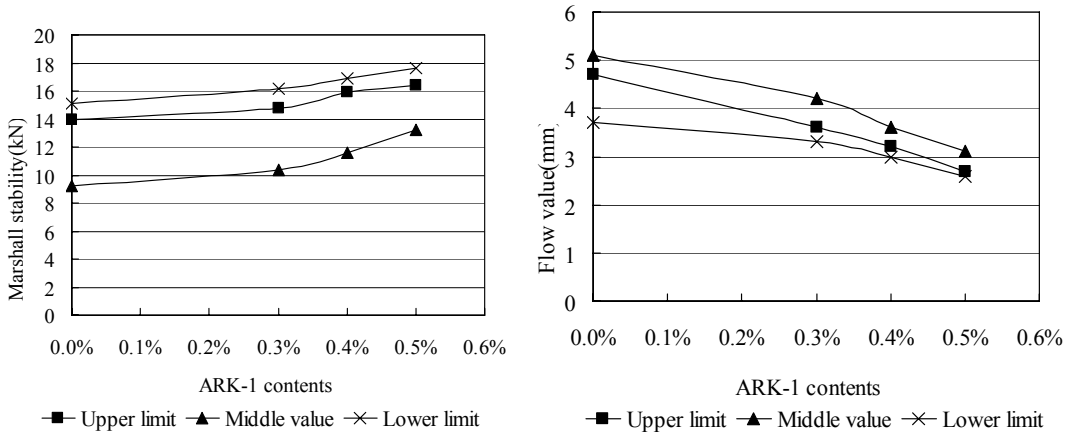

Figure 1. Results of the Marshall tests

Results of Wheel Tracking Test

Figure 2 shows Dynamic Stability and rutting depth of three gradations of AC-13 varying with ARK-1 contents. High-temperature stability of asphalt mixture with ARK-1 is obviously superior to that of asphalt mixture without ARK-1 because ARK-1 can improve elasticity of the asphalt mixture to resist permanent deformation. The results of Figure 2 that the rutting resistance of upper limit gradation is slightly better than that of the other two gradations are different from the results of Figure 1 that anti-deformation of lower limit gradation is better than that of the other two gradations. Sometimes it can be disucssed for us to absolutely rely on the results of the Marshall tests for evaluation the high-temperature stability of asphalt mixture. This opinion had been also given in previous work by the author (Sheng, 2001).

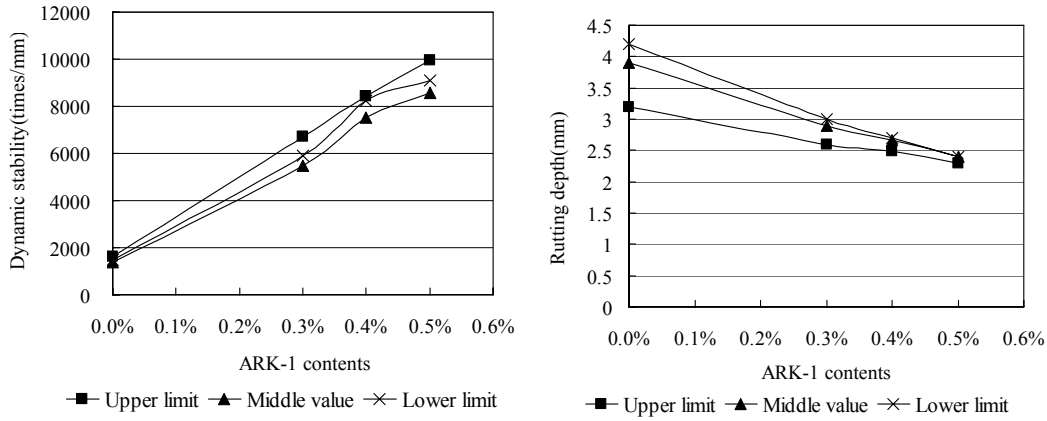

Figure 2. Results of the wheel tracking tests

Results of Water Stability and Cracking Resistance Tests

Marshall Immersion Test

Results of Marshall Immersion Test are presented in Table 2. Variation of residual stabilities of all samples with ARK-1 is no as obvious as that of Marshall Stability. Although residual stabilities of any samples with ARK-1 are gradually decreasing, immersed Marshall Stability of all samples with ARK-1 are higher than those of samples without ARK-1 if compared with the same type of gradations. So ARK-1 is beneficial to the improvement of water stability of asphalt mixture.

Table 2. Results of immersion Marshall tests

Types	ARK-1 contents (%)	Marshall stability(kN)	Immersed Marshall stability (kN)	Residual stability (%)
Upper limit	0.0	13.9	12.7	91.0
	0.3	14.8	13.4	91.0
	0.4	15.9	14.2	89.4
	0.5	16.4	14.7	89.8
Middle value	0.0	9.2	8.3	90.2
	0.3	10.4	9.3	89.8
	0.4	11.6	10.5	90.6
	0.5	13.2	12.0	90.8
Lower limit	0.0	15.1	14.2	93.8
	0.3	16.2	15.0	92.5
	0.4	16.9	15.5	91.6
	0.5	17.6	16.2	92.2

Results of Freeze-thaw Indirect Tension Test

Results of freeze-thaw Indirect Tension Test are shown in Table 3. Before and after suffered freeze-thaw process, indirect tensile strengths of all samples with ARK-1 are higher than those of samples with no ARK-1 and test strength ratios (TSR) of all samples exceed 80%. Ductility of samples with ARK-1 has been enhanced although TSR of samples with ARK-1 is reducing under the freeze-thaw condition.

Table 3. Results of freeze-thaw splitting tests

Types	Items ARK-1 contents(%)	Splitting tensile strength before freeze-thaw (MPa)	Splitting tensile strength after freez-thaw (MPa)	TSR (%)
Upper limit	0.0	0.564	0.544	96.5
	0.3	0.821	0.772	94.0
	0.4	0.942	0.864	91.7
	0.5	0.956	0.883	92.4
Middle value	0.0	0.645	0.631	97.8
	0.3	0.891	0.806	90.5
	0.4	0.945	0.872	92.3
	0.5	0.925	0.837	90.5
Lower limit	0.0	0.802	0.780	97.2
	0.3	1.103	1.006	91.2
	0.4	1.145	1.085	94.8
	0.5	1.212	1.091	90.0

Results of Bending Test

Results of bending test are shown in Table 4. Flexural-tensile strengths and strains of all samples with ARK-1 are higher than those of samples with no ARK-1 and stiffness modulus of samples with ARK-1 are slightly lower than those of samples with no ARK-1 except few samples. Cracking resistance of samples with ARK-1 has been improved but not so obviously as high-temperature stability of asphalt mixture. 0.4% ARK-1 combined with asphalt mixture is the more available and economical contents to improve cracking resistance of asphalt mixture.

Table 4. Results of bending tests

Types	ARK-1 contents(%)	Flexural-tensile strength (MPa)	Stiffness modulus (MPa)	Flexural-tensile strain (με)
Upper limit	0.0	10.5	6122	1715
	0.3	12.5	6288	1988

FIELD TESTS AND APPLICATION

Luoding freeway in the east of Gansu province is from Ning county of Qingyang city to Shibali of Anding region. This route is 57.898km long and design speed is 80km/h and subgrade is 24.5m wide including four 3.75m carriage ways,

3.0m central strip, 2.5m hard shoulder and 0.75m soil shoulder. In the design of pavement central strip and hard shoulder have the same pavement structure with carriage ways as shown in Table 5.

Table 5. The scheme of pavement structure

Structure layer	Material	Thickness(cm)
Upper layer	AC-16	4
Mid-layer	AC-20	5
Lower layer	AC-25	6
Upper base	cement stabilized gravel (5.5% cement)	34
Lower base	cement stabilized gravel (4% cement)	20

Two test sites were chosen in the 16th section of contracts situated in Taiping village of Huining town at Baiyin area. One test site (referred to"No.1") between stations 35+450 and 35+950 was constructed with 0.5% ARK-1 asphalt/ aggregate mix at upper layer and 0.3% ARK-1 at mid-layer. The other test site (referred to "No.2") between stations 35+950 and 36+450 was constructed with 6% (weight to weight ratio) SBS-modified asphalt binder/aggregate mix at upper layer and 4% SBS-modified asphalt binder/aggregate mix at mid-layer. The costs between ARK-1 and SBS-modified asphalt in the two test sites were analyzed in Table 6. 1

Table 6. The cost analysis ofARK-1 and SBS in the two test sites

Test sites	Layer	Admixture contents	Material costs (RMB)	Total costs (RMB)
No.1	Upper layer	0.5% ARK-1	￥265,400	￥573,600
	Mid-layer	0.3% ARK-1	￥308,200	
No.2	Upper layer	6% SBS	￥344,000	￥643,400
	Mid-layer	4% SBS	￥299,400	

The costs of upper layer and mid-layer in No.1 road could save 11% as cheap as those of the two layers in No.2 road. Rutting problems had not been observed in the two test sites after four hot summer seasons.

ARK-1 has much more application on highway construction due to its convenient storage and transportation, simple construction technology as well as lower costs than SBS-modified asphalt binder. For example, asphalt pavement with 0.4% ARK-1 at upper layer had been used in the section of steep slope road from Lanzhou to Lintao city. Many national trunk highways in Qinghai province, such as 109, 214, 215 and 227 routes, had utilized ARK-1 to improve the high-temperature stability of asphalt pavement.

CONCLUSIONS

Based on the laboratory work conducted and the field tests in this research, the following conclusions and recommendations are drawn:

1. ARK-1 can reinforce interactions among asphalts, mineral aggregates and powders, and can enhance flexibility of mixture to resist permanent deformations of pavement. So it is feasible to ameliorate pavement performance of asphalt mixture.

According to the results of the laboratory work, the influence of ARK-1 on pavement performance at high-temperature is obviously superior to that of ARK-1 on pavement performance at low-temperature and water stability.

2. ARK-1 has the simpler construction technique because it can be directly added into mineral aggregates and no obvious segregation problem has been observed during mixing procedure. The methods of storage and transportation of mixture with ARK-1 are similar to those of common asphalt mixture so that it is unnecessary to increase special equipments for pavement construction.

3. ARK-1 is often employed at upper and middle layer of asphalt pavement and propositional weight ratio of ARK-1 to aggregates is between 0.3%~0.5%. Compared with SBS-modified asphalt binder, asphalt pavement with ARK-1 can be save more than 20% costs of pavement construction per kilometer. Therefore, ARK-1 will have more application on pavement engineering.

ACKNOWLEDGMENTS

This research was supported by the Fund of Natural Science of Gansu Province (project number: 0803RJZA011) and by the Dr. Fund of Lanzhou University of Technology (project number: Z42001). The authors would like to thank the 16th project department of Luoding freeway for their technical support of test site.

ABSTRACT

The evaluation of seismic site response is particularly useful for geotechnical engineers involved in the design of foundations in liquefiable sites. The shake table test is aimed at observing and analyzing the site response under different effects of shaking frequency and intensity. The soil profile consisted of a clayey layer over liquefiable sand over clay. The shaking sequence applied to the model was a small scaled, small and large El Centro motion ($a_{max,\ base}\approx0.15g$, time interval 0.006 sec; $a_{max,\ base}\approx0.15g$, time interval 0.02 Sec; $a_{max,\ base}\approx0.50g$, time interval 0.02 Sec). The aim is to observe and analyze the site response under different shaking frequencies and intensities. The tests reproduced the macro-phenomena of soil liquefaction induced by earthquake. The excess pore water and peak accelerations under different shaking frequencies and intensities are discussed. The research has enhanced our current understanding on the mechanism of seismic soil-pile interaction during the development of liquefaction.

KEY WORDS

Liquefiable site, soil-pile-structure interaction, shaking frequency, shaking intensity, shake table test

INTRODUCTION

Geotechnical earthquake engineers have recognized the importance of the seismic induced soil response for the ground motion analysis and seismic design of many geotechnical installations, such as pile-supported bridges, tunnels, and buried pipelines. It is well known that loose, cohesion-less sands and silts below the water table develop high pore water pressures or liquefy during strong earthquake shaking. The high pore water pressures may lead to a significant degradation of strength and stiffness in soils, which in turn, results in increased soil deformation. Additionally, wave propagation theory stipulates that soil layers modify the characteristics of the input seismic waves while they are traveling though it (Kobayashi et al., 1986),

therefore influencing the acceleration record in soils. So seismic design of geotechnical installations in liquefiable ground is very different from that in non-liquefiable ground. It is very necessary to understand the seismic response of non-free liquefiable sites.

Some investigations of the seismic induced soil response have been reported (Trifunac, et al., 1996, Su, et al., 2006, Rayhani, et al., 2008) in terms of a different research method. This paper focuses on the shaking frequency and shaking intensity on seismic site response, based on shake table tests.

The shake table test is an effective approach for studying seismic site response. An advantage of the shake table test is that it facilitates performing a physical parameter study, and thus allows the observation of the effects of parameters such as duration, shake intensity, and soil properties. This paper focused on the seismic response of non-free liquefiable site based on shake table tests to make quantitative predictions of the prototype response. The prototype is the collapsed Shengli Bridge in the 1976 Tangshan earthquake. The dynamic properties of non-free liquefiable ground under three cases were obtained, namely the scaled El Centro excitation with peak accelerations of 0.15g and El Centro waves with peak accelerations of 0.15g and 0.50g. The experimental results can help to improve the understanding of seismic interaction of the pile group-soil-bridge structure and the nonlinear behaviour of the structures.

SHAKE TABLE TEST

The experimental model is schematically illustrated in Fig.1. The shake table model test was performed using the MTS shaking table facility at the state's key laboratory for Disaster Reduction in Civil Engineering, Tongji University, Shanghai, China.

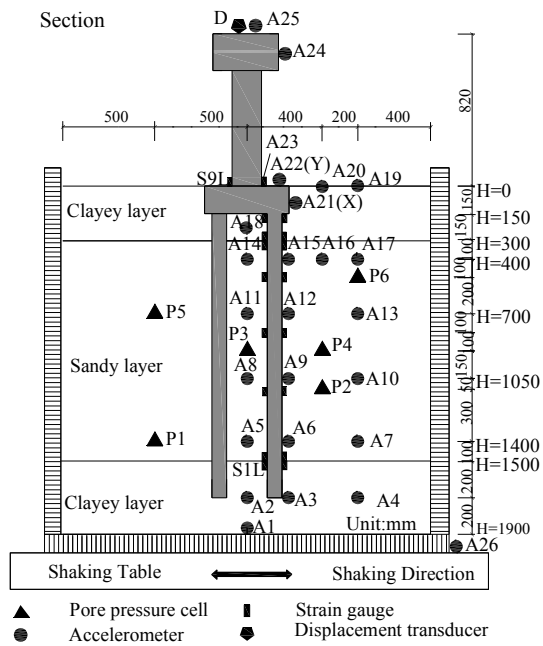

Fig.1 Side view of layout of instrumentation

The dimensions of the shaking table are 4m×4m, with maximum payload 25000kg. The laminar box is 2m long, 1.5m wide, and 2m high, developed by Wu (2004). The Shengli Bridge collapsed in the Tangshan Earthquake in 1976 is taken as the prototype for model simulation. The reduced scaling factor is 1:10. The model structure consists of a 2×2 pile group, pile cap, and column with a 360kg mass placed on it. They are prefabricated with micro concrete and galvanized iron wires. The pile-column is prefabricated with micro-concrete and the galvanized iron wires. The materials of the model ground used in this experiment are yellow sand and soft clay in Shanghai. The non-uniform coefficient is about 3.5. The average and maximum soil particle diameters are 0.35mm and 2mm, respectively.

The model was firstly subjected to white noise with a peak acceleration of 0.02g to find their natural periods of vibration. Then, it was shaken with a number of 1940 El Centro earthquakes conducted in series with sufficient time between shakes to allow for the dissipation of excess pore pressures. These earthquake motions were chosen because they contain different frequency content and shaking characteristics. The shaking sequence applied to the model was small and large El Centro motion (Case 1, $a_{max,\ base}\approx 0.15g$, time interval 0.006 sec; Case 2, $a_{max,\ base}\approx 0.15g$, time interval 0.02 Sec; Case 3, $a_{max,\ base}\approx 0.50g$, time interval 0.02 Sec). Comparison of the results from the three tests demonstrates the effects of shaking frequency and shaking intensity on seismic response of non-free liquefiable sites.

EXPERIMENTAL RESULTS AND ANALYSIS

Macroscopic Phenomena. Under the scaled 0.15g El Centro excitation, a little water appeared along the internal walls of the laminar box. Slight liquefaction occurred in the sandy layer. The column vibrated with very small amplitude. Under the 0.15g El Centro excitation, besides the same phenomena as the above, water appeared not only along the internal walls of the laminar box, but also around the pile cap.

Fig.2 Macro-phenomena under 0.50g El Centro excitation

Under the 0.50g El Centro wave, strong sand blasting, small sand hills, and water emitting occurred, with the whole sandy layer liquefied. The foundation settlement ranged from 3cm to 5cm, as seen in Fig.2-②, Fig.2-③ and Fig.2-⑥. Concrete peeling, bar bending, and tensile failures of the stirrups occurred at the bottom of the pier, shown in Fig.2-④. Some cracks appeared along the piles as shown in Fig.2-⑤. When the test finished, the whole foundation settlements ranged from 2cm to 5cm, seen in Fig.2-⑦.

Excess Pore pressure response. Fig.3 shows the input base motion for the three cases. Fig.4 shows the time histories of excess pore pressure at a depth of 0.70m for three cases, which shows a remarkable difference in response due to the shaking frequency and intensity. The excess pore pressure emerged at about 5.0 Sec in Case 1, much earlier than those in Cases 2 (about 12.0 Sec). The peak value, buildup rate, and dissipation rate in Case 1 is larger than in Case 2. It can be concluded that, the larger the shaking frequency, the less time it takes for the excess pore pressure to emerge, the larger the peak excess pressure, buildup rate and dissipation rate.

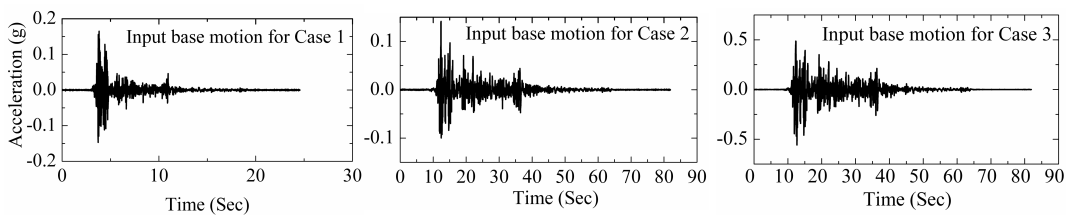

Fig.3 Input base motion for three cases

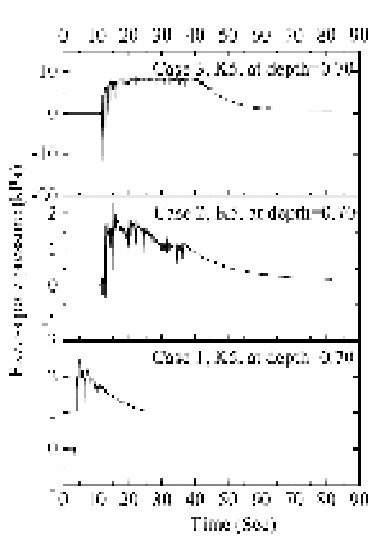

Fig.4 Time histories of excess pore pressure for K5

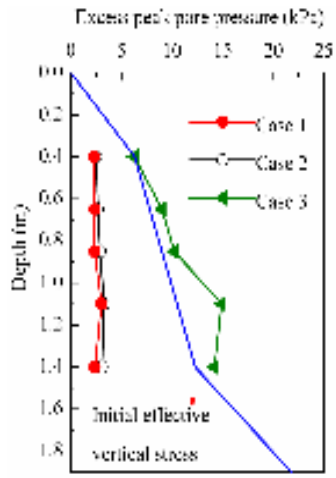

Fig.5 Variation of excess peak pore pressures with depth

It is seen from Fig.4 that the excess pore pressure emerged at almost the same time in Cases 2 and 3 (both at about 12.0 Sec). The peak excess pore pressure and dissipation rate in Case 3 are much larger than in Case 2. The excess peak pore pressure emerged later in Case 3 than in Case 2. It is observed that, the larger the shaking intensity, the larger the peak excess pore pressure and buildup rate, the later the peak excess pore pressure appears, and the slower the dissipation rate.

Fig.5 shows the variations of peak excess pore pressure with depth for three cases. It is clear that under large base input motion (case 3), the excess pore pressure near the ground surface of the sandy layer decreased after shaking. Large shear strain developed under low confinement and a slow dissipation process appear to be responsible for this phenomenon. Negative excess pore pressure developed in all three cases and in case 3 was the strongest, reaching values up to -15kPa. This may be the result of large shear strains with an un-drained dilative response of the liquefied soil. As indicated by the profiles of peak excess pore pressure in Fig.5, in which the solid line denotes the initial effective vertical stress of soil, the sand liquefied at all measured levels in Case 3, while the excess pore pressure ratios in Cases 1 and 2 are all less than 0.4. The excess pore pressure ratio is defined as the ratio between excess pore pressure and the initial effective vertical stress. It is obvious from Fig.5 that shaking frequency has little influence on the peak values of excess pore pressures; however, shaking intensity has the opposite effect.

Acceleration response. It is only when the earthquake is large enough to cause full liquefaction in the soil (case 3) that interesting observations can be made from the soil accelerations. The accelerations of soil between and around the piles were measured.

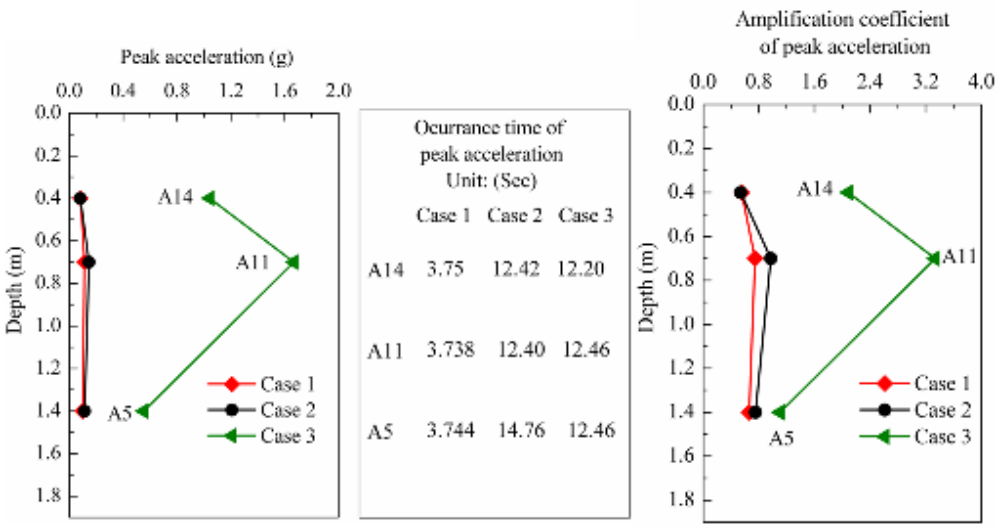

Fig.6 Variation of peak acceleration and amplification coefficient with depth for soil between the piles

Fig.6 shows the variation of peak acceleration and its amplification coefficient with the depth for sandy soil between piles. It was found that shaking frequency has little effect on the peak acceleration. Peak acceleration emerged later in Case 2 than that in Case 1. The shaking intensity has significant effect on peak acceleration. The acceleration records close to the sand surface decreased significantly due to the liquefaction process. Peak accelerations emerged at almost the same time when subjected to different shaking intensities.

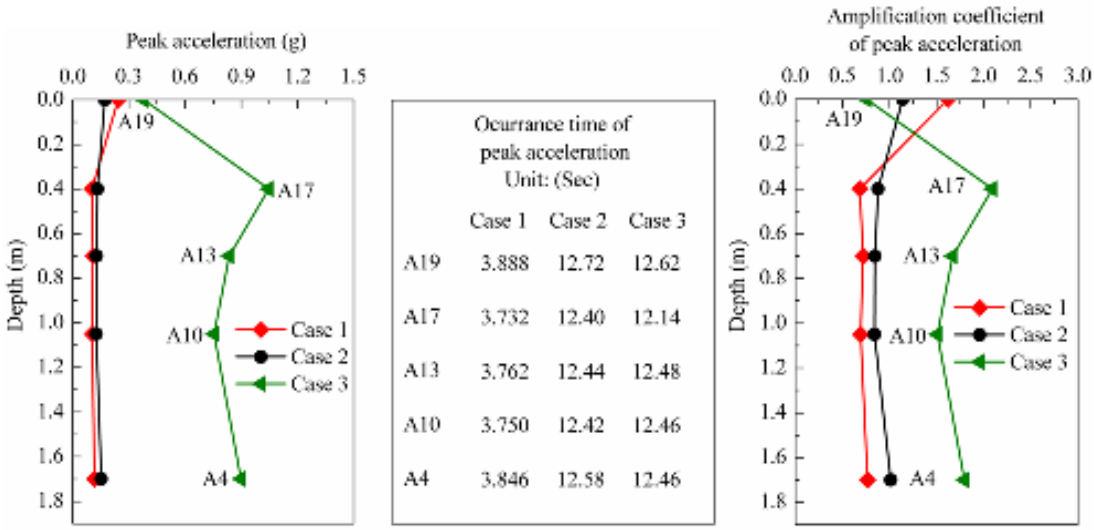

Fig.7 Variation of peak acceleration and amplification coefficient with depth for soil around the pile

As shown in Fig.7, the amplification coefficients of surface soil around the pile for Cases 1 and 2 are greater than 1.0, indicating the accelerations were amplified at the ground surface. Additionally, the acceleration at the surface was more strongly amplified under high shaking frequency. It is possible that the

introduction of piles leads to local densification and additional cyclic shear strains being mobilised in the vicinity of the piles. This would lead to dilative behaviour, which would manifest itself as an increase in accelerations. Slight de-amplification of the input motion at the surface in Case 3 is due to the onset of liquefaction. It is clear that shaking intensity has a significant effect on the variation of peak acceleration with depth, especially at the ground surface. The peak accelerations at the ground surface under different shaking intensities demonstrates the opposite variation trend. This phenomenon is partly due to the soil liquefaction.

Comparison of the results from Figs. 6 and 7 shows that a large difference occurs in the peak accelerations of soil between and around the piles. The peak accelerations of soil between the piles under the three cases have almost the same variation trends. However, under large input motion, the peak acceleration of soil around the soil takes the opposite variation trend, compared with other cases. Though soil liquefaction occurs, soil between the piles may be restricted by piles, resulting in the same trend of accelerations under the three cases. However, soil around the soil will laterally spread over underlying liquefied sand, leading to the difference in peak acceleration variations under different shaking intensities.

CONCLUSIONS

The study presents the macro-phenomena of the seismic disasters induced by earthquake. Under the 0.50g El Centro input excitation, concrete peeling, bar bending, and tensile failures of the stirrups occurred at the joints of the pier and the cap.

From the measured excess pore pressures, it is clear that, the greater the shaking frequency, the larger the peak excess pore pressure, buildup rate, and dissipation rate; the larger the shaking intensity, the larger the peak excess pore pressure and buildup rate. The slower the dissipation rate; negative excess pore pressure developed in all three cases, which may be the result of large shear strains with an un-drained dilative response of the liquefied soil.

The shaking frequency has little influence on soil accelerations between the piles and the shaking intensity has significant effect; accelerations of soil around the piles at the surface were more strongly amplified under high shaking frequency. Under large shaking intensity, the sand liquefies at all measured levels, with slight de-amplification of input motion at the surface due to the liquefaction process.

Abstract: The causes for rut distress in 13km continuous upgrade section of Jingzhu freeway in China were studied with repeated wheel tracking tests. The test structures were SMA16+AC20+AC25 and FAC13+FAC20+FAC25 that were the same as sections investigated. The rut tests were developed under two kinds of test conditions to compare rut-resisting capacity. For test condition 1, wheel loading pressure was 0.7Mpa and wheel moving speed was 21 cycles/ minute; for test condition 2, wheel loading pressure was 1.1Mpa and wheel moving speed was 7 cycles/ minute. Dynamic stability (DS) results show that asphalt mixtures used in the two surface course structures all satisfied the limitations of Chinese specifications. Testing results also show that FAC13+FAC20+FAC25 surface course is stronger to resist rut than SMA16+AC20+AC25 surface course. DS values of the two surface course combinations under test condition 1 are larger than the DS controlling standard(DS0) for asphalt mixtures, but the values under test condition 2 both decrease greatly even to be less than that of DS0. The test results are consistent with the rut distress found in the 13km continuous upgrade section. Based on these results, the authors suggest that rut test for the whole asphalt surface course should be developed under a special testing condition for long continuous upgrade section and the special condition should be set in terms of field truck moving speed and loading weight.
Key words: *asphalt surface course, rut*-resisting capacity*, continuous upgrade*

Introduction

A long continuous upgrade section will be designed when the alignment of mountain highways is restricted to local terrains. One of the main characteristics of asphalt pavements in long continuous upgrade section is the low moving speed of vehicles, which prolongs the wheel loading duration on pavements. Korkila-Tanttu (2007) concentrated on how loading speed affects the permanent deformation (rutting) of unbound pavement layers; Paulo A. (1998) studied the effect of truck moving speed on rut depth of bituminous mixtures of steep upgrade section by means of field investigation and laboratory testing.

The other main characteristic is that relative deep permanent deformation will appear in about every surface layer under heavy loading. Wu Rui-Lin(2008) developed a total thickness rutting test to study the effect of aggregate quality and temperature on rut resistance of asphalt pavements. With the combination of laboratory rutting tests on the sample from a corresponding location of road shoulders, Wang Hui（2007）analyzed the influence of the high temperature stability of every asphalt surface layer on rut; Yang Jun（2007）studied the influence of middle surface layer on rutting resistance with a circular road tracking test(CRT) and Hamburg wheel tracking test(HW TT). The contribution of each pavement layer to surface rutting was studied to characterize the rutting mechanism in flexible pavements (Haider 2006, Lin Chih-Hsien 2005, Haddock John E. 2005).

In this paper, total depth sample rut tests are developed under low moving speed and heavy loading pressure corresponding to the field condition of truck moving speed and axial loading to study rut-resisting capacity of the whole surface course.

Rut distress

There is a typical case about rut developing in long continuous upgrade section. That is the 13 km asphalt pavements upgrade section in Jingzhu freeway in Guangdong province in China. Two different asphalt surface course structures were used successively in that section. After almost the same serving time, rut distress found in the two asphalt surface courses are quite different.

The initial pavement structure in the long continuous upgrade section is 4.5cm SMA-16 topper surface layer + 5.5cm AC-20 middle surface layer + 6cm AC-25 bottom surface layer + 36cm 6% cement stabilized crushed-rock base course + 20cm 6% cement stabilized crushed-rock subbase, which was constructed in April 2003.

Rut distress was investigated on the initial pavement structure in April 2005. The investigated results are shown in Table 1. After the investigation, the surface course layers whose rut depth was deeper than 20mm were maintained with FAC mixture. The maintaining method was to dig surface course layers and then reconstruct it again. The reconstructed surface course was 4.5cm FAC-13 topper surface layer + 5.5cm FAC-20 middle surface layer + 6cm FAC-25 bottom surface layer. Mixtures of the 3 layers all used modified bituminous. About 2 years later, rut distress was investigated again on the reconstructed pavement structure in January 2007. The results are also shown in Table 1.

The data in Table 1 show that rut resisting capacity of the reconstructed asphalt surface course is stronger than that of the initial asphalt surface course. In general, SMA is stronger to resist rut than FAC, and AC is weaker to resist rut than FAC. This indicates that rut resisting capacity of the whole asphalt surface course needs to be tested and evaluated when designing the asphalt mixtures.

Table 1 Rut Depth in Serious Section

No.	length (m)	wheel track	initial surface course, 2 years later		reconstructed surface course, about 2 years later		upgrade slope
			average rut depth (mm)	maximum rut depth (mm)	average rut depth (mm)	maximum rut depth (mm)	

1	60	left	43.5	63	5	7	3%
		right	64.5	67	6.5	10	
2	196	left	13.7	31	4.2	7	1%
		right	21.1	50	9.5	22	
3	313	left	26	46	8.5	10	2%
		right	40.4	60	15	12	

Reappearing tests

Laboratory rut tests for initial and reconstructed asphalt surface layers of the continuous upgrade section were developed with improved wheel tracking testor (Fig.1). The improved wheel tracking testor enables loading pressure to vary from 0.7 to 1.4Mpa, test wheel moving speed to vary from 7 to 56 back and forth/minute, and sample height to vary from 3 to 20cm. The raw materials used for rut tests were the same as those used in initial and reconstructed asphalt surface course materials. The gradations for each layer are shown in Table 2. The bituminous binder is AH-70 for AC20 and AC25, SBS modified AH-70 for SMA16, FAC13, FAC20 and FAC25. The Methyl Cellulose for SMA16 is VIATOP80 produced by German JRS Company.

Fig.1 wheel tracking testor

Table 2 Gradation of bituminous mixture for each surface course

	Percent passing (%)												
size(mm)	31.5	26.5	19	16	13.2	9.5	4.75	2.36	1.18	0.6	0.3	0.15	0.075
SMA16			100	95	75	55	25	20	16.4	14.0	12.3	11.1	10.2
AC20		100	97.8	85	77.3	63.7	44.9	31.6	24.5	17.4	11.7	8.8	6.3
AC25	100	99.1	82.1	71.8	62.6	53	41.9	32.3	22.5	17	8.3	6.9	5.3
FAC13				100	95.9	68.6	33.7	29.3	22.3	16.6	11.8	9.3	6.8
FAC20		100	96	86.8	72.4	56.2	30	15.9	13.3	10.7	8.18	6.7	5.32
FAC25	100	96	82.5	72.5	63	51	26	20	14.5	10.5	9	6.5	5

In order to find the reasons for rut distress, laboratory rut tests were made on each layer of initial surface course and reconstructed surface course. Laboratory rut tests were also developed on the whole initial surface course and the whole reconstructed surface course. Rut test samples are shown in Table 3.

Table 3 Rut Test Samples

No.	rut test sample	No.	rut test sample
1	5cmSMA16(modified bituminous)	4	5cmFAC13(modified bituminous)
2	5cmAC20	5	5cmFAC20(modified bituminous)
3	4.5cmSMA16+5.5cmAC20	6	4.5cmFAC13+5.5cmFAC20

+6cmAC25	+6cmFAC25

Three kinds of testing conditions were introduced into rut tests, which are shown in Table 4. The standard testing condition was set in terms of Chinese Specifications. The nonstandard testing condition 1 and 2 were set only for the whole surface course. The nonstandard testing condition 2 was set in terms of field investigation results from the 13km long continuous upgrade section in Jingzhu freeway. Traffic investigation results show that trucks averagely overload 60% of the standard loading weight and move at about one-third of design speed averagely.

Table 4 Testing Conditions

conditions	standard condition	nonstandard condition 1	nonstandard condition 2
temperature	60℃	60℃	60℃
loading press	0.7 Mpa	0.7 Mpa	1.1 Mpa
moving speed	42 cycles/minute	42 cycles /minute	14 cycles /minute
Sample thickness	5cm	16cm	16cm

Testing samples were shaped with a rut shaping instrument. The samples were all 300mm long and 300mm wide. Combined samples marked with No.3 and No.6 in Table 3 were shaped successively from the bottom layer to the top layer.

The results of laboratory rut tests were expressed as dynamic stability (DS).To verify the feasibility of repeated loading tests, parts of DS results of repeated loading tests were compared with the testing results from asphalt mixture design of initial or reconstructed asphalt surface layers. The comparison are shown in Table 5, which were all obtained under the standard testing condition.

Table 5 The Precision of Reappearance Tests

Sample	DS of reappearance tests(cycles/mm)	DS* (cycles/mm)	Error	DS controlling standard (times/mm)
5cmSMA16	14098	11800	19.5%	3000
5cmAC20	1716	2097	18.2%	1000
5cmFAC13	10612	8986	18.1%	2800
5cmFAC20	5843	4910	19%	2800

DS*: DS from mixture design of initial or reconstructed asphalt surface layers

The data in Table 5 indicate that DS values of the 4 mixtures are all larger than those of the DS controlling standards of China. But it only indicates that these mixtures can resist rut under design axial loading and design vehicle speed. Considering rut distress found in the field, rut-resisting capacity of these mixtures' combination still needs to be further compared .

Results and Discussion

Rut test results under nonstandard condition are shown in Figure 2. The initial structure is marked with SMA16 + AC20 + AC25, and the reconstructed structure is marked with FAC13 + FAC20 + FAC25 in Figure 2. From Figure 2, some results can be found as below:

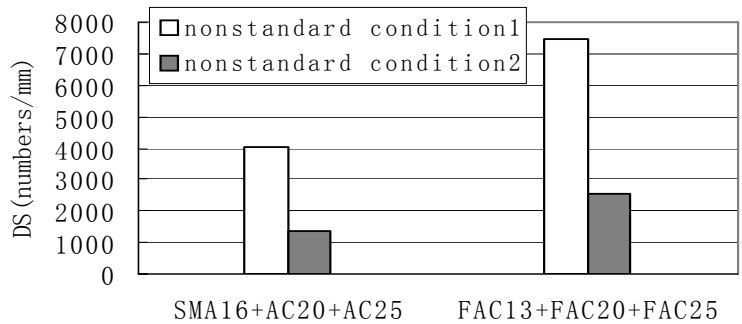

Fig. 2 DS of the whole surface course under nonstandard condition

(1)DS value of the whole initial surface course is about half of the whole reconstructed surface course. This indicates that rut-resisting capacity of FAC13+FAC20+FAC25 structure is greater than that of the SMA16+AC20+AC25 structure, which supports the investigated data in Table 1 very well. Because DS controlling standard for the whole surface course has not been set in China, it is hard to attribute the rut distress to designers.

(2)Although DS values of the two whole surface course structures under nonstandard condition 1 are all greater than 3000 cycles/mm, DS values under nonstandard condition 2 decrease greatly even to be less than the DS controlling standard for asphalt mixtures. This is the real cause for serious rut distress found in SMA16+AC20+AC25 structure.

Conclusions

In this paper, repeated loading tests have been developed with modified wheel tracking testor to compare rut-resisting capacity between SMA16+AC20+AC25 structure and FAC13+FAC20+FAC25 structure that had been used in the 13km continuous upgrade section successively. As mentioned above, some conclusions can be drawn as below:

(1)DS values of each layer of the asphalt mixtures all satisfy the corresponding DS controlling standards of China, but rut distress still happened. This indicates that only setting DS controlling standards for asphalt mixtures is unable to resist rut of surface course effectively.

(2)Rut resisting capability of the whole FAC13+FAC20+FAC25 structure is stronger than that of the whole SMA16+AC20+AC25 structure;

(3)Under 0.7 Mpa loading pressure and 21 cycles/ minute loading frequency, DS values of the whole surface course are larger than those of DS standards for asphalt mixtures. However, rut distress still happened. It indicates that this rut testing condition is not appropriate for the 13km continuous upgrade section asphalt surface course.

(4)Under 1.1 Mpa loading pressure and 7 cycles/ minute loading frequency, DS values of the whole surface course decrease greatly, even to be less than the DS controlling standard for asphalt mixtures, which induces rut distress directly.

(5)Test results are consistent with rut distress found in the 13km continuous upgrade section.

Based on these conclusions, the authors suggest:

(1)Rut test on the whole asphalt surface course under a special testing condition should be developed for long continuous upgrade sections. The special condition should be set in terms of field truck moving speed and loading weight.

(2)DS controlling standard of the whole asphalt surface course for long continuous upgrade section should be set

ABSTRACT

Bridge structures are subjected to thermal effects due to interaction with environmental conditions or due to special effects. Interaction with air temperature and solar radiation leads to seasonal and daily temperature changes in the bridge. At the present there is a more and more popular trend in using ANSYS software to simulate and analyze the finite element models in order to design automation and customization in bridge design. The ability to create automatic design has been an important research and engineering topic. This paper presents an operational system for automating engineers that integrates the Fortran program with ANSYS through APDL (ANSYS Parametric Design Language) in the Transient Thermal Simulation in bridges. In addition, we use an example to validate the program.

INTRODUCTION

ANSYS is one of the most famous and general Finite Element Analysis Software in the world. It has very powerful calculation and analysis ability. It is advanced technology, which integrates computer technology and engineering analysis technology. Design automation and customization with finite element analysis as a simulation tool is becoming more and more desired. , It is very important in transient thermal simulation in bridges.

ANSYS includes several modules: structure, thermal, and so on. When we aim at the thermal of structure, ANSYS can deal with three basic problems: thermal convection, thermal conduction, and thermal radiation. But the ambient condition and the temperature field is very complicated, so we need to consider a great deal of meteorology data, solar radiation, and complicated boundary conditions. In the past we converted this data and input the information to ANSYS manually (Josef, Erwin and Franz, 2003). This procedure has been regarded as not only time-costly but also less cost-effective. So, The Second Development Based on the ANSYS is necessary. We take APDL as the secondary development for ANSYS. The Fortran program is developed to generate the thermal parameter according to the energy theory.

THE SECONDARY DEVELOPMENT

The ANSYS program offers powerful second development to accommodate automation and customization. That is APDL. While customization is limited in that

only simple inputs and message menus can be generated. Speed can be slow for complex operations on large models such as with a great deal of meteorology input data. With the help of the Fortran program, initial conditions and boundary conditions for transient thermal simulations are generated. The output data from Fortran can be saved in array files that are read by APDL. Through macro command, ANSYS starts to run. Using the named parameters in ANSYS as the interface and the APDL for model manipulation, the user can accomplish the desired transient FE analysis and temperature response within ANSYS. Figure 1 shows a flow chart of the secondary development to simulate the transient thermal field. Each step requires special attention to achieve the final objective of the analysis.

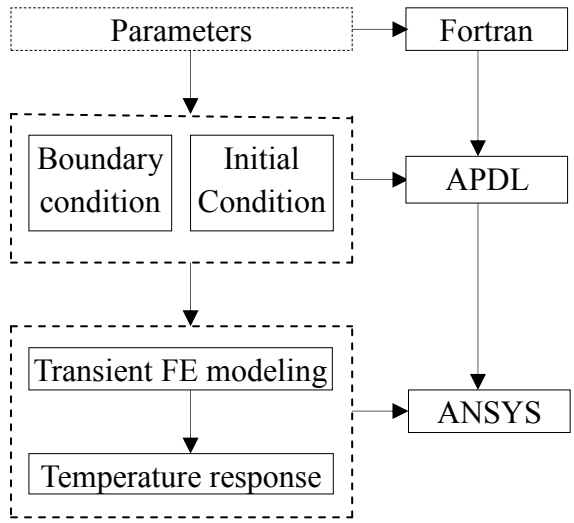

Figure 1. Procedure of the simulation.

Fortran program. The parameters to be considered in the transient thermal bridge design temperature are identified as belonging to the following groups (Tong, Tham and Lee, 2001):

Geometric: geometry of the cross section, bridge orientation

Material: thermal conductivity, density, specific heat, color

Geographical: altitude, latitude

Time: hour of the day, day of the year

Climatic: solar radiation, air temperature, wind speed

The first two parameters are internal factors related to bridge characteristics. The final three categories are external factors related to the environmental characteristics of the bridge location (Peng, Qiang, 2007).

After inputting thermal parameters, a Fortran program was used to evaluate the temperature conditions according to heat gain or loss by heat transfer for any specific situation (Figure 2).

APDL in thermal simulation. APDL stands for ANSYS Parametric Design Language, a scripting language that can be use to automate and customize common

tasks or even build your model in terms of parameters.

As with Fortran output arrays, the indices for initial temperatures and boundary temperatures are sequential integer numbers beginning with one. *DIM in APDL is used to define array parameters.

In transient thermal analysis, the uniform temperature is used during the first iteration of a solution to evaluate temperature-dependent material properties (Barr, Stanton and Eberhard, 2005). Initial conditions can be generated by TUNIF in APDL by assigning a uniform temperature to all nodes.

Thermal loads can be applied by SFL in APDL which generates boundary condition by specifying surface loads on the selected lines of area regions. For the bridge section, the line represents either edge of the section area elements. Thermal surface loads can be transferred from lines to elements with the SFTRAN or SBCTRAN commands.

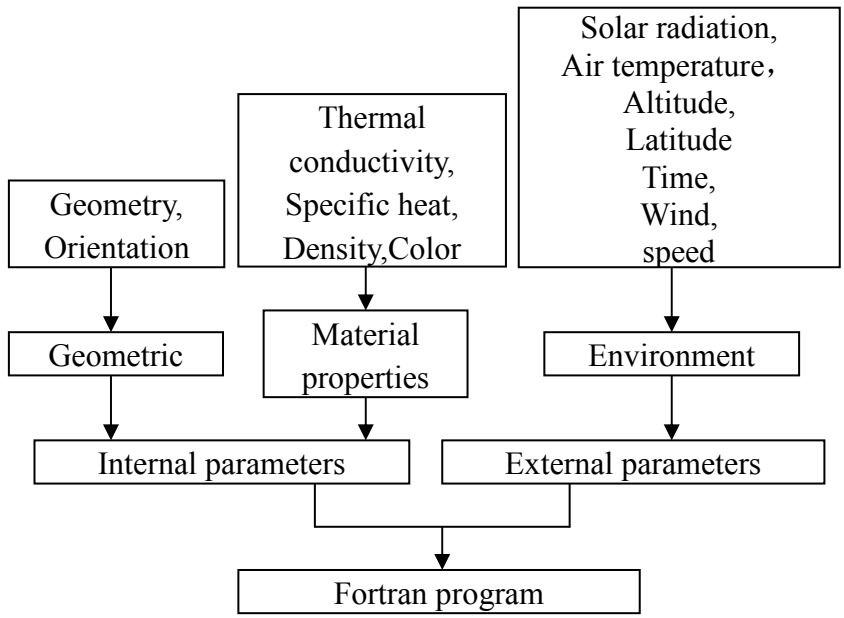

Figure 2. Parameters by Fortran program.

ANSYS. In the stage of pre-processing, we develop several works:

According to the requirements, one should take into account bridge structure dimension parameters such as length, width, section shape etc.

Material parameter. In our case, it is linear and isotropic; the density.

Element type.

FE model and meshing

Case study

Temperature variations with bridges can cause thermal stresses and deformations that are comparable in magnitude to stresses induced by vehicle loadings (Troy and Yoo,2003; Francis and Leslie,2001; Hui, Zi-shan and

Hong,2007). Thus, a bridge designer needs to calculate very detailed temperatures with thermal simulation, which often results in a large expenditure of time and effort (Song qing, Jin fei and Tongsheng, 2008; Fernando, Pedro,1993).

The temperature problem is caused by the thermal environment (Figure 3). Surface temperatures varying with the time result from numerous random inputs, namely, the surrounding air temperature, the solar energy, and convection caused by the wind vector. A computer Fortran program is developed to deal with this input data. Since times are continually changing, random and transient thermal parameters must also vary with these inputs. The final surface temperatures are computed according to the heat convection, thermal irradiation, and solar radiation.

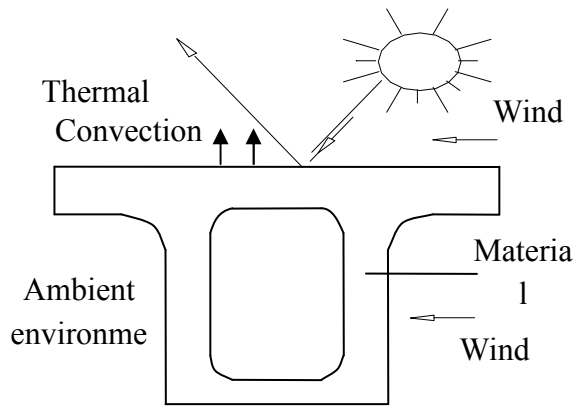

Figure 3. Temperature influence factors to concrete bridge.

In APDL, thermal parameter arrays outputted by Fortran program are defined as initial conditions and boundary conditions. As ANSYS batch file, key steps are provided below in APDL. The general structure of the batch file was to have a master file that initialized a few items such as simulation name, then called a series of scripts, followed by selected post-processing steps:

Initial conditions defined: variables initialized, options selected for later conditional checks

Geometry imported

Material model defined

Geometry meshed

Boundary conditions defined

Finite element model solved

In ANSYS post processing stage, we gain the thermal flux and the temperature field respectively. The simple way to observe the effect of the sunshine is thermal flux (Figure 4). Because the temperature of the inner is hotter than the outer, the thermal flux follows this direction. The temperature file shows the tendency that the surface temperature is higher than the bottom temperature (Figure

5). This is in agreement with theoretical analysis. After thermal analysis, the structural analysis is performed.

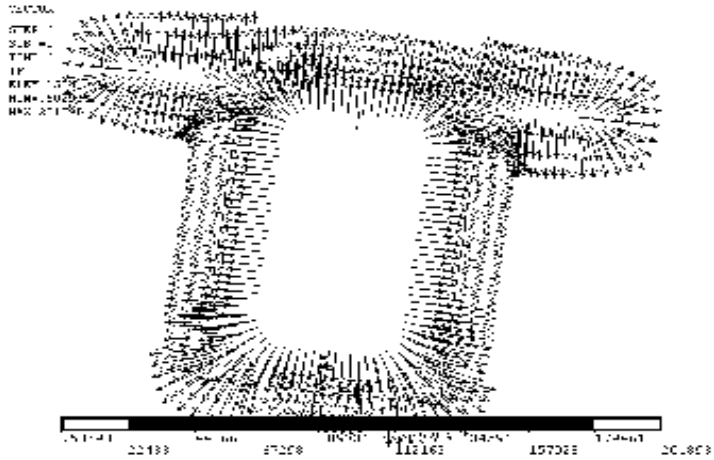

Figure 4. Thermal flux

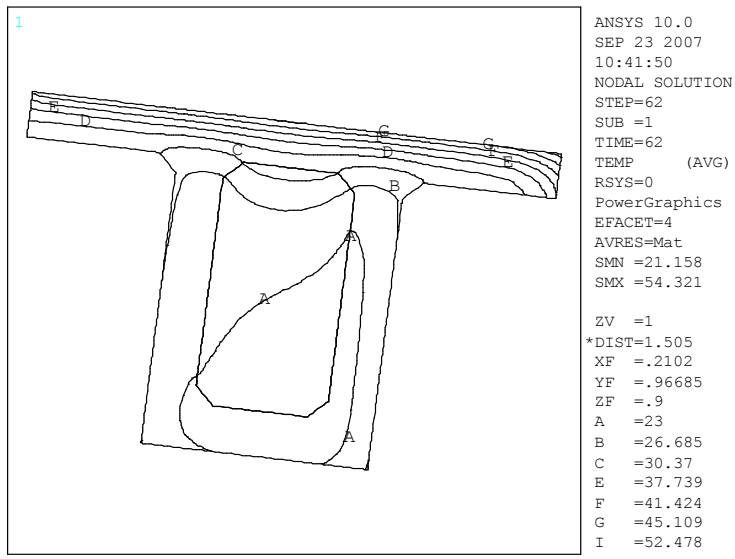

Figure 5. Temperature distribution.

Conclusion

This paper introduces the research of a general secondary development method for ANSYS. Combining Fortran and APDL, the initial and boundary conditions for thermal parameters in transient thermal simulations for bridges due to solar radiation has been developed. The calculation results matches the experimental results. It is shown that by this mean, the powerful functions of the FEA software ANSYS can extend the developing period, effectively reduce the programming works, lower the maintenance of the program needed, and guarantee the stability and the reliability of the program. The technology can be widely used in the pos-processing function of engineering calculation software.

Study on asphalt treated permeable base in permafrost regions

Dong xi-bin and Wang hai-biao and Li li-hui
School of Engineering Technique, Northeast Forestry University. Harbin,China email: xibindong@sina.com Harbin ,China；

ABSTRACT

Setting drainage system in the pavement could improve the pavement performance and extend service life of the road. According to the weather condition in north China, three kinds of open-graded ATPB were designed and their performances were evaluated using the analytic hierarchy process, and then we established the hierarchy model. The permeability, water stability, mechanical properties, and stability under low temperature of the mixtures were tested. It is concluded that ATPB-25 is a better material for permeable base of the pavement in permafrost regions.

Keywords: roads in permafrost region, asphalt treated permeable base, asphalt content; performance

Setting drainage system in the pavement could improve the pavement performance and extend service life of the road. Asphalt treated permeable base (ATPB) is a common case for asphalt pavement with internal water drainage system.

1. Design of Mixture Proportion

1.1 Materials

Dry clean basalt with no weathering and impurities was used in the experiment. Tests show that the basalt meets the quality requirements for the surface layer of asphalt pavement. Fine aggregate and fillers include basalt crumb and mineral powder. It is tested that the materials meet the quality requirements of fine aggregates and fillers for asphalt surface layer specified in “Road asphalt pavement construction technical specifications” (CTS). To meet the modified asphalt specified in the CTS, 4.5% SBS of modifier was added to Pacific Asphalt.

1.2 Design of Mineral Mixture Proportion

ATPB is composed of open graded gravel aggregates which are free or with small amount of fine materials less than 4.75mm in size. According to the mixture ranges specified in the CTS, three graded asphalt mixtures, ATPB-40, ATPB-30, and ATPB-25 were examined in this study.

1.3 Determination of the Asphalt Content

Determination of the asphalt content is the key point for designing of ATPB mixture. Since the asphalt treated permeable base is used below the surface layer, the horizontal shear force caused by loaded vehicle has relatively small impact on it. Therefore, Scattering Loss Test is not necessary. Schellenberg Binder Drainage Test combined with Marshall Test was adopted in this study to determine the optimal asphalt content.

Fund financing projects: the major breakthrough issue in Hei Longjiang Province：（GA06B302-4）；
Author of Correspondence: Wang hai-biao，email:wbcumt@163.com

1.3.1 Schellenberg Binder Drainage Test

Five asphalt contents with 0.4% interval were tested for each mixture (ATPB-40, ATPB-30, and ATPB-25). Among them, it was 1.8% ～ 3.4% for ATPB-40 and ATPB-30, respectively. It was 2.2%～3.8% for ATPB-40. The relationship between leakage loss and asphalt content under different scenarios was shown in Fig. 1.

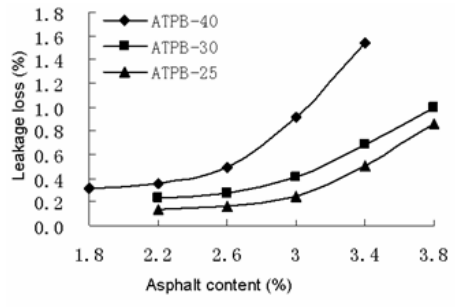

Fig1. Asphalt leakage tes

To determine the maximum asphalt content, dichotomy was used in this study. A function was fitted to the curve first, and then the second derivative of the function was calculated. The largest point of the second derivative could be obtained by dichotomy. Since the accuracy of asphalt content was 0.1, the error allowed could be ε=0.1.

The steps for determining the maximum asphalt content were as following：

Fitted function： $y = -0.472x^4 + 5.0781x^3 - 19.483x^2 + 32.172x - 19.135$

Where, x —asphalt content，%； Y —asphalt leakage loss，%。The second derivative of the function： $y'' = -5.664x^2 + 30.4686x - 38.966$。The biggest value of the y " determined by dichotomy is shown in Tab. 1。The approximate maximum point of the second derivative was calculated as 2.7%. Therefore, the maximum asphalt content for ATPB-40 was 2.7%。Similarly, the maximum asphalt content for ATPB-30 and ATPB-25 was 2.9% and 3.1%, respectively.

Tab 1. The maximum asphalt content of ATPB-40 determined by dichotomy.

Iterations	ak	bk	xk	f"(ak)	f"(bk)	f"(xk)	Reservation interval
1	2.2	3.0	2.6	0.6512	1.4638	1.9637	（2.6，3.0）
2	2.6	3.0	2.8	1.9637	1.4638	1.9403	（2.6，2.8）
3	2.6	2.8	2.7	1.9637	1.9403	2.0087	

1.3.2 Marshall Test

Five asphalt contents were prepared as the specimen for the large-scale Marshall Test. The results were shown in Tab 2-4.

Tab 2. Marshall Test for ATPB-40.

Asphalt content %	1.8	2.2	2.6	3.0	3.4
Gross bulk density ρ g/cm^3	1.972	1.986	1.999	2.027	2.065
Porosity vv %	26.22	25.23	24.25	22.22	20.27

Tab 3. Marshall Test for **ATPB-30.**

Asphalt content %	2.2	2.6	3.0	3.4	3.8
Gross bulk density ρ g/cm^3	1.964	1.978	2.001	2.029	2.047
Porosity vv %	25.18	24.19	22.83	21.27	20.07
Stability MS kN	8.27	10.25	10.43	9.67	9.24

Tab 4. Marshall Test for **ATPB-25.**

Asphalt content %	2.2	2.6	3.0	3.4	3.8
Gross bulk density ρ g/cm3	1.961	1.982	1.996	2.026	2.040
Porosity vv %	25.15	23.89	22.87	21.23	20.22
Stability MS kN	8.32	9.11	11.05	10.43	9.87

According to the Schellenberg Binder Drainage Test, the maximum asphalt content for ATPB-40, ATPB-30 and ATPB-25 was 2.7%, 2.9% and 3.1%, respectively, which were a little bit higher than the ones obtained by Marshall Test. To increase the water stability of the ATPB, higher asphalt content was encouraged. Therefore, the maximum asphalt content for ATPB-40, ATPB-30 and ATPB-25 was determined as 2.7%, 2.9% and 3.1%, respectively.

2 Permeability Test

Permeability coefficient is the index for evaluating the permeability of a material. A simplified test method was used in order to better meet the pavement actualcondition [4]. The time interval for 400 ml water completely seapage in a large Marshall specimen which was already immersed in water for one hour was recorded. The permeability coefficient (K) was calculated (Tab 5)

The permeability coefficient decreased from ATPB-40 to TPB-30, and to ATPB-25. But the difference is not significant. The permeability coefficients for all three mixtures meet the requirements of less than 0.35cm/s specified in "Design specifications for Highway Drainage".

Tab 5. Testing results for permeability coefficient.

Type of mixture	Asphalt content (%)	Porosity (%)	Time interval (t) (s)	Permeability coefficient (K)	
				cm/s	cm/s
		23.95	11.3	0.777	
ATPB-40	2.7	24.96	10.5	0.836	0.790
		23.54	11.6	0.757	
		23.03	12.1	0.725	
ATPB-30	2.9	24.27	11.1	0.791	0.751
		23.50	11.9	0.737	
		21.66	14.6	0.601	
ATPB-25	3.1	22.43	13.1	0.670	0.661
		22.92	12.3	0.713	

3 Analysis of Water Stability

ATPB drainage layer itself may be immersed in water for a long time period. Water damage may occur under water immersion and loaded vehicle passing. Therefore, water stability is required to the drainage ATPB. Immersed Marshall Test and Freeze-Thaw Splitting Test were used to evaluate the water stability of the mixture.

3.1 Immersed Marshall Test

The immersed residual stability MS_0 was calculated as $MS_0=MS_1/MS\times100\%$

Where MS is the Marshall stability of large-scale Marshall test specimen after compaction and molding, MS_1 is the Marshall stability of the specimen after immersion in the water for 48 h under constant temperature of 60℃. Testing results

were shown in Tab 6.

Tab 6. Marshall Testing results for three kinds of mixtures.

Mixture	Porosity （%）	Stability MS (kN)	Stability MS1 (kN)	Residual stability after immersion in water （%） MS0 （%）	
				Observed value	Required value
ATPB-40	24.29	10.02	9.03	90.1	＞75
ATPB-30	23.05	10.56	9.81	92.9	＞75
ATPB-25	22.92	11.17	10.57	94.6	＞75

3.2 Freeze-Thaw Splitting Test

Freeze-Thaw Splitting Test is used to test the water damage resistance of the ATPB. The requirement for the experiment is stricter than Immersed Marshall Test. Three curing processes of vacuum for water preserving, low temperature for freezing, and high temperature with water immersion are required. The procedure could better represent the real working condition of the ATPB under cold weather condition of north China. Testing results were shown in Tab 7.

After Immersed Marshall Test and Freeze-Thaw Splitting Test, all three mixtures could meet the requirements for water stability in the region with Class I rainfall. From Tab 6 and Tab 7, we noticed that the water stability of the three mixtures follows the sequence of ATPB-25＞ATPB-30＞ATPB-40.

Tab 7. Freeze-Thaw Splitting Test results for three kinds of mixture.

Mixture	Porosity （%）	Splitting tensile strength of the specimen in group B after freeze-thaw cycle R1(MPa)	Splitting tensile strength of the specimen in group B without freeze-thaw cycle R2(MPa)	Tensile strength ratio TSR= R1//R2 （%）	
				Observed value	Required value
ATPB-40	24.35	0.813	0.982	82.8	＞70
ATPB-30	23.09	0.845	0.994	85.0	＞70
ATPB-25	22.88	0.901	1.032	87.3	＞70

4 Analyses of Mechanical Properties

In China, semi-rigid base was adopted for most of asphalt pavements. Drainage ATPB is above the semi-rigid base and has lower rigidity. The ATPB is commonly under compression from the loaded vehicle passing. Therefore, compressive resilient modulus is a good indicator for the mechanical properties of the mixtures. The compressive resilient modulus of the mixture could be determined by uniaxial compression test of the specimen after static compressing (Tab 8).

Tab 8. Testing results of the compressive resilient modulus.

Mixture	Asphalt content （%）	Porosity （%）	Resilient modulus Er(Mpa)
ATPB-40	2.7	21.96	985.9
ATPB-30	2.9	21.35	1058.6
ATPB-25	3.1	21.76	1114.3

Fig. 8 shows that the compressive resilient modulus of all three mixtures of

ATPB fall between 800MPa～1200MPa, which meet the requirement to the material. The more coarse aggregates contained in the mixture, the higher is the porosity. Therefore, increasing the amount of coarse aggregate or asphalt in the mixture will cause the decrease of the material strength. The more asphalt in the mixture, the smaller of the compressive resilient modulus. The compressive resilient modulus of the three mixtures follow the sequence of ATPB-25＞ATPB-30＞ATPB-40.

5 Analyses of Material Stability under Low Temperature

Bending Creep Test was used to evaluate the deformation of the material under low temperature. Creep rate is a good indicator for the ATPB performance under low temperature. According to the weather condition in north China, Bending Creep Test was carried out at -10℃. Due to the large particle size of the mixture, cuboids specimen of 250mm×50 mm×50mm prepared by wheel rolling method were used for the test. Testing results were listed in Table 9.

Creep rate shows the rheological parameters of the material under varied temperature and loading conditions, which reflects the deformation resistance of the material. The higher is the creep rate, the greater is its ability to resist deformation, and the better is the resistance to cracking of the material under low temperature. Results showed that the resistance to deformation of ATPB-25 is higher than that of ATPB-30 and the resistance to deformation of ATPB-30 is higher than that of ATPB-40 under low temperature. The coarser is the ATPB mixture, the larger is the porosity and the lower is the resistance to deformation under low temperature.

Tab 9. Results for Bending Creep Test.

Mixture		Asphalt content (%)	Porosity (%)	Loading (N)	Stress level (MPa)	Creep rate 10^{-8}(1/s/MPa)	
ATPB-40	Specimen 1	2.7	24.73	250	0.59	2.07	2.47
	Specimen 2		23.65	250	0.61	2.46	
	Specimen 3		23.02	250	0.62	3.88	
ATPB-30	Specimen 4	2.9	22.96	250	0.60	2.78	3.04
	Specimen 5		23.44	250	0.58	3.80	
	Specimen 6		24.05	250	0.63	2.56	
ATPB-25	Specimen 7	3.1	22.98	250	0.62	2.73	3.37
	Specimen 8		22.31	250	0.57	3.41	
	Specimen 9		21.54	250	0.63	3.97	

6 General Performance Evaluations

Analytic hierarchy process was used for the general evaluation of the material properties. A hierarchy model with objective layer(Optimum ATPB), index layer （Water Permeability A_1、 Water Stability A_2 、Mechanical Property A_3、Stability under low Temperature A_4）, and scheme later （ATPB-40、ATPB-30、 ATPB-25）。

Among the four factors of A_1 to A_4, water permeability is the most important one while resistance to deformation is also required to the material. Additionally, to the road in permafrost region, water stability and material stability under low temperature have to be met. The factors were ranked by their importance with permeability was the most important, followed by water stability and material stability under low temperature. And permeability and mechanical properties are at

the same important level. Therefore, the judgment matrix is as follows:

$$A=\begin{bmatrix} 1 & 3 & 2 & 3 \\ 1/3 & 1 & 1/3 & 3 \\ 1/2 & 3 & 1 & 3 \\ 1/3 & 1/3 & 1/3 & 1 \end{bmatrix}$$

Root-squaring method was used for an approximation of the eigenvector for each judgment matrix. The single ordering weight value was then obtained. Results showed that the judgment met the requirement of consistency.

w_A=(0.437 0.161 0.309 0.093)。it means that the weight for permeability, water stability, mechanical property, and material stability under low temperature was 0.437, 0.161, 0.309, and 0.093, respectively.

Tab 10 shows that ATPB-25 has the highest score, followed by ATPB-30, and ATPB-40 has the lowest score. Therefore, ATPB-25 has the priority to be selected as the material for the permeable base of asphalt pavement in permafrost regions.

Tab 10 Results of Grading for Performance.

Index	permeability A1	water stability A2	mechanical property A3	stability under low temperature A4	Weighted score
Weight	0.437	0.161	0.309	0.093	
ATPB-40	1.5	0.5	0.5	0.5	0.937
ATPB-30	1.0	1.0	1.0	1.0	1.0
ATPB-25	0.5	1.5	1.5	1.5	1.063

7 Conclusions

The optimal asphalt content of the mixture was determined based on Schellenberg Binder Drainage Test and Marshall Test. Permeability, water stability, mechanical property, and material stability under low temperature of the three mixtures of ATPB were tested and analyzed. Results showed that ATPB-25 was more suitable as permeable base of asphalt pavement in permafrost regions.

ABSTRACT

The components of mixed filling roadbed are complex, and the variability is big. This paper focuses on the monitoring technology of construction quality after compacting mixed filling roadbed. Based on the vibratory roller and roadbed interactive dynamic characters, the dynamic model has been built. By analyzing the model, the relationship between the dynamic response acceleration of the vibratory roller and the roadbed structure resistance has been obtained. The continuous informative response of the vibratory roller can be monitored by using the monitoring system established on the basis of the vibratory roller. The correlation between the dynamic response acceleration and the corresponding deflection is good. After calibrating the acceleration by deflection, the controlled acceleration standard can be developed The feasibility and advanced characteristics have been validated by monitoring the construction quality of mixed filling roadbed.

INTRODUCTION

Based on statistic data, the amount of construction trash takes up thirty to forty percent of the whole trash in large or medium size cities, which is the biggest waste source. At present, most of the construction trashes are delivered to the suburb or places near villages without any treatment. They are piled up in the open air, or dumped into big or small pits as fillings, or even into the lake or sea. The places used to dispose the construction trash are getting farther and farther from the city, because the land for keeping trash becomes less. Such waste disposal influences extension of the city construction, especially the exploitation between the city and the country. Trash digging and disposing needs new land and brings pressure to the environment. This means new ways of trash disposal is needed. In this sense, mixed filling is a better choice for environment protection, saving resources and reducing construction cost.

Dynamic compaction is the most common method to deal with the mixed filling in the initial place. It can not only improve the capacity of mixed filling but also improve the uniformity in some extent. Dynamic compaction technique should be designed on the basis of the soil condition, concretion density, construction

efficiency and so on. The quality of dynamic compaction roadbed is unsteady because of so many influential factors. Sand replacement method is the main method to control the construction quality of mixed filling roadbed. The design compaction is the control index. This method is not suitable for grand grains, and the water level is used to measure the compaction difference between the dynamic compactions. Heavy dynamic penetrometer, plate static load test and bearing plate method are also used to measure the capacity. Because the uniformity of mixed filling is bad, these methods all have some limitation sometimes. The continuous monitoring technique has been established based on the dynamic response during rolling by vibratory roller. The relationship between dynamic response and normal index-deflection has been established. The dynamic response is calibrated by deflection. Based on all of these, the continuous monitoring and real-time control of the quality of mixed filling roadbed is realized.

PRINCIPLE OF CONTINUOUS TECHNOLOGY

Recognition principle of roadbed

The continuous monitoring equipment is essential for continuously monitoring the construction quality. The vibratory roller can be treated as dynamic excitation equipment, and the dynamic test can be achieved through its rolling process. The roller wheel is the key of the research. It can be expressed as a reaction from the resistance without considering the condition of the roadbed, which is shown in figure 1.

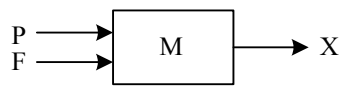

Figure 1. Recognition of roadbed resistance.

This is a problem with single input and multiple outputs. The recognizing work is not so complex because the system is linear. For the linear system, if one input is known, the other input can be obtained by analyzing the response. There are two inputs for the vibratory wheel. One is the exciting force from the roller itself; the other is the resistance from the roadbed. The first is named as P and it is already known, the second is named as F, and it is unknown. The response is named as X, and it can be obtained by monitoring. So F could be obtained with the aid of P and X (Xu and Gao 2007; 2005).

According to figure 1 and Newton second law, the dynamic equation was established as shown in equation 1 and 2.

$$M\ddot{x} + F(x) = P\sin\omega t \qquad (1)$$

$$P = me\omega^2 = 4\pi^2 mef^2 \qquad (2)$$

Where M—quality of roller wheel;

P—amplitude of exciting force;
e—eccentric distance;
m—eccentric quality;
ω—angle frequency, $\omega=2\pi f$;
F(x)—roadbed resistance.

The above equations seem to be simple. In fact, they are very complex. They are nonlinear elastic plastic dynamic equation, and it is difficult to solve. One difficulty is that the nonlinear relationship between F(x) and x is not clear, and the displacement contains elastic part and plastic part. The second difficulty is that the phase angle between exciting force and displacement is unknown. But we can analyze them qualitatively. This is the most common method to deal with nonlinear problems (Zhou 1998)

Theoretical calculation and measured data show that there is linear relationship between acceleration response and system resistance if the vibratory system is steady and the exciting force is fixed. So the acceleration of vibratory wheel is chosen as resistance index. It can reflect the changing information very well.

Continuous testing mode

While testing, the compaction process monitor system (CPMS) is fixed on the vibratory roller, and the dynamic response of the roller can be continuously monitored. The data can be calculated immediately and shown on the system screen. The changing information of roadbed compaction state is reflected by stiffness, intensity and stability, and can be comprehensively reflected by resistance. With the plastic deformation decreasing, the compaction state changes from a low steady system to a high steady system. The roadbed resistance increases continuously, and the dynamic response of roller increases too. All the variation can be reflected by CPMS. The testing mode is shown in figure 2.

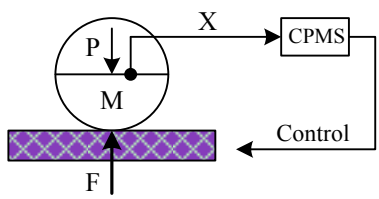

Figure 2. Continuous testing mode for roadbed compaction quality .

MONITORING AND ANALYZING

Test section

A newly constructed road in the suburb of Harbin is studied in this project. This area was lowland in the past, and later became a trash place for construction and

daily life waste. The drill data shows that the components of mixed filling are complex, and the thickness of the mixed fillings is different. There are organic clays containing much water under the layer of the mixed filling. The ground capacity is bad. So it is difficult to deal with it. Dynamic compaction at the initial place was adopted. The hammer weight is 2 tons. The falling distance is 10 meters. After two times of point compaction and one time of row compaction, the surface layer is shoved. Then an 18-ton vibratory roller is used to compact. The resilient modulus is more than 30MPa according to the pavement design.

The relationship between dynamic response X and reflection

YZ16JC vibratory roller is used in compaction of the mixed filling roadbed and the dynamic response testing. The quality of the mixed filling roadbed is measured and evaluated with this roller. The first step is to establish the relationship between the dynamic responses (acceleration) and the normal index (deflection).

When measuring, a section is selected at first, and no less then 30 points' deflections are tested by deflection vehicle. The position of the deflection should also be noted. Then the same section is tested by the vibratory roller with CPMS. After testing, the relationship between the deflection and the dynamic response acceleration are established as shown in Figure 3. The correlation coefficient is 0.87.

According this relationship, the whole section can be tested continuously by adopting the same roller and setting the same parameters.

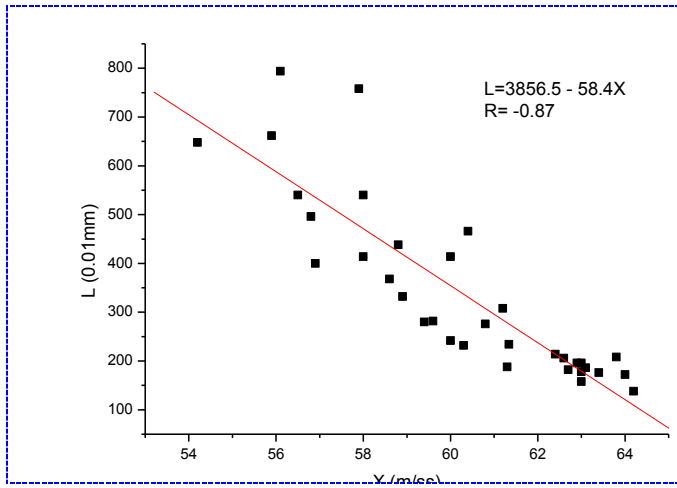

Figure 3. Relationship between deflection and dynamic testing results.

Analyzing the continuous testing results for roadbed quality

According to the pavement design, the resilient modulus should be more than 30MPa, and the corresponding resilient modulus of roadbed should be less than 258.7 (0.01mm) after it is modified by season parameters and roadbed humidity. According to the relationship between deflection and dynamic testing results, the

dynamic response acceleration is calibrated as less than 61.61m/ss. This value is the criterion for roadbed quality. If the acceleration of the testing point is more than this value, it means that this point is eligible. After inputting this value into CMPS, the information for eligible points and ineligible points are shown on the screen of the equipment. Figure 4 is the dynamic response information for the points on the wheel trail. X-axis is the testing distance, and y-axis is the ratio of the testing point acceleration to the criterion. After testing the whole section, the compaction conditions for the whole section are shown in figure 5 and 6. In thes two figures, x-axis is the strip number, and y-axis is the testing distance. Red means eligible and green means ineligible.

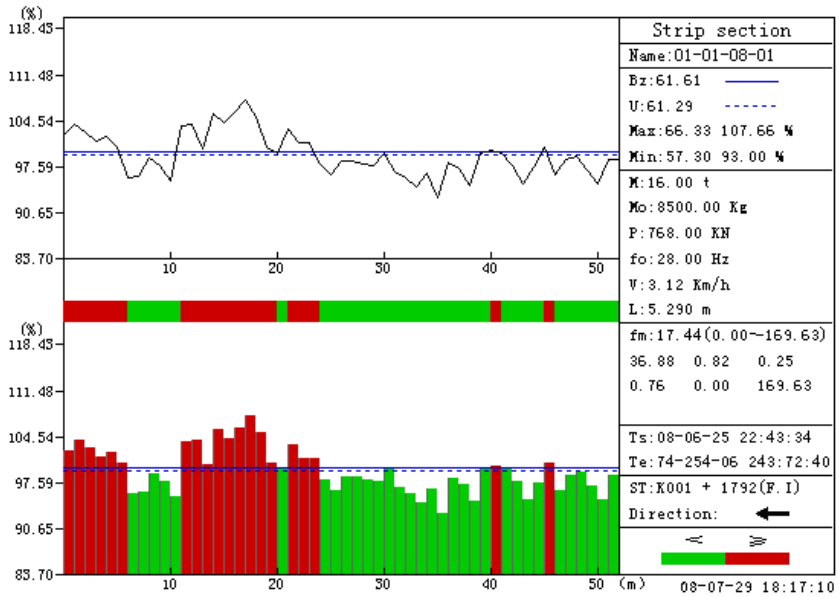

Figure 4. Dynamic response curve of one strip.

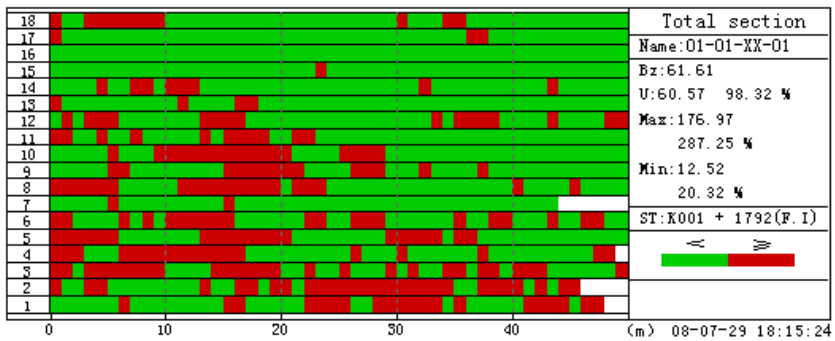

Figure 5. 18 strips results for mixed filling roadbed A.

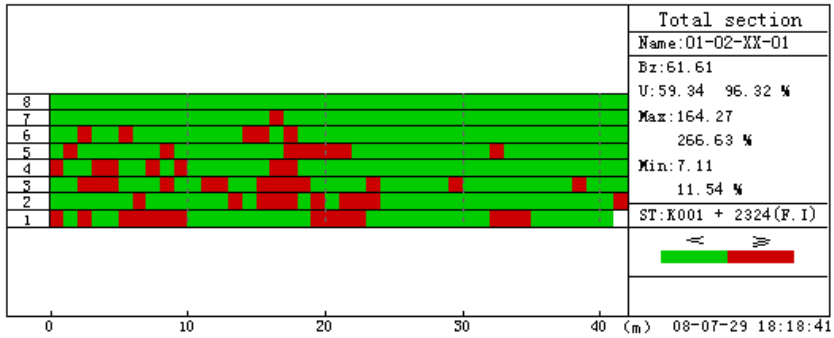

Figure 6. 8 strips results for mixed filling roadbed B .

Using this method, the construction quality after compaction is obtained. As shown in the figures, the ineligible areas are more than 50 percent, and the figure also shows that the compactions are uneven. These are the same with the deflection results. After testing, some representative points including those eligible and ineligible are chosen for further study. Meanwhile, several reasons are identified. One is that the mixed filling does not distribute well. The second is that there are some problems with the dynamic compaction technique. The surface layer is influenced by dynamic compaction greatly. After compaction, the surface layer is shoved and compacted. The compaction layer is so thick, and the deep hole after dynamic compacting can also affect the surface layer. The third reason is that the fine grains in the mixed filling contain a lot of water, sothat the dynamic compaction results are not good.

If the above results can be provided for the construction company and the quality control department, further improvement in construction technology can be made.

CONSLUSION

Continuous dynamic technology can control the overall compation quality during construction, and the output is easy to understand. There are difficulties in normal testing. The relationship between dynamic testing information and normal testing results has been established. Based on this relationship, the dynamic continuous technology can be used in construction quality testing. It is meaningful for monitoring the quality of roadbed, especially for the complex roadbed construction over the long term. It is also important for improving the construction technology, increasing working efficiency and ensuring the construction quality.

Abstract

The surface treatment method presented in the paper, a mineral aggregate layer paved on geo-textile coated with asphalt layers on both sides, can improve the performance of existing asphalt pavement surface such as slip resistance, waterproof, and wear resistance. The sample fabrication method is determined by structural characteristic of the treatment method. Eight structures with different asphalt and geo-textile combinations are selected for testing, and the optimal dosage of asphalt and mineral aggregate are determined. The optimal structural combination is obtained on the basis of testing the shear capability of the eight structures. The shear capability of the optimal structural combination is tested under different vertical pressures and temperatures by the shear capability test machine for asphalt road surface structure layers, which is developed by the research team. Test results show that the combination of KLMY90$^{\#}$ base asphalt and short fiber geo-textile with density of 300g/ m^2 is the optimal structure. The friction coefficient of the optimal structure is 0.5989.The results also show that shear capability under high temperature is better than which under low temperature. Finally, the construction procedureis also described . The test road shows that this surface treatment method is economical and effective .

Key Words: Existing asphalt surface, Surface treatment method, Structural combination, Friction coefficient, Shear capability, Construction.

1. Introduction

Surface treatment can be a highly economical highway maintenance option when properly constructed (Khaled, 2007). Surface treatment, usually thinner than 3cm, is constructed by the layer spread method or the mixing method. As the surface treatment layer is very thin, it can't improve the strength of road surface but can seal the cracks, improve the smoothness of road surface, increase the slip resistance and extend the life of pavement (R.Gary, 1997; Chen, 2005). Since the middle 1970s,

surface treatment techniques have been widely used all over the world, in such as France, New Zealand and Australia. Existing research shows that the average life of existing asphalt pavement will be prolonged by using surface treatment techniques (Zane, 2004; Tom, 2004). This paper presents the structure optimization, performance evaluation and construction methods for a surface treatment technique, a mineral aggregate layer paved on geo-textile coated with asphalt layers on both sides. This method has been used in New Zealand and Australia, but has not been used in China (Sheng, 2008).

2. Raw Materials and Sample Fabrication

2.1Raw Materials

Two kinds of asphalt are used in the research. One is KLMY90# base asphalt, the other is KLMY90# base asphalt with 4% SBS. Table 1 shows the test results of asphalt (JTJ052-2000, 2000). For mineral aggregate, macadam granite with single grain size (5~10mm) is used. The test results of the mineral aggregate are showed in the Table 2 (JTJ058-2000,2000).

Table 1. Test Results of Asphalt

Items		Base Asphalt	SBS Modified Asphalt
Penetration(25℃)/0.1mm	25℃	96	76
	5℃	12	16
Penetration Index PI		-0.45	1.77
Ductility/cm	25℃	>150	70

Geo-textile with long fiber and short fiber, whose density are 300g/ m^2 and 200g/ m^2 respectively , are used in this experiment

AC-16Ⅰconcrete mixture is adopted.

2.2 Sample Fabrication

The surface treatment method proposed in the paper is different from the traditional method for adding geo-textile. A layer spread method is used in the construction. The sequence of construction is asphalt—geo-textile—asphalt—mineral aggregate. The two layers of asphalt should cohere together through the geo-textile layer in order to form the integrity of the structure. A single layer of aggregates of the same size is paved. Meanwhile, the mineral aggregate should be embedded 2/3 into the top asphalt layer to combine with the asphalt adequately and the other 1/3 of the uncovered mineral aggregate provides wear-resistance and slip-resistance. The function of asphalt is to bond the different layers, and the function of geo-textile is to provide waterproof and improvement of the flexibility of pavement. Use of geo-textile can also reduce the temperature stress through controlling the temperature cracking. Geo-textile soaked by asphalt forms a waterproof coating that can prevent rain from infiltrating into the pavement (Jiang, 2000). Figure 1 shows the layer structure of the surface treatment technique. Figure 2 shows the actual effect of determining dosage of each layer's material.

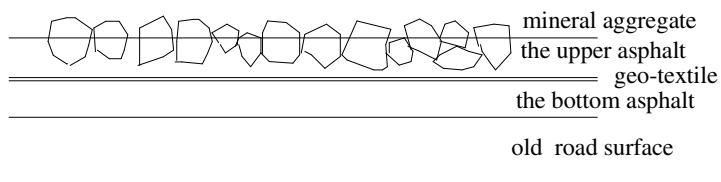

Figure 1. Layer structure of surface treatment

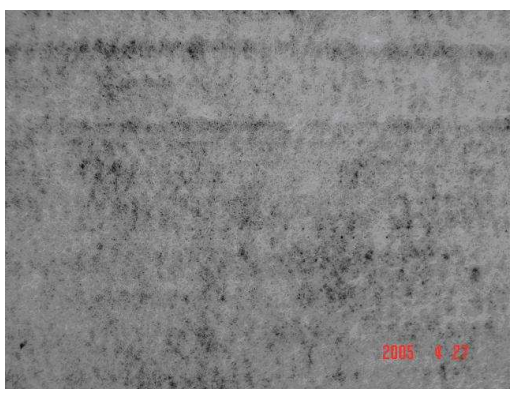

(a)

(b)

Figure 2. Actual effect of determining dosage of each layer's material, (a) Dosage of bottom asphalt and (b) Dosage of top asphalt and mineral aggregate

According to Figure 1 and Figure 2, sample fabrication is obtained after repeated tests. First, a rutting board, which is molded with AC-16 asphalt mixture, is formed as a basic sample. It should be heat conditioned in oven for about 2 hours at 60℃. Then, asphalt (Base asphalt is heated up to 160-170℃, SBS modified asphalt is heated up to 170-180℃) is brushed to the sample surface evenly. Meanwhile, the asphalt quantity of the bottom layer is weighed. Then the geo-textile is spread, after that, the sample is placed on the rutting machine to press twice under the pressure of 0.7MPa. Then, asphalt is evenly brushed to the sample again after heated to the required temperature. The asphalt quantity of the top layer is weighed. Then, an amount mineral aggregate determined beforehand is spread onto the sample surface evenly. The sample is then pressed 6 times under the pressure of 0.7MPa . Since mineral aggregate can't be uniformly arranged in a single layer, whether spalling will appear should be checked. During the test process, if the quantity of spalling of mineral aggregate is too big, the amount of aggregate shall be decreased in the next test, until the optimal quantity is obtained. Finally, the sample fabrication is finished after being pressed 6 times again under the pressure of 0.7MPa.

2.3 Material Dosage Determination

Since the layer of mineral aggregate is one stone diameter thick, dosage of mineral aggregate can be calculated first. The apparent density of the mineral aggregate is 2.65 g/cm^3 by testing. The grain diameter is 4.75mm～9.5mm (intermediate value 7mm is used in calculation). The plane size of the sample is 30cm×30cm. Under the assumption that mineral aggregate is of uniformly sized spheres (the volume of each sphere is (4/3) x π x0.35^3=0.18cm^3), and mineral aggregate is evenly distributed on the sample surface, the total volume can be calculated as 0.18(cm^3)×(30/0.7)×(30/0.7)=330.6 cm ^{3}, so the dosage of mineral aggregate is 330.6(cm^3)×2.65(g/cm ^{3})=876g. Optimal dosages of different structures are obtained on the basis of repeated tests. The results are shown in Tables 3 and 4.

Table 3 Test Results of Mineral Aggregate Dosage

Asphalt	Base Asphalt				SBS Modified Asphalt			
Geo-textile	Long Fiber 300g/m^2	Short Fiber 300g/m^2	Long Fiber 200g/m^2	Short Fiber 200g/m^2	Long Fiber 300g/m^2	Short Fiber 300g/m^2	Long Fiber 200g/m^2	Short Fiber 200g/m^2
Calculated Dosage/g	876	876	876	876	876	876	876	876
Spalling Dosage/g	176	106	156	146	86	106	76	106
Actual Dosage /g	700	770	720	730	790	770	800	770

Unitage/(g/m^2)	7778	8556	8000	8111	8778	8556	8889	8556

Table4. Test Results of Asphalt Dosage

Asphalt	Base Asphalt				SBS Modified Asphalt			
Geo-textile	Long Fiber 300g/m^2	Short Fiber 300g/m^2	Long Fiber 200g/m^2	Short Fiber 200g/m^2	Long Fiber 300g/m^2	Short Fiber 300g/m^2	Long Fiber 200g/m^2	Short Fiber 200g/m^2
Dosage of the Bottom Layer/(g/m^2)	1111	1222	889	1000	1333	1333	1222	1222
Dosage of the Upper Layer/(g/m^2)	1333	1333	1111	1111	1444	1556	1333	1444
Total Dosage/(g/m^2)	2444	2555	2000	2111	2777	2889	2555	2666

Table 4 shows that the dosages of asphalt are different for different kinds of geo-textile. From the test data, the dosage of modified asphalt is more than base asphalt; the dosage of geo-textile with density of 300g/m^2 is more than the geo-textile with density of 200g/m^2 and the dosage of long fiber geo-textile is more than that for short fiber geo-textile.

3. Test of Shear Capability

The road surface should be wear and skid resistant, so shear capability is a key parameter to evaluate the performance. The shear capability test machine for asphalt road surface structure layers, developed by the research team, is used to test the shear capability.

3.1 Testing Machine

The mechanism of the testing machine is to test the friction coefficient *f* between surface treatment layer and a rubber plate. In other words, it is to get the ratio of pull force *F* and vertical load *N*. The pressure *N* is acted on the test piece by a jack. The pressure value can be measured by transducers. Mineral aggregate will be peeled off when both vertical and horizontal forces are applied. At last, the test piece will be removed. The friction coefficient will be measured finally. The diagram of the machine is shown in Figure 4.

Figure 4. Diagram of shear capability test machine for asphalt road surface structure layers

3.2 Test Results and Analysis

3.2.1 Influence of structure

The vertical pressure *N* is basically set as 0.7MPa（25KN）, but it varies with the horizontal pull. A vertical pressure *N* will appear while the horizontal pull reaches the max. The temperature is set as 20C in the experiment. The result is shown in Table 5.

Table 5, Max Horizontal Pull under Fixed Vertical Pressure.

Asphalt	Base Asphalt				SBS Modified Asphalt			
Geo-textile	Long Fiber 300g/m^2	Short Fiber 300g/m^2	Long Fiber 200g/m^2	Short Fiber 200g/m^2	Long Fiber 300g/m^2	Short Fiber 300g/m^2	Long Fiber 200g/m^2	Short Fiber 200g/m^2
Vertical Pressure *N*/KN	26.85	26.04	27.70	27.40	25.33	25.79	25.01	25.12
The Max Horizontal Pull *F*/KN	25.67	25.23	24.94	24.69	23.22	23.84	22.56	22.87
F/N	0.956	0.969	0.900	0.901	0.917	0.924	0.902	0.910

The data in Table 5 indicates that base asphalt is better than SBS modified asphalt. Test results also show that geo-textile with density of 300g/m^2 is better than the geo-textile with density of 200g/m^2. There is no obvious influence by using geo-textile with long-fiber and short-fiber, but geo-textile with short-fiber takes less asphalt dosage than geo-textile with long-fiber. So combination of base asphalt with geo-textile with density of 300g/m^2 and long-fiber is the best structure according to

the test results.

3.2.2 Influence of vertical pressure

Three different vertical pressures are adopted and the temperature is set as 20C in the experiment. The test results are shown in Table 6.

Table 6. Test Results of the Max Horizontal Pull with Different Vertical Pressure

Pressure/MPa	The Max Horizontal Pull *F*/KN	Vertical Pressure *N*/KN	*F/N*
0.5	8.57	14.54	0.589
0.7	12.53	21.07	0.595
0.9	15.91	26.80	0.594

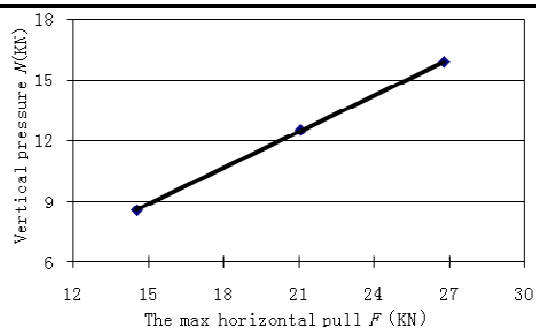

Figure 6. Relation of Max Horizontal Pull *F* and Vertical Pressure *N*

Figure 6 indicates that there is a good linear relationship between the max horizontal pull *F* and vertical pressure *N*. The correlative equation is: $F=0.5989N-0.1219$（$R=0.9999$）.The friction coefficient is 0.5989.

3.2.3 Influence of temperature

Four different temperatures are adopted for testing at the vertical pressure *N* set as 0.7MPa（25KN）. The test results are shown in Table 7.

Table 7. Test Results of the Max Horizontal Pull with Different Temperatures

Temperature/℃	The Max Horizontal Pull *F*/KN	Vertical Pressure *N*/KN	*F/N*
0	15.58	24.64	0.63
20	11.30	19.82	0.57
40	10.60	19.63	0.54
60	8.96	17.23	0.52

Table 7 indicates that the max horizontal pull *F* decreases with the temperature. So the shear capability of the surface treatment is better in low temperature area than in high temperature area.

4. Construction and Testing

4.1 Construction procedure

The construction flow is: Disposal of existing pavement → Sprinkle the bottom layer asphalt → Spread geo-textile → Compact → Sprinkle the top layer asphalt → Spread crushed stones → Compact . The construction flow is shown in Figure 7.

Figure7. Construction flow in fieldwork

4.2 Testing

Table 7 shows the test results of smoothness, structural depth, friction coefficient and seepage conditions. From Table 7, it is evident that pavement performance such as smoothness, slip resistance, friction and waterproof are improved after the surface treatment.

Table 7. Test Results of Test Road

Items	Smoothness/mm	Structural Depth/mm	Friction Coefficient/mm	Seepage Situations/(ml/min)
Technical Requirements Results	≤10	≥0.60	≥54	≤10
Old Surface Pavement	14.5	0.45	30	Seepage*
Pavement After Surface Treatment	8.5	1.1	75	No seepage*

*Under the field acceptance test, since the systematic error of test, if test result of seepage is less than 5mL/min, the pavement is considered impermeable .

5. Conclusion

The method presented in this paper, a mineral aggregate layer paved on geo-textile coated with asphalt layers on both sides，can improve the efficiency of slip resistance, waterproof and wear resistance of existing asphalt pavement surface. Test results of shear capability show that combination of KLMY90# base asphalt, geo-textile with 300g/m^2 density and with short-fiber is the optimal structure. The friction coefficient of the optimal structure is 0.5989 according to the test results of shear capability under different vertical pressures. We have also discovered that the structure is better adapted in low temperature area on the basis of test results of shear capability under different temperatures. Finally, the construction procedure of the surface treatment is described in the paper. The test results show that pavement performance such as

smoothness, slip resistance, wear resistance and waterproof are improved after the surface treatment.

ABSTRACT

The use of reclaimed asphalt pavement (RAP) has proven to be economical and environmentally safe as being used extensively to produce new asphalt pavements. To examine the "black rock" problem of RAP material, a laboratory investigation was conducted in this study in which the blending process of simulated and actual RAP material with virgin binder was analyzed using an x-ray scanner. For this purpose, new aggregate was mixed with virgin binder containing 25% metal powder (by weight) at 4.5% asphalt content, and then the mixture was oven aged to simulate the RAP binder. Subsequently, the simulated RAP material was again mixed with new binder, without metal powder, to observe if the metal powder from the aggregate surface will combine with the added binder. Also, virgin binder with 25% metal powder was mixed with actual RAP to detect any dispersion of the powder into the asphalt film. Cross sectional images from the x-ray CT scanner indicated that the metal powder has diffused from and into the asphalt film of the aggregate particles during the blending process. Thin layers (microlayers) of metal powder, with varying thicknesses, were observed in the vicinity of the aggregates' surfaces due to x-ray diffraction. The results provide clear evidence that simulated and actual RAP binders partially blend with the virgin binder to a certain extent.

INTRODUCTION

More than 90 percent of the United States roadway system is surfaced with asphalt concrete. Due to this fact, around 500 million tons of hot mix asphalt (HMA) have to be produced every year to cover new placement and rehabilitation works. One-fourth of these tons contain recycled asphalt pavement (RAP) making the HMA industry one of the biggest recyclers in America. The Federal Highway Administration (FHWA) estimates that approximately 90 million tons of asphalt concrete are removed yearly, with more than 80 percent being reused in highway

applications. About one-third of the removed material is recycled into asphalt pavements. Today, RAP is routinely accepted in asphalt paving mixtures as an aggregate replacement and as a portion of the binder for both base and surface courses in most states (McDaniel and Anderson 2001a, b).

Various research studies have been reported in the literature regarding the use different percentages of RAP in HMAs and their performance after placement (Kennedy et al. 1998, Shah et al. 2007). During the blending process, though, there are two major concerns for the engineers and researchers. The first concern relates to the amount of old asphalt binder that actually blends with the new (virgin) asphalt during the mixing process, while the second concern addresses the influence of the aged RAP binder on the composite binder properties. Based on experience and previous test results, the present common belief is that RAP does not act in the new mixture as a "black rock" but the aged asphalt does blend with the new asphalt during the mixing of the materials. These aspects of HMA mix design were addressed in the NCHRP Project 9-12 through fabrication of asphalt concrete specimens that simulated the actual practice, black rock, and total blending. As different cases of blending were evaluated using various Superpave tests at low and high temperatures, it was found out that there were no significant differences among them at low RAP contents. However, at higher RAP contents, usually over 25%, the differences became significant, with the black rock case showing lower stiffnesses and higher deformations than total blending and actual practice cases (Roberts et al. 1996, Soleymani et al. 2000). The partial blending between RAP and virgin binder, especially at high RAP contents, indicates that the hardened RAP binder has to be accounted for in the virgin binder selection (Zhai et al. 2000).

Huang et al. (2005) conducted a laboratory study on asphalt surface mixtures containing screened RAP to evaluate the degree of blending between the two binders. They stated that if the aged asphalt binder cannot fully blend with the virgin asphalt it will form a stiff layer on the aggregate's surface, underneath the virgin binder. Thus, a double-binder layer forms on the RAP's surface which may reduce the internal stresses of the compacted mixtures and eventually enhance their performance (Figure 1).

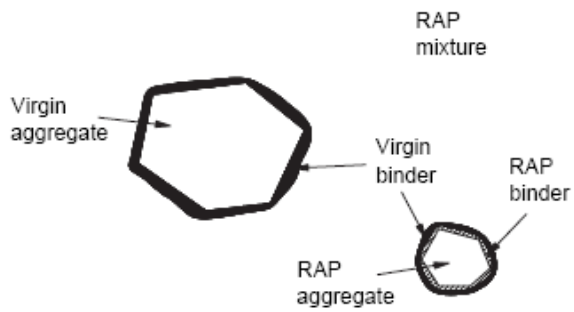

Figure 1. RAP-binder dual-layer system (Huang 2005)

In reality, the actual amount of blending that occurs in a mixture depends on many factors, among which the stiffness of the RAP binder, the compatibility of the RAP

and virgin binders, the characteristics of the hot-mix plant, the mixing temperature, and mix handling are the most important. Also, in the last decade imaging and image analysis techniques have been widely adopted for aggregate and asphalt pavement evaluation. Among these techniques, Computed Tomography (CT) represents a specialized X-ray imaging technique that creates a 3-D image of an object from a large series of 2D X-ray images taken around a single axis of rotation. By spinning the sample around its own axis data is collected from multiple angles, then a computer processes this information to create multiple images. These images are called "cross-sections" or "slices" and can be easily generated for 2D display to analyze the internal structure of the scanned object.

OBJECTIVE

The objective of the present study is to determine to what extent the RAP binder (simulated and actual) will merge with the virgin binder under normal mechanical mixing conditions. For this purpose, metallic powder in the amount of 25% by weight of total binder content was used in order to find out how close to the aggregate surface it “may reach”.

EXPERIMENTAL PLAN

A laboratory experimental plan was developed to investigate the blending effect of the aged asphalt in simulated and actual RAP during a normal mixing operation. This experiment evaluated new aggregate particles coated with asphalt containing 25% metal powder and subsequently mixed with virgin asphalt binder without metal powder. Also, RAP material was mixed with virgin binder containing 25% metal powder. The asphalt binder contents were 4.5% for new aggregate and 2.5% for RAP material, respectively. The amount of binder added to the RAP material was calculated using formulas provided in the NCHRP 452 report. The RAP material originally had 4.4% asphalt content.

Materials and Mixture Production

The virgin aggregate for this study was selected from No. 67 limestone. Only aggregate particles passing the 1/2 in. (12.5mm) sieve and retained in the No. 8 (2.36mm) sieve were used for the mixing with the virgin binder. Properties of the virgin aggregate and binder are presented in Tables 1 and 2. They were provided by Virginia Transportation Research Council (VTRC). The actual RAP material used for blending with the new asphalt binder contained PG64-22 binder. No binder extraction was performed on the RAP material. Also, only particles passing the 1/2 in. sieve and retained in the No. 8 sieve were selected for mixing. The virgin asphalt binder used in this study was a standard PG64-22. The metal powder combined with the virgin asphalt was from industrial grinding processes, with particle sizes ranging from 5 to 50 microns. 25% by weight of metal powder was added to the virgin binder before further mixing it with the new aggregate and RAP. To simulate the aged binder on the virgin aggregate, the mixture was kept for 36 hours in the oven at 120℃.

Subsequently, the simulated RAP containing 25% metal powder was mixed with virgin binder without any powder in it. Similarly, the actual RAP material was combined with virgin asphalt binder containing 25% metal powder. The blending was performed at 175℃ for 5 min. for all material comb inations using a laboratory mechanical mixer after the materials were heated up in a forced draft oven. The blending temperature was selected in order for the RAP particles to completely break down and blend with the virgin materials. As already known, the RAP particles have a coarser gradation than the RAP aggregate, so if the RAP material is not heated sufficiently, the RAP binder does not blend adequately with the virgin binder and the RAP will more likely act as a black rock material.

Table 1. Properties of virgin aggregate

Sieve Size	% Pass
12.5 mm	100
9.5 mm	87
4.75 mm	37.4
G_{sb}	2.651

Table 2. Properties of PG64-22 asphalt binder

Binder test	Test results	Specifications
Rotational viscosity @ 135℃(Pa.s) DSR (G*/sinδ) (kPa) @ 64℃ (Original binder)	0.56 1.64	3 Pa.s max 1 kPa min
RTFO aged binder @ 64℃ DSR (kPa)	3.46	2.20 kPa min
PAV aged binder @ 25℃ DSR (MPa)	3812.2	5000 kPa mi n

X-ray Scanning Equipment

The scanner used in this study was a low energy (50kV) CT scanner using an x-ray cone-beam to collect 2D radiographic (or angular) projections of an object while is rotated 180°or 360°(Figure 2). Its x-ray source has adjustable voltage and can use a range of filters for versatile adaptation to different object densities. Variable magnification (6-30 μm pixel size) is combined with object positioning for easy selection of the object part to be scanned. The x-ray flux is measured by a detector plane located behind the object. This scanning technique, also known as volume CT or 3D scanning uses a special reconstruction algorithm that processes the 2D projections into a volume that is the equivalent of many simultaneous and contiguous CT slices. The reconstruction process includes post alignment optimization and can be focused on a restricted volume of interest. Reconstructed slices can be saved in BMP or JPG data format for subsequent creation of 3D models.

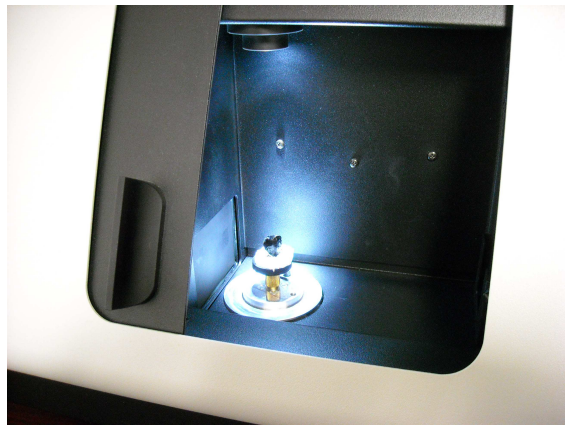

Figure 2. Aggregate particle inside x-ray CT scanner

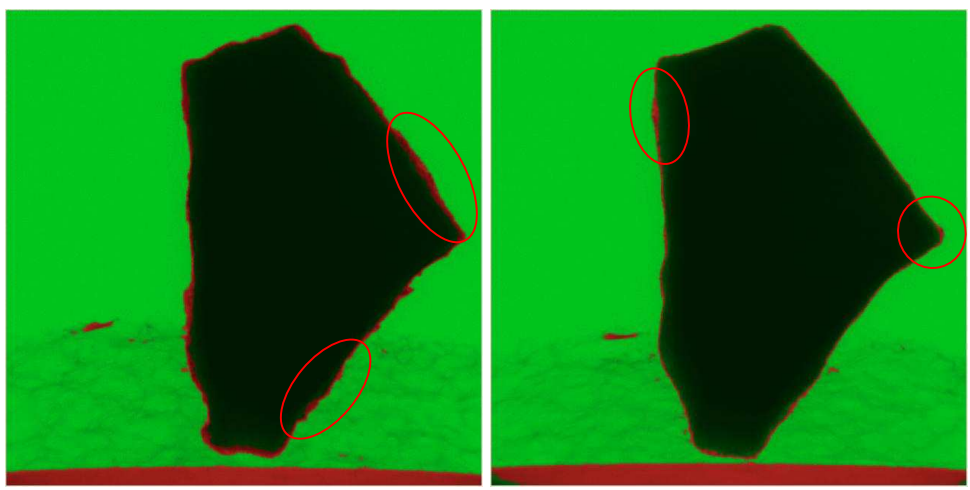
Aggregate Image Analysis

Ten new coarse aggregate particles and ten RAP particles were randomly selected for X-ray scanning before being mixed with virgin binder. All selected particles were taken from material retained in the 3/8" (9.5 mm) sieve. Same particles were scanned after being mixed with asphalt with and without metal powder in the same orientations and under the same conditions. Three-dimensional radiographic images of the aggregate particles were analyzed with the help of the Computerized Tomography (CT) imaging technique (Wang et al. 2004, 2008). This technique provides non-destructive three-dimensional visualization and characterization of the scanned objects and creates a series of two-dimensional cross-sectional images (slices) of the objects. Figures 3 and 4 show binary radiographic (angular) images of scanned aggregates in the same orientations. Using software capabilities asphalt binder film thicknesses were detected in the range of 15 to 760 microns.



(a) (b)

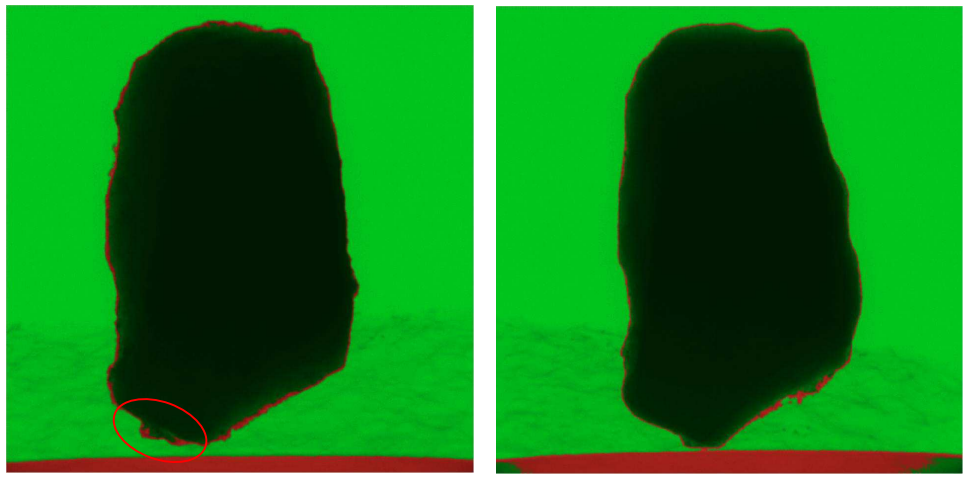


Figure 3. Binary angular images of (a) simulated RAP containing metal powder only and (b) simulated RAP remixed with virgin asphalt

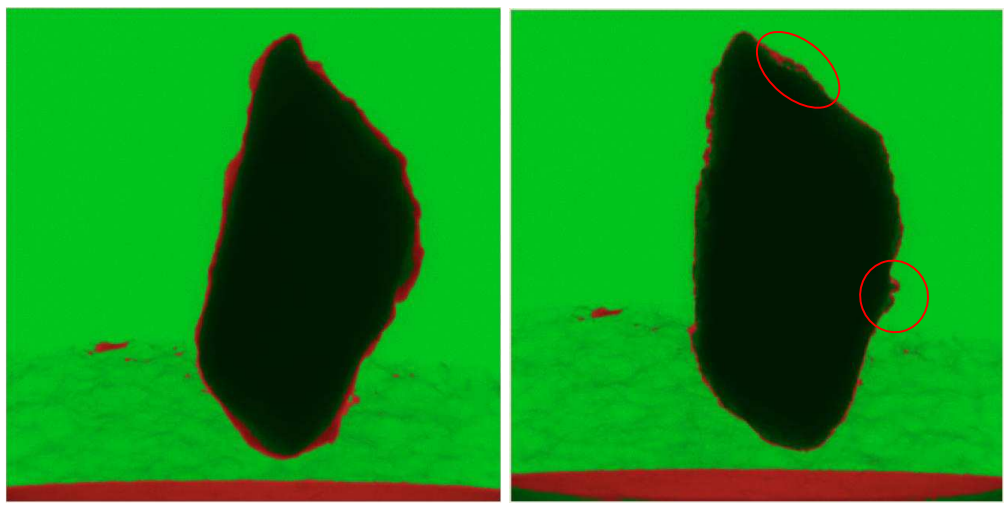
It can be observed from the figures that the asphalt binder is distributed differently on the surface of the aggregates before and after blending with virgin binder. Also, the metal powder (small black spots circled in red), has combined with the newly added or aged binder to different extents. Figures 3(a) and 3(b) picture the same aggregate particle, likewise Figure 4(a) and 4(b).



(a) (b)

Figure 4. Binary angular images of (a) actual RAP without metal powder and (b) actual RAP mixed with binder containing metal powder

Figures 5 through 8 present cross-sectional images (slices) of scanned aggregates having thicknesses ranging from 17 to 24 microns. They were acquired at three different locations, closer to the ends and from the middle of the aggregate. Their resolution is 1K x 1K. The contrast in these X-ray CT images is generated from differences in X-ray absorption which relates closely to density differences within the object. During scanning an X-rays cone beam is emitted continuously at different angles and after it has passed through the object the strength of the rays are measured

with a detector. Different contrasts are obtained depending on how dense the material they have passed through is. A computer software subsequently calculates the relative density of the material in the scanned cross section and draws a two-dimensional image of it.

The small white spots (circled in red) in the figures below, representing the x-rays diffraction as they interact with the metal powder, illustrate that the asphalt binder from actual and simulated RAP did blend with the added binder with or without metal powder. It can be observed from Figures 5 and 6 that the new aggregate originally mixed with binder containing metal powder was coated with thicker layers of powder (50 to 340 microns) than the remixed aggregate. Smaller amounts of powder or thinner layers (12 to 72 microns) were detected close to the aggregate's surface for the remixed case. This is illustrated by the red circles in Figure 6. Thus, metal powder layers were detected in the range of 12 to 340 microns for the simulated RAP. The three slices for the two cases were selected at the same z-axis positions for each aggregate at 1K x 1K resolution.

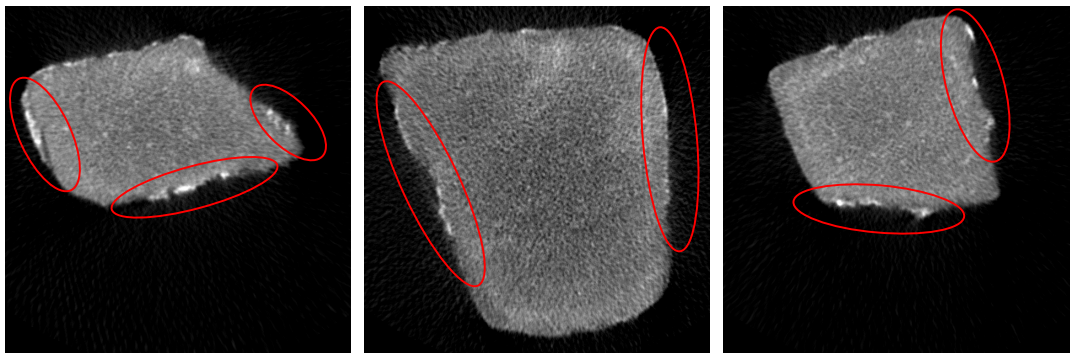


Figure 5. Simulated RAP aggregate coated with asphalt containing metal powder (white spots)

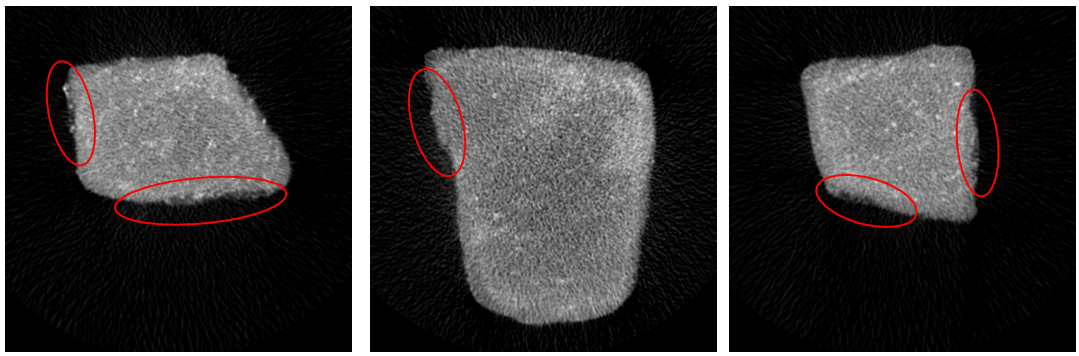

Figure 6. Simulated RAP aggregate remixed with virgin binder without metal powder

Figures 7 and 8 show actual RAP aggregate before and after being mixed with binder containing metal powder. Here also, thin metal powder layers (red circles in Fig. 8), ranging from 15 to 320 microns, have been spotted on the aggregates' surface or in its vicinity, meaning that the aged and virgin binder have combined to a certain extent. In this case, the bright (white) layers only can be observed on the actual RAP

aggregate combined with binder containing metal powder. Figures 5 and 6 present cross-sectional images of the same simulated RAP aggregate particle coated with asphalt binder with and without metal powder, while figures 7 and 8 show images of the same actual RAP aggregate particle before and after it was combined with virgin binder containing metal powder. Cross-sectional images were acquired at same height (z) position.

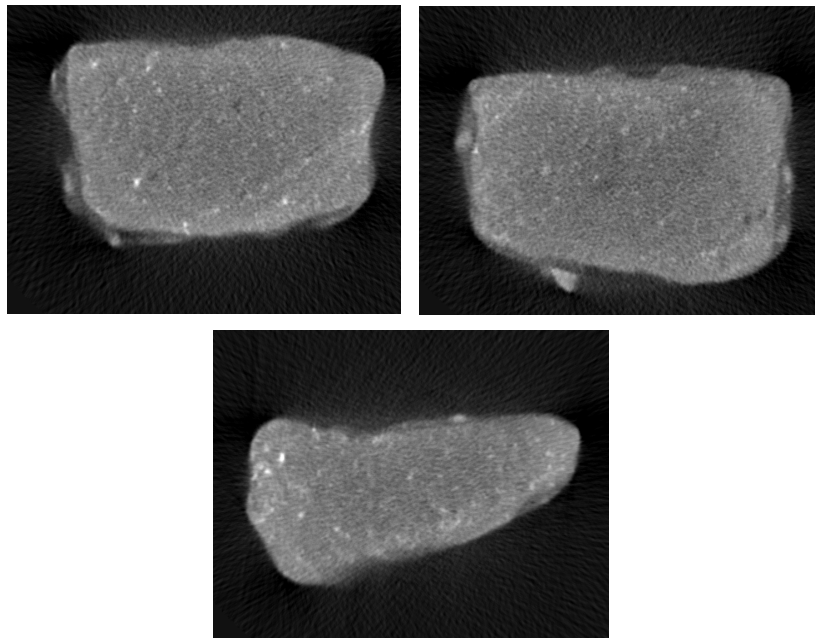

Figure 7. Actual RAP aggregate without metal powder

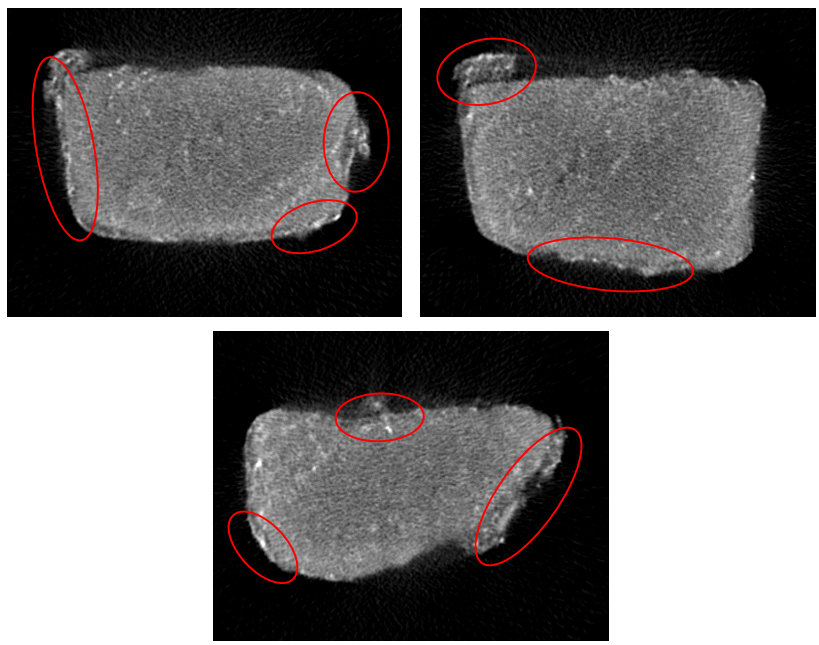

Figure 8. Actual RAP aggregate mixed with binder containing metal powder

SUMMARY AND CONCLUSIONS

This small study was conducted to investigate the blending of actual and simulated RAP binder with virgin asphalt binder with and without metal powder. One type of screened RAP and one type of new aggregate - limestone - were blended under pure mechanical blending along with the binders. It was discovered that partial blending apparently occurred to a certain extent, but it could not be determined if more blending took place in the case of simulated RAP compared to the actual RAP material. Computed tomography images presented in this paper represent only the materials under the test conditions in this study. It should also be mentioned that the mixtures in this study may not reflect the majority of mixtures used by the HMA industry. Additional research investigations are needed to cover a wide variety of materials under various conditions and combinations.

ABSTRACT

Ultra-High Performance Fiber Reinforced Concrete (UHPFRC), characterized by its outstanding mechanical and ductile performance, have received significant attention recently in the construction. In this paper, curing of UHPFRC cubes and prisms at 20^{o}C and 90^{o}C has been investigated to quantify the differences in both mechanical and ductile performance within the age of 91 days. The results shows that specimens cured at 20^{o}C gives approximately 20%, 10% and 15% lower performance in compressive strength, flexural strength and fracture energy than specimens cured at 90^{o}C, respectively. However, the 20^{o}C-cured specimens not only achieve above 120MPa, 20MPa and 18kJ/mm^2 in compressive strength, flexural strength and fracture energy, but also show advantage in maintaining flexural resistance in the ductile deformation. The results of the research demonstrate the feasibility of in-situ concrete placement and construction of UHPFRC.

INTRODUCTIONUltra-High Performance Fiber Reinforced Concrete (UHPFRC), demonstrates comprehensive high performance in workability, mechanical and durable behavior in the construction. The UHPFRC mix improves the homogeneity by using sand with particle size between 0.15 and 0.6 mm, increases the density by using silica fume as partial cement replacement and improves the ductility by integrating high-quality steel fibers (Richard 1994-96, Soutsos 2005). The current definition of UHPFRC is that the slump, the compressive strength, the flexural strength and the fracture energy are greater than 240mm, 100MPa and 15000 J/mm^2, respectively (Pu 2004, Zhao G. 2004, Chanvillard 2003). In recent years the UHPFRC has been successfully applied to dam repair, bridges, laying pavement, as well as high-level structures (M. E. Schmidt 2005, V.C. Li 2004).

The heat-curing procedure of UHPFRC is used in order to improve the microstructure, reduce curing time and increase early strength (P. Richard 1994, M. Cheyrezy 1994, Z. Helene 1996, T.T. Le 2007, S. Liu 2003, M. Urs 2008). However, it is not only energy-consuming and costly but also restricts the fabrication of UHPFRC products to pre-casting factories. Normal temperature curing would be expected to reduce the early aging material properties, but the increase in usability and the actual long-term material properties may still be sufficiently high. The

comparison of mechanical performance of UHPFRC with and without elevated temperature curing, which could lead to this material being used for in-situ construction instead of factory fabrication, is not yet to be available in the relevant literature. In this paper, the UHPFRC with 0.15 water/binder ratio was produced with steel fiber, polycabonxylate-based superplasticizer and two types of building sands with different maximum particle sizes. Cubes and bending specimens of UHPFRC were tested within the time interval of 91 days (7, 28, 56, 91days) to determine the influence of curing regime on the mechanical performance including compressive strength, flexural strength and fracture energy, and the experimental results shows the possibility of extending UHPFRC from pre-casting factory to the in-situ pouring construction.

MATERIALSPortland cement (52.5N CEM I) and two types of supplementary cementitious materials were used in this study, i.e. ground granulated blast-furnace slag (GGBS) and silica fume (SF). The chemical and mechanical properties of cement, GGBS and SF used in this study are shown in Table 1.

Table1. Chemical and Mechanical Properties of Cement, Silica Fume (SF) and Ground Granulated Blast-furnace Slag (GGBS)

		Cement I 52.5N	SF	GGBS
Chemical composition（%）	SiO_2	18.7	93.1	35
	Al_2O_3	6.3	0.9	12
	Fe_2O_3	3.2	2.0	0.2
	CaO	64.7	0.4	40
	MgO	0.7	1.2	10
	Na_2O_{eq}	0.13	0.3	-
	SO_3	3.1	0.3	-
	Cl^-	0.025	0.09	-
Physical property	Bulk density (kg/m^3)	1200	321.3	1050
	Specific surface (m^2/kg)	460	20000	470

Two types of building sands, Fine Ordinary sand–type I (FOS-I) and Fine Ordinary Sand-type II (FOS-II) were used and Figure 1 shows the particle shape and distribution of FOS-I and FOS-II. The superplasitizer used in this study was polycarboxylate-based, and the steel fibers (BS EN 10016 Part 1) are made using high carbon steel with a tensile strength of 2000MPa and each fiber is coated with brass and is 0.2mm in diameter and 13mm in length.

SPECIMEN PREPARATION The mix design is shown in Table 2. The steel fiber content in UHPFRC is 2% by volume of the total mixture (A. Oner 2007). Use of the polycarboxylate-based superplasitizer enabled a water-binder ratio of 0.15 to achieved, which met the low water requirement of UHPFRC (P. Richard 1995, G. Chanvillard 2003).

Table 2. Mix Proportion of UHPFRC

Cementitious component(level of cement replacement) (kg/m^3)			Aggregate sand (kg/m^3)	Water-binder ratio	Superplasticizer(% solid by weight of binder)
Cement	GGBS	SF			
657	429.8 (35%)	119.4 (10%)	1050	0.15	1.05%

Two groups of UHPFRC specimens were investigated using FOS-I and FOS-II. In each group specimens were cast comprising 50mm cubes for compressive strength (BS EN 1881 Part 116) and 50x50x200mm prisms for flexural strength (BS EN 12390 Part5). The 90°C-cured specimens were stored in a hot water bath from an age of 1 day until 7 days, and then stored in air at room temperature until testing. The 20°C-cured specimens were kept in a standard curing tank until testing.

EXPERIMENTAL TESTS All cube specimens were tested using a loading rate of 0.8kN/s (BS EN 1881 Part 116). The prism specimens were tested under four-point loading using displacement control and using a testing machine controlled by an external displacement transducer, such that the mid-span deflection rate of the prism specimen was held constant throughout the test. The fracture energy (P. Richard 1994) of specimens tested was calculated by integrating the area under the flexural stress versus deflection up to 1.25mm. The mechanical test schedule of UHPFRC specimens is shown in Table 3.

Table3. Test schedule of mechanical properties of UHPFRC

RESULTS AND DISCUSSION

1. Compressive and flexural strength

Figure 2 shows the compressive strength development of UHPFRC using FOS-I and FOS-II under 20°C and 90°C curing. The use of FOS-I and FOS-II had little influence on the compressive strength development. The compressive strength of UHPFRC cubes fell within the range of 160-180MPa from 7 to 182 days, while the 20°C–cured specimens achieved the compressive strength of 120MPa at 20 days and continued to increase. By the age of 180 days, the compressive strength of 20°C–cured specimens stayed at approximately 140MPa which is about 80% of 90°C-cured specimens.

Figure 3 shows the flexural strength development versus the age of UHPFRC. Under 90°C curing, the flexural strength did not change significantly with age and the mean flexural strength was approximately 24MPa. Under 20°C curing, the flexural strength increased from 20MPa at 7 days to 22MPa at 91 days, which is about 90% of 90°C cured specimens.

2. Flexural ductility

Under various curing conditions, failures of the tested UHPFRC specimens show ductile performance under flexural strength tests. Figure 4 shows typical flexural stress versus deflection curve. After crack appeared and started to propagation, fiber bridging effort across the crack section would be dominant in bearing the further loading (K. Y. Leung 1992). The transformation from linear to nonlinear increasing of flexural stress represents the tensile stress transferring from concrete matrix to fibers across the crack section. With the increasing concrete strength by the elevated curing temperature, the higher maximum linear flexural stress was achieved accordingly. After the crack section opening, the stress across the crack section continually distributed which resulted to the unsteady shape of the curve. Stress-deflection curve of 90°C-cured specimens rose faster than 20°C-cured specimens because of stronger adhesion between fiber and concrete matrix.

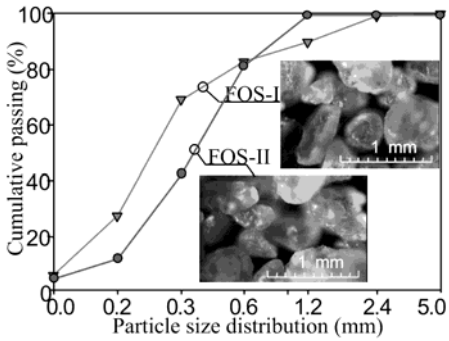

Figure 1. Particle size distribution and micrograph (50x) of the sand particles

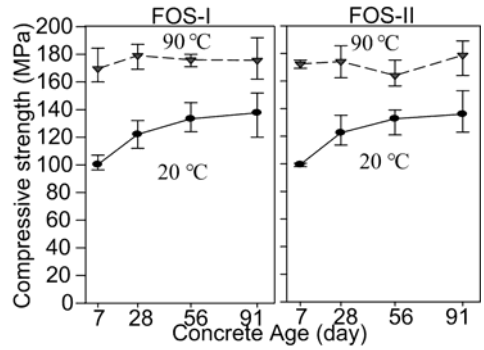

Figure 2. Compressive strength development of UHPFRC

Concrete fracture energy (P. Richard 1994), as the shaded area in Figure 4, can be regarded as the measurement of the efficiency of the fiber bridging effort (M. Cheyrezy 1994). The development of fracture energy of UHPFRC prisms versus age up to 91 days is shown in Figure 5. Although the 90°C-cured UHPFRC specimens exhibited higher compressive strength and fracture energy, the 20°C-cured specimens showed larger mid-span displacement at the peak flexural stress and better ductility at the yielding stage. As shown in Figure 4, $\delta_{20°C}$ and $\delta_{90°C}$ are the mid-span displacement at the peak flexural stress of the UHPFRC prisms cured under 20°C and 90°C, respectively. $\theta_{20°C}$ and $\theta_{90°C}$ are the flexural stress decreasing angle from the mid-span displacement δ_J to $2\delta_J$, respectively. On the whole, a general principle, i.e. $\delta_{20°C}>\delta_{90°C}$ and $\theta_{20°C}<\theta_{90°C}$, was found in all tested specimens. Figure 6a shows the development of deflection at peak flexural stress versus age of UHPFRC. The deflection at peak stress of the tested 90°C-cured specimens stayed approximately at 0.55mm while that the 20°C-cured specimens increased with age and stayed between 0.7mm to 0.75mm. Figure 6b shows the flexural stress decreasing rate from δ_J to $2\delta_J$, i.e. the tangent of $\theta_{20°C}$ and $\theta_{90°C}$ in the unit of MPa/mm, versus age from 7 to 56 days. The decreasing rate of the tested 90°C-cured specimens stayed approximately at -6MPa/mm while that of the 20°C-cured specimens decrease from -3.5MPa to

-4.5MPa from age of 7 to 28 days，it stayed approximately at -4.5MPa/mm from age of 28 to 56 days.

CONCLUSION

In this paper, experimental investigations have been conduct on the mechanical and ductile performance of UHPFRC under 20°C and 90°C curing within the age of 91 days, and the results shows:

(1) The mechanical performance of 20°C and 90°C cured UHPFRC stabilized after the age of 28 days and 7 days, respectively. Comparison of the mechanical properties from UHPFRC cured at 90°C and 20°C shows that 20°C-cured UHPFRC is approximately 20% lower in compressive strength, 10% lower in flexural strength

and 15% lower in fracture energy than that of 90°C-cured UHPFRC.

(2) The 20°C-cured UHPFRC excelled the 90°C-cured in ductility including displacement at the peak flexural stress and the post flexural stress decreasing rate.

(3) Within parameters investigations, the grading and maximum particle size of aggregate sand do not influence the mechanical strength development of UHPFRC.

Although the 90°C-cured condition leads to higher mechanical strength, the 20°C-cured UHPFRC, similar to the in-situ construction curing, could lead to a more attractive product when considering other aspects related both to economy and to the environment. A small reduction in mechanical properties from the 20°C-cured must be balanced against cost savings from high-temperature curing and pre-casting procedures.

ABSTRACT

To establish the unified description for strands in prestressed concrete girder bridges, a NURBS strands model is proposed in which Non-Uniform Rational Basic Spline (NURBS) is adopted. Prestressed strands in design and construction are analyzed, which presents the reasons for selection of NURBS as the strands model. Compared with the Fold Line Approximation Model (FLAM), the NURBS model needs fewer parameters for pre-processor and gives higher accuracy in the calculation of prestress equivalent loads and loss of tendon forces. The example using the NURBS model is fit to be a unified description method for strands in all kinds of prestressed structures.

ITRODUCTION

Prestressing effects analysis plays a significant role in design and calculation of prestressed concrete bridges. The quality of structural design, especially for statically indeterminate continuous post-tensioned concrete bridges, significantly depends on the accuracy of prestressing effects analysis. Among the three basic viewpoints or analytical ways of prestressing members, the load balancing as first introduced by Lin (1963), is the predominant method nowadays, in which prestressing is viewed as an attempt to balance a portion of the load on the members. Together with the concentrated force acting on the end of the beam, the vertical forces compose a system of external loads which can be looked upon as a separation body free from the original structure. Respectively, concentrated force is the action arising from the points of anchorage and abrupt turning of tendon, and distributed force is the action arising from curvature part. The distributed force is constant only when the profile is strictly arc because of the invariant curvature. In the actual engineering circumstances, the profiles of tendon are so complex that there are no general functions that can be used to describe them. Accordingly, mathematical modeling of tendon and its relative calculation become important for solving problems of prestressing effects analysis.

Xiao (2002) presented a model of prestressing tendon in which the geometry profile was idealized as a series of straight segments and thus called the fold-line approximate (FLA) method. Theoretically, the fold-lines approximate the original curve at the precision level of engineering and the equivalent loads are accordingly transformed from distributed forces to a series of concentrated forces. Although the

FLA is simple and directly perceived to some extent, there are several associated shortcomings including: (1) as a spatial curve, the profile of tendon is of first and secondary continuity which are lost after transforming into fold-lines and leads to some error; (2) the tedious fold-lines dividing not only increases the preprocess of calculation but also makes it hard to control the error induced from human operation; and (3) the FLA is inconvenient for alignment adjustment, especially during the repetition check in the process of structure design. The above latent defects of the FLA are not negligible according to the theory of prestressing effects analysis.

This paper introduces a spline curve instead of the PLA and offers a new model based on the Non-Uniform Rational Basic Spline (NURBS). This NURBS model, expressing geometry profile with simplicity and accuracy, is easy for evaluating equivalent loads. Through examination of numerical examples, the NURBS model is demonstrated to be a unified way for expressing prestressing tendon and one that can be applied to the actual design of structures.

NURBS MODELING OF TENDON

Engineers are initially familiar with spline functions or curves from their application in the finite strip method. In fact, spline curves can be widely used in more complex circumstances of engineering. Applying spline as model of tendon is indicated by its nature that in the actual construction the tendon is fixed on scattered locations of the duct. So the final result of construction is indeed scattered points fitting the curve of the original one no matter it is a arc curve or a parabolic curve in the working drawing. Spline, however, has been a perfect solution in the field of computer graphics (Qin 1985, Li 1998). The main reason for selecting NURBS as model of tendon is the advantage over other splines—the local modification scheme that means that changing the position of control points only affects the curve on nearby intervals. The local modification scheme provides NURBS curve with necessary flexibility that when some control points are adjusted the other part of the curve does not vary notable. This benefit offers engineers with great efficiency and accuracy for design. There are more advantages that are not stated here (Philippe 1996).

A NURBS of k degree is defined as such：

$$\overline{P}(u)=\frac{\sum_{i=0}^{n}\omega_i\vec{d}_iB_{i,k}(u)}{\sum_{i=0}^{n}\omega_iB_{i,k}(u)} \tag{1}$$

where $\omega_i, i=0,1,...,n$ are the weights，$d_i, i=0,1,...,n$ are control points，$B_{i,k}(u)$ are B-spline basis function of k-degree of point *i,* which is deduced from the recurrence formula of the point vector of B-spline basis function U= [u_0, $u1$, u_{n+k+1}] as Eq. (2).

$$B_{i,m}(x) = \frac{x - x_i}{x_{i+m-1} - x_i} \cdot B_{i,m-1}(x) + \frac{x_{i+m} - x}{x_{i+m-1} - x_{i+1}} \cdot B_{i+1,m-1}(x) \tag{2a}$$

$$B_{i,1}(x) = \begin{cases} 1, & x \in [x_i, x_{i+1}] \\ 0, & x \notin [x_i, x_{i+1}] \end{cases} \tag{2b}$$

The B-spline applied in the finite spline method is actually a special form of Eq. (1) with k = 3 and the knots distributed in uniform or equal-spacing intervals, in which there is a denominator term called uniform non-rational B-spline(UNRBS). Otherwise, it is called the Non-Uniform Rational Basic Spline (NURBS).

When modeling the tendon, it is difficult to ensure a uniform knots vector so that the fixed points in construction become even in the meaning of parameter *x*. Also, the Non-Rational B-spline cannot describe exactly the second order curves except for the parabolic ones. NURBS, however, is not limited to this constraint, and can be used to precisely express all the curves including the straight lines, second order parametric curves and any free curves. For this reason, the NURBS was defined as the unique mathematic method for geometric shape in the 1991 STEP standards for data exchange of industry products.

APPLICATION AND EXTENDING OF NURBS++

The first problem of the NURBS tendon model comes with programming since its algorithm is much more complex than regular curves. Piegl and Tiller (1996) and Shi (1994) discussed or expounded about the NURBS; while much software on CAD exhibit the ability of forming NURBS. Philippe (1996) developed a graphic library for program—the NURBS++ to facilitate the application of NURBS, which is used in this paper to model tendon. The application and extending of NURBS++ are discussed as followed.

NURBS++ is based on two basic data types, the Vector class and Matrix class, both having the powerful mathematic operation and memory to allocate functions and thus can be easily used. Based on the Vector and Matrix curves and surface classes are developed as the child class of NurbsCurve class.

Although the NurbsCurve provides functions to calculate the length of curve and the derivatives of k-1 degree, there are some variables such as curvature at any points that is needed for equivalent load of prestressing tendon and for the accumulation of angles between tendon and horizontal line used for formulating friction loss. These, however cannot be directly obtained from the functions of NurbsCurve. Therefore, it is necessary to extend the original library of NURBS++ for such purposes.

Distribution load induced by the prestressing tendon is defined as:

$$q(x) = N_y(x) \cdot \kappa(x) \tag{3}$$

where $q(x)$, $N_y(x)$, $\kappa(x)$ are the distribution load, prestressing force and curvature at coordination x, respectively. Accordingly, curvature computing actually is a procedure of getting curvature based on the first and second order derivatives of the profile line of tendon：

$$\kappa = \frac{y''x' - x''y'}{[(x')^2 + (y')^2]^{3/2}} \tag{4}$$

It should be noted that the variables x and y in the Eq. (4) are functions of parameter t while the variable x in Eq. (3) is the coordinate. To void abrupt turning of distribution load, that is to keep the second order continuity, the degree is defined as 3. When the function that executes Eq. (3) and (4) is extended in NURBS++, the calculation of distribution load of the prestressing tendon can be used to call this function.

As calculating frictional losses, the angular change of tendon from jacking end to point x is required while generally it is difficult to get as well as curvature. The curvature, however, has been solved with the above function in NURBS++. So, the angular can be gotten with Eq. (5):

$$\theta = \int \kappa(x)dx \tag{5}$$

After extending the NURBS++, the Strand class is programmed with one NurbsCurve object as its member variable and the modeling of tendon and its relative operation is built in this class.

EXAMPLES

Two examples are given here to examine the accuracy and convenience of the NURBS tendon model.

Example 1: A part of tendon is an arc with its radius R = 170 m, x∈ [-30 m, 30 m] and the prestressing force is 1000 kN, as shown in Fig. (1a). The arc is fitted with 5 dispersed points, with coordinates at (-30, -2.668)、(-15, -0.6631)、(0, 0)、(15, 0.6631)、(30, -2.668).

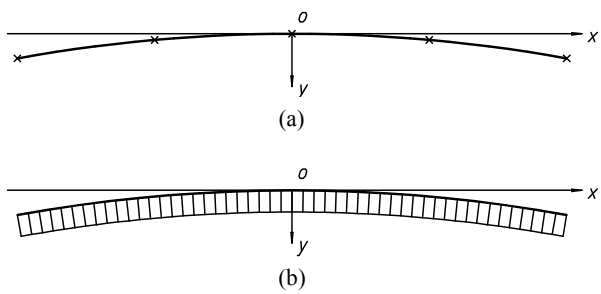

Fig. 1 Arch Tendon Profile

Figure 1(b) shows the curve fitted with NURBS++. The $\kappa(x)$ equals to 5.888×10^{-3} m^{-1}, the length of arc s is 60.316 m，and the angular θ equals 0.355 rad. Theoretically, the geometric parameters of arc are $\kappa \equiv 1/170 = 5.882\times10^{-3}$ m^{-1}，s = 60.315 m，θ = 0.355 rad.. Substituting the value of curvature into Eq. (3), the equivalent load of prestressing can be obtained as $q(x)$ =1 000$\times5.888\times10^{-3}$ = 5.888 kNm^{-1}. Compared with the result of FLA，the total concentrated force $F_y = 5.888\times60$ = 353.28 kN, the NURBS model is obviously better. The results produced from FLA and NURBS are compared in Table.1.

Table 1. Fold Line approximation and the NURBS model

Number of Knots	FLA 5	FLA 17	FLA 33	NURBS 5
Length of arc (m)	60.296	60.315	60.315	60.316
Angular (rad.)	0.2657	0.3324	0.3436	0.355
Force on nodes (kN)	883.00	22.10	11.00	—
Total force (kN)	264.90	336.00	352.00	353.28

Table 1 shows that, with the knots number increasing，the error of PLA become smaller. However, the knots number needs to be higher for the further precision. Conclusively, the NURBS model provides better precision and efficiency while needs fewer parameters than the PLA model.

Example 2: A post-tension prestressed girder bridge is of 2-span with one prestressing tendon as shown in Figure 2. The dispersed knots are expressed with "×". Considering the symmetry about axis Y of the tendon profile, only half coordinate of knots are listed in the Table 2 and the curve of tendon are fitted by the spline function using the engineering graphic software, AutoCAD. The equivalent load (only including distribution loads) is shown in the Figures 2 (a~d).

Table 2 Points coordination of the tendon

Points	1	2	3	4	5	6	7
x(m)	0.00	2.00	5.00	7.00	13	15	20
y(m)	-0.15	-0.30	-1.00	-1.35	-1.70	-1.70	1.00

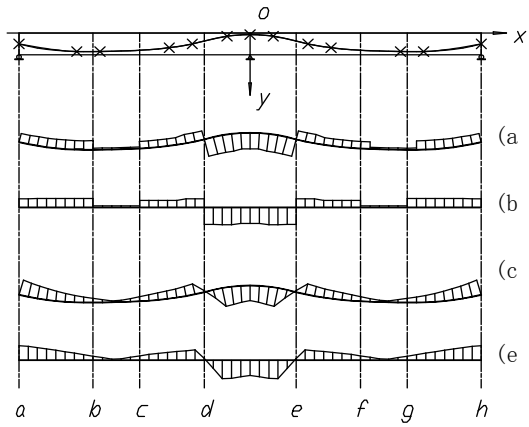

Fig. 2 Tendon with Free Profile

In Figure 2, (a) gives the second order (k=2) NURBS fitting the prestressing tendon and equivalent loads; (b) is the vertical component of (a); (c) gives the third order (k=3) NURBS fitting the prestressing tendon and equivalent loads; and (d) shows the vertical component of (c). This example adopts the second and the third order NURBS curve respectively to fit the tendon profile. Both schemes are good at the precision of lines as shown in Figures 2 (a) and (c). While on the equivalent loads, the result of the second order NURBS curve is not continuous at the points of c、d、e、f、 g, the third order curve apparently gets the continually varying distribution loads. Accordingly, it is necessary to adopt the third order NURBS to obtain reasonable result.

CONCLUSION

In this paper, numerical model of prestressing tendon is discussed and a new one—NURBS model is presented, which provides better precision and much efficiency than the PLA method. It is believed that the NURBS model is especially suitable for the analysis of the post-tensioned prestressing girder bridges. Through extending the library NURBS++, this model is conveniently available in the program. Further, for the flexibility in any plane and spatial curves, the NURBS model can be applied for analyzing more complex structures such as the curve girder prestressed bridges and circle shape prestressing tendons and thus can be used as an unified description method.

Abstract

This paper focused on developing pavement formance model for the pavement maintenance of expressway in Northwest of China. It included traffic analysis, identification of typical pavement distresses, and pavement performance evaluation. There were three primary distresses in these expressways, transverse cracking, potholes, and rutting. The performance index and pavement performance evaluation model were developed suitable for expressway maintenance in Northwest. The model was evaluated using fuzzy mathematics. In conclusion, the modeling results agreed with expert evaluation.

Keywords: expressway, asphalt pavement, distress, maintenance, method

Foreword

China began to construct expressway since the 1970´s when it has been common in America and Europe. On Dec.31, 1988, the first expressway from Shanghai to Jiading was opened to traffic. This section of expressway was 18.5 km in length. From then on, the expressway mileage has increased rapidly. There were about 5.4×10^4 km expressway in China by the end of 2007, after 20 years' rapid development. The total length was about 6.03×10^4 km by the end of 2008(China Highway Magazine Agency.2005), which put China in the second position in the world. The freeway network will reach 8.5×10^4 km by 2020, which will be close to that of USA in terms of total mileage, according to "The Plan of National Expressway Network". China plans to construct significant amount of motorways for next decades .

Under the repeated vehicle loads and the environmental impact, the performance of expressway pavement deteriorates in terms of pavement strength, stiffness, stability, roughness and anti-skid ability. The serviceability and life of pavements will be severely affected if the distresses cannot be repaired as needed. This study focused on the maintenance of expressways in the Northwest of China.

1 Performance Evaluation of In-service Expressway

1.1 Traffic

Based on investigation, the traffic consisted of about 32.3%, 28.2 and 18.0% trucks, trailers and cars, respectively. More than 70.7% of trucks were overloaded by 100-200%. Overloading is common in the Northwest of China, due to its abundant natural resources, especially coal. Heavy traffic, especially overloaded trucks, was the major reason of the pavement distresses.

1.2 The typical pavement distress

The expressway asphalt pavement were investigated in terms of distress types and causes, factors affecting performance, maintenance conditions, traffic, geotechnical conditions, and

climate in the field. It was concluded that there were three primary distresses in expressways, transverse cracking, potholes, and rutting.

1.3 Field investigation

The basic cross section of a typical Northwest expressway consists of 2 lanes, one lane for one direction. The lane width is 3.75m, with 3.0m shoulder. For every 1000m within the stationing between k83 and k56, 22 sections were selected for field investigation. The results are shown in Figures 1～4.

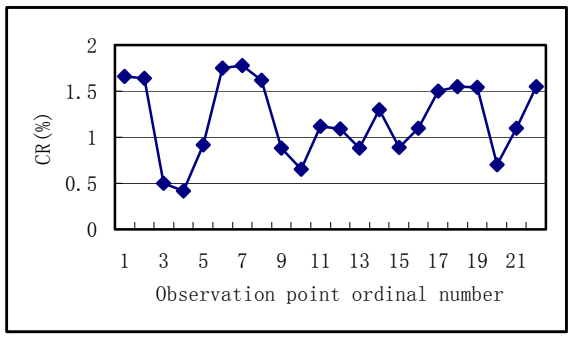

Figure 1. Survey data of transverse cracking.

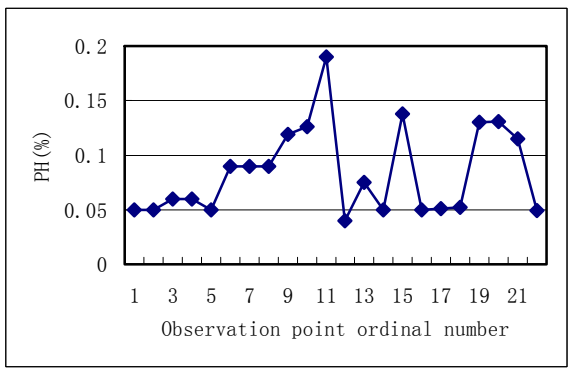

Figure 2. Survey data of potholes.

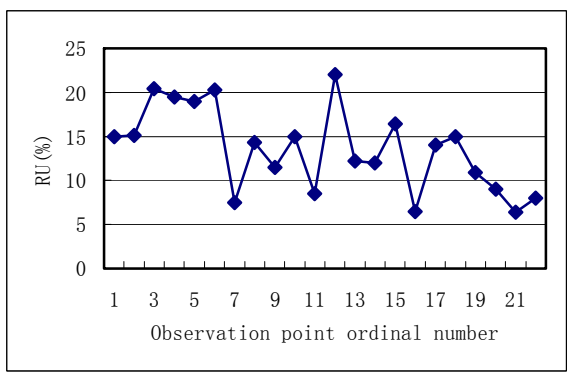

Figure 3. Survey data of rutting.

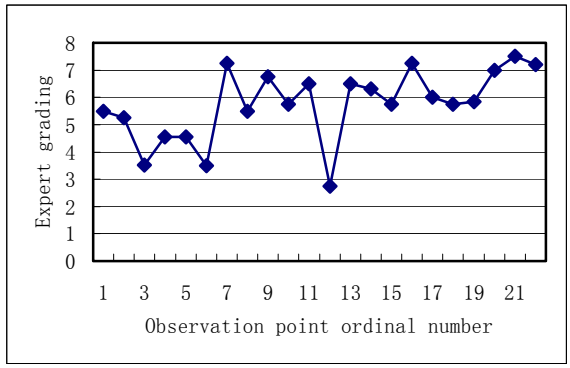

Figure 4. Result of expert grading.

2 Pavement performance evaluation model

The first pavement performance evaluation model was based onpresent serviceability index (PSI) and was developed by the American Association of State Highway Transportation Officials (AASHTO). PSI is essential to the development of pavement maintenance techniques and pavement management systems. Many countries have developed their own models, based on PSI. A pavement performance evaluation model was developed for the expressways in the Northwest of China in this paper.

2.1 Factor selection

The progression rates of transverse cracking, potholes and rutting were selected as primary factors in the model.

2.2 Grading method

The expert system was also used in this study, based on ten-point system. The results were showed in Table 1.

Table 1. Description of Expert System.

Score	Grade	Road condition
10~8	excellent	very smooth
8~6	fine	no or little distresses and smooth
6~4	medium	little distress and rough
4~2	second	some distress, discomfort and very rough
2~0	poor	severely distressed

2.3 Modeling

Equation 1 was selected as the model, based on the three typical distresses.

$$PCI=f(CR, PH, RU) \qquad \text{(Equation 1)}$$

Using multi-variable regression analysis, Equation 1 can be rewritten as Equation 2.

$$PCI=\alpha_1+\alpha_2 f(CR)+ \alpha_3 f(PH)+ \alpha_4 f(RU) \qquad \text{(Equation 2)}$$

Where PCI is pavement performance index, CR is transverse cracking damage rate, PH is potholes damage rate, and RU is rutting damage rate.

Single-variable regression analysis was conducted using different functions like $y = a + bx$,

$y = ae^{bx}$, $y = ae^{\frac{b}{x}}$, $y = ax^b$, $y = a + b\ln x$, $y = a + b\ln(x+1)$, $\frac{1}{y} = a + \frac{b}{x}$,

$y = b(x-c)^2 + a$, $y = \dfrac{1}{a + be^{-x}}$, $y = a + b\sin x$, $y = a + b\cos x$, $y = a + b\tan x$ and so on.

Correlation function between expert grading and survey data are showed in Table 2.

Table 2. Correlation function between expert grading(M) and survey data.

Variable(%)	function	correlation coefficient
CR	$M = 5.6723 + 0.0317\tan CR$	0.2534
PH	$M = 6.9206e^{\frac{-0.0151}{PH}}$	0.3479
RU	$M = 7.6803 - 0.0091RU^2$	0.9640

Using $0.0317\tan CR$, $e^{\frac{-0.0151}{PH}}$ and $0.0091RU^2$ as index of multi-variable regression analysis (Wang Binhui.2003), the results are shown in Table 3.

Table 3. Result of non linearity multi-variable regression analysis.

variable (%)	regression equation	correlation coefficient
CR/RU	$M_1 = 7.6535 + 0.0049\tan CR - 0.0091RU^2$	0.9647
PH/RU	$M_2 = 7.6243 + 0.3373e^{\frac{-0.0151}{PH}} - 0.0092RU^2$	0.9642
CR/PH	$M_3 = 6.8316 + 0.0382\tan CR - 5.3820e^{\frac{-0.0151}{PH}}$	0.4491
CR/PH/RU	$M_4 = 7.6216 + 0.0045\tan CR + 0.2058e^{\frac{-0.0151}{PH}} - 0.0091RU^2$	0.9648

Relationship between M and M_1, M_2, M_3 and M_4 are shown as Figure 1~5

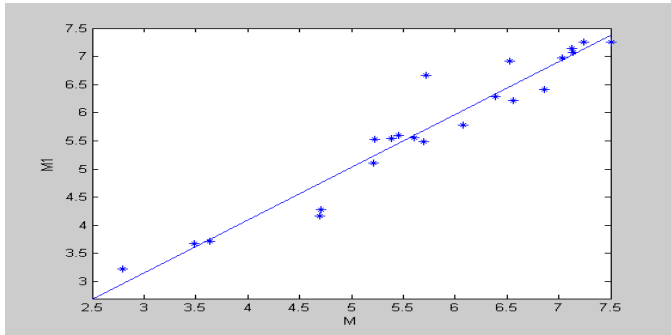

Figure 5. Relationship between M1 and M.

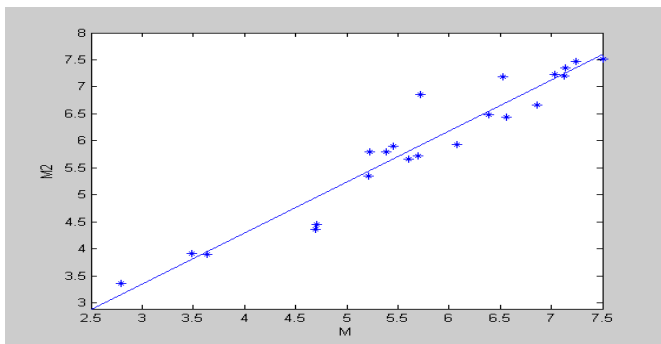

Figure 6. Relationship between M2 and M.

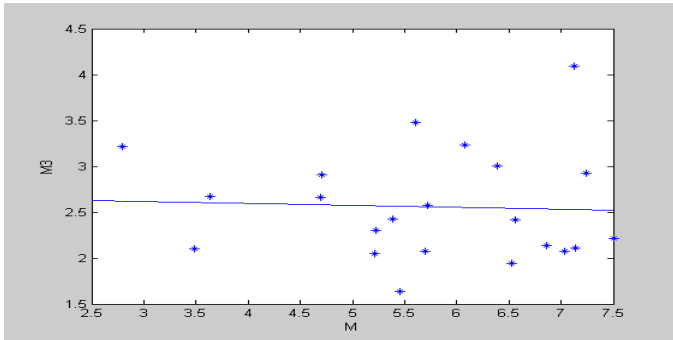

Figure 7. Relationship between M3 and M.

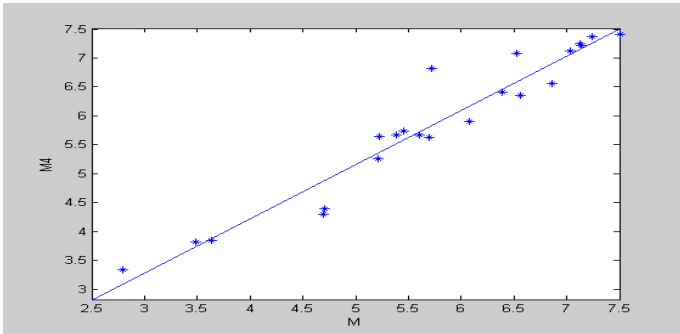

Figure 8. Relationship between M4 and M.

The highest correlation coefficient was 0.9648 between M and M_4. Therefore, M_4 was selected,

$M_4 = 7.6216 + 0.0045 \tan CR + 0.2058 e^{\frac{-0.0151}{PH}} - 0.0091 RU^2$.

2.4 Model Evaluation

Model was evaluated using fuzzy mathematics as below.

Disjoint set is, V={excellent，fine，medium，second，poor}

Result, B=0/ excellent +0.46/ fine +0.36/ medium +0.18/ second +0/ poor

Representation by fuzzy vector, B=（0，0.46，0.36，0.18，0）

The results was found to be either fine ore medium, according to μ_B=0.46 and μ_B=0.36. In conclusion, the modeling results agreed with expert evaluation.

3 Conclusion

The pavement maintenance becomes more and more important with the significant amount of construction of expressway in China. A pavement performance evaluation model was developed for the Northwest of China. The model selected was,

$PCI = 7.6216 + 0.0045 \tan CR + 0.2058 e^{\frac{-0.0151}{PH}} - 0.0091 RU^2$, which can also be used in the maintenance of non-freeway with similiar conditions.

ABSTRACT

System principle and composition including image acquisition, image processing and image interpretation for pavement crack automatic recognition based on digital image processing are presented. In order to improve crack identification rate, pavement image retrogression reasons are introduced and stochastic and complex characteristics for pavement images are analyzed. Wiener filtering theory is investigated to overcome the problem that some classical methods will weaken useful image details when restrain noise. Results show that Wiener filtering can preserve image edge information and remove some noise from non-uniform illumination, imaging systems, pavement material and grain's texture through the analysis for representative examples.

KEYWORDS: pavement non-destructive detection, Wiener filtering, digital image processing, crack recognition

INTRODUCTION

Visual rating systems are used in most pavement cracks surveys. It has disadvantages such as poor repeatability and reproducibility and it is not safe for inspectors. More recently, advances in electronic sensors and computer systems have provided the opportunity of using advanced technologies in pavement distress data collection. Existing automatic real-time detection systems focus on the low identification rate and classification difficulty (Wang et al. 2002). First, a lot of noise in pavement images caused by the road environment itself brings in recognition and classification difficulties. Second, it is lack of easy and effective identification and classification algorithm (Zhang 2004).

Pavement images contain information from road surface, the rough texture, aggregate and uneven illumination. A variety of enhanced technologies including histogram equalization, median filtering, low-pass filtering and high-pass filtering

and fuzzy technology have been applied (Chou et al. 1995, Siriphan et al. 1997, Koutsopoulos et al.1993). A different approach is proposed and discussed in this paper.

PAVEMENT CRACKS IMAGE RECOGNITION SYSTEM PRINCIPLE

The basic function of this system is shown in Figure 1. This system can be divided into three parts: image acquisition, image processing and image interpretation. Image acquisition includes the recording of the pavement distress data by a moving vehicle. Image processing includes following steps: (a) image preprocessing, i.e. reduce noise, (b) image identification (the extraction of pavement distresses in an image from the background and obtaining a binary image), and (c) image interpretation (the identification of distresses, i.e. whether a surface cracking is longitudinal or transverse, as well as their quantification, i.e. the measurement of their extent and severity).

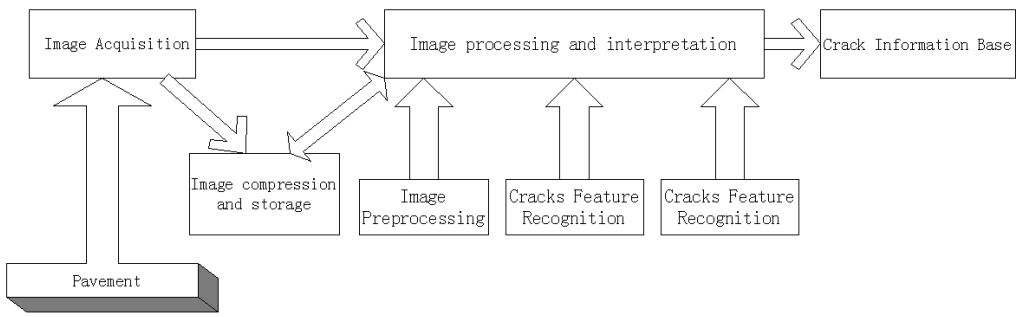

Figure 1. Pavement Cracks Image Recognition System Principle

WIENER FILTERING FOR THE IMAGE

Wiener filtering is a basic and commonly used modern filtering method. It treats minimum mean square error as the optimal standard. and the optimal estimation can be obtained by Fourier transform of the input random signal and noise auto-correlation (Ruan 2001, Yi et al. 2000).

Image filtering using Wiener filtering is to remove image noise and restore degraded images. In order to achieve this goal, mathematical expression about $\hat{f}$ must firstly be formulated to make the indicator reach a limit value. Before the accurate solutions can be solved, the estimation $\hat{f}$ of the original image f is viewed as a random variable so the image can be seen as a random process. Under normal circumstances, it can be treated as a stable random process. Assuming

covariance matrix $R_{ff} = E\{ff^T\}$ and noise covariance matrix $R_{nn} = E\{nn^\tau\}$ of image are known, a linear filtering approach is selected to estimate $\hat{f}$ to make $E\{\|f - \hat{f}\|^2\}$ the smallest. It can be achieved to

$$\hat{f} = R_{ff} H^T (HR_{ff} H^T + R_{nn})^{-1} y \tag{1}$$
