
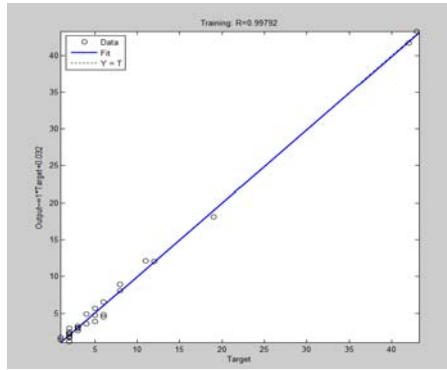

Figure6. Output error of the model. **Figure7. Output fitness of the model.**

The error training result and the target fitness are shown as Figure 7 and Figure 8, and the forecast results are shown in Table 4. The actual and the forecasted value match well. For example, the opposite error is 0.00599% for the first testing stylebook which shows that the model can better analyze the relation of the conflict reasons and the conflict accounts.

Table 4. Comparison between the actual value and the forecast value.

Number of testing stylebook	①	②	□
actual value(times)	43	42	44
the forecasted value(times)	43.2579	41.6871	43.7568
opposite error（%）	0.00599	0.00745	0.00553

5 CONCLUSIONS

(1) The fuzzy cluster analysis results indicate the conflict between through bicycles and right-turning motors is the most representative at grade intersection.

(2) The failure tree analysis results show that the minimal cut sets of the conflict between through bicycles and turning motor vehicles has thirteen patterns.

(3) The fuzzy neural network model of the vehicle-bicycle conflicts at grade

intersections is established, and the analysis results indicate that combination of the failure tree and fuzzy neural network can better analyze the relation of the conflict reasons and the conflict accounts.

Research on the Prediction Model of Traffic Accidents Using the Least Square Support Vector Machine

Zhang Wei-hua, Sun Qian and Sun Hao

School of Mechanical and Automotive Engineering, Hefei University of Technology, Hefei 230009, china; PH (86)-0551-2901338 EXT 2512; FAX (86)-0551-2903450; email:ahweihua@163.com

ABSTRACT

This paper analyzes the advantages of the least square support vector machine in the prediction of traffic accidents, decided the set of input vectors and output vectors and then established the model of prediction of traffic accidents by the use of the least square support vector machine. During the course of predicting, the related data of nationwide traffic safety from 1953 to 2006 was divided into the training set and the testing set and was simulated by the use of MATLAB7.0. The specific parameters of the model were gained by the training of the least square support vector machine. The testing set data was predicted. Predictive errors were calculated and compared with the prediction results of the support vector machine model. Simulation results represented that the model of prediction of traffic accidents based on the least square support vector machine had lower computational cost and higher predictive accuracy than the neural network prediction model and the support vector machine model.

INTRODUCTION

Recently our country's basic construction installation approached perfection. The substantial increase of automobiles owned and passenger turnover quantity impelled economic development, while it also brought negative impacts such as the problem that the traffic accident rate is at a high level should be urgently solved.

Generalizing and analyzing the related data of traffic safety in former years and then finding the internal laws of the traffic accident occurrence, at last forecasting the future conditions of traffic accident occurrence could provide related basis for policies of the traffic management department and have important significance.

Traffic accident prediction methods are many such as regression model methods, analysis hierarchy process (Yuan Wei, 2007) and so on. The flaws of those methods are that the models could not voluntarily adjust based the data differences when data regression and therefore prediction results are not precise enough. At present the methods which have a voluntary adjustment function are widely used for regression forecasts such as neural network models. However, the neural network model depends on the quality and quantity of learning data and could not dominate

convergence excessively; therefore prediction speed and effect are not perfect.

The support vector machine (hereinafter shortened as SVM) is a kind of realization method in the application of statistics theory that can solve the practical problems of small sample size, nonlinearity, high-dimension, local minimum (Vladimir N.Vapnik, 1999; Kim,2003) and so on by the use of a structural risk minimization standard based on risk minimization. Compared with the standard SVM, the least square support vector machine (hereinafter shortened as LS-SVM) regression performances are better and the calculation results are more precise. LS-SVM has a very obvious advantage of possessing the road traffic safety.

This paper establishes the traffic accident prediction model by the use of LS-SVM and gained the simulation results in order to validate the result by the use of related data of nationwide road traffic safety from 1953 to 2006.

LS-SVM PREDICTION MODEL OF TRAFFIC ACCIDENT

The choice of input vectors set and output vectors set. The reasons for road accident occurrence are various and therefore have randomness. People, vehicles, road conditions are the basic factors that influence road traffic safety. This paper chose nationwide highway mileage, motor vehicle population, population, passenger turnover volume and freight turnover volume as the input vectors set of accident prediction model by the integrative analysis of road, people, vehicle and environment factors.

The output vector that reflects the level of traffic safety sufficiently, therefore has three characteristics (GuoYing-shi, 2006): measurability, representativeness, comparability. This paper used three synthetic evaluation indexes including number of deaths, number of injured and number accidents in order to evaluate the traffic safety level.

The establishment of the LS-SVM traffic accident prediction model. For the known data vectors $\{x_j, y_j\}_{j=1}^{N}$ in N years (this paper used the relevant data from 1953 to 2006), input vector set $x_j = \{x_j^1, x_j^2, x_j^3, x_j^4 x_j^5\} =$ {highway mileage, motor vehicle population, population, passenger turnover volume and freight turnover volume}, as $x_j \in R^5$. The output vector set is the evaluation indexes of number of deaths, number injured and number of accidents as $y_j \in R$.

$$y_j = f(x_j) + e_j \qquad (1)$$

Where $f(x_j)$ is fitting value, e_j is deviation of fitting value and practical value.

Defining nonlinear mapping $\varphi(\cdot)$, relative data of nonlinear in (1) is mapped

from original space to character space $(\varphi(x_1),\varphi(x_2),\cdots\varphi(x_N)$, original nonlinear model is translated into linear model of character space，as LS-SVM model ：

$$f(x_j)=w^T\varphi(x_j)+b \qquad (2)$$

Where w, b are parameters which need to be identified in the model.

The parameters which need to be identified in (2) are processed by the use of the structural risk minimum standard：

$$R=\tfrac{1}{2}\left\|\vec{w}\right\|^2+\gamma * R_{emp} \qquad (3)$$

Where γ is regularization parameter, R_{emp} is the loss function.

Based on the prediction model of LS-SVM traffic accidents, loss function is chosen quadratic error as $e_j^{\ 2}$ in objective function, expression of optimal estimation function is：

$$J=\min\frac{1}{2}\vec{w}^T\vec{w}+\gamma\sum_{j=1}^{N}e_j^{\ 2} \qquad (4)$$

The constraint condition is:

$$y_j=w^T\varphi\left(x_j\right)+b+e_j\ \ j=1,2,\cdots,N \qquad (5)$$

From lagrangian function solution (4)，by the basis of KKT condition (Flake, 2002; Deng Nai-yang, 2004), the partial derivative of the lagrangian function is deduced ：

$$\vec{w}=\sum_{j=1}^{N}\alpha_j\varphi(\vec{x}_j);\ \ \sum_{j=1}^{N}\alpha_j=0$$

$$\alpha_j=\gamma e_j;\ \ \vec{x}^T\varphi(\vec{x}_j)+b+e_j-y_j=0 \qquad (6)$$

The kernel function is defined by the basis of Mercer condition (Zhang Xue-gong, 2000). This paper chose the Gauss radial machine kernel function ：

$$K(x,x_i)=\exp\left\{-\frac{\left\|\vec{x}_j-\vec{x}_v\right\|^2}{\sigma^2}\right\} \qquad (7)$$

Where $\left\|\vec{x}_j-\vec{x}_v\right\|^2=\sqrt{\sum_{k=1}^{5}(x_j^k-x_v^k)^2}$， σ is the kernel width.

（7）is substituted into（6），the optimization problem is translated into the solution of a linear equation：

$$f(\vec{x}_v)=\sum_{j=1}^{N}\alpha_j\exp\left\{-\frac{\left\|\vec{x}_j-\vec{x}_v\right\|^2}{\sigma^2}\right\}+b \qquad (8)$$

Where： $\vec{x}_j$ is input data vector of the training year, $\vec{x}_v$ is input data vector of the testing year. $f(\vec{x}_v)$ is the output vector set.

The prediction model of the LS-SVM traffic accidents has been established. The output vectors of the prediction model of the number of deaths, number injured and number of accidents are different. The parameters α_j and b are calculated and then the prediction model is obtained.

TESTING THE PREDICTION MODEL OF LS-SVM TRAFFIC ACCIDENTS

The input vector set is the nationwide highway mileage, motor vehicle population, population, passenger turnover volume and freight turnover volume (data source is national statistics bureau databases), the output vector set is the set of three indexes death number, injured number and accident number from 1953 to 2006.

The normalization of whole data. The determined input and output data obtain 8 aspects, such as data unit and order of magnitude are different. If the original data are used directly, it might appear that the data in the wide scale submerges the variational data in the smaller scale and therefore the accuracy of prediction result is reduced. The calculation of the Gauss radial machine kernel function involves the vector inner-product, so excessive value might cause difficult calculation and then influence the calculation efficiency of the whole model. Based on the above analysis, 8 aspects of the data are normalized.

$$A_i^{/} = \frac{A_i}{\|A\|_2} = \frac{A_i}{\sqrt{A_1^2 + A_2^2 + \cdots + A_i^2}} \qquad (9)$$

Where $\|\cdot\|_2$ is 2-norm of vector.

LS-SVM death number prediction simulation testing. Input data and output data in 1970, 1971, 1980, 1981, 1990, 1991, 1999, and 2000 are extracted from the total samples as a testing set; the other data are the training set. They are trained and tested respectively.

Vector machine regularization parameter C and RBF kernel function parameter σ^2 should be validated in LS-SVM. This paper validated the parameter value by the cross validation method (Li Xiao-yu, 2005; Han Liu, 2004). The training set was divided into 3 parts. Samples square sum of error were calculated and validated by 3-fold cross-validation, then two of them were used to train, the other one was used to validate. The appropriate value selections were determined by the basis of the model performance on the validation set.

Make sure $C = 1500$, $\sigma^2 = 0.7$. Through training the LS-SVM, parameters

α_j and b are obtained, where $b=0.6923$, α_j are seen as in Table 1.

CONCLUSION

This paper constructs traffic accident prediction model by the use of LS-SVM, chooses highway mileage, motor vehicle population, population, passenger turnover volume and freight turnover volume as the input vectors set, death number, injured number and accident number as the output vectors set, and then makes a simulated testing based the related data of nationwide traffic safety from 1953 to 2006.

The simulated result indicates the model which this paper establishes has the follow advantages:

(1) Training speed is fast, prediction efficiency is high.

LS-SVM generalizes training problem into the solution of linear equation. Not like the standard SVM, quadratic form programming problem should be solved. Because the solution of linear equation is easier and faster than quadratic form programming problem, the solution algorithm of LS-SVM is easy. The prediction model of traffic accident which is established by the use of LS-SVM has faster calculation and higher efficiency besides the advantages which standard SVM dealing with nonlinear equation has.

(2) The prediction result of model is precise.

LS-SVM, as branch of SVM, could study the structure of problem model automatically based risk minimum principle, so the complexity and structure of model could be adjust continuously by the change of just one control parameter to ensure the stability and accuracy when prediction model of traffic accident training and testing.

ABSTRACT

In order to deal with the application problems of anti-slide pile, a new structure type of anti-slide pile called Anti-slide Pile System Composed of Arch and Truss Structure is put forward. By applying the FEM software MIDAS/CIVIL, one landslide treatment engineering example was designed to compare the top displacement with the two other kinds of conventional piles, single-row anti-slide pile, and double-row anti-slide pile in a straight line under the same forces. The results demonstrated that the displacement of this new kind of pile on the top is much smaller than the two other kinds of conventional piles. The distribution of the deformation is also more rational and controlled easily. After examined by ANSYS, Anti-slide Pile System Composed of Arch and Truss Structure is feasible, and the global stiffness of the anti-slide pile is increased significantly so that the top displacement of the pile is decreased significantly. Therefore, this new kind of pile has a wide application in landslide treatment engineering.
Keywords: Anti-slide pile, MIDAS/CIVIL, ANSYS, displacement, global stiffness

INTRODUCTION

Landslide that endangers the safety and stability of highway engineering is one of the most common styles of highway disasters. As an efficient engineering measure of landslide treatment, anti-slide pile is currently used largely in landslide treatment. However, the top displacement of the conventional anti-slide pile is too large and leads to the slop failure. According to the application and problems of anti-slide pile in highway landslide treatment, a new structure type of anti-slide pile called Anti-slide Pile Composed of Arch and Truss Structure System is put forward. By using the finite element method, the analytical results show that this new kind of anti-slide pile is completely feasible.

The Birth of Anti-slide Pile Composed of Arch and Truss Structure. Currently, there have been many kinds of structure types of anti-slide pile accommodating to highway characteristics. As for the treatment of the slope engineering, the anti-slide pile is set under the bottom of the landslide on the stable sliding and geological structure surface. Although most of the treatments are successful, there are also many problems. Greater safety reserve leads to the economic wastes. At the same time, from the aspect of the displacement and the internal force of the pile, many are greater. To increase the capability of the pile and to lower the displacements of the top as well as strengthen the stability of the pile, this paper puts forth a new kind of Anti-slide Pile Composed of Arch and Truss Structure.

Anti-slide Pile Composed of Arch and Truss Structure. The plan of Anti-slide Pile Composed of Arch and Truss Structure is circular with locking beams combined among the piles in order to increase the overall stiffness of the structure by making full use of the arch and reducing the displacement of the top of each pile as shown in Figure 1 and Figure 2.

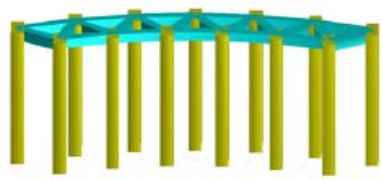

Figure 1. The structure model of anti-slide pile.

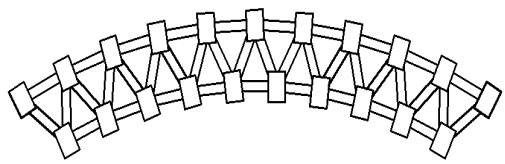

Figure 2. The layout plan of anti-slide pile.

This new kind of anti-slide pile is based on the advantages of mechanical characteristics of the arch and truss structure. The axis of the arch is circular so that the horizontal force, which is perpendicular to the way of the sliding, will exist when the arch is encountered by the thrust of the slide .At the same time, the geological conditions will be good to adapt to the horizontal force. If not, the link is also set between the two sides as shown in Figure 3.

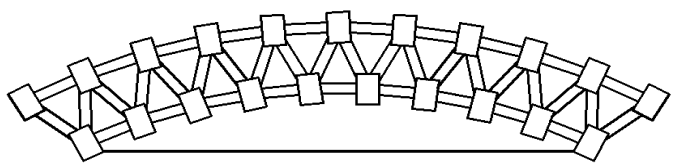

Figure 3. The layout plan of anti-slide pile with link.

Description and Design of the Engineering Sample. This paper selects the fourth slope of the HuRongXi national highway (K177 + 000-K178 + 400), which are key projects in China. The slope in this sample is like a sector (22 m × 140 m × 170 m) that has a narrow front-end and a broad tail. The volume is almost 523,600 m^3. This paper designed and calculated the single and double-row linear pile and Pile Composed of Arch and Truss Structure in order to compare the results with each other.

Single-row Straight Anti-slide Pile. In the fourth sliding slope, there are thirteen straight piles, and its section is 2,500 mm x 1,500 mm, while the spacing is 2,500 mm. The length of the pile is 28,000 mm of which 10,000 mm remains in the consolidation stage shown in Figure 4 and Figure 5. After simulated and solved by FEM software MIDAS/CIVIL, the results show that the maximum top displacement of the pile is 110 mm. It demonstrates that this straight pile is not feasible because of the large deformation on the top and will most likely slide again.

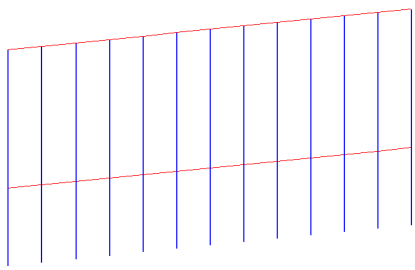

Figure 4. The model of single-row pile.

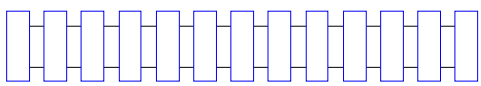

Figure 5. The layout plan of single-row.

Double-row Straight Anti-slide Pile. Getting rid of one pile in the single-row pile to enlarge the stiffness in the double-row Straight Anti-slide Pile is modeled and analyzed in MIDAS/CIVIL as shown in Figure 6 and Figure 7; however, the space increases to 4,500 mm. The results show that the top displacement is 40 mm, which is smaller than single-row Straight Anti-slide Pile.

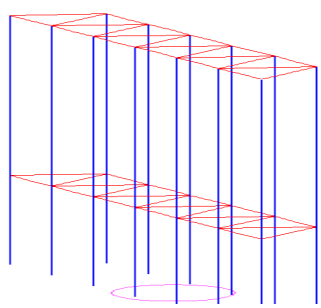

Figure 6. The 3D model of double-row pile.

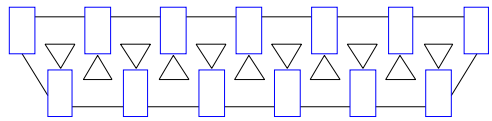

Figure 7. The layout plan of double-row pile.

Anti-slide Pile Composed of Arch and Truss Structure. The layout plan of this new kind of anti-slide pile is a circular arch that looks like the arch. According to the fourth slide, the design parameter value is in Table 1.

Table 1. Parameter value of the anti-slide pile.

Parameter	Inside Diameter	Outside Diameter	Included angle	Cross Section
Value	33800 mm	37100 mm	4°	2,500 × 1,500 mm^2

Modeled and analyzed in MIDAS/CIVIL as shown in Figure 8 and Figure 9, the results show that the top displacement is 9 mm, which is much smaller than double-row Straight Anti-slide Pile. Thus, the analysis of the model concluded that Anti-slide Pile Composed of Arch and Truss Structure has many advantages compared to other straight anti-slide piles, such as mechanical behavior, the distribution of the internal force, and top displacement.

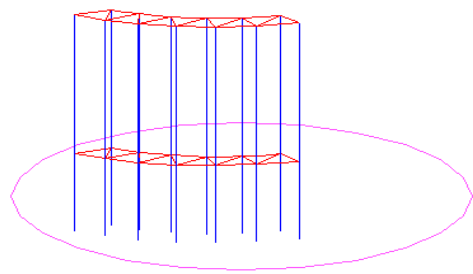

Figure 8. The 3D model of the new pile.

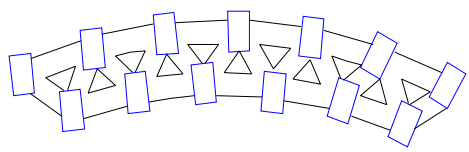

Figure 9. The layout plan of the new pile.

Checked by ANSYS10.0 (STRUCTURE). For verification the accuracy of the results above, the model and design were also analyzed in general FEM software ANSYS in order to optimize the design parameter value. To display the deformation of the pile and the soil, the 3D model would be more effective. Single-row and double-row Straight Anti-slide Pile and Anti-slide Pile Composed of Arch and Truss Structure were modeled by using the bottom to top element method.

Next, grids were generated in the way of manual and free method with quadrangle and triangles shown in Figure 10. In order to deduce the influence of stress concentration, the mesh was subdivided, especially at the key regions. At the bottom of the pile, the DOFS are all fixed in the direction of x, y, z, and at the sliding area, the direction of y was set. To simulate the force between the soil and piles, 733300N/M^2 was applied on the area of xz.

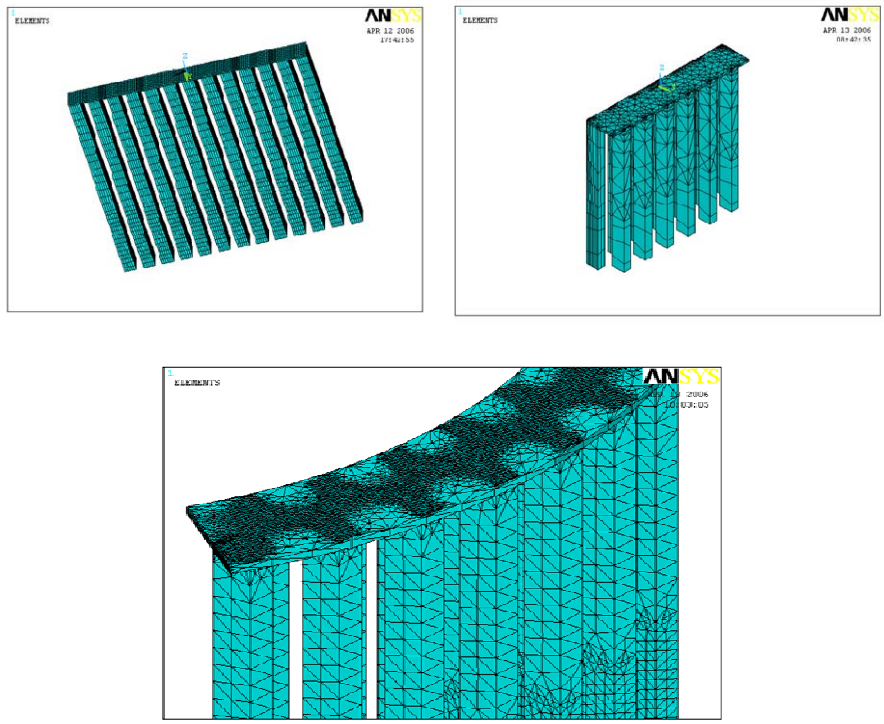

Figure 10. The mesh partition model of the piles.

After solved in ANSYS, the result shown in Figure 11 was obvious by observing the displacement contour map. By comparative analysis, Anti-slide Pile Composed of Arch and Truss Structure has the smallest displacement in the direction of y on the top of the piles as shown in Table 2.

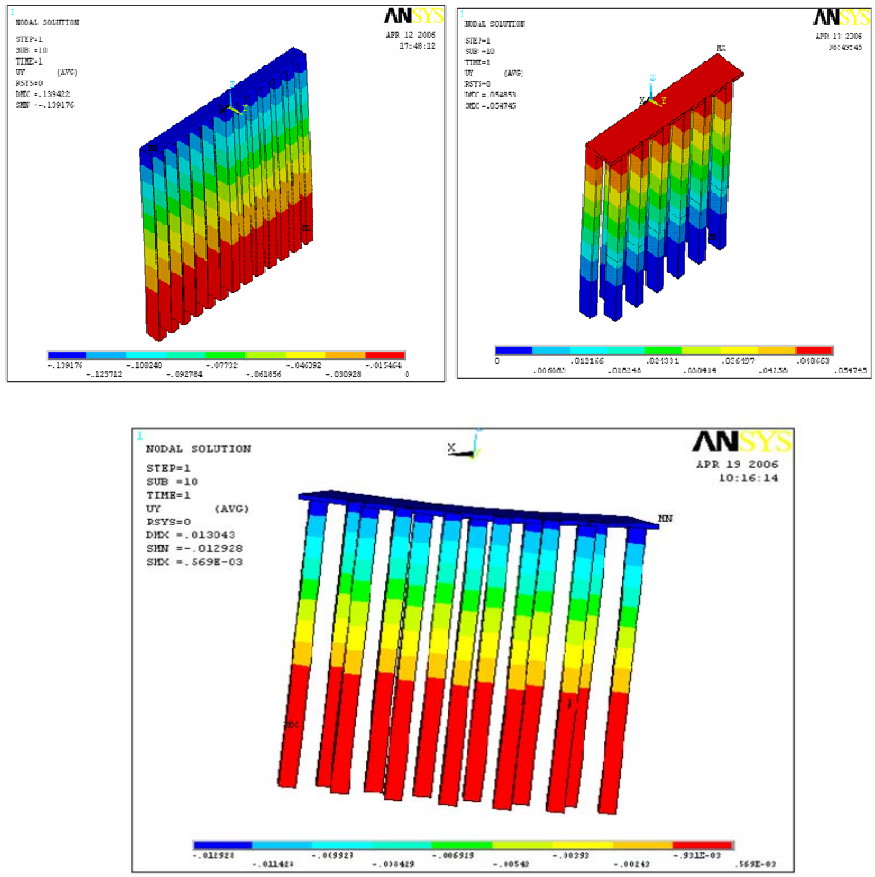

Figure 11. The displacement isoline of three kinds of piles.

As is shown in Table 2, the displacement of Anti-slide Pile Composed of Arch and Truss Structure has fallen remarkably when comparing to the other two kinds of piles. The top displacement of the double-row pile (55 mm) declined by 60% to the single-row pile (139 mm), but the new pile is more than 76% than that of the double-row pile. The distribution of the deformation along the new kind of the pile is more rational and smaller than the other side. With the existing arch and truss structure, the overall stiffness of the new pile increased so the deformation was lower than the other two conventional piles. At the same time, the turn of the arch and the pile on the top was restricted with a rigid joint in order to resist the overturn of all and create greater stability.

Table 2. The comparison of the displacement on the top of the piles.

Software	Single-row pile	Double-row pile	The new pile
MIDAS	100 mm	40 mm	9 mm
ANSYS	139 mm	55 mm	13 mm

CONCLUSION

The Pile Composed of Arch and Truss Structure has been developed and acknowledged by the FEM software MIDAS/CIVIL and ANSYS. The main conclusions are as follows: Firstly, by taking advantages of the arch and truss mechanical property to increase the overall stiffness, the planout of the pile, which is a circular arc, is reasonable and decreases the deformation of the slope. Secondly, due to considering the pile-soil effects in 3D space, the distribution of deformation along the new pile and the displacement on the top are much smaller than the conventional piles. Thirdly, the position of the new pile is diversified based on the local terrain and the geological condition for the purpose of using the advantages of the arch and truss. Fourthly, the cost of the pile, which is constructed by reinforced concrete, will greatly be reduced because of the smaller deformation accordingly. So the new pile has a wonderful prospect in highway slope treatment engineering.

ABSTRACT

This paper explores the influences of fatigue on a driver's sensation, judgment, and operating characteristics. Researching the effects of fatigue on driving has great significance for the prevention and reduction of the accidents caused by fatigue. By analyzing the influences of fatigue on driving, different methods of experimental psychological testing and investigation fatigue can be used to research the driver's sensation, judgment, and operating characteristics under different degrees of fatigue., and confirm the relationship between the driving fatigue degree and the driving characteristics evaluation after testing the indicator. This research determines the value of appraisal indicators on driving characteristics under different degrees of fatigue. The findings provide the reference basis for the related departments to constitute or revise the rules of driving time.

Keywords: fatigue degree; experimental psychology; indicator of driving characteristics; continuous driving time

INTRODUCTION

Driver fatigue easily leads to erroneous driving behavior. According to statistics, 40~70 percent of traffic accidents is due to driving fatigue (Jian 2002). In those accidents, the ones caused by perception fatigue accounted for 40.1 percent, and the accidents caused by judgment fatigue accounted for 41.5 percent. Perception and judgment fatigue of the drivers are the main reasons for accidents (Williamson and Boufous 2006). To research the impact of fatigue on drivers, propose the measurements from the aspect of technology and management are very necessary for reducing traffic accidents caused by driving fatigue. Based on the road traffic conditions, use the methods of Experimental Psychology Testing and subjective fatigue investigative methods, research the impact of fatigue on indicators of a driver's perception, and research judgment and operating characteristics after continuously driving. Analyze the changing rules of the evaluation indicators;

determine indicator's value and its evaluation degree on driving characteristics under different fatigue levels. Provide the reference basis for the related departments to constitute or revise the rules of driving time.

THE INFLUENCE ANALYSIS OF FATIGUE ON DRIVING SAFETY

Driver fatigue might easily lead to a decline in perception, judgment, and vehicle operation after long periods of driving time, and it could definitely increase the risk of traffic accidents occurring. Driving fatigue can be divided into three phases that are perception, judgment, and operation. These three phases of fatigue may impact traffic safety in different ways (Harbluk et al. 2007). Figure 1 shows the influences of driving fatigue on safety.

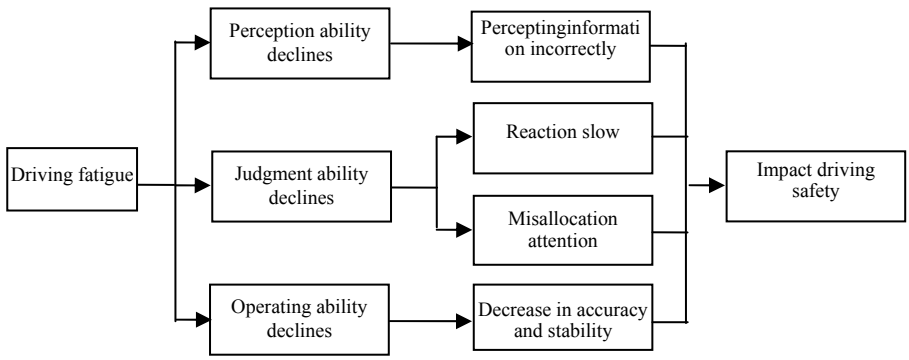

Figure 1. Influence of fatigue on driving safety.

TESTING OF FATIGUE ON DRIVING CHARACTERISTICS

Evaluation indicators of driving characteristics and experimental apparatus

Choose the experimental apparatus that can measure indicators accurately and conveniently to the best of our abilities. Compared with others, select the Experimental Psychology equipment produced from Beijing University Laboratory, shown in Table 1 (Ma and Pei, 2009).

Experimental design

The selection of survey sample

According to the smallest sample size calculation results (Summala et al. 1998), 40 drivers with good health and no history of traffic accidents were selected, among those 32 male drivers and 8 female drivers with an average age of 37 with an average driving experience of 18.2 years. Each driver should accept at least two experiments. Researchers tested a total number of 120 samples.

Table 1. Testing indicators and instruments.

Categories	Evaluation indicators	Experimental equipment
Perception	Depth perception difference	Depth perception test instrument
	Speed perception difference	Speed perception test instrument
Reaction and judgment	Choice reaction time	Visual reaction time instrument
	attention appointment	Attention appointment instrument
Operating	Number of correct optical number response	Attention appointment instrument
	Number of wrong judgment in action	Action judgment instrument

Experimental site

The experimental road is Sui-man Highway, and the section is Harbin-Daqing, which has a design speed of 120km/h. On Daqing-Qiqihar the design speed is100km/h. The traffic flow on these highways is basically in a state of freedom, so the impact of vehicle and environmental factors will be reduced. The testing vehicles were all cars.

The testing method and program

Researchers used psychological equipment to test the driver's perception, judgment, and operating characteristics in order to analyze the evaluation indicators of driving characteristics and to record the driver's subjective feeling of fatigue at the same time. Subjective fatigue is divided into five degree with the first being the most sober, and the last one is presented the highest sleepiness.

THE RELATIONSHIP BETWEEN FATIGUE AND EVALUATION INDICATORS OF DRIVING CHARACTERISTICS

Correlation analysis between fatigue and evaluation indicators

Delete the incomplete, unstable, and abnormal data and determine the available sample is 108. Calculate the correlation coefficient of variables based on the correlation analysis method of Spearman (Summala et al. 1998, Patten et al. 2006) shown in Table 2. The subjective fatigue degree can reflect the fatigue character more accurately.

The analysis of the influence of driving fatigue on driving characteristics

The influence of driving fatigue on the ability of depth reception

Researchers test the ability of depth perception on drivers with different degrees, of fatigue and analyze the relationship between fatigue degree and depth perception. Figure 2 shows these results. From Figure 2, we can see that there are

significant differences in the ability of depth perception of drivers who are experiencing fatigue to those who are not under the influence of fatigue. As fatigue increases, a driver's depth perception decreases.

Table 2. Relationship between subjective fatigue degree and testing indicators.

Testing indicators	Samples	Subjective fatigue degree	
		Correlation coefficient *R*	Significant level *P*
Depth perception	108	0.683	< 0.01
Speed perception	108	0.755	< 0.01
Choice react time	108	0.728	< 0.01
Attention appointment	108	-0.795	< 0.01
Correct operation number	108	-0.777	< 0.01
Disoperation number	108	0.779	< 0.01
driving time	108	0.875	< 0.01

The influence of driving fatigue on the ability of speed perception

The relation between fatigue degrees and the ability of speed perception of drivers is shown in Figure 3. With the increase of fatigue degree, the ability of speed perception is decreased significantly. Fatigued drivers perceive their driving speed as higher than the actual speed they are traveling. The ability of perceived speed difference of drivers in fatigue status is higher than those who are in non-fatigue status.

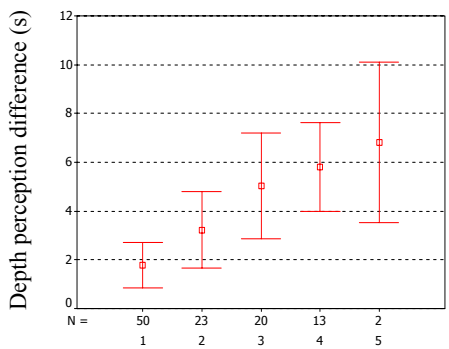

Figure 2. Relation between fatigue degree and depth perception difference.

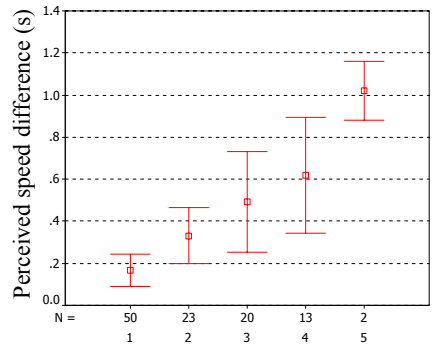

Figure 3. Relation between fatigue degree and perceived speed difference.

The influence of driving fatigue on ability of reaction

The relation between fatigue degrees and the ability of reaction of drivers is shown in Figure 4. From Figure 4, we can see that there are significant differences in the ability of drivers to react to different situations. The ability of fatigued drivers to react is significantly lower than those who are in non-fatigue status. As the fatigue degree increases, the ability of a driver's reaction decreases.

The influence of driving fatigue on ability of attention appointment

The relation between fatigue degrees and the ability of attention appointment of drivers are shown in Figure 5. From Figure 5, we can see that there was a negative correlation between the attention appointment of drivers and fatigue degree. With the increasing of fatigue degree, the ability of reaction is decreasing obviously, and there are significant differences in the ability of attention appointment under different status.

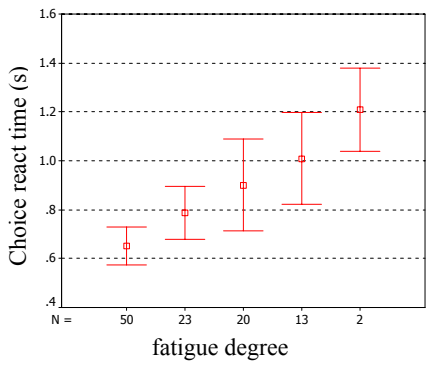

Figure 4. Relation between fatigue degree and choice react time.

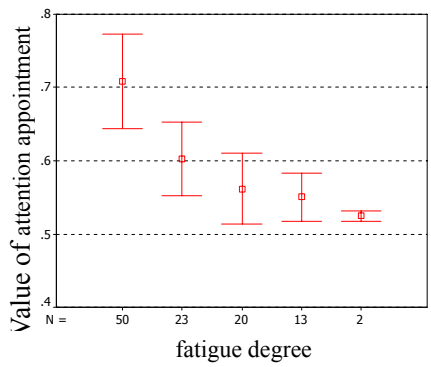

Figure 5. Relation between fatigue degree and attention appointment.

The impact of driving fatigue on correct operation number of light reaction

The relation between fatigue degrees and the ability of correct operation number of light reaction of drivers are shown in Figure 6. From Figure 6, we can see that with the increasing of fatigue degree, the correct operation number of drivers in the unit time is decreasing obviously. It is more accurate for non-fatigue drivers to complete an operation.

The impact of driving fatigue on the ability of operation judgment

The relation between fatigue degrees and the ability of operation judgment of light reaction of drivers is shown in Figure 7. From Figure 7, there are obvious differences on the ability of operation judgment of drivers. When they are in the states of fatigue, the number of disoperation decreases.

According to the method of fuzzy clustering analysis, determine the synthesis evaluation classification of driving characteristics (Ma 2007). Table 3 shows the result.

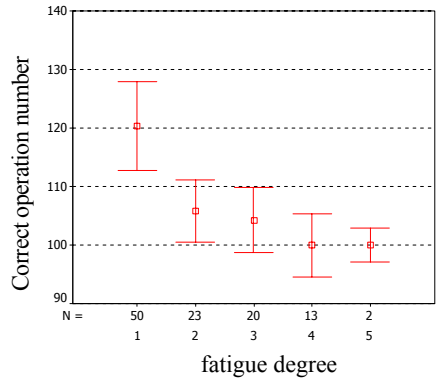

Figure 6. Relation between fatigue degree and correct operation number.

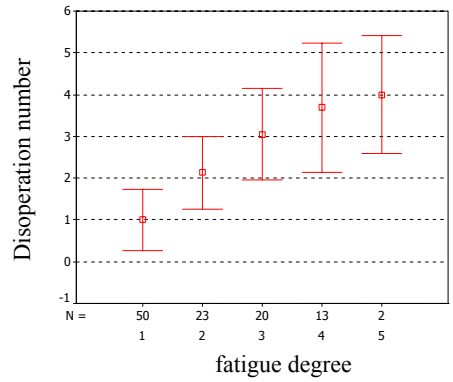

Figure 7. Relation between fatigue degree and disoperation number.

Testing indicators	Subjective fatigue degree				
	1	2	3	4	5
Driving time (min)	80	115	190	210	240
Depth perception (mm)	1.593~2.174	3.061~4.162	4.039~6.607	4.489~10.511	8.534~36.366
Speed perception (s)	0.149~0.194	0.303~0.393	0.430~0.701	0.634~1.236	0.897~2.291
Choice react time(s)	0.632~0.679	0.760~0.837	0.858~1.058	1.039~1.411	1.143~2.734
Attention appointment	0.689~0.727	0.578~0.619	0.527~0.577	0.512~0.563	0.487~0.589
Correct operation number	117.4~122.2	104.2~107.97	99.26~104.87	91.34~103.66	94.59~125.41
Disoperation number	0.78~1.18	2.08~2.64	2.65~3.85	3.45~7.55	5.32~16.71
Synthesis indicators value	0.93	0.85	0.67	0.51	0.37
Synthesis classification	Excellent	Good	General	Bad	Worse

As is shown in Table 3, the drivers' perception, choice, and operation characteristics are impacted by fatigue degree; there are obviously differences between single and synthesis evaluation classification under the same fatigue degree. If degree of subjective fatigue is between 1 and 2, the synthesis evaluation classifications of driving characteristics is in the state of good, with the increase of the fatigue degree, the synthesis evaluation classifications of driving characteristics drop gradually. When the fatigue degree is at 4, the synthesis evaluation classifications of driving characteristics is in the state of bad, and the drivers may make mistakes on speed perception, choice, and operation, all of which could easily lead to a traffic accident.

CONCLUSION

A driver's subjective can be used as driving fatigue evaluation indicators; With the increase of continuous driving time, the degree of subjective fatigue of the driver is increasing, and the general level of driving characteristics decreases gradually; When the fatigue degree is 4, the driver's driving characteristics are in a poor state, the speed of perception and ability to react are incorrect. The research of fatigue on driver's perception, judgment, and operating characteristics would provide a reference for determining continuous time and improving the regulations of driving safety.

ABSTRACT

Dilemma zone is dynamically featured both in location and length at signalized intersections. This study presents a proof-of-concept development of the innovative methodology for characterizing the dynamics of dilemma zones using video-capture techniques. With availability of ground-truth video and extracted vehicle trajectory data, various dilemma zone contributing factors, such as vehicle type, speed at the onset of yellow indication, onset acceleration/deceleration, dilemma zone behavior (pass or stop), yellow duration, and arrival type can be identified and/or quantified. More importantly, the study quantitatively distinguishes and models the risky zone and option zone, both of which constitute a dilemma zone under varied speeds and yellow durations. The paper demonstrates a significant advancement in dilemma zone data analysis and modeling, which provides a solid basis for further research on modeling the dynamics of dilemma zones and loop detectors placement for dilemma zone protection problems in the future.

INTRODUCTION

Among all possible factors contributing to vehicle collisions at high-speed signalized intersections, the yellow phase dilemma is one of the major problems that have not been fully solved yet. A dilemma zone (DZ) is defined as a roadway segment within which a vehicle approaching an intersection during the yellow interval can neither safely clear the intersection, nor stop comfortably at the stop line (Gazis et al, 1960). As is illustrated by Figure 1.a, the DZ is formed due to the minimum safe stopping distance (X_c) being longer than the maximum yellow clearance distance (X_0).

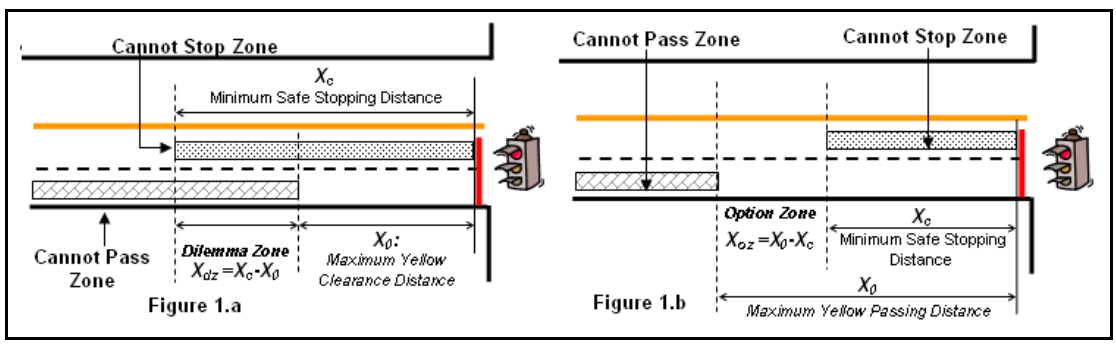

Figure 1. Formation of Dilemma Zone and Option Zone.

With existence of DZ, the drivers are exposed to a potentially hazardous condition in which a rear end accident may occur if the leading vehicle stops abruptly during the yellow interval. An angle accident may occur if the driver attempts to cross the intersection at the onset of the red interval (Pant et al., 2005). The concept of DZ along with its mathematical model, the GHM model, is further applied in the handbooks of the Institute of Transportation Engineers (ITE, 1982) for determining the safe yellow change interval. Although it is assumed that the DZ can be eliminated ($X_0 \geq X_c$) when the yellow interval is calculated based on the ITE formula (ITE, 1982), more and more researchers (Saito et al., 1990; Koll et al., 2004) now agree that even when $X_0 \geq X_c$, drivers within the range between X_c and X_0 at the yellow onset still experience indecisiveness (dilemma) about whether to pass or to stop. This range is known as the option zone (OZ), as illustrated by Figure 1.b, and has been proved to be a potential cause of intersection crashes as well.

Both DZ and OZ are dynamically featured in location and length (Moon and Coleman, 2002; Chang and Liu, 2006). This dynamics is caused due to varying drivers' aggressiveness upon seeing the yellow indication, and can be reflected by the varying values of contributing factors, such as the driver's perception-reaction time (PRT), and the acceleration/deceleration rate. Traditionally, the locations of the DZ and OZ are determined based on theoretically estimated values of these contributing factors (Pant et al., 2005; FHWA, 2006), which have been proved to be incapable of representing the DZ/OZ dynamics, and yield inaccurate DZ/OZ locations. Recently, Chang and Liu (2006) used *fixed spatial-point* trajectory data to facilitate studying the dynamic features of dilemma zone. They computed the DZ lengths based on the GHM model by using the average values of the contributing factors obtained from the trajectory data. It is a big advance in modeling the dynamic dilemma zone using trajectory data. But, computing the DZ lengths with those average factor values is still hard to reflect the DZ dynamics as well as the exact DZ locations.

This research demonstrates a novel method that uses *time-based* yellow-onset trajectories to model the dynamic dilemma zones. A video-capture-based software program VEVID (Vehicle Video-Capture Data Collector) is developed by the authors (Wei et al, 2005) to extract high-resolution (up to 30 frames per second) *time-based* trajectory data at the yellow onsets. It enables obtaining the vehicle's speed and distance from stop line at the exact instant when the signal indication changes from green to yellow. With the availability of the yellow-onset trajectories, the dilemma zone model can be calibrated based on the real driving behaviors, and reflect the exact locations of the dynamic DZ and OZ.

NEW UNDERSTANDING AND MODELING OF DILEMMA ZONE

In GHM model, the yellow interval is supposed to be used for clearing vehicles through the entire intersection (including the width of the intersection). However, based on field observations, when a driver perceives the yellow indication, he/she does not consider whether he/she could clear the intersection completely during the yellow interval. Actually, his/her concern is whether he/she could pass the stop line before the onset of the red indication. Therefore, in this study, the intersection width and vehicle's length are not considered when calculating the maximum yellow passing distance X_0.

Also, results from previous studies indicate that the values of dilemma contributing factors are not constant but vary at different approach speeds: the deceleration rate for stopping increases as the approach speed increases (Moon et al., 2003; Gates et al., 2007); the acceleration rate for passing decreases as the approach speed increases (Gazis et al., 1960); and the perception-reaction time (PRT) of drivers decreases as the approach speed increases (faster drivers reacts more quickly) (Gates et al., 2007).

Based on these understandings, the GHM model can be modified into the following equations:

$$X_c(V_0) = V_0\delta_{stop}(V_0) + \frac{V_0^2}{2 \cdot a_{stop}(V_0)} \quad (1)$$

$$X_0(V_0) = V_0\tau + \frac{1}{2}a_{pass}(V_0) \cdot [\tau - \delta_{pass}(V_0)]^2 \quad (2)$$

Where, V_0 = vehicle's approach speed (ft/s);
$X_c(V_0)$ = minimum stopping distance at speed V_0 (ft);
$X_0(V_0)$ = maximum yellow passing distance at speed V_0 (ft);
$\delta_{stop}(V_0)$ = minimum PRT for safe stopping at speed V_0 (s);
$a_{stop}(V_0)$ = maximum deceleration rate for stopping at speed V_0 ft^2/s);
$\delta_{pass}(V_0)$ = minimum PRT for safe passing at speed V_0 (s);
$a_{pass}(V_0)$ = maximum acceleration rate for passing at speed V_0 (ft^2/s);
τ = duration of the yellow interval (s).

As discussed earlier, both OZ and DZ are actually two types of yellow dilemma zones while they have different characteristics. DZ is a risky zone (RZ) that retains a hazardous chance for a vehicle happening to be located within this zone to run red, because the yellow duration is insufficient for the vehicle to safely pass the stop line while not sufficient distance for the vehicle to stop before the stop line. While not as risky as the DZ, the OZ potentially causes the driver's hesitation in the decision-making process when deciding whether stop or pass. Therefore, the dilemma zone is defined in this paper as a general concept and it is composed of risky zone and option zone, which are referred to DZ and OZ discussed in the previous section of the paper. The length of the RZ can be modeled by Equation (3), when $X_c > X_0$, while the length of the OZ can be modeled by Equation (4), when $X_0 > X_c$.

$$L_{RZ}(V_0) = X_c(V_0) - X_0(V_0) = V_0\delta_{stop}(V_0) + \frac{V_0^2}{2 \cdot a_{stop}(V_0)} - \{V_0\tau + \frac{1}{2}a_{pass}(V_0) \cdot [\tau - \delta_{pass}(V_0)]^2\} \quad (3)$$

$$L_{OZ}(V_0) = X_0(V_0) - X_c(V_0) = V_0\tau + \frac{1}{2}a_{pass}(V_0) \cdot [\tau - \delta_{pass}(V_0)]^2 - [V_0\delta_{stop}(V_0) + \frac{V_0^2}{2 \cdot a_{stop}(V_0)}] \quad (4)$$

According to the equations, it is obvious that the location of the dilemma zone is highly related to the contributing factors: $\delta_{stop}(V_0)$, $a_{stop}(V_0)$, $\delta_{pass}(V_0)$, and $a_{pass}(V_0)$. In order to determine appropriate values of these factors which reflect the real-world driving behaviors, field observations need to be conducted. And, the observed

yellow-onset trajectories can be used as ground-truth data to calibrate the dilemma zone model.

DATA COLLECTION AND TRAJECTORY EXTRACTION

The intersection of OH-4 and Seward Rd is selected as the case study site (see Figure 2), where the speed limit is 50 mph and the yellow interval is 4.5 seconds on the OH-4 approaches. In order to guarantee the full coverage of the dilemma zone, two camcorders were placed at the right of way of the eastbound OH-4 at 300 ft and 500 ft from the stop line, respectively. They were synchronized before videotaping. Totally, 6.5-hour period of traffic operation was videotaped at this location.

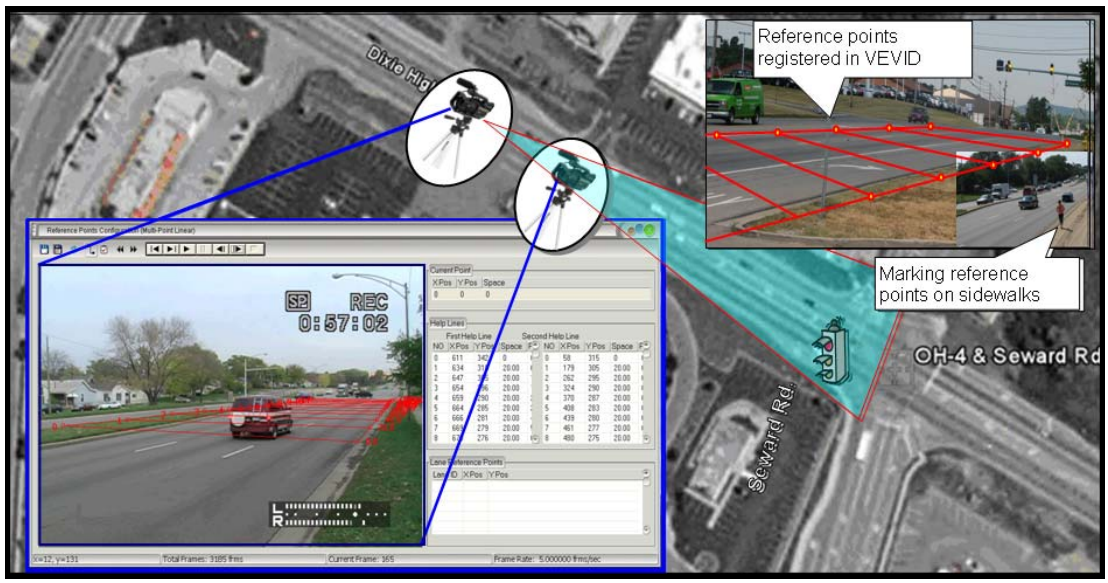

Figure 2. Video Data Collection and Trajectory Data Extraction.

In field, reference points were set up from the stop line to the position of the camcorder at a fixed spacing of 20 ft along the curbs of both sides. They were used for VEVID to convert the screen-measured distance into the real world distance (Wei et al, 2005). A chalk was used to mark those points on the curbs, and then a surveyor stepped on each mark for a short while (e.g., 5 seconds). All these actions were recorded by the camcorder.

In office, the video was played back, and the reference points were recognized and registered into the database of VEVID by identifying the surveyor's feet locations when he stepped on the marks in the video, as shown in the top-right corner of Figure 2. In VEVID, the video can pause at each exact yellow onset, and real world yellow-onset distance from the targeted vehicle to the stop line can be obtained by simply clicking the mouse over the contacting point between the rear tire (or front tire) and the pavement. With this distance, the yellow onset speed can be derived by dividing the distance interval between the frame of yellow onset and the preceding frame by the time interval. (e.g., time interval between two consecutive frames at the frame rate of 30 fps is 1/30 second).

Besides the yellow-onset distance and speed, the acceleration rate for passing and the deceleration rate for stopping were also derived and recorded. The drivers'

PRTs for stopping were recorded as well by counting the time elapsed from the yellow onset to the instant when the illumination of the brake light is observed.

During each yellow interval, only the last-to-pass (excluding those run-reds) and the first-to-stop vehicle in each through lane were targeted for extracting the trajectory data, because only these vehicles directly contribute to the formation of dilemma zone. Totally, 522 qualified vehicle samples were obtained.

MODEL CALIBRATION WITH TRAJECTORY DATA

In order to obtain the ground-truth data for the model calibration, observed yellow-onset trajectories of the first-to-stop and last-to-pass vehicles are respectively plotted on coordinate systems with the yellow-onset speed on the vertical axis and the yellow-onset distance from the stop line on the horizontal axis. Then, the ground-truth profiles of the observed minimum stopping distance X_c' and observed maximum yellow passing distance X_0' are mathematically modelled by performing regression analysis on those samples with the closest stopping distances and the furthest passing distances at various speeds, as illustrated by Figure 3 and Figure 4. The resulted relationship between X_c' and V_0 and the relationship between X_0' and V_0 can be expressed by the following equations.

$$X_c' = 0.0337V_0^2 - 0.3142V_0 + 145 \quad (5)$$
$$R^2 = 0.968$$

$$X_0' = 0.0675V_0^2 - 2.0076V_0 + 250 \quad (6)$$
$$R^2 = 0.9001$$

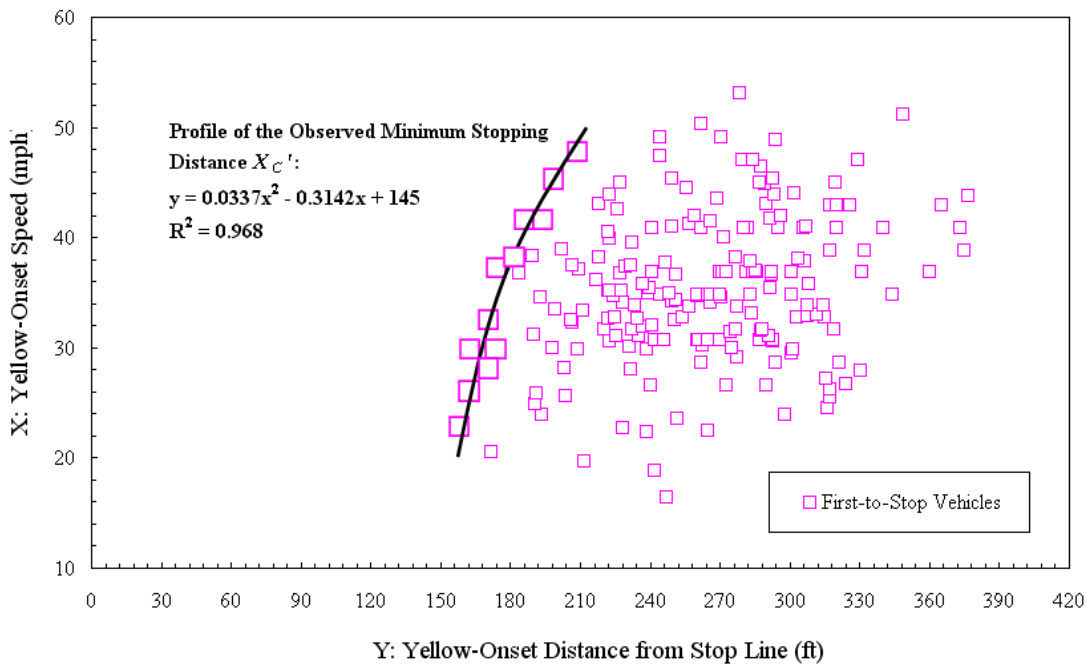

Figure 3. Yellow-Onset Trajectories and Regression Model *of* X_c'.

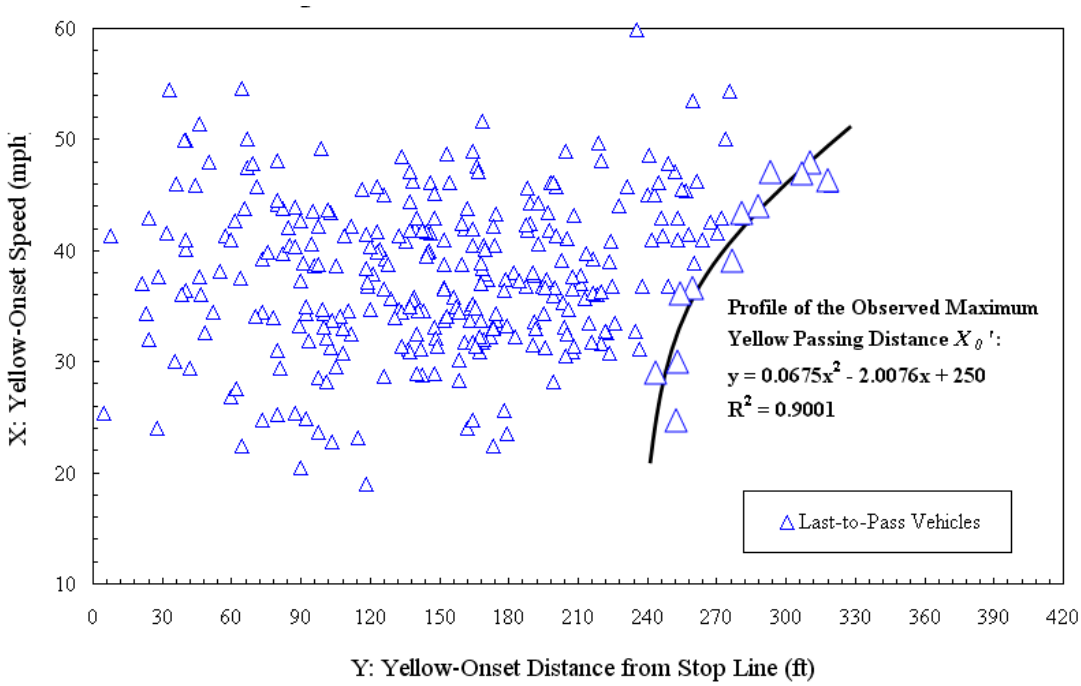

Figure 4. Yellow-Onset Trajectories and Regression Model *of* X_0'.

With the availability of the ground-truth profiles of X_0' and X_c', a process of trial-and-fit method is then employed for calibrating the X_0 and X_c models, as illustrated by Figure 5. Appropriate values of the contributing factors are obtained through fitting the modelled X_c and X_0 values (based upon Equations (1) and (2)) to the ground-truth X_0' and X_c' values (based upon Equations (5) and (6)) at each given speed.

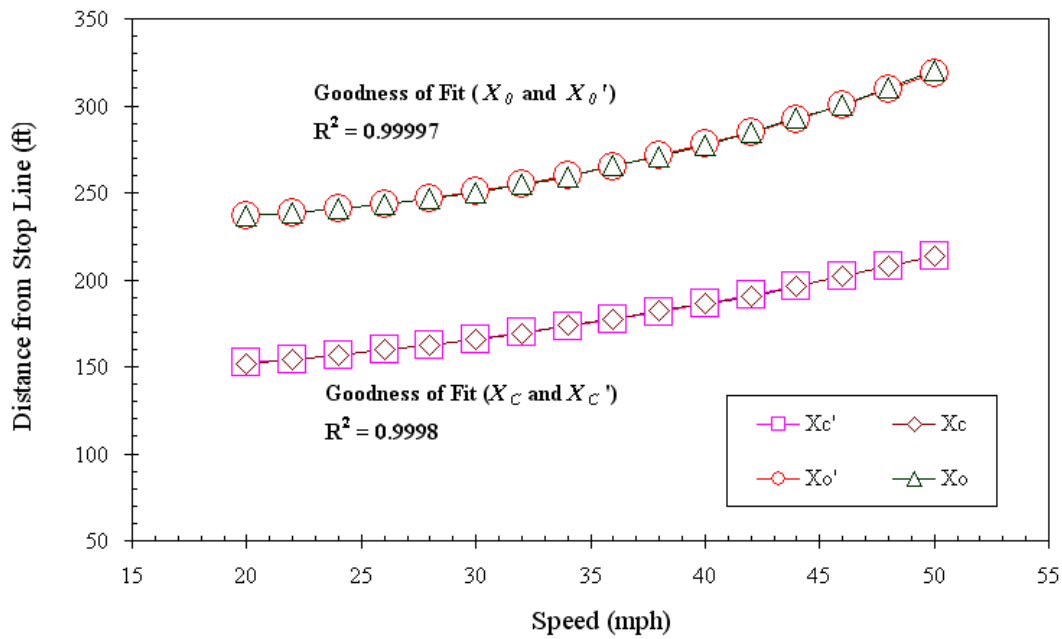

Figure 5. Model Calibration using the Trial-and-Fit Method

Note that during the calibration process, values of the contributing factors are guaranteed satisfying the following constrains: the deceleration rate for stopping increases as the approach speed increases; the acceleration rate for passing decreases as the approach speed increases; both PRTs for stopping and passing decrease as the approach speed increases; and all values of the contributing factors are within the observed ranges.

The goodness-of-fit analysis shows that the correlation coefficient R^2 is 0.9998 between the profiles of X_c and X_c', while the number is 0.9997 between the profiles of X_0 and X_0'. Both R^2 values indicate a good fitting. Through the model calibration, appropriate values of $\delta_{stop}(V_0)$, $a_{stop}(V_0)$, $\delta_{pass}(V_0)$, and $a_{pass}(V_0)$ at various speeds are obtained and shown in Table 1.

Table 1. Calibrated Values of the Contributing Factors.

V_0 (mph)	$\delta_{stop}(V_0)$ (s)	$a_{stop}(V_0)$ (ft/s^2)	$\delta_{pass}(V_0)$ (s)	$a_{pass}(V_0)$ (ft/s^2)
20	0.6	-3.2	0.505	13.01

DEVELOPMENT OF DILEMMA ZONE LOOKUP CHART

Based on the calibrated dilemma zone model, a dilemma zone lookup chart can be simply developed for practical use. It provides a convenient tool that identifies whether the risky zone or the option zone exists, and what the location and length of the dilemma zone are, for a specific speed and under a certain yellow duration. Figure 6 is the dilemma zone look-up chart developed based on the factor values in Table 1.

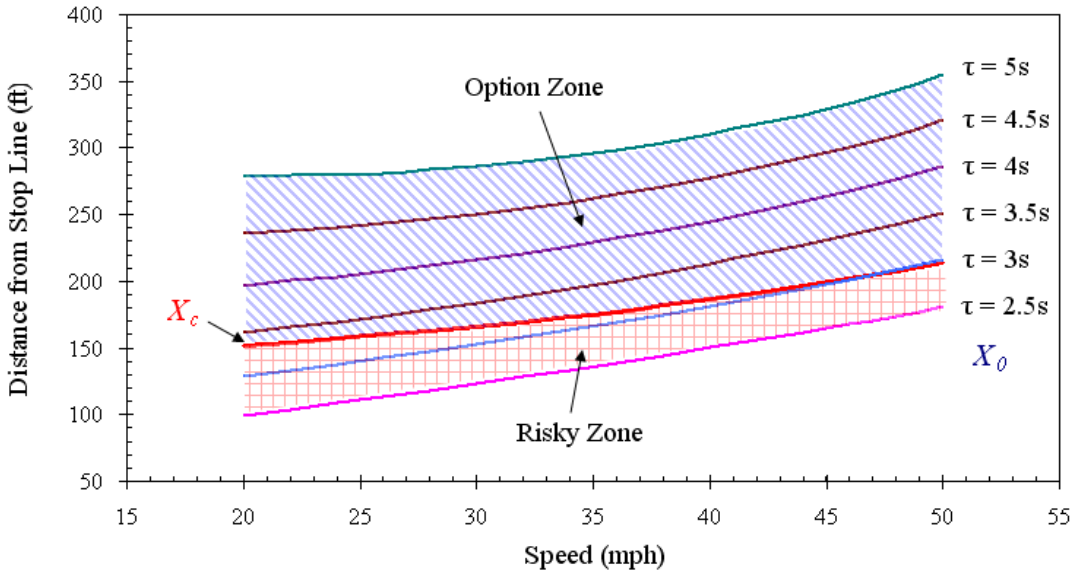

Figure 6. Dilemma Zone Lookup Chart.

In Figure 6, there is only one X_c profile, because the value of X_c does not change with the yellow durations according to Equation (1). For a specific speed and a certain yellow duration, a risky zone exists when the X_0 profile is under the X_c profile; otherwise, an option zone exists. It also indicates from the chart that the length of option zone becomes longer as the yellow duration increases, while the length of risky zone becomes shorter as the yellow duration increases. Both of the findings are in accordance with the results of previous studies (Saito et al, 1990; Koll et al, 2004).

CONCLUSION

This study conducted a proof-of-concept development of an innovative methodology for modelling the dynamic dilemma zones using video-capture techniques and time-based trajectory data. Contributing factors calibrated from the field-observed trajectory data well reflect the dynamic yellow-dilemma-related driving behaviors in the reality. As a result, the developed dilemma zone lookup chart provides a convenient tool for identifying the real location and length of dilemma zone, and is suitable for practical use. The methodology provides a solid basis for further research on the optimal placement of loop detectors for dilemma zone protection in future.

ABSTRACT

The primary objective of the study is to evaluate safety performances of different exit ramps used in Florida. More specific, the research objectives include: (1) to evaluate the impacts of different ramp configurations on safety performance; and (2) to identify the different factors contributing to the crashes happening on the exit ramp sections. 389 sites were investigated throughout Florida by four ramp configurations, diamond, out connection, free-flow loop and parclo loop. Cross-sectional comparisons and crash predictive model were used to quantify the impacts. The result shows that the out connection ramps appear to have the lowest average crash. The predictive model indicates that replacing an out connection exit ramp with a diamond, free-flow, and parclo loop will increase crashes counts by 26.90%, 68.47% and 48.72% respectively. This study will help transportation decision makers develop technical guidelines governing the selection of the optimum design on freeway exit ramps.

Keywords: Exit Ramp, Configuration, Generalized Regression Model, Safety Performance

INTRODUCTION

Freeways provide the primary transportation networks by achieving the highest functional hierarchy of highway systems by design purposes. The AASHTO Green Book (A Policy on the Design of Geometric Highways and Streets) (ASSHTO 2004) defines the design standards on the highway facilities such as the ramps, interchanges and frontage roads. In order to accommodate high traffic demands of safety on freeways, exit ramps and secondary crossroads, designing proper handlings of freeways and ramps are essential in the highway systems. Also, the crash is a direct index on safety evaluations. The wide variety of site geometric conditions, traffic volumes, highway types, and design layouts could eliminate or increase conflict points at some degrees while crashes related to conflict points at some levels. Successful managements on the exit ramp sections could obtain benefits on economics and gain satisfactions on safety improvements. The newest instruction is the ITE "Freeway and Interchange Geometric Design Handbook" edited by Joel (2006). The handbook focuses on geometric and operational characteristics of

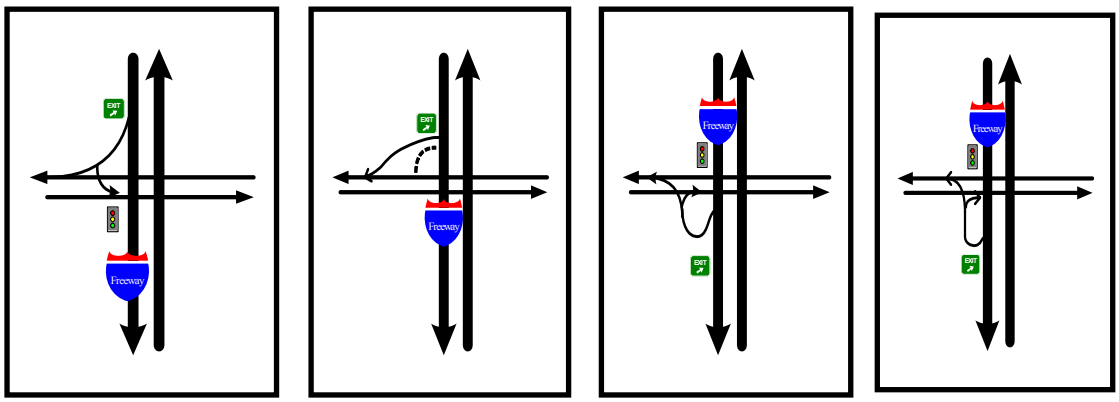
freeways and interchanges. The book recognized that geometric design procedures for freeways and interchanges may vary. It also provides the evidence that is valued as an accompaniment of the AASHTO Green book (ASSHTO 2004), the Highway Capacity Manual (HCM 2000), and Traffic engineering Handbook 5th Edition (Pline 1999). "Ramp Management and Control Handbook" (FHWA 2006), aims to manage ramp policies, strategies and technologies as to improve safety on the exit ramp and the influential areas.

Several types of exit ramps are used for traffic to exit freeways; however, the impacts of exit ramp types on the safety performance have not been well studied or documented until recently and little focus has been put on the safety issues in the State of Florida as well. So this study would conduct comprehensive crash comparisons and analyses on freeway exit ramp sections. The results will help transportation decision makers develop tailored technical guidelines governing the selection of the optimum exit ramps and the related factors to be used on freeway exit ramp sections. Since the limit work that has been performed, a few tentative conclusions could be drawn. Moreover, the various influential factors on the safety performance at entire exit ramp sections need to be revised since previous studies have a few limitations. Lord and Bonneson (2005) calibrated predictive models for different ramp configurations at 44 selected sites. The ramp design configurations addressed in this study included diagonal ramps, non-free-flow loop ramps, free-flow loop ramps, and outer connection ramps. The non-free-flow (parclo flow loop) ramp experienced twice as many accidents as other types of ramps. Bauer and Harwood (1998) modeled the Negative Binomial regression model on the entire ramp section as well and concluded that diamond ramp have slight less crash frequency comparing to other ramp types when other influential variables remain constant. At the same year, Khorashadi (1998) used another method known as ANOVA test to forecast the relationship among ramp configurations, geometry parameters and crash frequencies. This study found that the geometric elements had much weaker impacts than the ramp configurations.

It is obvious that few studies consider the following two issues in the safety effects, widening and ramp terminal treatments. Widening in this study is defined as the number of lanes changing after the pointed nose or in the middle of the entire ramp. The definition of ramp terminal treatments in "Ramp Management and Control Handbook" is those can be implemented at ramp/arterial connections as to better manage traffic exiting the ramp facility. Diverse terminal control strategies have the potentials to affect operations on the exit ramp and adjacent arterials. Accordingly, different terminal control designs or different combinations of terminal designs might have various powers on the safety aspects of entire ramp sections.

The objective of the study is to evaluate safety performances of different exit ramps used in Florida and nationals. The research objectives can divide into two parts. The first one is to evaluate how the impacts of different exit ramp types on the safety performance of freeway exit ramps. The second one focuses on identifying the different factors contributing to the crashes happening on the ramp sections. The four different configurations and other parameters on the entire exit ramp sections are

examined as well to find their effects on the safety features for the entire ramps. Base on the result in this study, it would be a way to judge what kind of geometric, traffic, and combinations of the correlated conditions have the best safety performance on the freeway diverge sections and entire exit ramp sections. Four widely used configurations in United States are identified in the study. They are defined as diamond exit ramps, out connection exit ramps, free-flow loop exit ramps and parclo loop exit ramps. From Figure 1-A to Figure-D illustrate the four ramp configurations which describe the shape of ramps in simplified modes.



A. Diamond Loop **B. Outer Connection** **C. Free-flow Loop** **D. Parclo**

FIGURE 1 Typical Four Exit Ramp Configurations

Figure 1-A is a diamond exit ramp which is a one-way road with both left and right turnings at terminals. Figure 1-B is an out connection exit ramp which only supplies the single turn at the ends of exit ramps. Figure 1-C and 1-D are two classic loop ramps that make at least 270 degrees of turning movements to the secondary roads. Free-flow loop ramps are designed as full cloverleaf ramps with or without collector or distributor roads on the ramp segments. The parclo loop exit ramp is a partial cloverleaf ramp which has a preference to provide an arrangement setting the right exiting vehicles.

METHODOLOGY and DATA COLLECTION

Crash Data

Crash frequencies or crash rates are two indicators that are generally used in the safety studies to compare different treatments. The resource of the noticed crashes is only from police long form crash report which describes specific features for each crash. In this study, crash rate is defined as crashes per million vehicles per vehicle miles traveled for a specific section. Crash rates are used as a criterion for more truthful for segments under the same geometric and traffic conditions to narrow the impacts of these important factors. The crash rate, r, for a particular freeway segment can be calculated in the following formula:

$$r = \frac{1{,}000{,}000 \times A}{365 \times T \times V \times L} \quad (1)$$

Where, r = crash rate at a freeway segment (crashes per million vehicles per mile); A= number of report crashes (crashes per year); T= number of years; V= average daily traffic volume (vehicles per day); L= length of the freeway segment (miles).

Cross-Sectional Comparison Approach

The cross-sectional comparison analysis is satisfactory to provide adequate and reasonable consequences. In this study, cross-sectional comparison was conducted to measure exit ramp sections with four configurations. On the basis of the collected crash data, statistical analysis was conducted to quantitatively evaluate the safety impacts of different exit ramp types. Hypothesis tests are utilized to test whether the observed differences of the selected variables such as mean values between two or more groups have significantly variation in a statistical term. The average crash number and crash rate from one type to another one were examined if they are significantly different. At a 90% confidence level, T-test is used as follows:

$$t_0 = \frac{\overline{X}_1 - \overline{X}_2}{\sqrt{s_p^2(\frac{1}{n_1} + \frac{1}{n_2})}} \quad (2)$$

Statistical Predictive Model

In order to identify the factors that contribute to the crashes and quantify the effects on crashes at selected sites, generalized linear models are used for modeling crashes at selected segments. Generalized linear models are the expansion forms of the classical linear regression models. The classical linear regression model assumes that the dependent variable is continuous and normally distributed with a constant variance. Numerous previous studies have suggested the use of Poisson models or Negative-Binomial (NB) Models for modeling crash data. If the linear predictor is a linear function of the explanatory variables, the fitted crash prediction model takes the functional form as below:

$$\mu_i = \exp(\beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + ... + \beta_k x_{ik}) \quad (3)$$

Where, β_0, β_1,…β_k = coefficients of explanatory variables;x_{i1}, x_{i2}, … …x_{ik} = explanatory variables. Two parameters are often used for evaluating the goodness-of-fit of a generalized linear model, the scaled deviance (SD) and the Pearson's χ^2.

Data Collection

The crash frequency is related to the segment length since different distances might have different effects on the number of crashes when other situations are equal. The entire ramp section is the length of the exit ramp itself. The definition means that the painted nose is the beginning of exit ramp and the end of terminals is the closing stages for the exit ramp. Figure 2 present the ramp segment lengths for four ramp configurations as mentioned above. From the four figures, four bold lines added to each one illustrate the study field for ramps.

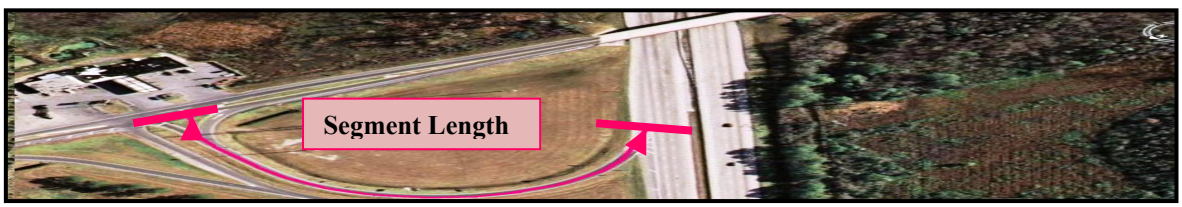

Figure 2-D. Parclo Loop Exit Ramp Segment Length

FIGURE 2. Exit Ramp Segment Lengths for Four Ramp Configurations

DATA ANALYSIS

As mentioned previously, the cross-sectional comparisons were conducted to compare the effects of the four ramp configurations on the safety performance of the exit ramp sections respectively. A total of 389 sites with 247sites for diamond ramps, 93 sites for out collection ramps, 26 sites for free-flow loop ramps, and 23 sites for parco loop ramps were categorized. A total of 2520 crashes were stated for the entire segments for three years from 2004 to 2006. The sites were grouped for four configurations simply named as D (Diamond), O (Out-connector), F (Free-flow Loop) and P (Parclo Loop). The average crash frequencies for the four groups are 2.20, 2.32, 2.21 and 1.00 crashes per site per year. Summary statistics for average crash frequency and average crash rate by four exit ramp configuration groups were given in Table 1. The average crash frequencies indicate the parclo loop group has the less average crash frequency, however the average crash rates point out that the out

connection group has the best safety performance while considering the ramp volume and ramp length. The average crash rate is more reliable as it eliminates the impacts of different ramp volumes and ramp distances. The free-flow loop group has more potential crashes in terms of the maximum average crash rate comparing to the others.

The average crash rate for the free-flow loop group is almost 162%, and 69% more than the out connection group and the diamond group. This result shows different ramp configurations might influence the exit ramps in different ways and the free-flow ramp would have more chances to occur crashes. The conclusion is consistent with previous studies. In the past researches (Bauer and Harwood 1998, Joe. et. al 1999), diamond ramps had the best safety performances comparing to other ramp configurations. But the out connection ramps have less average crash rate than the diamond ramps. This might be the reason that the out connection ramps are widely used as the freeway interchanges that have high design standards than normal exits. These improved standards might be better sign locations before and after the entrances of exit ramps, better road conditions, or less variations along the exit ramps. For the loop exits, parclo loop ramps reported 16.7% less average crash rate than free-flow loop ramps.

Table 1 Summary of Average Crash Frequency and Crash Rate

	Crash Frequency				Crash Rate			
Type	D	O	F	P	D	O	F	P
No. of Sites	247	93	26	23	247	93	26	23
Total Crashes	544	216	57	23	544	216	57	23
Average Crash	2.20	2.32	2.21	1.00	3.47	2.24	5.86	4.88
SD.	2.46	3.44	2.20	1.09	6.35	3.89	8.33	8.9
Median	1.33	1.33	2	0.67	1.86	0.85	2.16	2.20
Max	11	22	8	4	77.11	22.25	37.28	41.51
Min	0	0	0	0	0	0	0	0

Table 2 Statistical Hypotheses Tests

Crash Type	Statistics for Two Mean Tests: 90%					
	D:O	D:F	D:P	O:F	O:P	F:P
Frequency	NO	NO	YES	NO	YES	YES
Rate	YES	YES	NO	YES	YES	NO

The average crash frequency and crash rate for each population were tested at a 90% confidence level. Table 2 listed all the results for the hypothesis tests. The comparison of the average number of crashes for the diamond exit ramps and the out connection exit ramps showing “D:O” is significantly different at 90% confidence level, listing “YES” in the table. For the crash rate, the out connection exit ramps have significant difference to the other three configurations. The out connection ramps have the least average crash rate so that it has the best safety performance among the four configurations at 90% confidence level. The free-flow ramps have the highest average crash rate and the hypothesis tests documented this configuration is more dangerous than the diamond and out connection.

Crash Predictive Model

The crash prediction model was developed to identify the factors that contribute to the crashes reported at selected exit ramp segments. Considering the available data source, a total of 388 observation sites were included in the model. One site did not have ramp design speeds which were believed significantly important to crashes. The dependent variable of the model is the average crash frequency per year reported at selected exit ramp sections. 19 independent variables were initially considered when building the crash prediction model. The crash modeling starts from a Poisson model. For an adequate model, the scaled deviance and Pearson's χ^2 divided by the degrees of freedom shall be close to one. In this study, the Pearson's χ^2 divided by the degrees of freedom was found to be 5.84, indicating the fact that the crash data are overdispersed and NB models shall be used. Stepwise regression method was used to select independent variables in the model. 8 variables were not found to be statistically significant. The best model contains 11 independent variables. The regression results of the best model are given in Table 3. The scaled deviance and Pearson's χ^2 divided by the degrees of freedom are 1.18 and 1.06 which are reasonably close to one, indicating the fact that the model is adequately fitted. The final equation of the model is:

$$Y = \exp(-1.0721 - 0.2253 X_1 + 0.4392 X_2 + 0.2973 X_3 - 0.2608 X_4 - 0.0062 X_5 + 0.6861 X_6 + 0.3679 X_7 + 0.2470 X_8 - 0.0978 X_9 + 0.0129 X_{10} + 0.0580 X_{11}) \quad (4)$$

Where, Y = expected average crash frequency in an exit ramp section (crashes/year), X_1 = 1 if the site has an out connection exit ramp, 0 others; X_2 = 1 if the site has a free-flow loop exit ramp, 0 others; X_3 = 1 if the site has parclo loop exit ramp, 0 others; X_4 = Length of the entire exit ramp (mile); X_5 = Number of lanes on the ramp sections; X_6 = 1 if the number of lanes widening after the entrance of exit ramps, 0 no; X_7 =Upstream distances between exit ramp terminal and first intersection (mile); X_8 = ADT per year in thousands on exit ramp sections; X_9 = Ramp shoulder width (mile); X_{10} =Post speed limit on mainline (mph); X_{11} = Post or suggested speed limit on exit ramp sections (mph).

Table 3 Regression Results for Crash Prediction Model for Exit Ramp Sections

Criteria for Goodness of Fit				
Criteria	DF	Value	Value/DF	
Deviance	375	441.8539	1.1783	
Scaled Deviance	375	441.8359	1.1783	
Pearson Chi-Square	375	397.9857	1.0613	
Scaled Pearson	375	397.9857	1.0613	
Log Likelihood	3221.6867			
Analysis of Parameter				
Parameter	Coefficient	S. Error	χ^2	Pr >
Intercept	-1.0721	0.8577	0.6089	0.11

Out-connect exit ramp	-0.2253	0.1577	0.0837	0.05
Free-flow loop exit ramp	0.4392	0.2428	0.9150	0.07
Parclo loop exit ramp	0.2973	0.2897	0.2704	0.09
Length of entire ramp	-0.2608	0.3117	0.3502	0.04
Number of lanes on exit ramp	-0.0062	0.1477	0.2833	0.03
Widening	0.6861	0.1466	0.9732	<0.0
Secondary Upstream	0.3679	0.1689	0.6990	0.02
ADT in thousands on ramp	0.2470	0.0860	0.4155	0.00
Should width	-0.0978	0.0775	0.0540	0.02
Post speed limit on mainline	0.0129	0.0093	0.0311	<0.0
Post or suggested speed limit	0.0580	0.0133	0.840	<0.0
Dispersion	1.1143	0.0993		

All selected independent variables were statistically significant with a 90% confidence level. The coefficients of the model show that the crash counts at exit ramp sections increase with the mainline lane number , ramp ADT, post speed limit both on mainline sections and ramp sections, distances from ramp terminals to the first upstream intersection, and widening, but decrease with the ramp length, the exit ramp lane number, and ramp shoulder type. With the increase of number of lanes on the exit ramp sections, the situation is different from diverge areas. Since more number of lanes on the ramp sections might diminish vehicle distributions on the ramp sections which are particular transition from freeway sections to the secondary roads. The desperation of vehicles would diminish conflict points on the ramp section. With longer ramp length, the impacts of freeway diverge areas and secondary cross roads would be minimal, so fewer crashes would occur comparing to those short distance ramps. With larger should width, drivers have more flexible spaces while dangerous situations happened especially for loop exit ramps that need more space to avoid angle and sideswipe crashes.

ADT exit ramp sections would increase the opportunities occurring crashes. It is consistent with previous studies. Post speed limits both on mainline and ramp sections have positive influences on the crashes. Since ramp speed is much lower than freeway segments, such as 25-40 mph, drivers would continually maintain high speed on the ramp section while the post speed limit is high; however usually ramp sections did not have a high design standard comparing to freeways. This would mistake drivers so that chances of having potential crashes would rise. Another two positive variables are the widening conditions and distance from ramp terminals to first upstream intersection. It is institutive that widening would cause more merging or diverging maneuvers which were generally the main reasons of happening crashes. The coefficient of distance from ramp terminals to first upstream intersection is 0.3679 which has a significant increase in crash frequency while the increasing the distances. It means if the intersection is far away the ramp terminals, it would raise the chances of happening crashes. If the intersection is nearby the ramp terminals, more attentions would paid at those intersection areas as most drivers are more sensitive to intersections than the normal driveways or roadways.

The coefficients for the three indicator variables have different signs, indicating the fact that the site with the out connection exit ramp has the least numbers of crashes. This conclusion is consistent with the result of our cross-sectional comparison. Based on the model, the sign of out connection exit ramp is negative. It can concluded that replacing a diamond exit ramp with an out connection exit ramp, will reduce crashes in the sections by exp (0.2253)-1=26.90%. However, replacing a diamond exit ramp with a free-flow loop ramp and a parclo loop ramp will increase crash counts at exit ramp by exp (0.4392)-1=56.86%, and exp (0.2973)-1= 35.62%. Thus, we can calculate the increasing percentages for replacing an out connection exit ramp with 68.47% and 48.72%. While only concerning on the loop exit ramp, replacing a parclo loop exit ramp with a free-flow loop exit ramp would increase crash counts by exp (0.4392-0.2973)-1=15.66%.

CONCLUSION

A total of 389 exit ramp sites were collected, 247 sites for the diamond exit ramps, 93 sites for the out connection ramps, 26 sites for the free-flow loop ramps and 23 sites for the parclo loop ramps. Summary of safety evaluation were given in following conclusions:

1) The average crash rates on four ramp configurations show that the out connection group has the best safety performance. The free-flow loop ramp is more dangerous in terms of the greatest average crash rate comparing to others.
2) The signs of the coefficients in the model indicate that the crash counts at exit ramp sections increase with the mainline lane number, ramp ADT, post speed limit both on mainline sections and ramp sections, distances from ramp terminals to the first upstream intersection, and widening, but decrease with the ramp length, the exit ramp lane number and ramp shoulder type.
3) The coefficients for ramp configurations indicate the fact that the site with the out connection exit ramp has the least numbers of crashes. Based on the model, replacing an out connection exit ramp with a diamond exit ramp, a free-flow loop ramp and a parclo loop ramp will increase crashes at exit ramp sections by 26.90%, 68.47%, and 48.72%. For the loop exit ramp, replacing a parclo loop exit ramp with a free-flow loop exit ramp would increase crashes by 15.6%.

The study provided technical specifications for transportation agencies to develop tailored guidelines or practical design instructions. Transportation engineers, researchers and investigators would benefit from the study as well. The results of this study would help transportation decision makers select the optimal exit ramp types and design combinations in our freeway mainline segments.

ABSTRACT

The confirmed pre-impact velocity is the base of accident reconstruction and responsibility identification. The uncertainty of pre-impact velocity calculation is defined as the warp between the result of accident reconstruction and fact, caused by the error from measurement and estimation, or some unknown information. To deal with this problem, a fuzzy rule-based evidential reasoning algorithm is employed in pre-impact velocity calculation. Taking certain influencing factors into consideration, referring variables are taken as the sub-attributes of the pre-impact velocity. The process is building a multiple hierarchical structure model presented with an evidential reasoning algorithm. The quantitative sub-attributes can be calculated with aggregating different degrees, and combined degrees of belief and uncertain belief of all the sub-attributes for the calculation to the pre-impact velocity through evidential reasoning algorithm. The results show that this algorithm is applicable to analyze the calculation results of collision velocity. And uncertainty analysis of accident reconstruction is significant and essential.

INTRODUCTION

Accident reconstruction is important when analyzing an accident and confirming who is responsible for the accident. The reconstruction process is often influenced by some uncertain factor. For example, in the spot measurement, the surveyors need to measure some parameters with instrumental and qualitative estimation, mainly involving geometric parameters, environmental parameters, motion parameters, vehicle parameters, anthropometric parameters, and experimental parameter,. Because of the error from measurement and estimation, the difference

between the result of accident reconstruction and fact comes out, which is defined as uncertainty.

For road accident identification, the pre-impact velocity confirmed is one of the important factors for the analysis of road accidents, which is the basis of responsibility identification. Sometimes the special value of pre-impact velocity is not necessarily a concern. The range of pre-impact velocity confirmed is perhaps enough. Therefore, the analysis of uncertainty is brought on the further perceivable lay. On the basis of the uncertain degree estimation, the result of velocity estimation would be suitable to actual circumstances under the same unknown condition.

In this paper, attention is focused on the problem of the effect of referring parameter variables on pre-impact velocity with uncertainty.

UNCERTAIN PARAMETER ANALYSIS WITH CLASSICAL MODELS

There are several methods to use when calculating the pre-crashing speed, namely momentum equation, kinetic energy theorem, energy conservation, to list a few. By the energy-work equivalence principle, after vehicles collide, the vehicles' separation speeds were determined using McHenry-Marquard's theoretical-empirical dependencies, derived from the energy-work equivalence principle. In the model, the frictional impulses are ignored. In the post-crash movement, two vehicles remain in contact with the ground[1]. Vehicles' angular velocities at separation follow as:

$$\omega_j^{(sep)} = \operatorname{sgn}\Delta\varphi_j \cdot \sqrt{\frac{\mu_j \cdot g \cdot \Delta\varphi_j{}^2}{(I_j/(m_j \cdot L_j)) \cdot \left|\Delta\varphi_j\right| \cdot (1-f_j) + (s_j/1.7)}} \tag{1}$$

Where j is the number of the vehicle, $\Delta\varphi_j$ the total angle of rotation in post-impact motion (rad), μ_j the friction coefficient, g the gravity coefficient, 9.81(m/s^2), I_j the moment of inertia (kg m^2), m_j the real mass(m), L_j the wheel base (m), f_j the coefficient of post-impact motion drag (from 0 for all wheels freely rotating to 1 for all wheels locked), and s_j the distance between center of gravities (CGs) of vehicles' impact and rest position (m)[1]. Speeds of vehicles' CGs at separation follow as:

$$v_j^{(sep)} = 1.7 \cdot \left[\frac{\mu_j \cdot g \cdot \left|\Delta\varphi_j\right|}{\omega_j^{(sep)}} - \frac{I_j \cdot \left|\omega_j^{(sep)}\right| \cdot (1-f_j)}{m_j \cdot L_j} \right] \quad (j=1,2) \tag{2}$$

In the article, the example is chosen from literature [1], in order to have a comparison analysis. By the momentum conservation, not take into account the restitution coefficient and sliding energy loss during crash process. Therefore, angular velocities at impact are 0[1]. The principle of momentum conservation follows as:

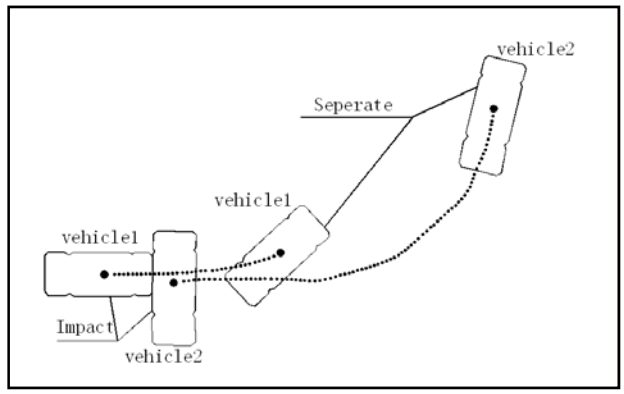

Figure 1. Two vehicle collision hint.

$$m_1 v_1^{(imp)} \cdot \sin(\alpha_1^{(imp)} - \alpha_2^{(imp)}) = m_1 v_1^{(sep)} \cdot \sin(\alpha_1^{(sep)} - \alpha_2^{(imp)}) + m_2 v_2^{(sep)} \sin(\alpha_2^{(sep)} - \alpha_2^{(imp)})$$

(3)

Throughout the formulas (1), (2), and (3), the impact velocities are functions referring some variables, following as:

$$v_j^{(imp)} = z(\mu_1, I_1, m_1, f_1, s_1, \mu_2, I_2, m_2, f_2, s_2, \alpha_1^{(sep)}, \alpha_2^{(sep)}, \alpha_1^{(imp)}, \alpha_2^{(imp)}) \quad (j=1,2) \qquad (4)$$

As can be easily noticed, formula (4) is complicated for referring independent variables. The uncertainty of pre-impact velocity is brought on by all the uncertainty of these referring independent variables. Because of the variety of the independent variables, if we cannot deal with the information redundancy brought on by the referring variables and the relativity among the variables, the uncertainty may be beyond its rational range. Therefore, we need to choose a valid method to deal with.

EVIDENTIAL REASONING ALGORITHM

In the article, the evidential reasoning algorithm based Dempster-Shafer was used to measure the uncertainty of the pre-crash velocity. This method can solve the problem of the redundancy and relativity between the independent variables.

Define the top attribute of pre-impact velocity expressed by *E*. *E* has *L* (*L=14*) sub-attributes (referring independent variables), and *L* attributes are quantitative and associated with the top attribute of pre-impact velocity, which is expressed by a set: $E = \{e_1, e_2, \ldots, e_i, \ldots, e_L\}$.

Due to different sub-attributes with different dimensions, the description of different sub-attributes needs to be aggregated into a comparable index for uncertainty calculation. Therefore, the notion of assessment grade is brought in. In short, it is acceptable for the assessments of an attribute to be distributed among different grades. And a set of grades with a degree of belief structure is employed in assessing an attribute.

Let *H* represent the set of the assessment grades of an attribute, $H=\{H_n,$

n=1, ……, N }. In this article, N is set to be 5, the description as H_1={smallest}, H_2={smaller}, H_3={average}, H_4={large}, and H_5={largest}.

$$B=\{\beta_n, n=1, \ldots\ldots, N\}, 0\le\beta_n\le 1, \ \sum_{n=1}^{N}\beta_n \le 1 \ \text{ and } \ \beta_H = 1-\sum_{n=1}^{N}\beta_n \tag{5}$$

B is defined as the set of degrees of belief about which an attribute is assessed to be H, while β_H is defined as the uncertain degree of belief for the attribute.

$S(E)=\{(H_n, \beta_n), n=1, \ldots, N\}$ represents that top attribute E is assessed to grade H_n with degree of belief β_n, n=1, …, N. While β_H is defined as the belief of unassigned to any individual grade after all the N grades have been considered. The tenet of evidential reasoning algorithm is to aggregate the sets of grades with degree of belief of all sub-attributes, in order to calculate the belief degree with grades of top attribute, including the belief degree of uncertainty.

For a sub-attribute e_i, $B_i=\{\beta_{n,i}, n=1, \ldots\ldots, N\}$ is used to represent its assessment. Therefore, $S(e_i)=\{(H_n, \beta_{n,i}), n=1, \ldots, N\}(i=1, \ldots\ldots, L)$. For all sub-attributes, the numeric value of an assessment can be transformed to the set of equivalent grades.

Let $h_{N,i}$ be the largest feasible value and $h_{1,i}$ the smallest. That is a large value $h_{n+1,i}$ is larger to a smaller value $h_{n,i}$. Suppose a value $h_{n,i}$ for a sub-attribute is judged to be equivalent to a grade $H_n(n=1,\ldots\ldots, N)$. Then a value h_j on e_i is represented to a grade set with degrees of belief by using the following formulae [3].

$$\beta_{n,i} = \frac{h_{n+1,i}-h_j}{h_{n+1,i}-h_{n,i}} \ \text{ and } \ \beta_{n+1,i} = 1-\beta_{n,i}, \text{ if } h_{n,i}\le h\le h_{n+1,i} \tag{6}$$

$$\beta_{k,i} = 0 \quad \text{for } k=1, \ldots\ldots, N \text{ and } k\ne n, n+1 \tag{7}$$

$$S(e_i(h_j))=\{(h_{n,i}, \beta_{n,i}), n=1, \ldots\ldots, N\} \tag{8}$$

In this paper, pre-impact speed was taken as the top attribute. Table 1 shows 14 sub-attributes.

Let ω_i be the weight of the sub-attribute e_i in the assessment to top attribute E and $0\le\omega_i\le 1$, $\sum_{i=1}^{L}\omega_i = 1$.

$$m_{n,i}=\omega_i\beta_{n,i} \qquad (n=1, \ldots\ldots, N;\ i=1, 2, \ldots\ldots, L) \tag{9}$$

$$m_{H,i} = 1-\sum_{n=1}^{N} m_{n,i} \qquad (i=1, 2, \ldots\ldots, L) \tag{10}$$

Let $m_{n,i}$ be the basic probability mass representing the degree to which the ith sub-attribute e_i supports the hypothesis that top attribute E is assessed to the grade H_n.

$m_{H,i}$ is the remaining probability mass unassigned to any individual grade after

all the N grades have been considered for assessing the top-attribute. $m_{H,i}$ can be broken down into two parts, which are $\overline{m}_{H,i}$ and $\widetilde{m}_{H,i}$ [4].

Table 1. Hierarchical structure of pre-impact velocity with influencing factors.

Top attribute	Sub-attribute	Weight	Numerical value
	Friction coefficient μ_1	0.10	[0.6, 0.8]
	Moment of inertia I_1	0.08	[1187, 1587]
	Mass m_1	0.09	[960, 1020]
	Post-impact motion drag coefficient f_1	0.06	[0.6. 0.8]
	Distance between CG in initial and final positions s_1	0.07	[5.8, 6.2]
	Friction coefficient μ_2	0.10	[0.6, 0.8]
	Moment of inertia I_2	0.08	[1677, 2077]
	Mass m_2	0.10	[1090, 1250]
	Post-impact motion drag coefficient f_2	0.06	[0.4, 0.8]
$v_1^{(imp)}$	Distance between CG in initial and final positions s_2	0.07	[14.1, 14.5]
	Direction of vector of vehicle 1 impact velocity $\alpha_1^{(imp)}$	0.04	[-2.0 , 2.0]
	Direction of separation velocity vector $\alpha_1^{(sep)}$	0.04	[-2.37 , 3.63]
	Direction of vector of vehicle 1 impact velocity $\alpha_2^{(imp)}$	0.04	[-2.0 , 2.0]
	Direction of separation velocity vector $\alpha_2^{(sep)}$	0.04	[-1.32 , 4.68]

$$\overline{m}_{H,i} = 1 - \omega_i \quad \text{and} \quad \widetilde{m}_{H,i} = \omega_i \left(1 - \sum_{n=1}^{N} \beta_{n,i} \right) \quad (i=1, 2, \ldots\ldots, L) \tag{11}$$

To obtain the combined degrees of belief of all sub-attributes, $E_{I(i)}$ is firstly defined as the subset of the first i sub-attributes as follows:

$$E_{I(i)}=\{e_1, e_2, \ldots, e_i\} \; i \in [1, \mathrm{L}] \tag{12}$$

Let $m_{n,I(i)}$ be a probability mass defined as the degree to which all the i attributes in $E_{I(i)}$ support the hypothesis that the E is assessed to the grade H_n; let $m_{H,I(i)}$ be the remaining probability mass unassigned to individual grades after all the sub-attributes in $E_{I(i)}$ have been assessed. The relationships (13) and (14) are obviously constructed when i=1.

$$m_{n,I(1)} = m_{n,1} \qquad for\ n=1, 2, \ldots\ldots, N \tag{13}$$

$$m_{H,I(1)} = m_{H,1} \tag{14}$$

Then, based on the above definition and limits, the deduction of an evidential reasoning algorithm can be followed as[4][5]:

$$m_{n,I(i+1)} = K_{I(i+1)} [m_{n,I(i)} m_{n,i+1} + m_{H,I(i)} m_{n,i+1} + m_{n,I(i)} m_{H,i+1}] \quad (n=1, 2, \ldots\ldots, N) \tag{15}$$

$$m_{H,I(i)} = \widetilde{m}_{H,I(i)} + \overline{m}_{H,I(i)} \quad (i=1, 2, \ldots\ldots, L) \tag{16}$$

$$K_{I(i+1)} = \left[1 - \sum_{t=1}^{N} \sum_{\substack{j=1 \\ j \neq t}}^{N} m_{t,I(i)} m_{j,i+1} \right]^{-1} \tag{17}$$

$$\overline{m}_{H,I(i+1)} = K_{I(i+1)} \overline{m}_{H,I(i)} \overline{m}_{H,i+1} \tag{18}$$

$$\widetilde{m}_{H,I(i+1)} = K_{I(i+1)} [\widetilde{m}_{H,I(i)} \widetilde{m}_{H,i+1} + \overline{m}_{H,I(i)} \widetilde{m}_{H,i+1} + \widetilde{m}_{H,I(i)} \overline{m}_{H,i+1}] \tag{19}$$

Where K is the disturbed coefficient in the D-S theory, in the special evidential reasoning algorithm, and $K_{I(i+1)}$ is defined as a normalizing factor.

In summary, after all L assessments have been aggregated, the combined degrees of belief of all sub-attributes for assessment back to attribute E calculated by

$$\beta_n = \frac{m_{n,I(L)}}{1 - \overline{m}_{H,I(L)}} \qquad (n=1, 2, \ldots\ldots, N) \tag{20}$$

$$\beta_H = \frac{\widetilde{m}_{H,I(L)}}{1 - \overline{m}_{H,I(L)}} \tag{21}$$

SOLUTION AND COMPARISION ANALYSIS

In order to use the evidential reasoning approach to calculate the speed and its uncertainty, some numeric values need to be normalized first to eliminate the possible adverse influences coming from different sizes of various variables.

Throughout the calculation of the evidential reasoning approach, the result from the algorithm is the set of beliefs with different degrees. Therefore, we should set up certain functions to describe the speed.

In the case study, the speed function is set up to be a linear function with $v(H_1)$=67, $v(H_2)$=77, $v(H_3)$=87, $v(H_4)$=97, and $v(H_5)$=107. The speed function can be also set up in another nonlinear form.

The fact that the expected value of vehicle 1 speed obtained in evidential reasoning approach calculations (82.8-95.6km/h) is closer to the real value (87.7 km/h), and the uncertain degree of the speed is 0.125, therefore, the minimum value of vehicle 1 speed is 82.8 km/h, and the utmost value is 95.6km/h. If choosing the average one, the value is 89.2km/h.

Compared to the calculation results of Wach and Unarski (2007), the results are shown in the Table 2. As can be seen, the different calculation results of pre-impact speed due to the precision of the vehicle's final position obtained in literature [1]. In classical calculations and PC-Crash software, the result of speed is separately 86.8km/h and 84.0km/m, which is also closer to 87.7km/h [1]. Therefore, using the evidential reasoning algorithm calculates reasoning results in a relatively brief way, and the results are credible. Last but not least, a variety of factors are

generally considered with evidential reasoning algorithm, which is valuable. Based on the reasoning weight confirmed, the obtained result is due to the reasoning weight of the sub-attribute.

Table 2. Calculation results of pre-impact speed of vehicle 1 with different model.

classical model	PC-Crash	evidential reasoning algorithm	Monte carlo simulation (precision of position)
86.8km/h	84.0km/m	82.8km/h (minimum value) 95.6km/h (maximum value) 0.125 (uncertain degree)	76-91 km/h (10%) 68-101 km/h (20%) 58-112 km/h (30%)

CONCLUSIONS

The appropriate way to obtain the uncertainty of the pre-impact is to apply a reasoning decision method. Although some method is used, the solution process is based on the probability of distribution analysis, and the sensitivity analysis is given.

Applying the evidential reasoning approach for the solution of the pre-impact is reasonable and creditable, which gives the results as the distribution of probability density with different degrees and uncertainty.

The result is credible and valuable, and can be as the basis for responsibility identification. The uncertainty calculation is valuable and necessary, but we can also choose another method to calculate the uncertainty, or considering other influencing factors.

ABSTRACT

This paper studies the relationships of various vertical grades at longer slope mountainous terrain highways on the driver's heart rate. This paper analyzes the vertical grade effects by measuring the driver's heart-rate and the vehicle speed using the auto-recording heart-rate instrument and motive GPS respectively. The research results suggest that the profile grade at the long slope alignment should not be more than 5% for mountain highways and signing improvements which may reduce accidents in such terrains.

INTRODUCTION

In many highways in mountain areas, there are greater elevation changes and sharp horizontal curves because of the terrain and poor economic conditions. Probably traffic accidents are often caused by vehicles running on such highways due to brake destruction while braking in extreme conditions. Usually these situations have become a challenge for highways in the mountainous areas of Western China. In current conditions, the design norms must be strictly controlled to reduce the traffic accidents in consideration to the concept of 'taking humans as the basis and the tolerant design'. Therefore, it becomes increasingly important to research the reasonable design parameters of the alignment of the highways in terms of the roadway safety, the driver's comfort and other aspects.

The safe highways not only have good alignments but also meet the need of the driver's comfort. The psychological pressure and the physiological burden on the driver must be controlled at a minimal level (Liu Z. Q., Gong Z., Cai D., 2003). The experiments of the reasonable profile grade at long slope alignment of mountain highways is based on the driver's physiological reactions with the variance of heart-rate and the vehicle speed as the quantification indexes to evaluate the design parameters of the alignment. By making driving experiments in different sections of the mountain highways at various grades, the experiment results are used to study relationships between the driver's heart-rate, the vehicle

speed, and the longitudinal gradient of the long slope alignment. This paper advances some auxiliary parameters of the profile grade design based on the driver's psychological and physiological burdens.

EXPERIMENT INSTRUMENT AND METHODS

Drivers suffer from the physiological burden as well as the psychological burden. The commonly-used research methods of the driver's physiological burden include flicker fusion frequency, the variance in heart rate, the variance of blood pressure, the variance of ElectroEncephaloGraph (EEG), change in respiratory rate, dispersion of skin potentials, and eye movements. The experiment research shows that it is feasible and effective to use the variance of heart rate as an evaluation index of a driver's psychological pressure in driving (Pan X.D., 2001, 2003).

In order to show the relationship between the heart rate and the highway alignment, this experiment uses the variance of heart rate and the free vehicle speed as the evaluation index. The variance of heart rate is the dispersion of the mean of the driver's heart rate in the process of driving experiment and that of driver's heart rate prior to the experiment. When the variance in heart rate is 5 to 10 P/min, it shows that the driver's psychological and physiological burdens are normal. Free vehicle speed refers to the idea that the driving speed is decided by the driver's feeling, thus avoiding the driver's psychological and physiological burdens caused by limiting the driving speed. When the free vehicle speed of the driver exceeds the limit of this highway's design speed, it indicates that there exists some potential safety problem in this section of the highway.

Instruments used in the experiment and data collection: (1) The motive GPS (Global Position System) instrument is used to measure the driver's location (longitude and latitude), vehicle speed and time, etc. Portable computers are used to record and store the data measured using GPS (Ashley S., 2003)

(2) Auto-recording heart rate instrument, "Century 3000" made in USA is used to monitor and measure the information of the driver's heart rate, and it is convenient and stable for measuring the variance of the heart rate during driving.

Highways and time of experiment: This experiment selects some mountain highways of low design speed, complicated driving conditions and obvious end long slopes in order to make clear the impact of the long slope alignment of the mountain highways on the driver' s psychology and physiology. Ten sections of B-grade road were selected, which include most longitudinal gradients of 0~7%. All the sections in this road are typically those where traffic accidents often occur. In order to reduce the influence of the weather, temperature and humidity, the experiments were conducted in early spring and in dry weather.

Vehicle and driver choice: A seven-seat microbus was used for the experiment. Considering the representativeness of drivers' experience and age, six male drivers at all age groups old, middle-aged, and young were the drivers of the experiment.

THE PROCESS OF THE EXPERIMENT

Experiment purpose: This experiment is intended to gain the parameters at the long slope alignment of mountain highways, the data of the variance of the driver's heart rate and vehicle speed by recording the drivers' behavior in different slope alignments of the mountain highways. This data is used to evaluate whether the longitudinal gradients are within reasonable tolerance.

Experiment theory: The psychology of the drivers on the long slope alignment of mountain highways may have different degrees of strain as they meet different longitudinal gradients at the long slope section, and their heart rates can quantitatively reflect this kind of strain. The driver's vehicle speed and location (longitude and latitude) at different times can be measured by the motive GPS. the design parameters of the number of kilometer stakes and the profile grade in the experiment highway can be obtained by changing the coordinates of longitude and latitude, and consulting the design documents of the alignment of this experiment section (Ashley S., 2003; Dornhemima, 2004). Drivers' heart rates at different times can be measured by the auto-recording heart rate instrument. Part of the experiment data after they are arranged and disposed are shown in Table 1. The following analyses and researches are all based on this experiment data after they are arranged and disposed.

Table 1. Part of the Experiment Data After Arranged and Disposed

Kilometer stake number	Arriving time (h:m:s)	Vehicle speed (km/h)	Profile Grade, I (%)	Variance of heart rate, H (P/min)

ANALYSIS AND DISCUSSION

From the experiment data, the vehicle speed (V) and the mean heart rate (H) increases when the drivers drive on the different longitudinal gradient (i) at long slope alignment.

The distribution discrete points (i,V), (i, H) are shown in Figure 1, and Figure 2. By using the MATLAB software and the theory of nonlinear least mean square problem (Wei L., Gao L. M, Yu Q., et al., 2004) the fitting equation of discrete points (i,V),(i, H) is derived. The fitting equations are shown in Table 2 and fitting curves are shown in Figure 3 and Figure 4.

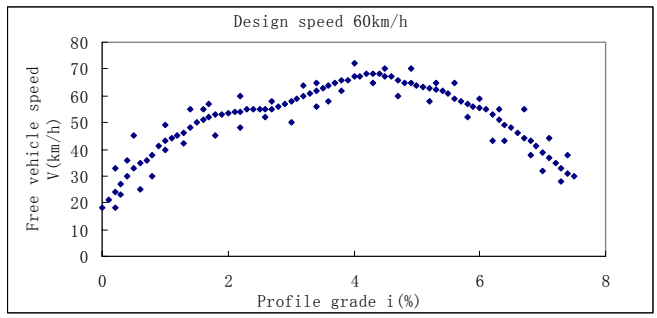

Figure 1. Discrete-points（i，v）distribution.

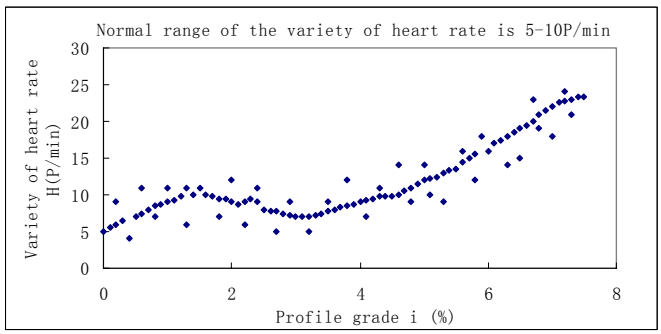

Figure 2. Discrete-points（H，v）distribution.

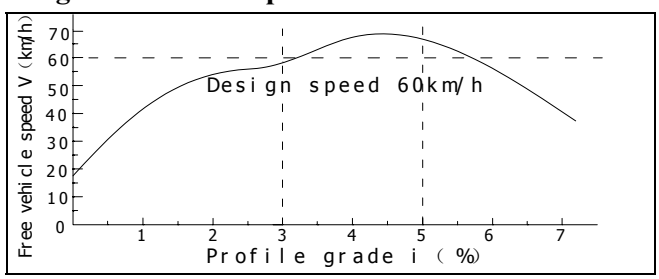

Figure 3. Fitting relation of i and V.

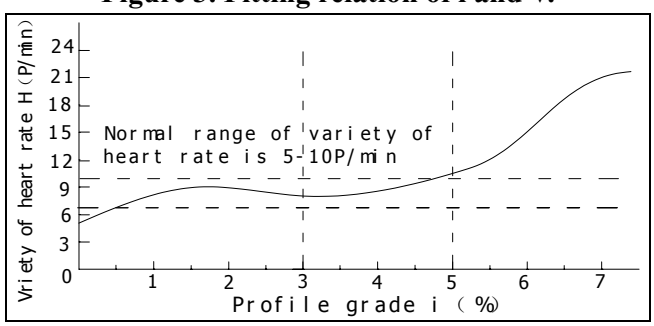

Figure 4. Fitting relation of i and H.

When the driver drives on the different longitudinal gradient at the long slope alignment of mountain highways, a quantitative analysis of the above fitting equations derived are presented in Table 2. The fitting curves in Figures 1 through 4 demonstrate the following:

(1) When $i \le 3\%$, the vehicle speed has a sharp increase and the psychological stress of the driver also slightly increases because of effect of vehicle's gravity divided in the direction of the longitudinal slope. At this moment,

the driver doesn't brake, but he is very careful, so driving at such section was usually safe.

(2) When $3\% < i \le 5\%$, the driver's heart rate may increase because the longitudinal gradient at this alignment becomes bigger, but as the driver brakes, his strain is eliminated. However, the acceleration caused by the vehicle gravity divided in the direction of the longitudinal slope becomes large, so the vehicle speed also becomes larger. At that time, the phenomena of overtaking and over speeding will easily occur. In the investigation of traffic accidents on this highway, overtaking and over speeding are the main reasons to cause accidents. Therefore, warning signs of "No overtaking" and "No over speeding" must be set up in these sections, and some of the crucial sections should become slowing-down belts.

(3) When $i > 5\%$, the driver's psychological stress has a sharp increase because he has to brake to overcome the ever-increasing acceleration. Though the vehicle slows down to some degree, the brake's temperature increases because of continual braking, which causes the brake to fail to work, and accidents usually occur for this reason. So the longitudinal gradient at the long slope section of mountain highways should not be more than 5%.

Table 2. Fitting equation of free vehicle-speed (V), heart-rate increasing number (H) and longitudinal gradient (i).

Fitting equation of V and i	$v = 0.75i^3 - 8.5i^2 + 31.75i + 18$	$i \le 3\%$
	$v = -1.5i^3 + 13i^2 - 26.5i + 60$	$3\% < i \le 5\%$
	$v = 1.1i^3 - 20.9i^2 + 116.6i - 133$	$i > 5\%$
Fitting equation of H and i	$H = 0.33i^3 - 2.5i^2 + 3.2i + 5$	$i \le 3\%$
	$H = 0.1i^3 - 1.75i^2 + 11.65i - 15$	$3\% < i \le 5\%$
	$H = 1.67i^3 + 25i^2 - 151i + 306.7$	$i > 5\%$

CONCLUSION

The following conclusion is drawn on the basis of the study of the relationships between the driver's heart-rate, operating speed, and the longitudinal gradient of the long slope alignment of the mountain highways. These study recommendations could be used as a reference to design mountainous highway alignments and be used by the highway managers.

(1) The longitudinal gradient at the long slope alignments of mountain highway should not be more than 5%.

(2) Clear signs of "No Overtaking" and "No Over Speeding" must be set up at the long slopes of 3% to 5% to improve the management of the present highways.

ABSTRACT

It is very important to have enough sight distance to ensure drivers drive safely on the road. Enough sight distance will give the driver enough time to judge the changes of road's direction and gradient accurately and then choose the correct driving line to avoid hitting rolling stocks and roadblocks or park the vehicle down on the emergency parking places at state of emergency. Based on the principle of the vertical curve design, this paper discusses the safe driving conditions on highways and doing research on the impacts of road sight distance. Combined with safety evaluation for one expressway, this paper proposes some reasonable recommendations for black spot treatment.

PREFACE

Highway safety analysis is the evaluation on planning, studying, designing achievement of highway and its affiliated facilities or on potential factors of the traffic safety. One of the key factors in evaluation is the level and the vertical sight distance. It is very important to have enough sight distance when drivers drive safely. Enough sight distance will give the driver enough time to judge the changes of road's direction and gradient accurately and then choose the correct driving line to avoid hitting rolling stocks and roadblocks or park the vehicle down on the emergency parking places at state of emergency (Harold Peterfeso. 1998).

There are many factors which influence stopping sight distance, such as dark plane bending on the road (it has the obstacle in the curve), crest vertical curve in vertical section and sag vertical curve below separate grade crossing. Carrying on the road vertical surface geometric design, we should pay attention to optimum composition of plane curve and vertical curve and avoid composition of dark plane bending and vertical curve, bright plane and crest vertical curve. When algebraic differences of gradients are big, their combination will give such feeling that drivers

give up smooth slope and shortcut and deliberately climb slope and turn around. This paper discusses the relationship among the design length of vertical curve, stopping sight distance and algebra difference of grades and the conditions which road alignment design should be reached for making sure driving safely.

FORMULAS OF STOPPING SIGHT DISTANCE

Crest vertical curve. In designing crest vertical curve, the smallest length of vertical curve should be satisfied with the demand of sight distance in order to drive safely. According to the relationship of the length of vertical curve and stopping sight distance, two cases will be discussed in the following (Zhang Yu-hua.2002) .

(1)Length of curve less than stopping sight distance ($L<S_T$)

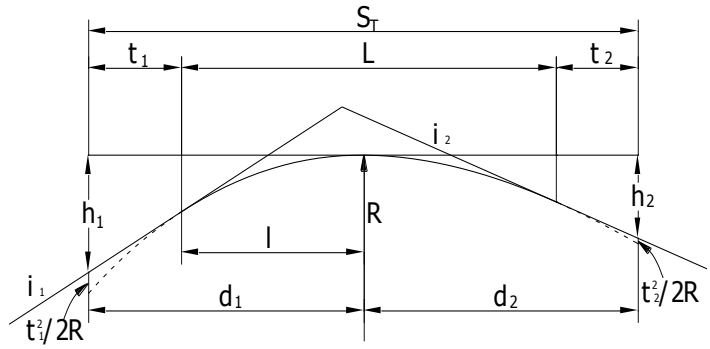

Figure 1. L<ST in crest vertical curve .

According to the Figure 1 and the length of sight distance $s_T = t_1 + L + t_2$, combined with vertical curve design formula, it can be gained as follows:

$$s_T = \frac{(\sqrt{h_1} + \sqrt{h_2})^2}{\omega} + \frac{L}{2} \qquad (1)$$

i_1: Grade of the tangent on the start point of vertical curve; measured in percent of slope; assigned to uphill grades in plus values and minus values in downhill grades

i_2: Grade of the tangent on the end point of vertical curve

ω: Algebraic difference of gradients ($=i_2-i_1$); measured in percent of slope

L: Length of vertical curve

s_T : Stopping sight distance

h_1, h_2: A value of 1.20m is usually taken as the eye level height above the road surface for an observer sitting in the vehicle and a value of 0.10m to an object height [3], which means h_1 will be 1.20m and h_2 will be 0.10m.

(2)Length of curve greater than or equal to stopping sight distance ($L \geq S_T$)

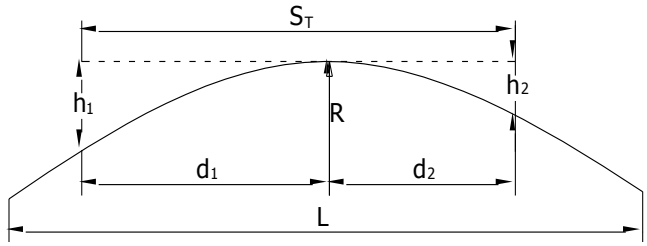

Figure 2. $L \geq ST$ in crest vertical curve .

The formula is derived from the Figure 2 and the length of sight distance $s_T = d_1 + d_2$, combined with vertical curve design formula as follows:

$$s_T = \sqrt{\frac{2L}{\omega}}(\sqrt{h_1} + \sqrt{h_2}) \qquad (2)$$

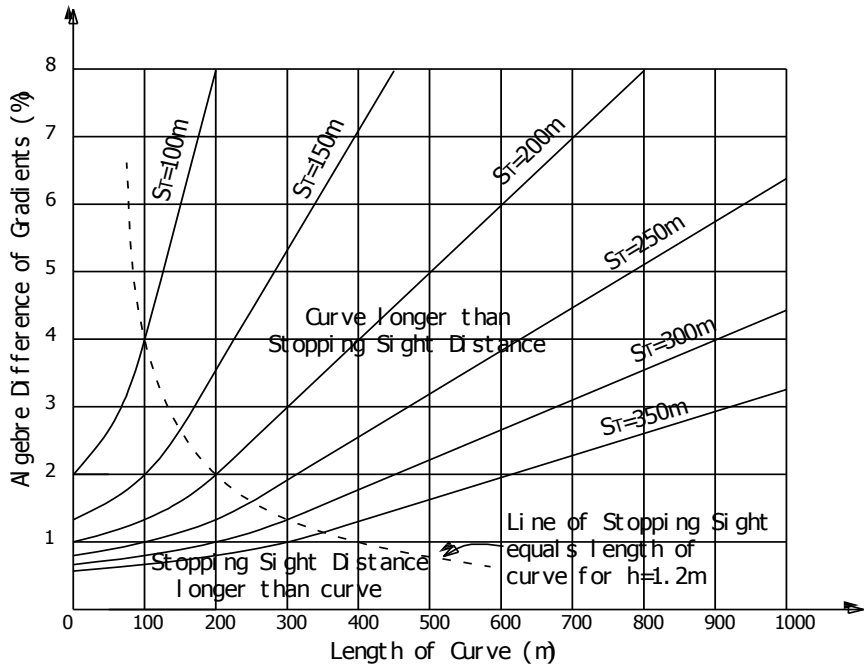

Figure 3. relationship among stopping sight distance, curve lengths and algebraic difference of gradients in crest vertical curve .

According to formulas (1) and (2), relationship among stopping sight distance, curve lengths and algebraic difference of gradients in crest vertical curve (Ioannis Taiganidis. 1998) is shown in Figure 3.

Comparing with the above two situations and combining with Figure 3, we can see that the impacts of formula (2) are greater than formula (1). So we should regard comparison between the calculation sight distance of formula (2) and the standard value as effective control. If calculation value is greater than or equal to the standard value, it meets the requirements.

Sagvertical curve. Designing minimum length of sag vertical curve should meet two requirements: first, ensuring traffic safety at night- adequate distance before lighting; second, ensuring sufficient distance for travel under the overpass. This paper mainly discusses the former.

There are two situations in the following discussion.

(1)Length of curve less than stopping sight distance ($L<S_T$)

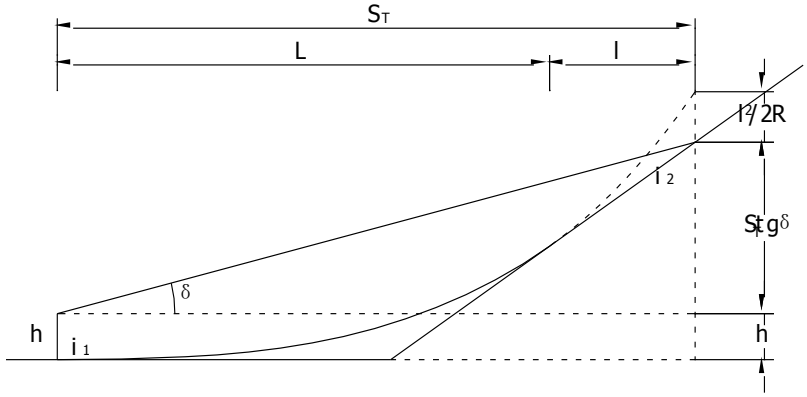

Figure 4. $L<S_T$ in sag vertical curve .

Shown in Figure 4, stopping sight distance and vertical curve design formula acquiring the formula as:

$$h + s_T tg\delta = \frac{\omega(2S_T - L)}{2} \qquad (3)$$

h: Height of lights of cars before, taken 0.75 m

δ: Beam spread angle of lights of car before, taken 1.5 degree[3].

(2)Length of curve greater than or equal to stopping sight distance ($L \geq S_T$)

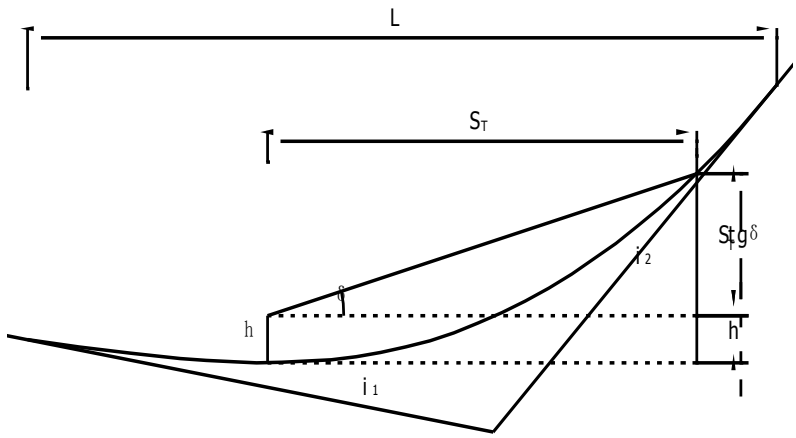

Figure 5. $L \geq S_T$ in sag vertical curve .

$$h + s_T tg\delta = \frac{S_T{}^2\omega}{2L} \qquad (4)$$

From the Figure 5, it can be gained as follows:

According to formulas (3), (4), figure 6 can be used to describe the

relationship among stopping sight distance, curve lengths and algebraic difference of gradients.

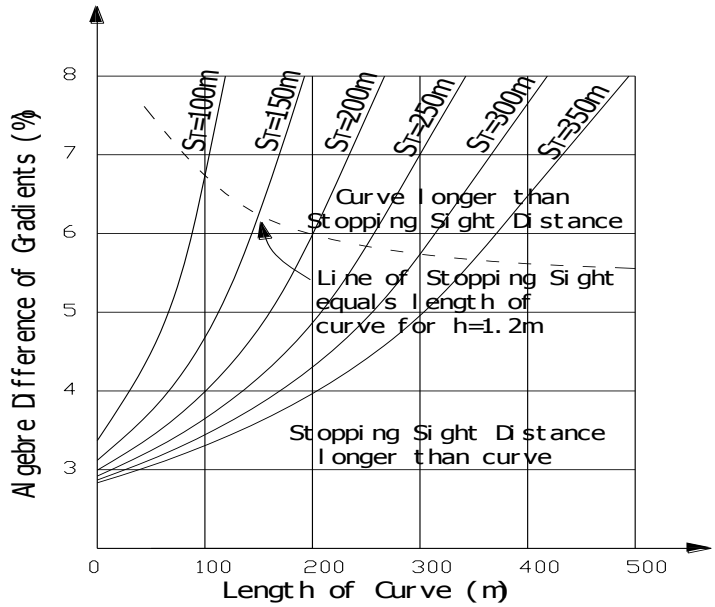

Figure 6. relationship among stopping sight distance, curve lengths and algebrai c difference of gradients .

Comparing with the above two situations and combining with Figure 6, we can see that the impacts of formula (4) is greater than formula (3). So we should regard comparison between the calculation sight distance of formula (4) and the standard value as effective control.

Result analysis. (1) Figure 3 and Figure 6 visually reflect the relationship among stopping sight distance, curve lengths and Slope. Under the proposed design of length of curve, we can directly determine whether the design meets the requirements of stopping sight distance or not from the Figure as long as slope is unchangeable.

(2) The relationship between algebra difference of grades and length of curve should be in one-to-one proportion while stopping sight distance is unchangeable. The bigger ω is, the longer the curve needs, the better it is for slope-climbing and at the same time it could avoid bumping at high speed because of shorter curve.

(3) When ω is invariable, the longer S_T is, the greater L will be. As a result, the curve becomes smoother and vision of racing driver is much wider than before, which means the driving will be safer and more comfortable.

(4) When design of length of curve and stopping sight distance do not meet the requirements because the terrain and environment factors are restrained.

APPLICATION

The study is conducted on a highway segment that is the major component of

national highway network planning. The total length is 199.334 km, and it was finished in October 2003. According to statistics, the rate of traffic accident is 7.81 times per km on the road during 2004. Based on the frequent traffic accidents and increasing traffic volume, the departments have decided to implement safety assessment for this section of road and then combining with the results present reform suggestion, finally confirm the implementation of identified six lanes extension design program. Contents of assessment mainly aim at types of traffic accidents, analysis of traffic flow characteristics, speed continuity, vertical-linear design quality, test of stopping sight distance, ultra-high road, sub grade drainage, interchange design and bridges and tunnels quality test. The results show that a full range of accident-prone section of the road presents big potential safety problems in ensuring driving distance, using the level and the vertical linear indicators and traffic engineering facilities and so on, while the lack of stopping sight distance is an important cause on certain sections of the high incidence of accidents.

This Application shows a section of the linear design indicators and distribution of the incident. In consecutive uphill and downhill sections, accident rate is 8.95 times per km from south to north, while 9.33 times per km from north to south. In light of the formulas (1), (2), (3), (4), and combining with Figure 3 and Figure 6, the results showed some of the vertical sight distance can not meet the requirements. The largest line-of-sight designed in this section is 140 m, instead of the standard value of 160 m. It is obvious that the lack of sight distance is the important cause of resulting in traffic accidents.

CONCLUSION

The majority of road traffic accidents are related to speeding and lack of sight distance. In order to guarantee the vehicles travel safety, we can test whether the alignment design is smooth and continuous, and whether sight distance meets the requirements by utilizing the perspective drawing, curvature chart, and the slope chart. If conditions are restrained on one section of road and alignment or sight distance can not meet requirements of design standard, we can take traffic engineering control measure to ensure the road traffic safety as much as possible.

Abstract

Disharmony of various factors in road system is one of important reasons that cause traffic accidents. In order to study how traffic accidents are influenced by various road factors, it is required to transform traditional linear prediction models into non-linear prediction ones. Considering above-mentioned problems, multifactorial model for road traffic accident prediction based on Grey-Radial Basis Function (RBF) neural networks is put forward by combining virtues of Grey theory that aim at handling "poor" information and weaken undulation of data sequence together with the superior capability of neural networks of adapting non-linear information. Finally, the results of a case study demonstrate that the combined model can effectually overcome the shortcoming that current prediction models only consider influence of one factor on the traffic accidents. The proposed models can also improve efficiency of system modeling and precision of the prediction.

Keywords: Traffic safety; Grey system prediction; Radial basis function (RBF) neural networks; Multifactorial prediction model

1. Introduction

Influencing factors of actual road system are various and complex that have characteristics of grey, uncertain, fuzzy and random. The issue of how to mathematically model the relationship of influence factors and prediction index based on qualitative cognition is a very interesting and worthwhile research field.

Owing to the characteristics of the road systems, obtaining the complete information for the system model under limited techniques and limited space-time condition are difficult or sometimes impossible, namely, the system is in a "poor" information condition. Grey system theory can effectively improve utilization rate of available information, which provides potential tool for analyzing and disposing "poor" information system. But grey dynamic modeling theories have drawbacks that are weak in parallel computation , self-organizing and self-adaptive capability (DENG 1990; LIU etc.1999). However, parallel distributing capability of neural network formed by learning, self-organizing and non-linear dynamics has the predominance on disposing mode information that is difficult to express by language. Nevertheless, neural network also has "black box" weakness (Robert etc.1998;

S.Massoud Amin.1998). Therefore, method of combining grey system theory with neural network theory is considered, which combines the advantages of grey theory that improves utilization rate of available information and the capability of neural network that disposes of non-linear adaptability information, to solve traffic accident prediction problem affected by various road factors (LIU 2007).

2. Methods

2.1. Grey System Prediction Models

The Grey System Prediction can effectively forecast multifactor system. Its basic idea is to build Model GM (1, N) for relationship of traffic accident and various influence factors, and to build Models GM (1, 1) for each influence factors respectively, which constitutes the Grey System Prediction Model for forecasting the system (DENG Julong.1990; LIU Sifeng etc.1999).

Grey differential equation of Model GM (1, N) is as fallows:

$$x_1^{(0)}(k) + az_1^{(1)}(k) = \sum_{i=2}^{N} b_i x_i^{(1)}(k) \tag{1}$$

The parameters matrix is elicited according to least-squares algorithm, computation equation as follows:

$$\hat{a} = [a, b_2, b_3, \cdots, b_N]^T = (B^T B)^{-1} B^T Y \tag{2}$$

Approximate Time Response Sequence of grey differential equation of Model GM (1, N) is as fallows:

$$\hat{x}_1^{(1)}(k+1) = \left(x_1^{(1)}(0) - \frac{1}{a} \sum_{i=2}^{N} b_i x_i^{(1)}(k+1) \right) \cdot e^{-ak} + \frac{1}{a} \sum_{i=2}^{N} b_i x_i^{(1)}(k+1) \qquad \mathrm{k} = 1, 2, \cdots, \mathrm{n} \tag{3}$$

Prediction values of the original data sequence $X_1^{(0)}$ are obtained by Inverse Accumulating Operation according to formula (4).

$$\hat{x}_1^{(0)}(k+1) = \alpha^{(1)} \hat{x}_1^{(1)}(k+1) = \hat{x}_1^{(1)}(k+1) - \hat{x}_1^{(1)}(k) \qquad \mathrm{k} = 1, 2, \cdots, \mathrm{n} \tag{4}$$

When N is equal to 1, Model GM (1, N) is same as Model GM (1, 1), so computation processes for Model GM (1, 1) are elided.

Residual Test and Posterior Variance Test are used for precision tests of the Grey System Prediction Models.

2.2. RBF neural network model

The RBF neural network has characteristics that are well approximation

precision, quick convergence speed and can't get stuck in a local minimum, etc., which can effectually overcome the shortcomings of BP neural networks.

The architecture of the RBF neural network is presented in Figure 1。The network consists of three layers: an input layer, a single layer of nonlinear processing neurons, and an output layer. The transfer function of the hidden layer is radial basis and the transfer function of the output layer is pure linear function. In practical applications, the most widely use of RBF is the Gaussian RBF.

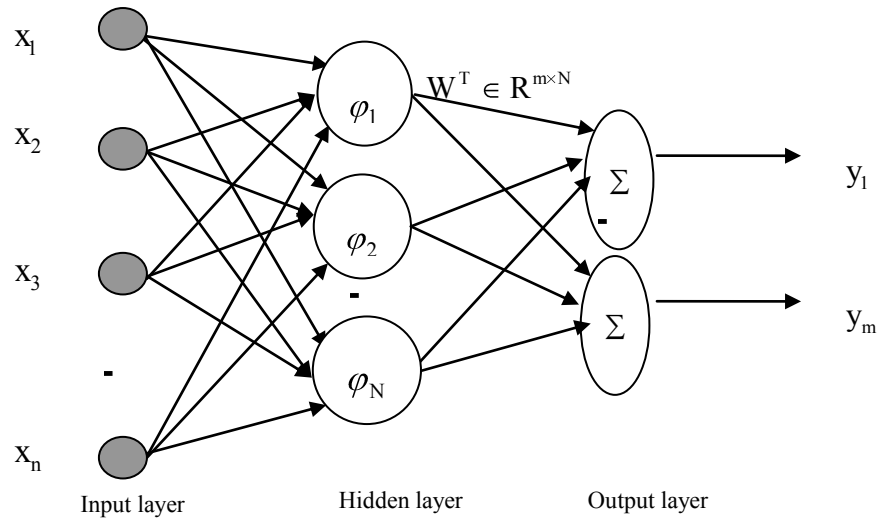

Figure 1. The RBF NN architecture .

Because of the length limit for papers, for particulars, refer to the literature (Fredric M. Ham, Ivica Kostanic.2003).

3. Grey -RBF neural networks combined prediction model

Assigning a weight to each prediction models is one of key problems of the combined prediction model. This paper confirms the weighs vector w_n according to optimization combined prediction method (LIU Zhaohui.2007).

Optimization combined weights vector is obtained by

$$w_n = \frac{E_n R_n}{R_n^T E_n R_n} \tag{5}$$

where $E_n = (c_{ij})_{n\times n}$ is a prediction error information matrix in which $c_{ij} = \sum_{t=1}^{N} e_{it} e_{jt}$

and R_n is a n dimension column vector with elements are all 1s.

If the combined prediction structure consists of two prediction methods, optimal combined weights coefficient are given by

$$w_1 = \frac{c_{22} - c_{12}}{c_{11} + c_{22} - 2c_{12}} \quad , \quad w_2 = \frac{c_{11} - c_{12}}{c_{11} + c_{22} - 2c_{12}} \tag{6}$$

Combined prediction value can be obtained by the Combined Prediction Model that is given by

$$\hat{y}_{ct} = \sum_{i=1}^{2} w_i \hat{y}_{it} = w_1 \hat{y}_{1t} + w_2 \hat{y}_{2t} \qquad t = 1, 2, \cdots, N \tag{7}$$

where $\hat{y}_{ct}$ is the combined prediction value, $\hat{y}_{1t}$ is the prediction value of the Grey System Prediction Model, $\hat{y}_{2t}$ is the prediction value of the RBF neural network model, w_1 is a weight assigned to the Grey System Prediction Model and w_2 is a weight assigned to the RBF neural network model.

4. Case study

On the basis of 19 factors that affect road traffic safety in literature (LIU Zhaohui.2007), which has been already given an order according to the weights value, three primary factors of alignment combination, safeguard facilities and sight distance are utilized to achieve multifactorial road traffic accidents forecasting based on Grey-RBF neural networks. Quantificational data of the road influence factors of certain high-grade highway are shown in Table 1.

Table 1. Original data sequences of road influence factor s.

$X_i^{(0)}$	Input data					Target data	
	2000	2001	2002	2003	2004	2005	2006
equivalent accident number $X_1^{(0)}$	187	213	232	195	176	162	167
alignment combination $X_2^{(0)}$	0.056	0.061	0.062	0.049	0.044	0.041	0.046
safeguard facilities $X_3^{(0)}$	0.386	0.453	0.493	0.625	0.671	0.671	0.758
sight distance $X_4^{(0)}$	4.695	4.863	4.871	4.938	4.915	4.883	4.880

In order that put original data in same range, initialization method is adopted to preprocess the data. By calculating, the simulation data of the Grey System Prediction Model are obtained, which is shown in Table 2.

Table 2 . Comparison the simulation data of the Grey System Prediction Model with the original data .

Sequence number	Original data	Simulation data	Residual error	Relative error
2	1.139	1.070364	0.068636	0.060260
3	1.241	1.314466	-0.073466	0.059199
4	1.043	1.112541	-0.069541	0.066674
5	0.941	0.976977	-0.035977	0.038233

Precision test's results of the Grey System Prediction Model conform to the requirements of precision grade (LIU Zhaohui.2007) which demonstrates the Grey System Prediction Model, can be used to forecast. Prediction results for the equivalent accident number are obtained by inverse initialization that shown in Table 4.

This paper adopts function newrbe() provided by MATLAB7 neural networks toolbox to design and train RBF networks. Function sim() is adopted to simulate prediction, function norm() is used to measure simulation degree of prediction value and original data. Utilizing characteristic of RBF network with the structure of self-adapted determine, the output is no relationship with initial weights, etc. to realize prediction of RBF neural networks on traffic accident numbers.

According to determinate network input factors (road influence factors) and output factor (equivalent accident number), data during 2000 to 2004 are adopted as the training samples of the network and data during 2005 to 2006 are adopted as the extrapolated testing samples of the network that are shown in Table 1 completely. By normalization operation, input data are transformed into sensitive area of input function. The sensitive area is interval 0, 1.

The Function newrbe() can automatically select neuron numbers of the hidden layer and produce a RBF neural network with zero error on training vectors. When input vectors and goal vectors are obtained, only the spread parameter 'SPREAD' for the hidden layer needs to be factitiously adjusted (note: each bias in the hidden layer is set to 0.8326/SPREAD in practical application), which determines an optimal value for the problem. Let SPREAD equal to 0.1, 0.2, …, 1.0, respectively, the approximate errors of the network are shown in literature (LIU Zhaohui.2007). When SPREAD is equal to 0.3, the prediction error of network is minimized by trial calculations (LIU Zhaohui.2007). Finally, by inverse normalization operation, prediction results of the RBF neural networks are obtained and prediction result of SPREAD=0.3 is used as final prediction value, which is shown in Table 3.

Table 3. Results o f inverse normalization operation of RBF.

SPREAD values	2005	2006	SPREAD values	2005	2006
spd=0.1	202.51	202.44	spd=0.6	177.16	182.84
spd=0.2	169.86	170.52	spd=0.7	234.91	232.33
spd=0.3	157.76	163.11	spd=0.8	201.29	217.47
spd=0.4	154.75	163.34	spd=0.9	179.48	209.67
spd=0.5	177.82	180.14	spd=1.0	163.18	204.78

Weights of each prediction model that constitute the combined prediction model are elicited by formula (6), namely $w_1 = 0.207$ and $w_2 = 0.793$. The combined prediction results calculated by formula (7) are shown in Table 4.

Table 4. Results of the Grey -RBF neural networks combined prediction for the equivalent accident number .

Year	Prediction values of the Grey system prediction	Prediction values of the RBF neural networks	Prediction values of the Grey-RBF neural networks combined prediction
2005	168	158	160
2006	159	163	162

According to the principle and the usage of integrated evaluation for prediction method, four indices are adopted to prove prediction effect of the combined prediction model that the results of evaluation are shown in Table 5. It indicates that the four indices of Grey-RBF neural network combined prediction all surpass those of grey system prediction and RBF neural networks prediction, which sufficiently demonstrates preponderance of the combined prediction method in the multifactor prediction of road traffic accidents.

Table 5. Evaluation on the effect of the combined prediction .

Prediction method	Mean absolute error	Mean absolute percent error	Theil coefficient	validity
Grey System Prediction	7.000	0.042	0.022	0.952
RBF neural networks prediction	4.000	0.024	0.012	0.975
Grey-RBF neural networks combined prediction	3.500	0.021	0.010	0.978

5. Conclusions

(1) The multifactorial prediction model for the road traffic accidents based on Grey-RBF neural network is put forward in this paper, which provides a new practicable solution for predicting the multifactor time sequence.

(2) The Grey System Prediction (GSP) not only synthetically considers the

influence of various road and environment factors on predicted frequencies of the road traffic accidents, but also can overcome the shortcoming of model GM(1, 1) that only aims at certain sequence of the complex road system to forecast. The RBF neural network prediction not only can effectually overcome the shortcomings of BP neural networks, such as long training time, slow convergence speed and prone to getting stuck in a local minimum, but also can obtain a good prediction effect even if the sample data isnot sufficient and can deal with instable data to a certain extent.

(3) The analysis results of this case study demonstrate that the combined model can effectually and accurately reflect future development trend of the traffic accidents in a complex road system affected by various factors.

ABSTRACT

This paper documents two shaking table test studies that characterized the key features of seismic soil-pile group-structure interaction systems involving the low-cap pile group and elevated-cap pile group in liquefiable ground. The shaking table tests were performed using the laminar shear box with depth of 2 m and plan dimensions of 2 m and 1.5 m. The base in both tests was excited by three different El Centro earthquake events. Some representative results were especially presented to study how cap type affected seismic response of bridge pile-column pier in liquefiable ground. It showed from the tests that seismic performance of low-cap pile group was better than that of elevated-cap pile group in liquefiable ground. Low-cap pile group presented to weaken more acceleration response of the pile especially in the upper pile parts when the sand layer hadn't been liquefied or liquefied incompletely, however elevated-cap pile could amplify acceleration response of the pile.

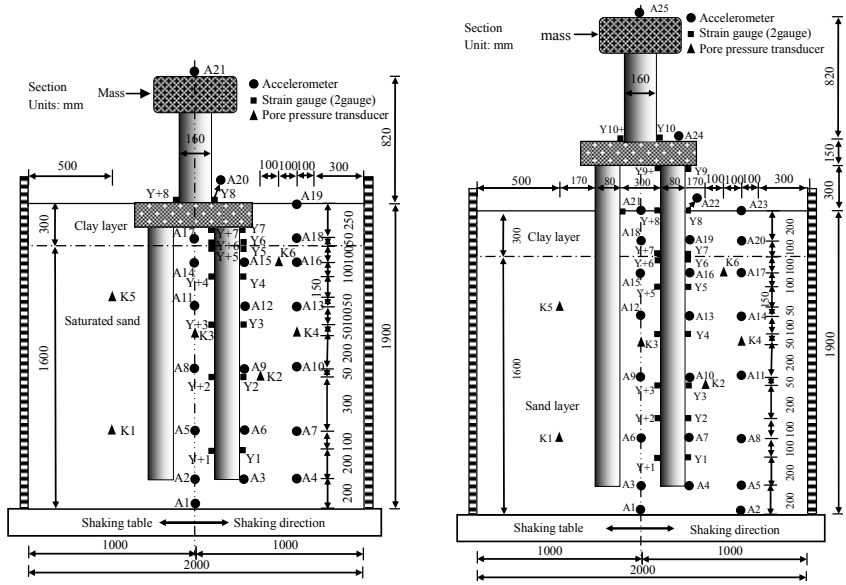
INTRODUCTION

One of the major sources of earthquake-induced damage to the piles was the occurrence of soil liquefaction, and the significance of liquefaction-related damage to the piles had been clearly demonstrated in strong earthquakes (Finn et al. 2002; Abdoun et al. 2002). Shaking table tests were often expected to provide reliable predictions of the performance of geotechnical systems during major seismic events. Shaking table tests had become an effective method to investigate and solve seismic problems of bridge piles in liquefied ground, so it had attracted much attention from the scholars at home and abroad recently, and the significant progress in this field had been made in Japan and America (Boulanger et al. 1999). Elevated-cap pile group was often applied in bridge engineering, and low-cap pile group which could reduce the vibration of bridge superstructure and improve the mechanical characteristics of bridge piles was widely used in bridge engineering (Fujii et al. 1998; Isemoto et al. 1998). Unfortunately, however, there was currently only limited information available regarding the seismic response of pile group with low cap and elevated cap of bridge in liquefiable ground. In this study, two shaking table tests for seismic soil-pile group-structure interaction in liquefiable ground with the same soil structure were completed to study acceleration characteristics of bridge pile-column pier in different types of pile cap including low cap and elevated cap.

FACILITIES AND TEST CONDITION

Shaking table tests were performed in the State Key Laboratory for Disaster Reduction in Civil Engineering, Tongji University, Shanghai, China, using MTS shaking table facility. The dimension of the table was 4 m×4 m, and the maximum payload was 25, 000 kg. The laminar shear box with 2 m high, 1.5 m wide and 2 m long (shaking direction) was designed and fabricated by Wu X.P. (Wu et al. 2002). Moving parts of the shear box approximately weighed 0.7 tons. This was typically 5% of the weight of the whole test model including the box. The shear box was designed to be sufficiently light compared to the weight of the test model. Therefore, the shear box produced nearly one-dimensional wave propagation fields, i.e. free-field conditions (Ling et al. 2004). The same soil profiles in both tests consisted of two horizontal soil layers. The test sand with a non-uniformity coefficient of 3.0, mean particle diameter of 0.32 mm, specific gravity of 2.72, maximum void ratio of 0.96, minimum void ratio of 0.57 and maximum diameter of 2 mm was obtained from Shanghai in China. The sand wasn't washed and was placed into the laminar shear box, partially filled with water in advance, using a free fall method for the saturated sand layer. No compaction efforts were made to densify the sand layer. The height of the lower sand layer with average void ratio of 0.8, relative density of about 51% and factor of permeability of about 0.0035 cm/s prepared was 1.6 m. This method for the desired saturated sand had been successfully used in the previous model studies by Ling X.Z. et al (Ling et al. 2004; 2005). The upper layer of 0.3 m thickness was normally consolidated reconstituted silty clay for the "model clay". The model clay had liquid and plastic limits of LL45 and PL28, and the plasticity index of PI 17. Also note the water table was approximately at the soil interface between the upper and lower soil layers to ensure the sand layer was completely submerged. The dimension of low-cap pile group and elevated-cap pile group was also presented in **Figure** 1. The piles, cap and column pier were modeled with fine-aggregate concrete and galvanized fine iron wires. All the bars embedded in the model structure were replaced by galvanized iron wire with different diameter and had the same bar mark "Φ". The vertical reinforcement for a pile with 80 mm diameter consisted of 9 Φ2 bars evenly distributed around a circle with a diameter of 70 mm and the confinement for the vertical steel was provided by Φ1 bar spirals with a pitch of 20 mm especially with a pitch of 10 mm within the range of 600 mm of the piles near the cap. A 5 mm concrete cover of the piles was maintained to protect the reinforcement bars. The vertical reinforcement of the pier with 160 mm diameter consisted of 32 Φ2 bars evenly distributed around a circle with a diameter of 150 mm and the confinement for the vertical steel was provided by Φ1 bar spirals with a pitch of 20 mm especially with a pitch of 10 mm within the range of 150 mm of the pier near the cap. A 5 mm concrete cover of the pier was still maintained. The concrete from the material specimen tests had an average 28-day compressive strength of 8.5 MPa. The top of the pier carried a mass of 360 kg to represent the inertial effect of bridge superstructure in both tests. **Figure** 1 shows the details of the soil-pile-structure systems. The container bases were excited by three El Centro earthquake events as the representative ground motion input, summarized in **Table** 1. Event B was the input shaking table motion with time scaling factor of $\sqrt{10}/1$. Events C and D were the earthquake events respectively with the peak amplitude of 0.15 g and 0.5 g without time scaling. Each shaking event was separated by an amount of

time that exceeded the time required for full dissipation of excess pore water pressure.



(a) test one (b) test two

Figure 1. Schematic figure of whole test system.

C	El Centro earthquake (NS)	0.15
D	El Centro earthquake (NS)	0.5

TYPICAL PHENOMENA

The law of excess pore pressure ratio in the sand almost remained uniform in both tests, so the results of pore pressure ratio in test one were adopted to explain the test phenomena. The time histories of the pore pressure ratio in the sand from test one is shown in **Figure** 3. Since the peak pore pressure ratio of the sand layer increased evidently bottom-up but less than 0.3, what's more, the sand layer hadn't liquefied and the structural damage of the soil was not serious, the ground surface and the column pier in both tests vibrated slightly in events B. In both tests the upper sand layer liquefied slightly; a little water perspired in the ground surface in event C. The vibration amplitude and the frequency of the column pier in both tests relatively decreased a little in event C compared with that in event B, which resulted from these factors including the peak pore pressure ratio of the sand decreasing bottom-up, the peak pore pressure ratio in the sand almost exceeding 0.6 and the weakened ability to transmit the soil vibration with the gradual development of sand liquefaction.

From both tests in event D the peak pore pressure ratio of the sand layer tended to decrease while the peak pore pressure ratio reached or exceeded the required pore pressure ratio for liquefaction (0.75-1.0); in addition, its duration

ranged from 30 s to 50 s, as a result, the sand layer liquefied completely and then the sand boil and waterspouts occurred strongly and lasted for a long time; the settlement of ground surface ranged from 4 cm to 6 cm; some wide cracks appeared near the pile heads and some cracks also were observed on the piles near the soil depth of about 1000 mm which indicated that the inertial effect and seismic soil-pile interaction all had significant effect on dynamical performance of the piles in liquefied ground. However, when the input shaking acceleration reached the peak in event D the piles around the soil interface broken off which led to the collapse of the superstructure, what's worse was that the big fracture region (transverse crack) appeared around the soil interface ranging from 20 cm to 50 cm and most of the main steel bars in the piles were pulled to snap which suggested that the breakage of the piles mainly occurred during soil liquefaction and the breakage region gradually expanded with the development of soil liquefaction. This was despite the fact that a large safety factor was employed in the design of bridge piles, but many case histories of their damage and failure in liquefied soil still happened. These results also suggested that low-cap pile was easier to obtain seismic demand than elevated-cap pile, so it was worthy to be recommended to adopt low-cap pile in liquefiable ground region.

Figure 3. Time histories of pore pressure ratio in test one.

ACCELERATION **RESPONSE** OF PILE-PIER

The magnification factor of the peak acceleration is defined as the ratio of the responded peak acceleration to the input peak acceleration. The peak acceleration magnification factor and the peak acceleration of the pile-column pier in tests one and two are presented in **Figure** 4 to **Figure** 6 in three different events; the datum in the brackets from the figures was the peak acceleration time of the pile (Unit: s) and the peak acceleration time of the pile group-column pier from tests one and two was almost consistent with the peak time of the input earthquake motion in three different earthquake events. Since in events B and C the sand layer hadn't liquefied or partly liquefied, the negative effect of soil liquefaction on the pile didn't occurred, the cap fixed in the clay layer had strong constraint effect on the pile head and the soil layer effectively restricted the pile body, but the soil-pile kinetic interaction was not evident, the peak acceleration and the magnification factor of the peak acceleration of low-cap pile trended to decrease bottom-up. Considering the incomplete liquefaction of the sand which was the same with that in test one and the constraint of the soil to the pile being effective, the soil-pile kinetic interaction wasn't also remarkable in events B and C, the peak acceleration and the peak acceleration magnification factor of the lower parts of the pile from bottom to top trended to decrease; however, elevated-cap pile was affected more by the inertia effect from the superstructure and the elevated-cap, so the peak acceleration and the peak acceleration magnification factor progressively increased on the upper parts of the pile. The soil had strong constraint effect on the pile and had powerful ability to transmit the vibration in event B, so the acceleration of both elevated-cap pile and low-cap pile in the soil had the attenuation effect on the input earthquake motion, on the contrary, the acceleration of elevated-cap pile above ground surface appeared to have amplification effect caused by inertia effect from the superstructure and the elevated-cap. The acceleration response of the lower part of the pile (below 700 mm) had amplification effect while the response of the upper part of the pile appeared damping effect on the input earthquake motion in test one under event C. The acceleration of the pile from test two manifested that the input earthquake motion were amplified with varying degree in event C. It's concluded that low-cap which effectively constrained the pile head especially in the upper segment of pile could decrease acceleration response of the pile much when the sand layer wasn't liquefied or liquefied incompletely; On the contrary, high-cap had the weak constraint effect on the pile head and could amplify acceleration response of the pile for the lack of the lateral support; the acceleration response of the pile was remarkably controlled by the cap type on the upper pile while it was dominated more by the soil constraint on the lower part of the pile. Since the sand layer liquefied completely in test one in event D, the soil-pile kinetic interaction and the inertial effect from the superstructure began to appear, the magnification factor of the peak acceleration of the pile revealed that the input earthquake motion was amplified more; the peak acceleration and its magnification factor of the pile gradually increased bottom-up, and the decrease of the acceleration was observed only around the soil interface. The acceleration response of the pile and column pier in test two under event D distorted for the pile broken down around the soil interface.

The peak acceleration and its magnification factor of the pile were bigger in

event C than in event B for the same test, which suggested that the pile responded more intensely to 0.15g El Centro earthquake wave and had no relation to the cap type, however, the peak acceleration and its magnification factor of the pile were relatively small on the pier top according with the phenomenon of the small vibration amplitude of the column pier under 0.15g El Centro earthquake event. These showed that the sand layers softened more evidently and the constraint from the soil to the pile tended to become weaker in the prototype earthquake wave (last for a longer time) than the scaled earthquake wave with the same amplitude.

The soil structure for tests one and two was destroyed slightly in events one and two; the ability to transmit vibration was still strong for the soil while the structure was constrained firmly by the soil, what's more, the peak acceleration of the column pier increased gradually bottom-up and the input earthquake motion was amplified evidently presenting the acceleration of the pier top. However, the peak acceleration of the column pier on low-cap pile decreased in event D, the peak acceleration of the pier top didn't increase because the ground liquefied completely but decrease reversely, and the magnification factor was smaller than that in events one and two, for which the explanation might be that the ability of the sand layer to transmit vibration weakened and the liquefied sand represented the damping action. Note that at present seismic design of bridge piles didn't take into account the advantageous effect that the liquefied sand layer could attenuate the earthquake wave, so it was worthy of further study. Elevated-cap pile group was broken so that peak acceleration of the pier top was very large in event D.

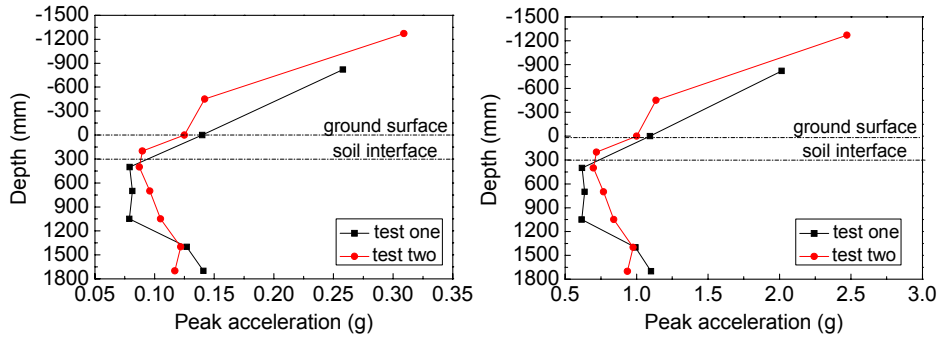

Figure 4. Peak acceleration of the pile and pier in event B.

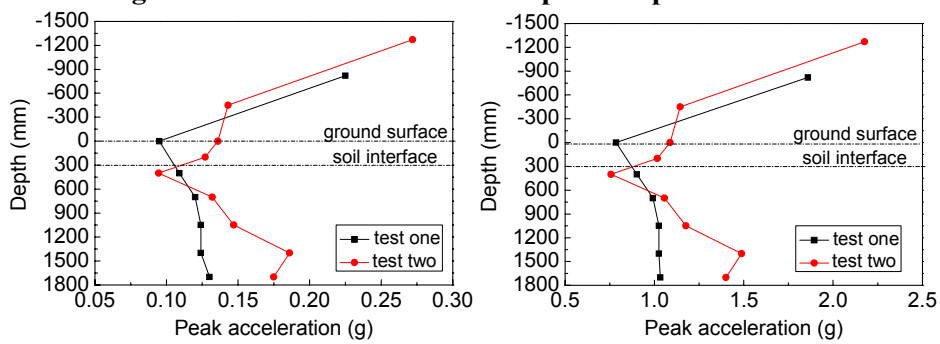

Figure 5. Peak acceleration of the pile and pier in event C.

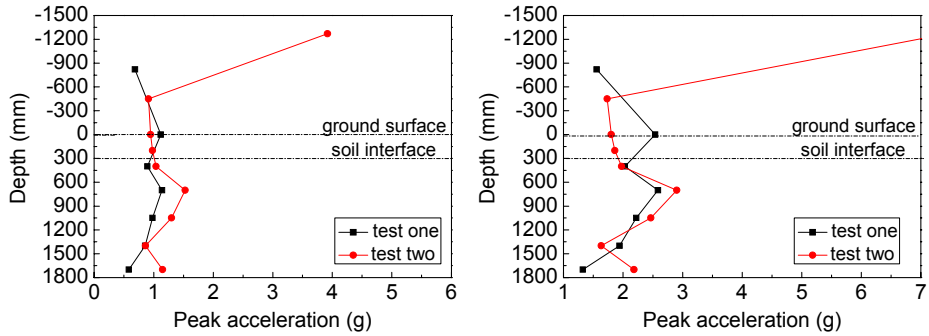

Figure 6. Peak acceleration of the pile and pier in event D.

The acceleration response of the pier top was mainly determined by rotation stiffness of the ground, translation stiffness and deformation stiffness of the structure. The peak acceleration and its magnification factor of the pier top were larger in test two than in test one which caused a larger displacement of the pier top in test two than in test one under events one and two, as a result, it would have a negative effect on the whole stability of the structural system and indicated that elevated-cap pile group was more helpful to amplify the acceleration of the pier top compared with low-cap pile. Considering the similar input earthquake motion, the same structure material and the nearly uniform structure displacement component in both tests, these were mainly because the low-cap was fixed in the clay layer so the rotation stiffness of low-cap pile group was larger, but the switch component and the translation component would be relatively small, however the rotation stiffness of elevated-cap pile group was smaller and the switch component and the translation component was relatively larger.

CONCLUSIONS

Compared with elevated-cap pile group, low-cap pile group was easier to satisfy seismic requirement of bridge piles in liquefiable ground.

When the sand layer didn't liquefy or partly liquefied, low cap obviously decreased the acceleration of the pile especially the upper pile segment; but elevated cap more played a role in amplifying the acceleration of the pile; the acceleration of the upper pile was significantly influenced by the cap type while the acceleration of the lower pile segment was more controlled by the restraint of the soil layer.

Whether the pile type was low cap and elevated cap or not the peak acceleration of the column pier gradually increased bottom-up and the acceleration of the pier top exhibited to amplify the input shaking acceleration evidently when the ground liquefied incompletely. The peak acceleration of the pier top on low-cap pile decreased a little as the ground liquefied completely, in addition, the peak acceleration of the column pier decreased gradually bottom-up.

ACKNOWLEDGEMENTS

Funding was provided by three National Natural Science Foundation of China (No.90815009, No.50378031 and No.50178027) and the shaking table tests were implemented in State Key Laboratory for Disaster Reduction in Civil Engineering in China. These supports are gratefully acknowledged.

ABSTRACT

As an effective scanning method with no damage, the CT scanning technique is used more widely in studying the dynamic deformation of frozen soil. Aiming at stability and dynamic deformation of frozen soil, the structural change before and after a dynamic tri-axial test, failure type and their main affecting factors of frozen soil taken from roadbed of Qinghai-Tibet Railway are discussed from microstructure according to CT scanning results. It indicates that water content, temperature and confining pressure are the main affecting factors. Change of density, strength and modulus during dynamical deformation decreases with an increase of water content and confining pressure, similarly the changes of the microstructure and structure. When temperature decreases, density, strength and modulus decrease rapidly, but the microstructure and structural changes decreases. When axial dynamic strength decreases, degradation of density, strength, modulus changes from large to small at the beginning and then from small to large, but structure change and demagnification are the reverse of that. The dynamic failure type of the frozen soil depends on the composite in condition of higher water content and lower temperature, but belongs to loose expand and border cracking when water content is lower, belongs to equally expand type when confining pressure or temperature is higher, belongs to composite and uniform expand type when confining pressure is lower and water content is higher, and belongs to loose failure type when confining pressure is higher and water content is lower. To frozen soil, these CT scanning results and recognition not only benefit the study pf stability and dynamic deformation, but also provide important data for further dynamic characteristics studies and establishing dynamic deformation models.

INTRODUCTION

CT scanning is a reliable detection method for the dynamic performance and deformation structural study of frozen soil (Pu et al 1995, Ma et al 1995, Liu et al 2002, Sun et al 2005, Ling et al 2003, Xu et al 2005). At present, according to

structural change of dynamic deformation of frozen soil, some research has completed many testing and theoretical studies of failure mechanisms (Ling et al 2003). Stability and dynamic deformation of Qinghai-Tibet Railway roadbed, based on low temperature dynamic tri-axial test condition, structural change, failure type and their main influence factors, are discussed from microstructure of CT scanning and some beneficial results are achieved.

MEASURING INTRODUCTION

The test was conducted in the State Key Laboratory of Frozen Soil Engineering CAS of China. An MTS-810 material testing machine with automatic numeric control and collection system was used to perform low temperature tri-axial testing. The CT scanning instrument was Siemens SOMATOM plus X-ray spiral CT machine with differentiating rate 0.35 mm×0.35 mm, least distinguish volume 0.12mm3(layer thick 1mm) and reduced density differentiating rate 0.3%(3Hu). These tests satisfied Standard for soil test method (GB50123/T-99), Code for Measurement Method of Dynamic Properties of Subsoil (GB50269/T-97), and German Siemens Corp. standard method (C1-015.208.05.03.02).

CT scanning included testing the same transect of the same specimen before and after dynamic tri-axial test in order to compare the changes. Also, the testing transects are modified to normalize the test data and eliminate error from differences in layer and size before and after the test. CT data is calculated by the Housfield formula, $ME=1000(\mu-1)$. in which, μ is the mass absorption coefficient, determined by clustering regression analysis of CT scanning results of several samples and was modified according to water content. Generally, only the main correction terms are considered in soil tests. The CT number is calculated approximately by $ME=1000[1-A(RD-S)](\mu-1)$, in which S represents the standard specimen diameter; R represents the equivalent diameter of the real specimen; D represents the average density of the soil; A represents a correction coefficient for the specimen.

Silty clay was sampled from the roadbed of the Beilu River section of Qinghai-Tibet Railway. Its plastic limit is 16.4%, liquid limit is 27.9%, dry density is 1.8g/cm^3(Wang et al 2005). For comparison of the results, standard specimen (62mm diameter, 125mm high) were batch made by the artificial frozen method using remolded silty clay. First, soil was made with water content of 13%, 18% and 23%, respectively. Then, in order to ensure its water content and homogeneous structure, setting the soil aside without evaporation for at least 6 hours. Thirdly, dies were filled and compacted layer by layer to the design dry density. After molding it was quickly frozen for about 48 hours at -30°C. After demolding and set aside for 24 hours with constant temperature of testing condition, the specimens were consolidated for 2 hours in the low temperature pressure cell of the tri-axial testing machine.

TESTING RESULTS

CT scanning results before dynamic tri-axial test. Data of CT scanning before low temperature tri-axial testing show that initial water content affects mass absorption coefficient of frozen soil to X rays directly. For instance, when the water content is 18% (DQ kinds of frozen soil), $\mu=1.304$. When the water content is 23%

(NO kinds of frozen soil), μ =1.167. To DQ kinds of frozen soil, CT number ME=1662.51, average square difference SD=141.73. To NO kinds of frozen soil, CT number ME=1512.91, average square difference SD=133.12. It can be concluded that the former possesses finer and closer structure, higher strength and larger modulus which is consistent with testing results of dynamic strength and dynamic shearing modulus of frozen soil. On CT photos, black represents high density, white represents low density and gray distribution represents uniformity of structure. So, from Figure 1, DQ kind of frozen soil is much finer and closer. This can be explained that water content of DQ kind of frozen soil is equal to the optimum water content (18%) and is easily compacted. From CT photos, it can also be found that structural characteristic of NO kind of frozen soil is weaker and compaction density is lower, and some black strip and plaque are distinctively visible.

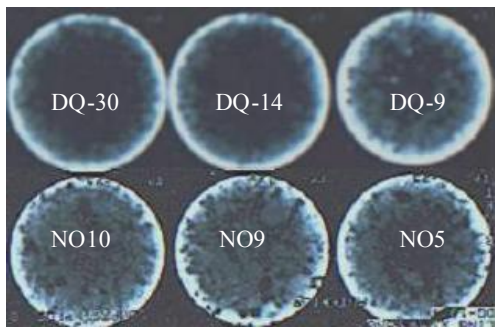

Figure 1. CT photos of frozen soil specimen transect before dynamic tri -axial test.

Comparison of CT scanning results. Through transect CT scanning parameters before and after dynamic tri-axial test, mean CT number increment and square deviation increment were calculated. Then the bar graphs were drawn to describe the relationship between water content, confining pressure, negative temperature, and axial dynamic load with two increments. According to these relationships, CT photos and common optics photos of dynamic deformation of soil specimen, some recognition on the effects of water content, confining pressure, negative temperature and axial load to dynamic deformation is achieved.

(1) Water content

After dynamic tests, the mean CT number increment increases greatly and are all negative when water content increases from 13% to 23% as shown in Figure 2. It indicates that the decrease in density, strength and modulus due to dynamic deformation becomes less. When water content increases from 13% to 23%, square deviation has a big decrease, and as the latter increases the former decreases. It indicates that the change of micro deformation mechanism and structural demagnification of frozen soil with higher water content changes less, but for deformation mechanism and structural demagnification, lower water content soil has bigger value. As shown in Figure 3, specimens with water content of 23% belong to composite failure. From the inner part to the edge, the structure changes gradually. Specimens with water content of 13% loose expand and border cracking type of failure. Structure of the inner part is fine and close, but in the border, there are wide

cracks. From Figure 4, which is from common optics photos, specimens with water content of 23% compress in the axial direction and expand in the diameter direction without any visible cracking. But, specimens with water content of 13% have distinctive shearing cracks. To sum up, water content deeply affects deformation, failure mechanism and structural change of frozen soil.

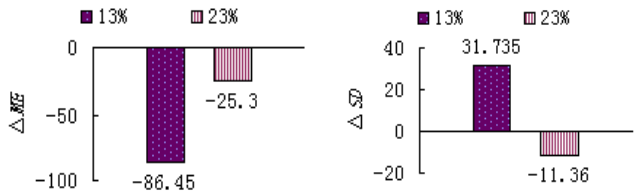

Figure 2. Bar graphs of CT data for frozen soil at varying water content .

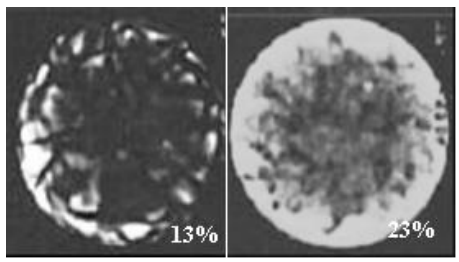

Figure 3. CT photos of frozen soil specimen transects after dynamic tri -axial test .

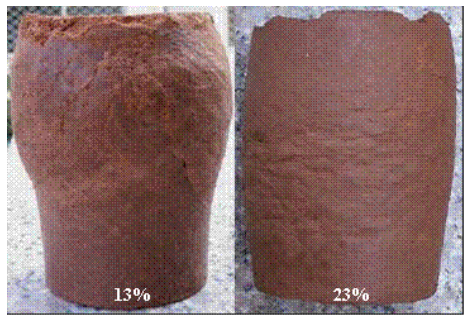

Figure 4. Photos of frozen soil specimens after dynamic tri -axial test.

(2) Confin ing pressure

As shown in Figure 5, confining pressure increases from 1MPa to 1.5MPa, mean CT number increment and square deviation increment both increase and remain negative. It indicates that the decrease in density, strength and modulus of frozen soil due to dynamic deformation becomes less as confining pressure increases. Higher confining pressure gets along with far less decrease of density, strength and structural characteristics. Under a confining pressure of 1.5MPa, the structure of the soil is finer and closer, and strength and modulus of it are higher compared with under a confining pressure 1.0MPa. This law is consistent with testing results of dynamic strength, maximum dynamic shearing modulus of frozen soil (Dynamic strength and maximum dynamic shearing modulus under confining pressure 1.5MPa are higher than that under confining pressure 1.0MPa).

As CT photos show in Figure 6, under confining pressure 1.0MPa and

1.5MPa, specimens show a type of uniform expand failure. From the inner part to the border, the failure effect becomes more serious. Structural characteristics change gradually. The inner part is fine and close, but in the border, there are wide cracks. From Figure 7, common optics photos, specimens under confining pressure 1.0MPa and 1.5MPa both have shearing cracks. Consequently, confining pressure affects deformation, failure mechanism and structural change of frozen soil to some extent, and significantly to failure mechanism.

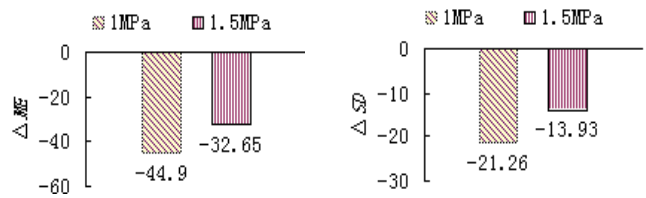

Figure 5. Bar graphs of CT data for frozen soil at varying confining pressure .

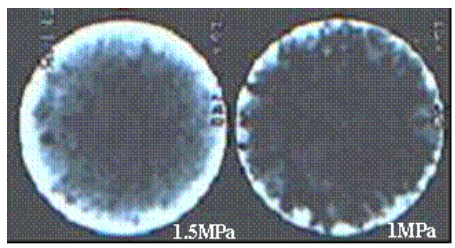

Figure 6. CT photos of frozen soil specimen transect after dynamic tri -axial test .

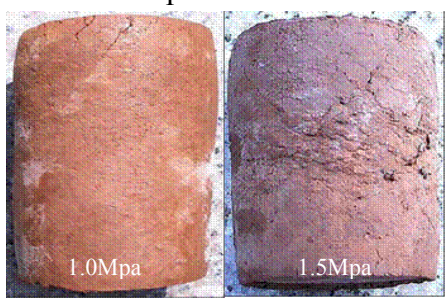

Figure 7. Photos of frozen soil specimens after dynamic tri -axial test.

(3) Negative temperature

As shown in Figure 8, temperature decreases from -2°C to -12°C, and mean CT number increment decreases and is less than zero. It indicates that the decrease of density, strength and modulus of frozen soil due to dynamic deformation becomes larger as temperature decreases. Square deviation increment (△SD) increases and remains negative. Lower negative temperature goes along with a far less decrease of density, strength and structural characteristics. That is to say, structural change and demagnification of frozen soil decreases with negative temperature drops down. This point fits the testing result that the stability of higher-temperature frozen soil is weaker than that of lower-temperature frozen soil well. Furthermore, change law of △ME and △SD with negative temperature can reflect the softening transform of the deformation mechanism. As CT photos show in Figure 9, at -2°C, small deformation

and large compact density of the inner part, loose structure and wide cracks of the border indicates an expand type of failure. At -12°C, similar structure and deformation of the transect, a little large compact density of the inner part, serious failure and many wide cracks indicate a composite type of failure. From Figure 10, common optics photos, specimens at -2°C failure due to compression at axial direction and expand in diameter direction, but at -12°C, there is no obvious deformation and failure characteristic.

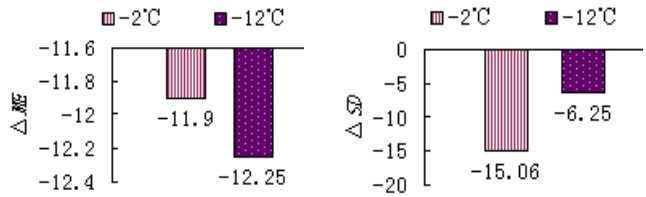

Figure 8. Bar graphs of CT data for frozen soil at varying low temperature .

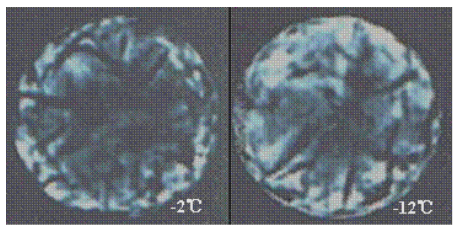

Figure 9. CT photos of frozen soil specimen transect after dynamic tri -axial test .

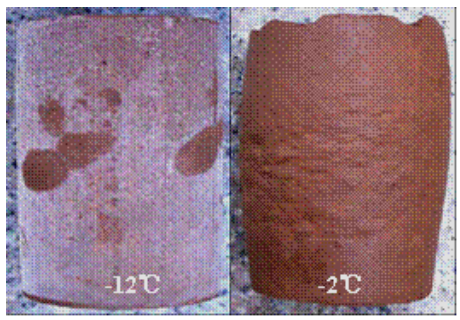

Figure 10. Photos of frozen soil specimens after dynamic tri -axial test.

(4) Intensity of axial dynamic load

As shown in Figure 11 and Figure 12, in the condition of confining pressure of 1MPa and water content of 23%, axial loads of 5.5MPa , 5MPa , 4.5MPa and 1.0MPa are applied successively. After the test, the mean CT number increment is negative and changes from increase to decrease. Square deviation increment is negative also, but changes from decrease to increase. It indicates that, along with decrease of dynamic load, a decrease in density, strength and modulus changes from large to small, then, to large, but the decrease of structural characteristics and demagnification change from small to large, then, to small. In condition of a confining pressure of 2MPa and water content of 13%, the law is similar except less change value. As CT photos shown in Figure 13, in condition of the confining pressure of 1.0MPa and water content of 23%, micro-characteristics of uniform deformation are obvious. The inner part of the transect exhibits a consistent deformation along with fine and close structure, but in the border, serious failure has

taken place. In the condition of a confining pressure of 2.0MPa and water content of 18%, the failure belongs to the loose type, and micro characteristics of integral failure are obvious. Structure of the whole section is dense with wide cracks. From the inner part to the border, failure effects becomes more serious. From Figure 14, common optics photos, plastic deformation is obvious in the condition of a confining pressure of 1MPa and water content 23%. But, shearing cracks, axial compression and expansion in diameter direction is obvious in condition of confine pressure 2MPa and water content 18%. It should be said that intensity of axial dynamic load can affect to dynamic deformation characteristics, failure mechanism and structural change to a degree, but it will be more significant when it is analyzed in combination with other factors.

CONCLUSIONS

(1) Water content, negative temperature, confining pressure and axial load are

all main affecting factors of dynamic deformation structure change and failure type.

(2) In low temperature dynamic tri-axial testing condition, change of density, strength and modulus during dynamical deformation decreases with increasing of water content and confining pressure, similar to change of microstructure and structure.

(3) With temperature decreasing, change of density, strength and modulus decrease rapidly, but the structural change and degrade of demagnification decreases.

(4) With axial dynamic strength decreasing, degrade of density, strength and modulus changes from large to small at beginning and then from small to large, but structure change and demagnification are the reverse of that.

(5) Dynamic failure type of the frozen soil belongs to composite in the condition of high water content and lower temperature, but belongs to loose expand and border cracking when water content is lower, belongs to uniform expand type when confining pressure or temperature is higher, belongs to composite and uniform expand type when confining pressure is lower and water content is higher, and belongs to loose failure type when confining pressure is higher and water content is lower.

ENDING WORDS

With rapid building and development of civil engineering in cold regions, dynamic performance and dynamic stability of frozen soil have taken great attention. CT scanning technique on frozen soil deformation and destroy are well developed, it provides an effective method for study dynamic performance, deformation structural change, failure type and affecting factors. On the base of many scholar's instructive study, using CT scanning technique, aiming at frozen silty clay taken from roadbed of Beilu River section of Qinghai-Tibet Railway, structural change of dynamic deformation, type of failure and its affecting factors interaction under low temperature are studied, especially reference (Xu et al 2005), supplemental testing item of micro mechanism and failure type under axial dynamic load are performed, some beneficial recognition are achieved.

ABSTRACT

The finite element analysis is used to investigate the effects of initial water content, freezing temperature and freeze-thaw layer thickness on the stability of the thawing slope in a seasonally frozen region of Northeast China. The finite element method with shear strength reduction technique is used to evaluate the stability of slopes under the freeze-thaw processing. The numerical results indicated that the slope stability decreases with increasing initial water content, debasing freezing temperature, increasing freeze-thaw layer thickness and thawing depth. Initial water content has the biggest influence on the slope stability. The above results enrich the investigations on the freeze-thaw stability of slopes in the seasonally frozen areas and provide the instructions for engineering practice controlling the freeze-thaw stability of slopes.

INTRODUCTION

China ranks third among the biggest four frozen soil countries of the world, and the area of seasonally frozen soil is $5.14\times10^6 km^2$. The engineering, such as road, construction, water conservancy, power station and mine are extensively distributed in the seasonally frozen regions. Especially in recent years, with the executing of the strategic of the western development and promoting the northeast, infrastructure of seasonally frozen regions will be more developed. Nevertheless, freeze-thaw hazard is becoming one of the primary problems restricting the engineering construction, and urgent need to be studied and solved. At the present time, the stability of slope and landslide control in unfrozen regions is investigated deeply, and plentiful and substantial results are obtained. Because the stability of slope in seasonally frozen regions is affected by more factors, such as repeated freeze-thaw, than in unfrozen regions, up to now, there are few studies of slopes in seasonally frozen regions and the data is dispersion(Harris et al 2000, LIU, H. J. et al 2006, Simonsen et al 2002, NIU, F. J., et al 2002, SHAN, W., et al 2008). Natural slope and manmade slope are distributed in the topical seasonally frozen soil distributed in most regions of the

Northeast China, and freeze-thaw stability becomes the important hidden danger of engineering construction. In view of the above content, according to the stable control problem of the slope in seasonally frozen regions of China's Northeast, the finite element analysis is used to investigate effects of initial water content, freezing temperature and freeze-thaw layer thickness on the freeze-thaw stability of the slope, thus to develop investigations of freeze-thaw stability in seasonally frozen regions.

FINITE ELEMENT ANALYSIS

Condition simplification. Because of the complication of the frozen soil, for simplification, some hypothesizes are as follows:

(1) Soil is assumed to the isotropic homogeneous material. The Northeastern China seasonally frozen region locate at the inner of Song-liao basin, where natural terrain fluctuates small and quaternary sedimentary changes small, soil is the material of isotropic homogeneous in the same slope, thus the simplification is basically reasonable.

(2) Hydrodynamic pressure and hydrostatic pressure of ground water are not considered, and there is not water supply and excretion of the boundary. Freeze-thaw failure and landslide occur in spring thawing period. There is no infiltration or infiltration content is little because of non-rainy season in spring thawing period, together with groundwater circulation usually occurs below freeze-thaw surface, so the effects of the ground water on freeze-thaw stability of the slope can be neglected.

(3) Soil is equitable freezing and thawing.

(4) Calculation model is simplified as plane strain problem because the dimension of cross section is much smaller than vertical section.

Relation of stress-strain. The shear strength of soil is the key factor of evaluating slope stability, and soil slope will be failure when maximum shear stress reaches failure limit. Based on this, the ideal elasto-plastic model based on Mohr-Coulomb yield criterion is adopted.

Definition of safety factor. The safety factor of the slope is defined as

$$F_s = \frac{\tau_f}{\tau_M} \tag{1}$$

where F_s=safety factor, τ_f=actual shear strength and τ_M=maximum shear strength at failure.

Introducing Mohr-Coulomb yield criterion, the safety factor can be expressed as

$$F_s = \frac{c + \sigma_n \tan\varphi}{c_c + \sigma_n \tan\varphi_c} \tag{2}$$

where c is the actual cohesion; φ is the actual friction angle, c_c is the cohesion at failure, φ_c is the friction angle at failure and σ_n is the actual normal stress component.

The parameters c and $\tan\varphi$ are reduced by the same proportion until the slope failure, so the safety factor can be further expressed as

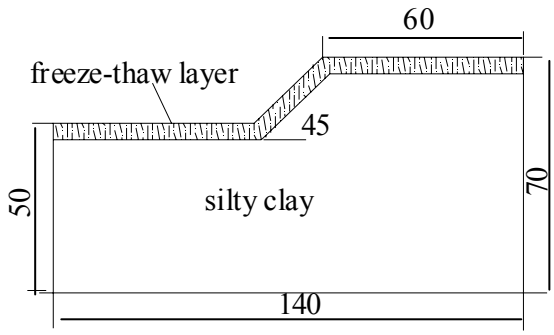
$$F_s = \frac{c}{c_c} = \frac{\tan\varphi}{\tan\varphi_c} \tag{3}$$

In the paper, evaluation criteria for the stability of the slope are synthetically

considered between plastic zone transfixion and displacement mutation of characteristic notes.

Calculation model and mesh generation. The concrete application of the numerical analysis on freeze-thaw stability of slopes is described based on a highway cut slope in a seasonally frozen region of China's northeast. The slope with a height of 20m and a gradient of 1:1 is analyzed with a two-dimensional finite element mesh, as shown in Figures 1 and 2. Calculation region is divided into two regions, frozen region and unfrozen region. The boundary condition of displacement constraint is adopted in the paper, that is, horizontal displacements are restricted at right and left boundaries and the vertical and horizontal displacements are restricted at the lower boundary. Based on the principle of virtual work, element matrix is formed, and total stiffness matrix is assembled by the direct stiffness method. Hooke's law is used to solve element stress.

Physical and mechanical parameters. The physical and mechanical parameters of the frozen soil, thawing soil and unfrozen soil are listed in Table 1.



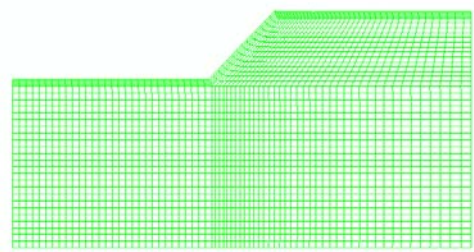


Figure 1. Profile sketch of slope (unit: m). **Figure 2. Partition scheme of slope.**

ANALYSIS OF INFLUENCE FACTORS

The practice shows that the primary factors affecting the stability of slope in seasonally frozen region are initial water content, freezing temperature and freeze-thaw layer. Based on the above example, the factors affecting freeze-thaw stability of slope are analyzed by the Finite Element Method (FEM).

Influence of initial water content. In order to investigate the influence of initial water content on the stability of the slope with different thawing depth (h), conditions are shown in Table 2.

Figure 3 depicts the relationship between safety factor and initial water content at different thawing depth (h). When h is constant, the safety factor of the thawing slope decreases with the initial water content increasing, that is, stability of the slope decreases. When $h \leq 1$m, there are less effects of initial water content on stability of the slope. Nevertheless, when $h \geq 1.5$m, there are obvious effects. When W_0 is constant, the safety factor of the thawing slope decreases with the thawing depth increasing. Especially when the initial water content exceeds 14%, the freeze-thaw stability of slope decreases rapidly with increasing the thawing depth.

Table 1. Physical and Mechanical Parameters of the Soil.

Type	Water content (%)	Unit weight (kN/m^3)	Elastic modulus (MPa)	Poisson ratio	Cohesion (kPa)	Friction angle (°)	Tem per-ature ℃
Thawing soil	11.80	18.00	5	0.38	15.20	28.70	-3
	11.80	18.00	5	0.38	15.10	28.67	-5
	11.80	18.00	5	0.38	15.00	28.64	-7
	11.80	18.00	5	0.38	14.80	28.63	-10
	11.80	18.00	5	0.38	14.50	28.60	-15
	13.06	18.20	5	0.38	12.93	28.49	-3
	14.17	18.38	5	0.38	11.02	28.40	-3
	15.40	18.58	5	0.38	9.52	28.21	-3
	16.80	18.80	5	0.38	7.74	28.10	-3
Unfrozen soil	-	17.00	6	0.35	28.00	30.00	-
Frozen soil	-	18.00	30	0.32	40.00	28.00	-

(**Note**：'-'signs that the temperature in thawing soil is the freezing temperature before the frozen soil thawing)

Table 2. Calculation Parameters of Different Conditions.

Condition	Initial water content (W_0)	Maximum of active layer (Z)	Freezing temperature (T)
A1	11.80%	2m	-3℃
A2	13.06%	2m	-3℃
A3	14.17%	2m	-3℃
A4	15.40%	2m	-3℃
A5	16.80%	2m	-3℃

The above results show that there are greater effects of initial water content on the stability of slope during the freeze-thaw process. The reason is that the volume of soil water rises during the freezing process, filling the gap of soil particles, promoting soil particles moment, and induce changes of soil structure, and hence make intensity change. As increasing of initial soil water content during the freezing process, the water migration to freezing front increases, and lead to more intensive change of soil structure. If the water can not discharge promptly when active layer soil melts, the mechanical parameters of melted soil would decrease significantly, and make stability

of melted slope decrease. Therefore, the freeze-thaw stability of slope decreases with increasing the initial water content and thawing depth. The relationship between safety factor and initial water content of slope of all the ice melting is linear descending, as shown in Figure 4.

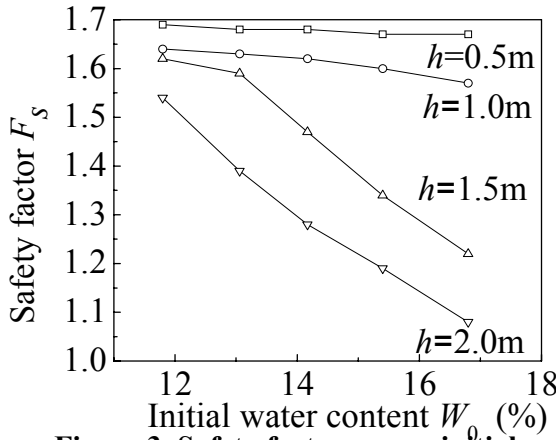

Figure 3. Safety factor versus initial water content at different *h*.

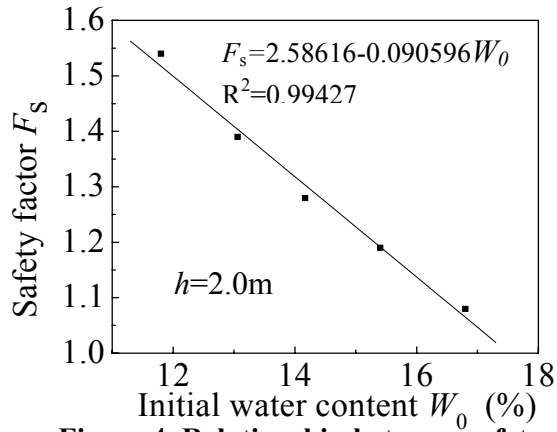

Figure 4. Relationship between safety. factor and initial water content.

Influence of freezing temperature. Freezing temperature affects the freezing rate and unfrozen water content after stably frozen, consequently affects the frozen-thawed soil structure. The mechanical properties of the frozen-thawed soil change with the different freezing temperature. In order to study the effects of freezing temperature on the stability of the slope with different thawing depth, the following five conditions are selected, that is, T=[-3, -5, -7, -10, -15]℃. Other parameters see condition of A1.

Figure 5 shows the relationship between safety factor and freezing temperature at different thawing depth. When h is constant, the safety factor of the thawing slope decreases with the freezing temperature decreasing, that is, stability of the slope decreases. When h≤1.5m, there are less effects of freezing temperature below -10℃on stability of the slope. When T is constant, the safety factor of the thawing slope decreases with the thawing depth increasing.

The above results show that there are certain effects of freezing temperature on the stability of slope. During the freezing process, temperature gradient of freezing temperature field increases with the freezing temperature decreased, which make the water freeze quickly at peak surface and the Mass and energy balance is destroyed, thus unfrozen water migrates to freezing surface quickly. Soil water content and structure are changed by freezing temperature, and induce the decrease of shear strength of thawing soil, consequently the stability of slope is decreased. Figure 6 shows the relationship between safety factor and freezing temperature when thawing depth is equal to freeze-thaw depth is linear descending.

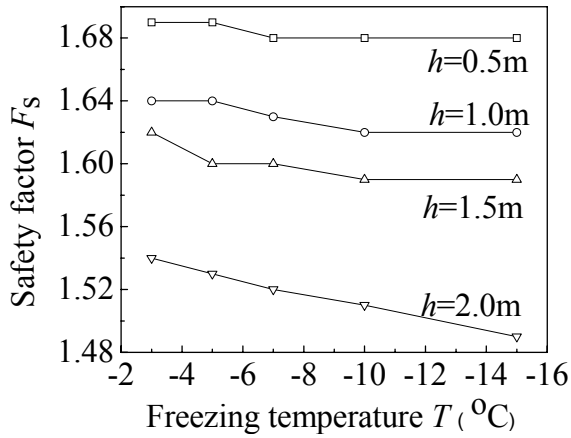

Figure 5. Safety factor versus freezing temperature.

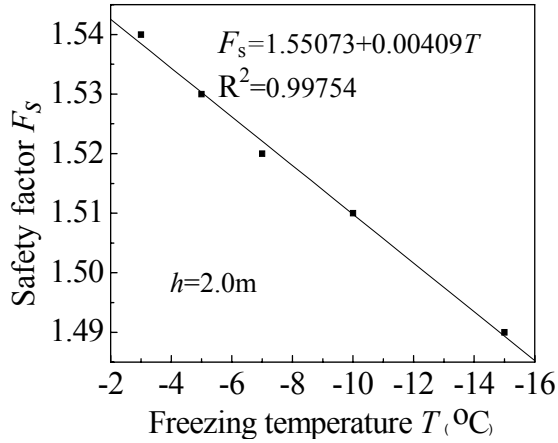

Figure 6. Relationship between safety factor and freezing temperature at different *h*.

Influence of freeze-thaw layer. In order to investigate the effects of seasonally freeze-thaw layer on the stability of the slope, the following five conditions are selected, that is, Z=[0.0, 0.5, 1.0, 1.5, 2.0]m. Others parameter see Table 3.

Table 3. Calculation Parameters of Different Conditions

Condition	Active layer (m)	Thawing depth (m)
H=20m β=45° W_0=11.8% T=-3℃	0.0	0.0
	0.5	0.5
	1.0	1.0
	1.5	1.5
	2.0	2.0

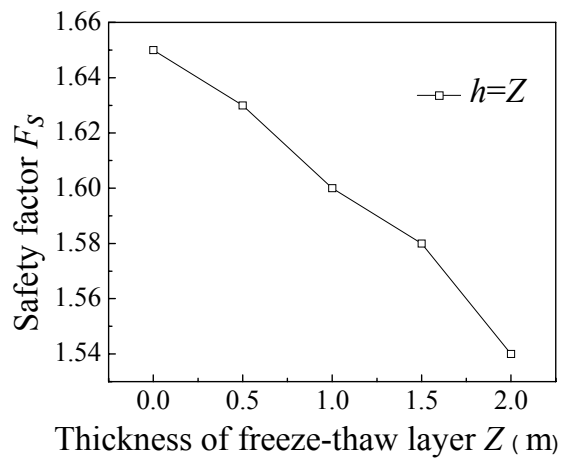

Figure 7. Safety factor versus thickness of freeze-thaw layer at *h*=*Z*.

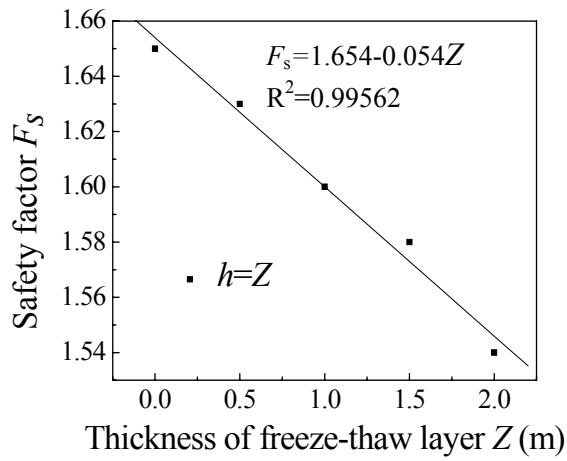

Figure 8. Relation between safety factors and thickness of the freeze-thaw layer.

Figure 7 depicts the relationship between safety factor and thickness of active layer when thawing depth is equal to active layer. The safety factor of the thawing slope decreases with the active layer increasing, that is, stability of the slope

decreases. Because the mechanical parameters of soil decrease during freeze-thaw process, the downslide trend of slope is apparent with the thawing depth decreased, and the stability of slope decreases.

Figure 8 shows the relationship between safety factor and thickness of active layer when thawing depth is equal to freeze-thaw depth. Linear descending relationship between safety factor and thickness of active layer is obtained.

CONCLUSIONS

The following conclusions are obtained:

(1) Freeze-thaw stability of the slope decreases with increasing initial water content, reducing freezing temperature, increasing freeze-thaw layer thickness and thawing depth.

(2) The relationships between safety factor and initial water content freezing temperature and freeze-thaw layer are all linear descending, and the fit formulas which can predict the freeze-thaw stability of slope in seasonally frozen region are obtained.

ABSTRACT

Based on the elastic-plastic finite element method and limiting equilibrium theory, this paper focuses on the high slope stability and analyses the influence by the work environment and strength of the high slope structural plane at Hang-Yong Natural Gas Pipeline in China. The numerical results reveal that this high slope is in the ultimate equilibrium state and it maybe occurs to rapidly slide when it is in heavy rainfall condition; Draining the groundwater level and infusing slurry on the weak structural plane could improve the stress condition and advance emergency capacity inside slope; and the slope safety coefficient may reach 1.61 integrating the two methods proposed. However, it must adopt other engineering method to reduce the tensile damage at after-edge of slope. All above studies are significant for supplying the basis references to reinforcement methods and monitoring the high slope in safety.

INTRODUCTION

This engineering slope locates at an inclined ramp in Yinzhou county, Ningbo City of China, along the Hang-Yong Natural Gas Pipeline. In history, this slope had three landslips happen in the direction of E140°S, which landslide body fissure distributes at after-edge and two sides and leading edge, the figure of after-edge is an approximately vertical arc and northern and southern side is an arc as a whole. The first landslide happened in 1956 and could not be researched cause of long time, the second landslide happened in 1995 with a 2.0-4.0m high of posterior wall and a superficial layer 2000m^3 cubage of slide slope, and the third landslide happened in April 2005 with a 0.5-1.6m high of posterior wall, which several fissures with a 2-5cm width occurred in slope body firstly, the fissures became obviously and wider subsequently, last the slope happened to slide at leading edge with a small capacity 300m^3.

At present, this side slope is creeping deformation, and it may occurs to rapidly slide in the condition of heavy rainfall according to the site exploration, which could

directly pose hazard on the adjacent Hang-Yong Gas San-Shan Station and it's pipelines without effective reinforement in time, and it could lead to unmeasurable economic losses and aftermath. Therefore, this paper study and estimates the high slope's stability based on the elastic-plastic finite element method and limiting equilibrium theory, and the different reinforcement methods are calculated and analyzed to provide the guiding datum to reinforcement scheme and safety monitor subsequently.

ENGINEERING GEOLOGY SURVEY AND SLIDE GENESIS

This slope developed on the erosion - abrasion hilly area. The direction of the hill is South-North direction and the gradient is about 20°-30°. The exposed stratum is composed of the gravel silty clay (Q_4) and the ignimbrite (J_3x). Moreover, three structural planes with a 1-3 lines in per meter and 0.5-15 meter extension are developed in this area.

There is a weak structure plane in the slope body according to the drilling data and fissure feature. As is shown in Figure 1, this slope could be subdivided into three parts: the lower part is the anti-slide portion with 30 meters length, which failure face is gentle and weak interlayer in intensive weathered bedrock, there are tensile and fanlike fissure at edge. The middle part is the main slide portion with 40 meters length, which failure face dip angle is changeable from 7° to 40° and it is the contact face between intensive and weak weathered bedrock. The upper part is the pull-type slide portion with 25 meters length, which the fissure is tensile and the slide plane is the contact face between intensive (native soil) and weak weathered bedrock.

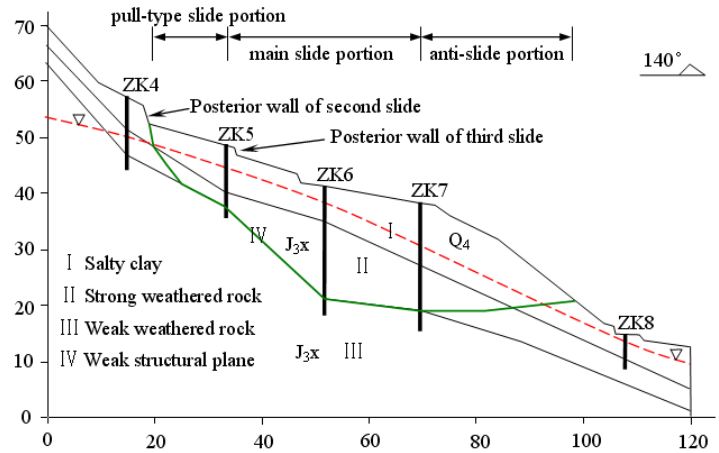

Figure 1. Engineering geology map of slope (unit: m).

Many factors lead to incipient fault in this slope. The first is the thicker native soil (maximizing 20 meters) with a weak machnical property. The second is the heavy rainfall increasing the rock-soil gravity and the saturated slope matter softening the native soil layer and intensively weathering bedrock and the mechanical strength of structure face. Moreover, the human engineering practice, such as chronically irrational quarrying and excavation slope for road in the slope leading-edge, has posed incipient fault on the slope destabilization.

STABILITY ANALYSIS

Constitutive model and mechanical parameters. Using the finite element ZZYFEM2005 to analyze the slope stability (Zhang et al 2007, Zhu et al 2008,Yu and Zhu 2004), which the slope materials are assumed to be an isotropic body and the calculation model is simplified to be a plane strain. As is shown in Figure 2, the calculation range is 120m×70m, and the horizontal placement is zero at two sides, and the vertical placement is zero at lower boundary. There are 3706 quadrilateral unit with same parameter and 3602 node points in this model. It adopts the Goodman contact face and the nonlinear elastic model for constitutive relation at structural plane in slope body, and the ideal elastic-plastic model in other material constitutive relation, and the Drucker-Prager yield criterion for rock mass. The physical mechanics parameters are listed in Table 1. Most of them are determined by the engineering geology exploration results, consulting the structural deterioration and degree of weathering in rock body and the similar other engineering parameters (Ye 1991).

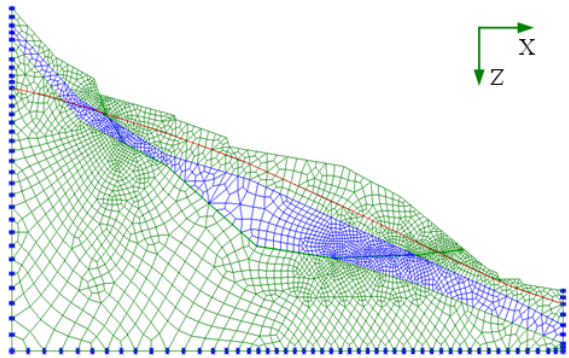

Figure 2. Finite element mesh of slope in nature condition (unit: m).

Table 1. Mechanics Parameters of Slope Materials.

	Condition	Elastic modulus MPa	Poisson ratio	Unit weight kN/m^3	Cohesion kPa	Friction angle °	Shear stiffness kN/m	Normal stiffness kN/m
I	N	8.0	0.30	18.5	250	28	—	—
	S	7.5	0.30	21.5	220	25	—	—
II	N	600	0.35	22.5	750	30	—	—
	S	580	0.35	23.0	700	28	—	—
III	N	657	0.35	24.5	830	35	—	—
	S	650	0.35	25.0	800	32	—	—
IV	N	—	—	21.5	23	12	4810	41600
	S	—	—	22.0	12	9	4000	38900

Note: "N" represents the natural condition, and "S" represents the saturated condition.

Slope safety factor. The global slope safety factor is equal to the ratio between anti-slide force and slide force at structure face for the rocky slope containing weak structure face (Ling and Cai 2002, Li et al 2003, Zheng et al 2005). It utilizes the finite element program to calculate the stress at joints in weak structure face to establish the

integral slope safety factor F_s, which overcomes the shortcoming that the bottom force at rock-soil strip is not the real stress in limiting equilibrium theory.

$$F_s = \frac{\sum_{i=1}^{N} T_{fi}}{\sum_{i=1}^{N} T_i} = \frac{\sum_{i=1}^{N} \left(c_i + \sigma_{ni} . \tan \varphi_i \right) A_i}{\sum_{i=1}^{N} \tau_{si} A_i} \tag{1}$$

Where N represents the slide numbers in slide body, T_i represents the slide force of No.i slide plane along slide direction, T_{fi} represents the anti-slide force of No.i slide plane along slide direction and A_i represents the area of No.i slide plane after taking out tensile region.

Stability analysis. It obtains any point's stress, yielding approach and state through the finite element calculation in natural condition in this slope. The maximal shear stress nephogram is shown in Figure 3. It displays that the maximal shear stress foamats the concentrated zone nearby the built-in point of structural plane and it emerges in saturated intensive weathered bedrock. Moreover, the unidirectional tension failure appears at the after-edge of slope surface as is shown in Figure 4, which it coincides with site exploration; and the slope is in ultimate equilibrium state because the integral safety factor of slope is 0.97. The stress in concentrated zone of maximal shear stress is increasing in complete saturation state than natural satae cause of locally abundant precipitation rain fall, here the slope in a destabilizing state becase the interface betwwen soil and rock is obvious and safety factor of slope is 0.90.

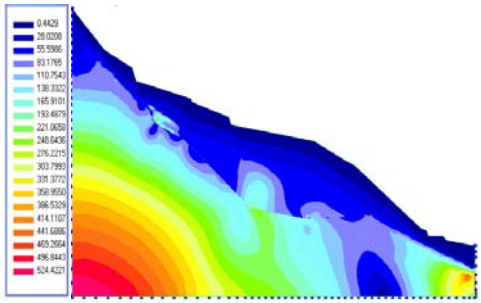

Figure 3. Nephogram of $\tau_{\max}$ in nature condition.

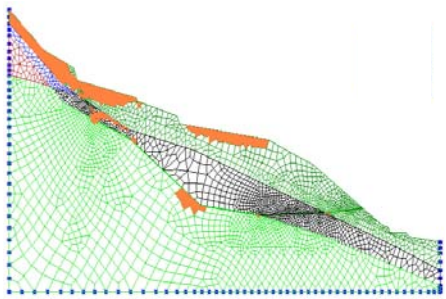

Figure 4. Distribution of yield zone in nature condition.

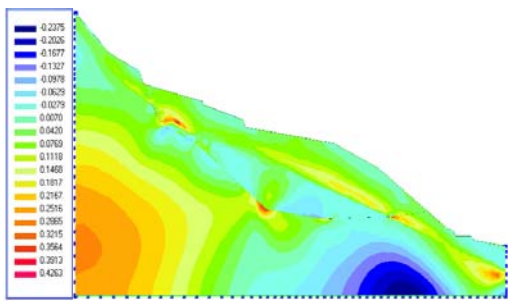

Figure 5. Nephogram of η in nature condition.

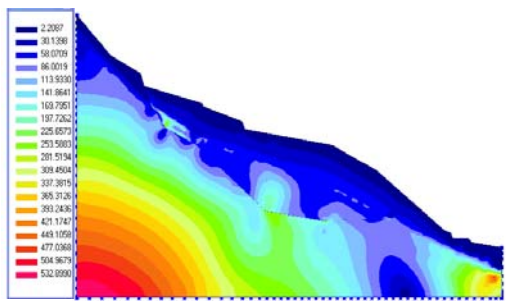

Figure 6. Distribution of $\tau_{\max}$ in saturated condition.

ANALYSIS OF DIFFERENT REINFORCEMENT METHODS

Draining groundwater level. The mainly treating methods are setting

drainage system, draining the groundwater level and decreasing infiltration flow to display the strength of structural plane and rock-soil body for the high slope with higher groundwater level and structure face. The maximal shear stress and approaching degree of yield is displayed in Figure.7 in condition of the groundwater level under the entire structural plane; which the range of stress concentrated zone decreased and the maximal shear stress cut down comparing with it in natural state; the approaching degree of yield reduced too and the maximal approaching degree of yield of slope body unit is close to 0.27. Here the slope safety factor is 1.26 and 0.29 higher than it in natural state and it increased the slope emergency capacity.

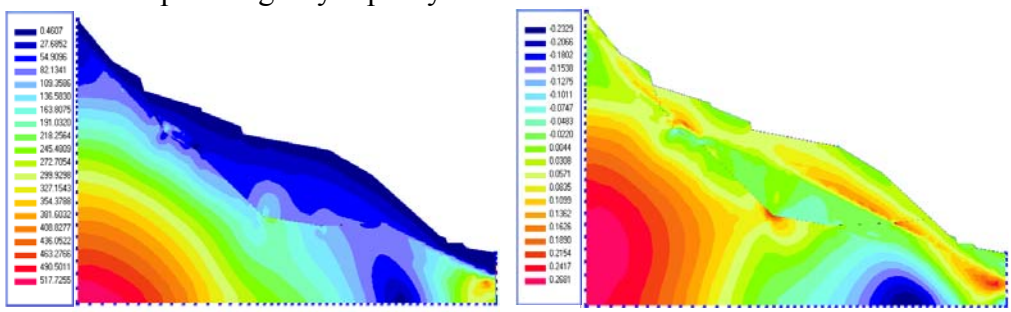

Figure 7. Nephogram of τ_{max} and η under drained slope (Fs=1.26).

Infused slurry of structure plane. The infused slurry is common in slope reinforcement, which infused slurry with High pressure could increase the strength indexing of structure face utilizing existing drilling hole. Table 2 lists the calculation parameter of this slope after infusing slurry. The maximal shear stress and approaching degree of yield are displayed in Figure 8 through finite element method calculation, which the maximal shear stress decrease and the approaching degree of yield reduce comparing with it in natural state; the integrating safety factor is 1.29, therefore the entire slope stability is enhanced effectively.

Table 2. Mechanics Parameters of Structure Face after Infusing the Slurry.

Type	Unit weight kN/m^3	Cohesive kPa	Friction angle °	Shear stiffness kN/m	Normal stiffness kN/m
Natural structure plane	22.0	30	15	4810	41600
Saturated structure plane	22.5	16	12	4000	38900

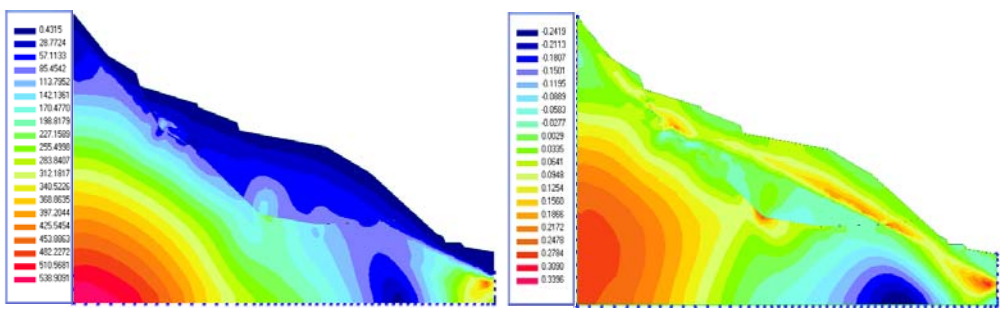

Figure 8. Nephogram of τ_{max} and η under infused slurry slope (Fs=1.29).

Draining groundwater level and infusing slurry slope body. The maximal shear stress and approaching degree of yield are displayed in Figure 9 after integrating

lowering groundwater level and infusing slurry in slope body. Comparing with it in natural state, the distribution condition of maximal shear stress is improved largely and the stress concentrated zone is reduced greatly, meanwhile it displays a uniform sandwich and the approaching degree of yield declines (the maximal is 0.26), here the integrating safety factor is 1.61.

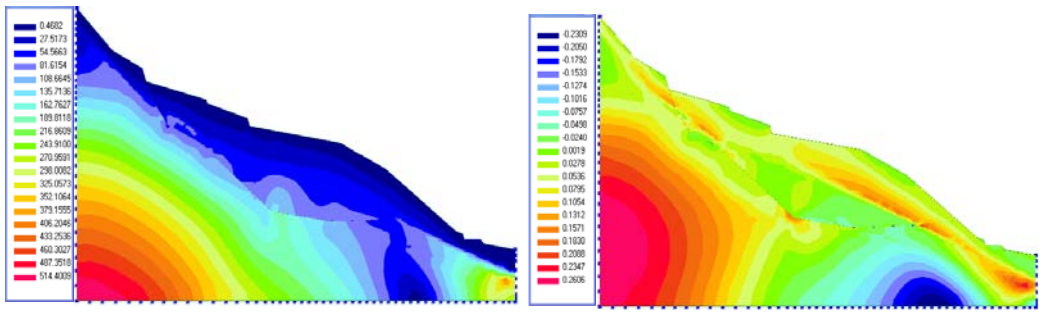

Figure 9. Nephogram of τ_{max} and η under infused slurry and drained slope (Fs=1.61).

Results comparison. Table 3 lists the results of contrast among anti-slide force, slide force and slope safety factor at structural plane in different engineering condition, which the slide force simultaneously increases along with the anti-slide force addition at the structural plane. The different is that the anti-slide force increase more rapidness than the slide force with completely saturated state exceptions. Therefore it could ensure the slope stability when the safety factor of slope gradually increases in engineering condition ③, ④ and ⑤

Table 3. Comparison between Slide Force and Anti-Slide Force in Different Engineering Conditions.

Engineering condition	Engineering condition description	Anti-slide force (kN)	Slide force (kN)	Safety factor
①	Natural condition	4335	4484	0.97
②	Completely saturated condition	4483	4941	0.90
③	Draining grounder water lever	5994	4761	1.26
④	Infusing slurry on structure plane	6188	4810	1.29
⑤	Combine the ③ and ④	7498	4643	1.61

CONCLUSIONS

Taking the high slope along Hang-Yong Natural Gas Pipeline as an example, the stability is analyzed through finite element numeric calculation at structural plane in different engineering condition, results display that it has the vital significance for the strength of structure face and work environment to integrating slope stability. Main conclusions are concluded as follows:

(1) This high slope is in ultimate equilibrium state and creep deformation stage at present, which it may occurs to rapidly slide when it is induced by disadvantage factors, especially the continuously heavy rainfall leading to completely saturated condition. therefore it may imperil the safety of gas line and job facilities at the slope leading edge.

(2) Strength of structure face is the main factor to affect the slope stability. The slope safety factor arrives at 1.25 when the groundwater drains to keep the level beneath structure face and the structure face is in natural state; and the integrating slope safety factor reaches 1.29 after infusing slurry to improve the strength of structure face, and the slope safety factor hits a peak of 1.61 integrating above two methods. The three choice schemes could improve the stress condition inside slope and greatly increase the anti-slide force, which it effectively increases the integrating safety of high slope and adds the emergency capacity.

(3) Three proposed reinforcement methods above could not eliminate the tensile failure at after-edge of slope face, and it must complement other reinforcement engineering, such as vegetative cover, to improve the tensile strength of superficial soil and prevent failure enlargement at after-edge and rainwater infiltration that it could affect the integrating safety of high slope.

ABSTRACT

To overcome the disadvantages of the limit equilibrium method and the finite element method on evaluation the stability of slope with the weak structural plane, the elastic-plastic finite element method, the Goodman joint element and the limit equilibrium method are utilized together, and two concepts, that are the joint element safety factor and the node yielding degree, are introduced to evaluate the slope stability with the weak structural plane, and the correspond calculation codes are programmed. Finally, a man-made slope case is analyzed to validate the numerical model and program codes. The stress, strain, displacement, the node yielding degree of the slope and the force of weak structural plane are calculated by elastic-plastic finite element method, and the element safety factor of the slope with the weak structural plane are calculated with the limit equilibrium method. That numerical results are agree well with the engineering fact indicates the program coded are reliable, and the proposed numerical model and two introduced concepts can not only consider the influence of the relation of stress and strain on the slope stability, but also evaluate the stability of the slope with single stability factor of safety which is well known in geotechnical engineering. All of above are meaningful to evaluated the slope stability and provide a new and simple numerical approach.

INTRODUCTION

With development of economic and society, more and more man-made slope are created. For example, natural slopes are excavated to construct the roads, railways, dams and other projects in mountainous area. Therefore, stability evaluation of engineering slope is very necessary and significant for protecting these projects keep in safety and from disasters. During the past three decades, many researches have been studying on the stability of slope, and have achieved many fruits. The limit equilibrium method (LEM) has still been playing the most important role in the slope

stability analysis (Duncan 1996, Chen 2003). It is able to provide a safety factor of a slope without the knowledge of the initial conditions with the result that the LEM is favored by many engineers, although the LEM does not consider the relation of stress-strain of geo-materials. Recently, as the many particular advantages of the finite element method (FEM) over the limit equilibrium method, especially the development of the numerical simulation technology, the finite element method has achieved a greater attention and increasing applications in the slope stability analysis (Zhang et al 2007, Zhu et al 2008, Tan et al 2008). However, using the FEM to ensure the safety factor for engineer is difficult and can not instruct the engineering practice. Fortunately, the strength reduction FEM are proposed and developed (Zhao et al 2003, Zheng et al 2004), the safety factor can present by reducing the strength parameters continuously until meeting some convergence criteria(Griffiths et al 1999, Zheng et al 2004, Fang et al 2008), but the calculation process is complex and the results are subjective.

Therefore, to overcome the disadvantages of the LEM and FEM, a simple approach, combining the LEM and the FEM, are introduced based on the nonlinear stress-strain relation and the Goodman joint element to establish the numerical simulated model, and the corresponding codes are programmed based the Fortran Language to evaluate the stability of slope with the weak structural plane. The joint element safety factor and the node yield degree are introduced to evaluate the slope stability. Finally, a case is analyzed to validate the numerical model and the program codes.

THEORY OF SLOPE STABILITY

Elastic-plastic relation of stress-strain. Most mechanics behaviors of geo-materials are nonlinear. It is well recognized that stress-strain relations do not remain linear, even for the low stress levels. So the elastic-plastic model is used to describe the relation of the stress and the strain for the geotechnical material. Slope stability nonlinear FEM usually adopts perfect elastic-plastic model, whose increment form is,

$$\{d\sigma\} = \left[D_{ep} \right] \{d\varepsilon\} = \left[D_e - D_p \right] \{d\varepsilon\} \tag{1}$$

Where: $d\sigma$ is the stress increment, $d\varepsilon$ is the strain increment, $[D_e]$ is the elastic matrix, $[D_p]$ is the plastic matrix, and $[D_{ep}]$ is the elastic-plastic matrix.

For the perfect elastic-plastic materials, the elastic-plastic matrix $[D_p]$ could be calculated as,

$$D_p = \frac{[D]\left\{\frac{\partial g}{\partial \sigma}\right\} \left\{\frac{\partial f}{\partial \sigma}\right\}^T [D]}{A + \left\{\frac{\partial f}{\partial \sigma}\right\}^T [D]\left\{\frac{\partial g}{\partial \sigma}\right\}} \tag{2}$$

Where: A is a parameter to present the material hardening. For the perfect elastic-plastic model, A is equal to 0. While adopting associated flow rule, $g \equiv f$ =0.

Simulation of weak structural plane. Using the Goodman joint element to simulate the weak structural plane of slope, and do not consider the coupling effect between the normal and the tangential. Its increment form could present as:

$$\begin{Bmatrix} d\tau_s \\ d\sigma_n \end{Bmatrix} = \begin{bmatrix} k_s & 0 \\ 0 & k_n \end{bmatrix} \begin{Bmatrix} du_s \\ du_n \end{Bmatrix} \tag{3}$$

Where: $d\tau_s$ is the shear stress increment, $d\sigma_n$ is the normal stress increment, k_s is the shear stiffness of the weak structural plane, and k_n is the normal stiffness of the weak structural plane.

Node yielding degree. The weak structural plane is one of the sensitive influence factors on the slope stability. However, that whether the slope body is yield and generate a new sliding plane is easily ignored if only consider safety condition of the weak structure plane. Therefore, using the node yielding degree to present the process of node enter into yield state (Yu and Zhu 2004). For the Drucker-Prager criterion, the node yielding degree is:

$$\eta = \frac{\alpha I_1 + \sqrt{J_2}}{k} \tag{4}$$

Where: $\alpha = -\sin\varphi \Big/ \left(\sqrt{3} \cdot \sqrt{3 + \sin^2\varphi}\right)$, $k = -c \cdot \sin\varphi \Big/ \sqrt{3 + \sin^2\varphi}$, I_1 is the first invariant of stress tensor, and J_2 is the second invariant of stress deviator tensor. If the yielding degree is greater than or equal to 1.0, the node meets the yield state. Otherwise, the node is the normal state.

Joint element safety factor of slope. According the limit equilibrium theory, the global safety factor of soil and rock slope with weak structural plane is equal to the ratio that the total resisting shear force divide by the shear force on structure plane (Li et al 2003, Zheng et al 2005). Through the finite numerical analysis to achieve each element stress of the structural plane, and the joint element safety factor F_s^i is,

$$F_s^i = \frac{T_{fi}}{T_i} = \frac{c_i + \sigma_{ni} . \tan\varphi_i}{\tau_{si}} \tag{5}$$

and the global safety factor of slope F_s is,

$$F_s = \sum_{i=1}^{n} F_s^i \tag{6}$$

Where: n is the total number of slip planes element, F_s^i is the element safety factor, T_i is the shear force along the shear direction on the i^{th} slip plane element, T_{f_i} is the resisting shear force along the shear direction on the i^{th} slip plane element, and F_s is the global safety factor of slope

Based the above numerical theories of slope stabiliy, the codes to simulate the slope stability are programmed. The stress, displacement, node yield degree and the element safety factor can gain through these codes to evaluate the slope stability.

STABILITY ANALYSIS OF SLOPE

Engineering geology of slope. This engineering slope case is locates at a slanting hillside along the Hangzhou-Ningbo natural gas pipeline of China. In history, this slope has taken place three severe slides, the main sliding direction is about N140°E, the surface sliding split mainly is the tensile and shear splits distributing on posterior edge, both sides and front edge of the slope, the sliding posterior edge boundary is about vertical arced, the north and south side is nearly arced.

Figure 1 shows the engineering geology profile of slope case. The profile direction is about N140°E, and the gradient of slope is 20°-30°. According to the geology exploration, the slope stratum contains the salty clay (Q4) and the ignimbrite (J_3x). The groundwater level is about 4m-10m. In slope, a weak structural plane (i.e., $\overline{ABCDEF}$) through the salty clay and the strong weathered rock appears in the slope foot. Influenced by the rainfall, the surface of slope appeared many tensional fractures, therefore, to protect the natural gas pipeline and the road from destroyed by the landslip, the stability of this slope need to evaluate.

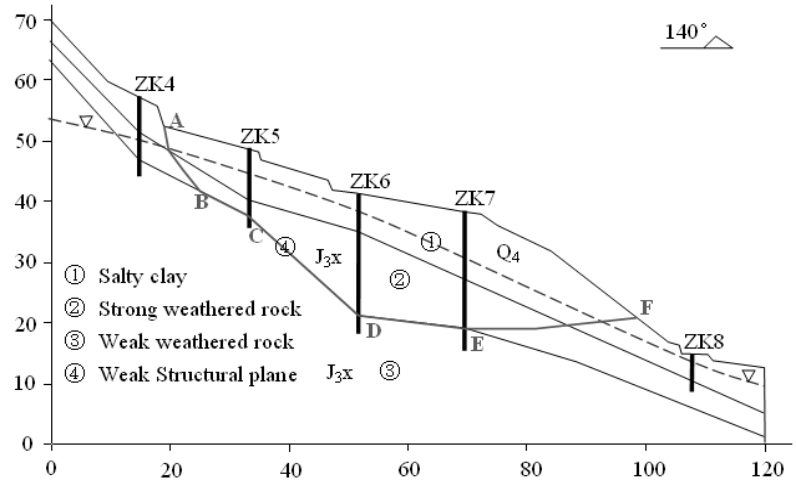

Figure 1. Engineering geology profile of slope (unit: m).

Numerical model. The geotechnical materials of this slope are assumed to the homogeneous body and the numerical model is simplified to two-dimension the plane strain problem. As is shown in the Figure 2, the calculation geometry of the finite element model is 120m in length and 70m in height, the displacements of

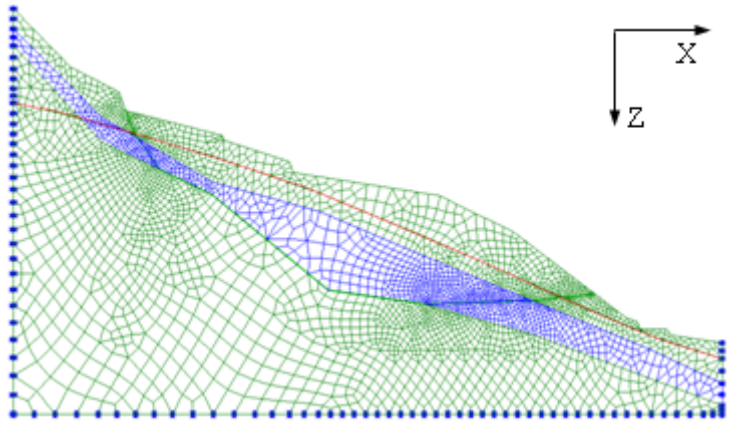

Figure 2. Finite element mesh of slope in natural conditon (unit: m).

horizontal and the vertical direction are zero. The geometry model is subdivided into 3706 isoparametric quadrilateral elements and 3602 nodes. The soil and the bed rock are used the ideal elastic-plastic model, and the structural plane in slope is simulated by Goodman joint element. Additionally, the Drucker-Prager strength criterion is adopted in this model.

According to the parameter test experiments, the physical and mechanical parameters of the geotechnical materials in this model are listed in Table 1, and part mechanical parameters are got by the back analysis (Zhang et al 2008) or reference (Ye 1991)

Table 1. Mechanics Parameters of Slope Materials.

NO.	State	Elastic modulus MPa	Poisson ratio	Unit weight kN/m^3	Cohesion kPa	Friction angle °	Shear stiffness kN/m	Normal stiffness kN/m
①	N	8.0	0.30	18.5	250	28	—	—

④	N	—	—	21.5	23	12	4810	41600
	S	—	—	22.0	12	9	4000	38900

Note: “N” represents the natural condition, and “S” represents the saturated condition.

NUMERICAL RESULT AND ANALYSIS

Through the program codes, the stress, strain, displacment, node yielding degree and element safety factor are gained to evluate the slope stability. Figure 3 shows the maximum shear stress nephogram of slope in nature condition. Note that most zones of the maximum shear stress distribute on its rules, but influnced the structural plane, three concentration zones are formed near the the structural plane,

and the maximum shear stress can approach to 214kPa.

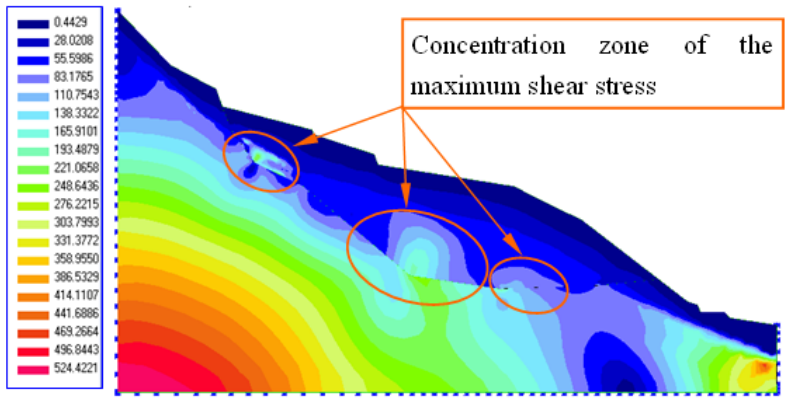

Figure 3. Nephogram of maximum shear stress of slope in nature condition.

Figure 4 shows the nephogram of yielding degree of slope in nature condition. Note that the largest yielding degree of slope is only 0.426, and the area is not reach into the yield state. However, because of the soil strengh is lower than bedrock strengh, the potential sliding surface is developed on the boundary plane betweent the saturated soil and the weathered rock, it should be give an greaer attention on reinforcement the slope.

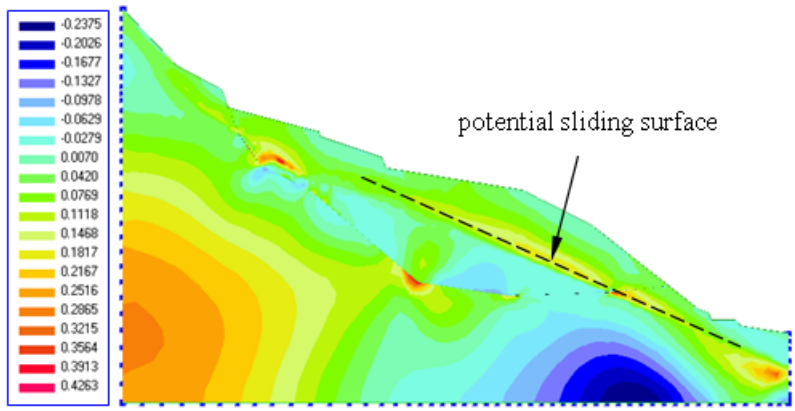

Figure 4. Nephogram of the yielding degree of slope in nature condition.

To reflect the force distribution on the weak structural plane, Figure 5 shows the force distribution of the weak structural plane along the element from A to F. Note that the resisting shear force and the shear force are positive correlation and maximum shear force approach to 236kN happed on element No.55. On the most elements, the shear force is equal to the resisting shear force, and most of element safety factor are greater than 1.0 too. However, the safety factor from No.0 to No.50 are less than 1.0, especially on the element from No.40 to No.55 (i.e., from point C

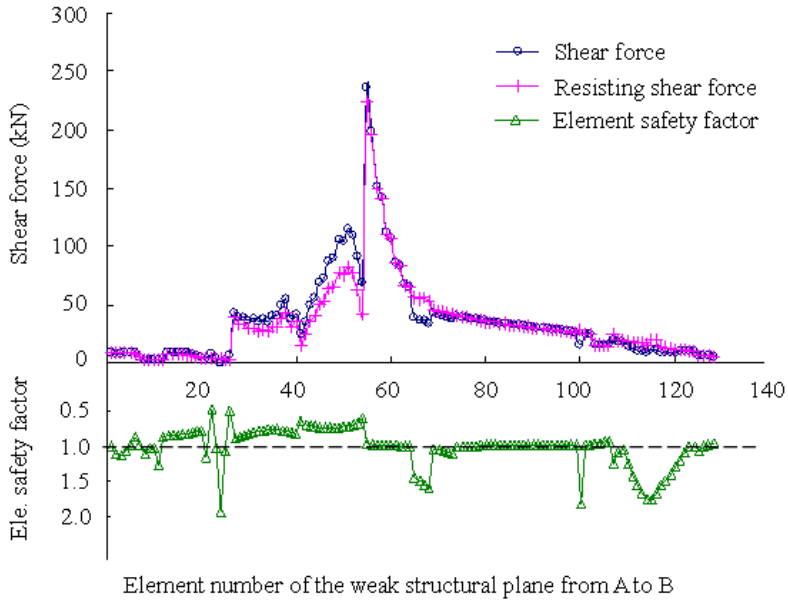

Figure 5. Force and element safety factor of the weak structural plane.

and point D), the shear force is greater than the resisting shear force.

Therefore, the main unsteady reason of this slope is that the resisting shear force can not resist the shear force on the No.12 to No.55. One of good approach to keep the slope in safety is improving the resisting shear force of these elements. Moreover, Numerical reslult shows that the total shear force of the structural plane is 4484kN, and the total resisting shear force is 4335kN, the resisting shear force can not resist the shear fore, and the entire safety factor of slope is 0.97, so the slope is at limit equilibrium state, this result is in good agreement with the actual phenomenon of the case slope, which verifies the reliability and rationality of the numerical model and program code.

CONCLUSIONS

Based on the 2-D nonlinear finite method and limit equilibrium method, the numerical simulation model proposed in this paper and its program code are verified by the slope case, it shows that:

(1) The proposed numerical simulation model can overcome the disadvantage of limit equilibrium method and the finite method. The stress-stain relations of the geo-materials are considered and the global safety is provided for engineer design.

(2) The program codes are reliability and rationality to evaluate the slope stability with the weak structural plane. Using this method can not only calculate the element safety factor, but also give the element shear force and resisting shear force. Moreover, the potential sliding surface is easly presented by the nephogram of the yielding degree.

(3) The proposed numerical simulation model and the program codes are able to evaluate the similarly slope stability, which give an insight on evaluation the slope stability and meaningful for reinforcement the slope.

ABSTRACT

The vibration characteristics of embankment induced by passing trains in the Qinghai-Tibet railway were investigated, and the effects of vibratory load of train on soil-in-ice layer were quantitatively evaluated, based on the self-programming software of vehicle-track-embankment dynamic coupled system. The results indicate that: (1) the maximum dynamic compressive stress induced by locomotives is apparently higher than that by trailers. (2) Vibrational energy of the embankment top surface concentrates on the interval from 0.5Hz to 10Hz, and dominant frequency of soil-in-ice layer top surface is within 3Hz; (3) The phenomenon of stress concentration emerging in ballast at rail supporting position is apparent, and the distribution of maximum dynamic compressive stress of roadbed surface is in the shape of saddle. (4) Vibratory load of train has main effect on embankment in an ellipse-shaped zone about 6m under sleeper. (5) The maximum dynamic compressive stress level of soil-in-ice layer top surface induced by trailers is about 16.7~19.8% that of embankment top surface, and negative exponential function is used to fit the attenuation relationship of embankment dynamic compressive stress versus depth. (6) Embankment vibration displacement is predominant in the vertical direction, and the dynamic displacement of soil-in-ice layer top surface can be neglected. The conclusions are the reliable theoretical basis for engineering design and safety analysis of Qinghai-Tibet railway operation.

INTRODUCTION

With the opening to traffic of Qinghai-Tibet Railway, China scientific academia has made significant progress in the world problem of road building engineering in permafrost regions. Currently, dynamic performance of embankment with frozen layers and simulation of geothermal field mechanism have been further researched by domestic and foreign scholars, and great achievements has been

obtained (Cheng 2005, Wu et al 2002, Ling et al 2002, Wang et al 2005, Zhu et al 2007, etc). However, road construction work in permafrost regions is still the world wide difficult problem, for the disease rate of route is 30% approximately. The permafrost engineering reliability evaluation of Qinghai-Tibet railway is a complicated work under the trend of global temperature rising, thus the question is whether subgrade vibration deformation can meet demand of railway normal operation and disease rate is less than 15%. Accordingly, the characteristics of embankment vibration induced by passing trains in the Qinghai-Tibet railway were investigated, and the effect of train vibratory load on soil-in-ice layer was quantitatively evaluated in the paper, based on the embankment structure of the Beiluhe test section in the permafrost region along Qinghai-Tibet Railway and the self-programming software of vehicle-track-embankment dynamic coupled system. The results are the reliable theoretical basis for engineering design and Qinghai-Tibet railway operation safety evaluation.

DYNAMIC FINITE ELEMENT ANALYSIS MODEL

Test section situation. The Beiluhe test section is in the arid climate region of the Qinghai–Tibet Plateau. The mean annual air temperature in the region is −5.2℃, and the highest temperature gets up to 23.2℃, and the lowest temperature is -37.7℃. The frozen period lasts about 7 to 8 months, from September to April next year (Niu et al 2002), and the maximum thickness of snow cover is 14 cm. From state key laboratory of frozen soil engineering of Chinese Academy of Sciences, the following data is obtained: the depth of permafrost table is 2 to 3 m, and the mean annual ground temperature is -2.0 to -1.0℃ in the test secton; the soil consists of fine sand, silty sand, gravel sand, clay, mudstone and sandstone; the section locates in basically stable low temperature district according to the secondary zonation, where subsoil ice is extraordinarily enriched and soil-in-ice layer is continuous distribution. The route of the section, adopting 50 kg seamed steel rail, 1800 sleepers of type II per kilometer and 450mm thick ballast, is slightly curved single-line in service, with the curvature radius of approximate 1000 meters.

Calculation model. The embankment with heat pipe situated at DK1137+700, with 3.5m height and 11.3m width of top surface, has been adopted as subject investigated. Subgrade profile and geological condition can be seen in Figure 1 and Table 1. Afterwards, the calculation of static and dynamic analysis is conducted by self-programming software (ZL-RNTLM). Two-dimensional finite element plane strain model of sleeper-ballast-embankment-field system is shown in Figure 2, which has 12697 joints, 125277 quadrilateral elements and 10 beam elements. The calculation width of each side of foundation extends to 31m, and the calculation depth is 30m. The viscous boundary is adopted, in addition time histories of interaction force of track and sleeper are used as train vibratory loads acting on beam elements of sleeper, which is shown in Figure 3.

Constitutive relation and parameters selection. Equivalent linearization model is employed in finite element analysis. The calculation parameters of ballast, roadbed surface layer, embankment fill, and the strata are listed in Table 1, based on dynamic triaxial test of frozen soil under transportation loads and literature data of frozen soil dynamics at home and abroad. The beam element of sleeper is linear elastic and its

Elastic Modulus E is 30GPa. Section area and moment of inertia of the beam element below the track are $0.04585m^2$ and $1.59\times10^{-4}m^4$, respectively, and those of intermediate regime of the beam element are $0.0339m^2$ and $7.639\times10^{-5}m^4$, respectively.

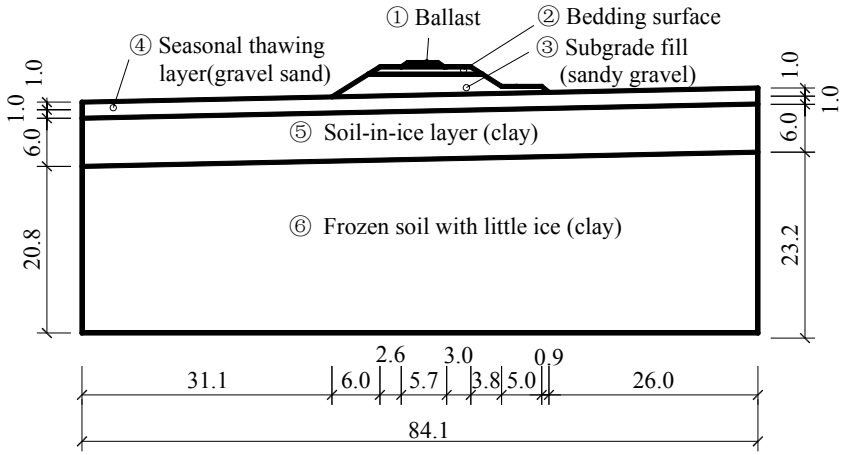

Figure 1. Profile and strata structure of subgrade (units: m).

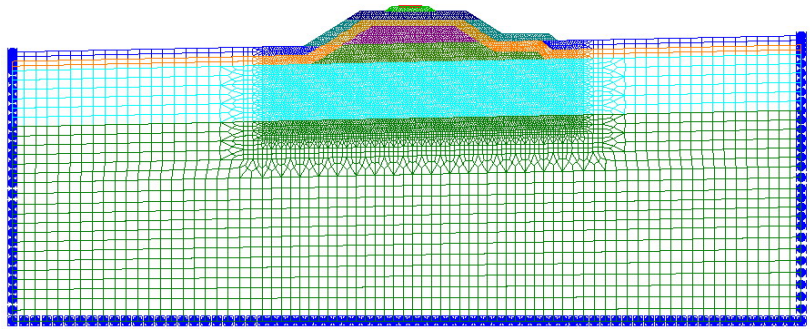

Figure 2. Finite element model of sleeper-ballast-embankment-field system.

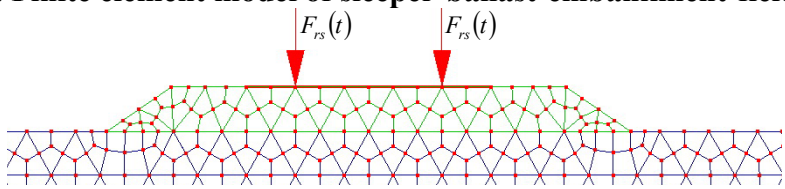

Figure 3. Beam element of sleeper and input of load.

SIMULATION OF TRAIN VIBRATORY LOAD

Dynamic analysis model of vehicle-track shown in Figure 4 is a coupled system, which is composed of vehicle model, track model and wheel-rail coupled model. The vehicle model is a multi-freedom vibrating system constituted by multiple vehicles, bogie, wheelset, secondary spring and damping shock absorber. The track model is infinite Euler beam model supported by three-layer elastic system. Three-layer mass-spring-damper system is used to simulate sleeper, ballast and embankment. Then the software ZL-TNTLM of vehicle-track coupled dynamic system is programmed based on the model. Afterwars dynamic emulation analysis on the section DK1137+700 in Qinghai-Tibet Railway is conducted by the self-compiling program under the coupled pulse excitations of mileage vertical profile irregularity and broad rail gap (10 mm). The incentive curve of sleeper nearby

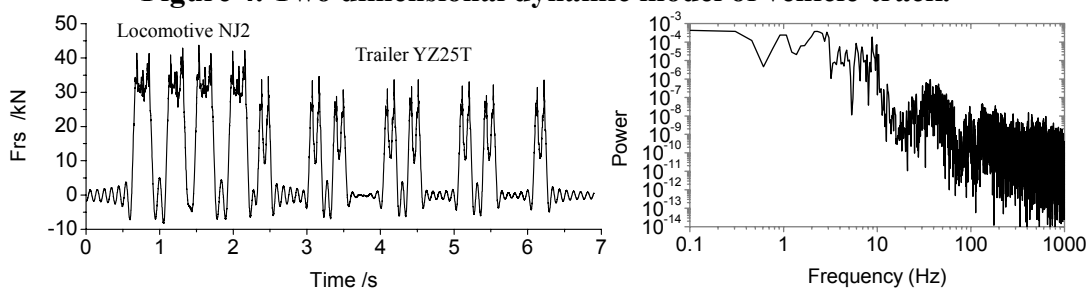

Figure 5. Time history and frequency analysis of the force exerted on sleeper.

RESULTS ANALYSIS

The vibration response analysis of the permafrost embankment induced by trains in winter is carried out by the finite model of sleeper-ballast-embankment-field system depicted in Figure 3, and by exerting the load time history shown in Figure 5 on sleeper. Figure 6 shows the time history and spectrum analysis of the subgrade dynamic compressive stress σ_{dz}, and H is distance to the bottom of sleeper. Note that maximum dynamic compressive stress of subgrade surface is 48.2 kPa during locomotives passing by, apparently bigger than 27.3kPa during trailers passing by; the vibration peaks of the embankment top surface appear as bogies passing by, and also occur near the sleeper action rate *f*, i.e. 46.9Hz, and its dominant frequency is within 10Hz; the subgrade vibration attenuates with the depth increasing, and high frequency component at soil-in-ice layer top surface disappears, aferwards the vibration dominant frequency is within 3Hz due to energy dissipation and filtering action of ground.

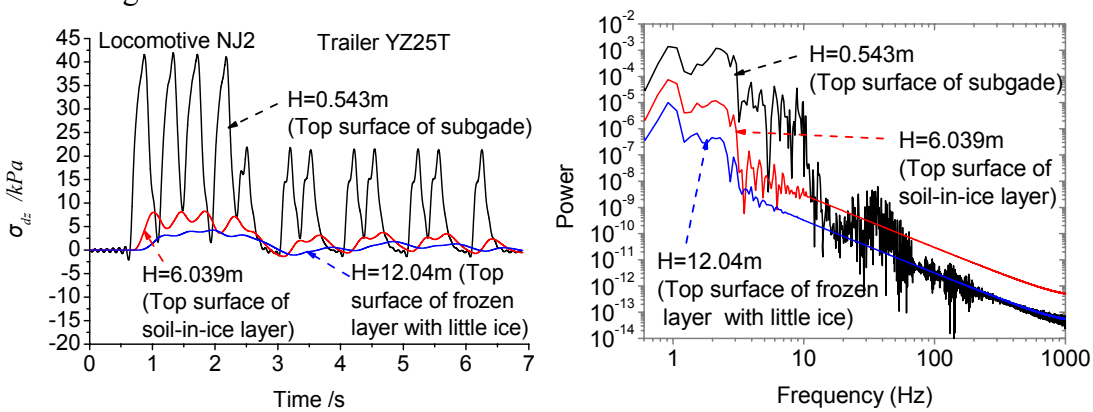

Figure 6. The time history and frequency analysis of subgrade dynamic compressive stress (K917, V=94km/h).

The distribution of subgrade dynamic compressive stress $\sigma_{dz\max}$ induced by train traffic is shown in Figure 7, which shows that: stress concentration of the roadbed near rail is apparent, the distribution of maximum dynamic compressive stress of roadbed surface is in the shape of saddle, and the main vibratory response of embankment is in an ellipse-shaped zone about 6m depth under the sleeper; maximum dynamic compressive stress of the soil-in-ice layer top surface induced by locomotive is 9.56kPa, which is 19.8% that of subgrade surface; maximum dynamic compressive

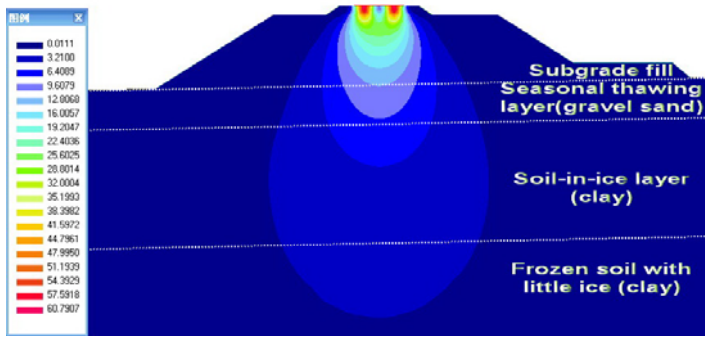

Figure 7. Maximum subgrade dynamic compressive stress (locomotive, K917, V=94km/h, units: kPa).

stress of the soil-in-ice layer top surface induced by trailer is 4.57kPa, which is 16.7% that of subgrade surface and the negative exponential function is used to fit the attenuation relationship of embankment dynamic compressive stress versus depth.

The distribution of maximum dynamic elastic displacement during train traffic is depicted in Figure 8 and Figure 9. Therein from Figure 8, it can be seen that the maximum horizontal dynamic displacement is symmetrically distributed in the subgrade profile, and predominant at the ballast near the rail supporting place and roadbed close to the brim of sleeper, and from Figure 9, the maximum vertical dynamic elastic displacement mainly focus on the ballast near the rail supporting place and the roadbed surface. It is demonstrated that embankment vibration displacement is prominent in the vertical direction, and the maximum horizontal displacement of ballast surface is 0.006mm and the vertical one is 0.244mm, however, the maximum vertical dynamic displacement of soil-in-ice layer surface is 0.000868mm, which is about 0.36% that of roadbed surface and can be negligible.

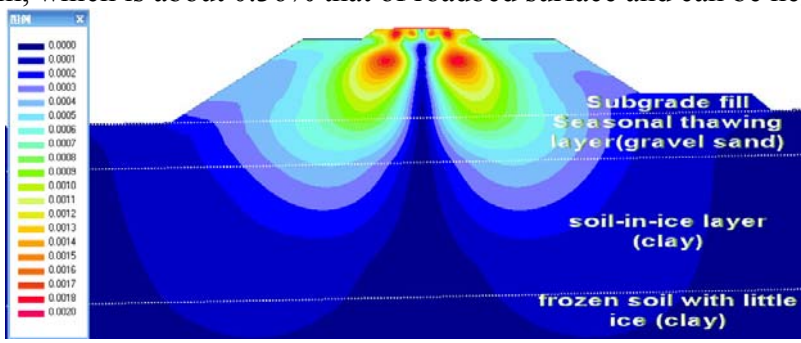

Figure 8. Maximum horizontal dynamic elastic displacement (units: cm).

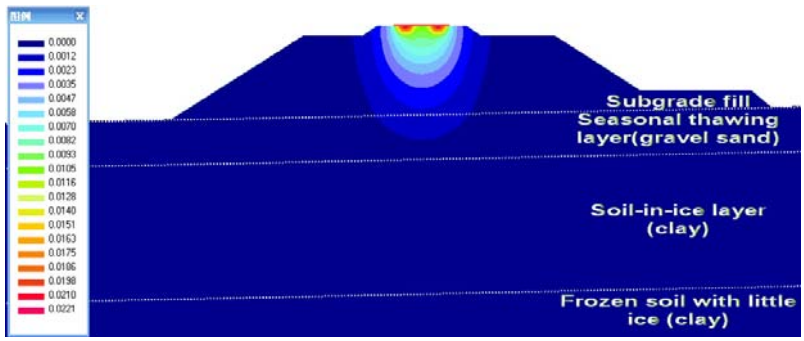

Figure 9. Maximum vertical dynamic elastic displacement (units: cm).

CONCLUSIONS

According to analysis of vibration response of the permafrost embankment induced by passing trains in the Qinghai-Tibet railway based on the established finite element model of sleeper-ballast-embankment-field system and the self-programming software of vehicle-track-embankment coupled dynamic system. The conclusions can be drawed as follows:

1) The maximum dynamic compressive stress induced by locomotives is apparently higher than that by trailers, and peaks are always appearing as bogies passing by. Vibrational energy of the embankment top surface is predominant between 0.5 Hz to 10Hz, and dominant frequency of soil-in-ice layer top surface is within 3 Hz.

2) Vibratory load of embankment from trains is mainly in an ellipse-shaped zone about 6m depth under sleeper. The phenomenon of stress concentration in the ballast close to sleeper is apparent, and the distribution of maximum dynamic compressive stress of roadbed surface is saddle in shape, and the maximum dynamic compressive stress of soil-in-ice layer top surface induced by passing trailers is about 16.7-19.8% that of roadbed top surface. The attenuation relationship of embankment dynamic compressive stress versus depth can be fitted by negative exponential function.

3) Embankment vibration displacement is mainly prominent in the vertical direction, and the dynamic displacement of soil-in-ice layer top surface is very small and can be neglected.

Abstract: Because of the importance of seismic engineering, a practical cable-stayed bridge under the earthquake reaction is analyzed. The dynamic calculation model of the large-span cable-stayed bridge is created by ANSYS. The reaction of the bridge and the stay cable under seldom occurred earthquake is analyzed. The rationality of its design is checked. The results demonstrate that the failure of the dropped beam in superstructure and the shear failure of the bridge tower and pier can not occur under the seismic design grade specified by seismic code. The emergency capacity of the cable is enough in the safety standards. The results demonstrate that the design of the large-span cable-stayed bridge is reasonable.
Key words: cable, cable-stayed bridge, earthquake, dynamic model, seismic grade

1 Introduction

China is a country with much threatening earthquake. Especially, a terrible earthquake of 8 grade stroke Wenchuan in the Sichuan Province on May 12, 2008. The number of death people is up to 69,136 and 17,686 people is missing. The total direct losing of economy reaches 8,451 hundred billions substantially. This terrible earthquake brings huge injury into the body and spirit of every Chinese people. In the Wenchuan earthquake, all of main lines of communication and lifeline engineering are damaged completely, including highway, bridge, railway, and so on, which makes it very difficult to develop rescue behavior. Because of the importance of bridge engineering in economy and traffic, the response rule of these engineering under seldom occurred earthquake and the rationality of their seismic protection are paid more attention by seismic researchers from many countries (Irvine H. M., 1981; Cremona C., 2003).

Because of the importance of seismic engineering, a practical cable-stayed bridge under the earthquake reaction is analyzed. The reaction of the bridge and the

stay cable under seldom occurred earthquake is analyzed (Matteo J, Deodatis G and Billington DF, 1995). Several failure forms under seldom occurred earthquake, including bending failure, shear failure, the failure of the dropped beam and bearing damage are studied. The seismic design of the large-span cable-stayed bridge is checked (Faber M. H., Enelund S. and Rackwitz R., 2003).

2 Finite Element Model of Cable-stayed Bridge

2.1 General condition of engineering

The bridge system can be seen in Figure.1. The main part of bridge is a cable-stay bridge with single tower and two planes of cables. Every span is 40, 108, 16, 26m. The structure system consists of piers, tower and beams, and the connection among these components are fixed. The tower presents fold line with straight top and inclined lower side. The height of tower on the top of the bridge cover is 50m. On vertical elevation of tower, the inclined lower side is 30m high with 12° inclination angle, and the straight top is 20m high. The transverse form of tower presents reverse Y shape. The main beam of main span has the cross section with double triangle box-shaped and ribbed plate. The cables of main span are distributed in half sector and double cable plates. The distance of adjacent cable is 8m. The steel wire of cables is galvanized with the diameter of 7mm, and has high strength and low laxity. The standard strength of steel wire is 1,670Mpa. The cables on the right side of tower are numbered from A1 to A11. The cables on the left side of tower are numbered from B1 to B3. The serial number of cables and piers are showed in Figure 1.

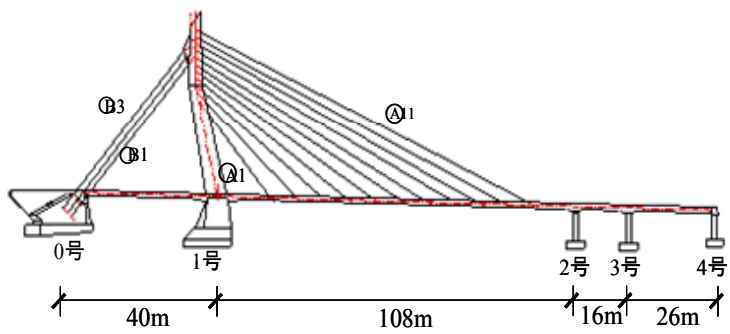

Figure 1. Elevation view of cable-stayed bridge.

2.2 Finite Element Model using ANSYS

2.2.1 Material Property and Element Selection

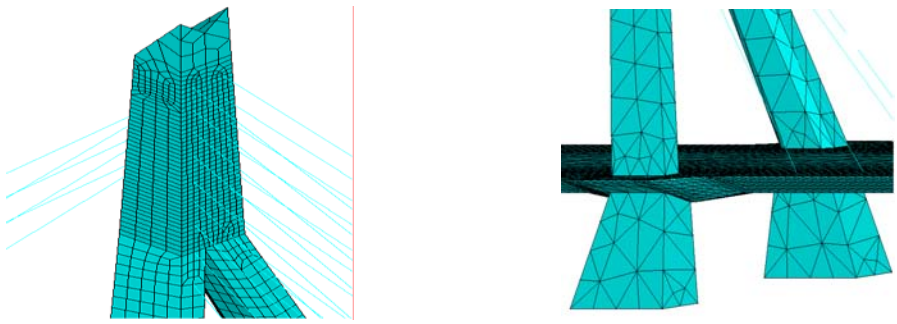
The main body of cable-stayed bridge consists of main beam, stayed cables and tower. Material properties of every component are shown in Table 1. In the modeling process of ANSYS, 3D solid element “SOLID65” is used for reinforcement concrete. Shell element “SHELL63” is used for steel plate. Linear element “LINK10” is used for cables.

Table 1. Material properties.

Material	Young's modulus/Pa	Poisson ratio	Density/(kg/m^3)	Component
Steel	2.1×10^{11}	0.3	7850	Stayed cables
Steel	2.1×10^{11}	0.3	7800	Upper tower
Concrete C50	3.45×10^{10}	0.1677	2550	Main beam、Tower、Tower piers
Concrete C30	3.0×10^{10}	0.1677	2550	Bridge piers

2.2.2 Finite Element Model and Boundary Condition Simulation

The model of the whole bridge is set up by the material properties and elements in Table 1. The connection of bridge piers and the ground is assumed to be fixed connection. The connection parts between tower and main beam are poured together by concrete. The structure in the anchoring region of cables is sophisticated, so that cable elements are set up by natural nodes on tower and beam. The finite element model of upper tower, No.1 bridge pier and lower tower is shown in Figure 2.



(a) Upper tower model (b) No.1 Bridge pier and lower tower model

Figure 2. Finite element model.

3 Modal Analysis of Cable-stayed Bridge

The frequencies and modals are analyzed by ANSYS. The modal extraction method is subspace iterative method. The former six natural frequencies are shown in Table 2. The former six modals are shown in Figure 3.

Table 2. Former six natural frequencies (unit: Hz).

First (vertical)	Second (transverse)	Third (vertical)	Fourth (transverse)	Fifth (torsion)	Sixth (torsion)
1.5362	3.3074	3.5428	3.9731	5.2880	5.4872

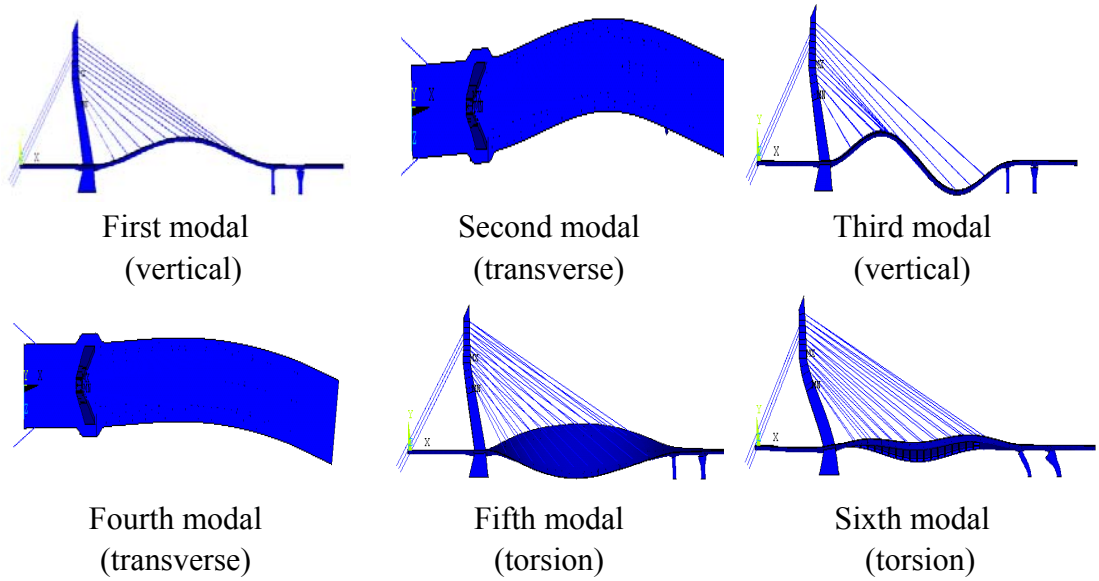


Figure 3. Former six modals.

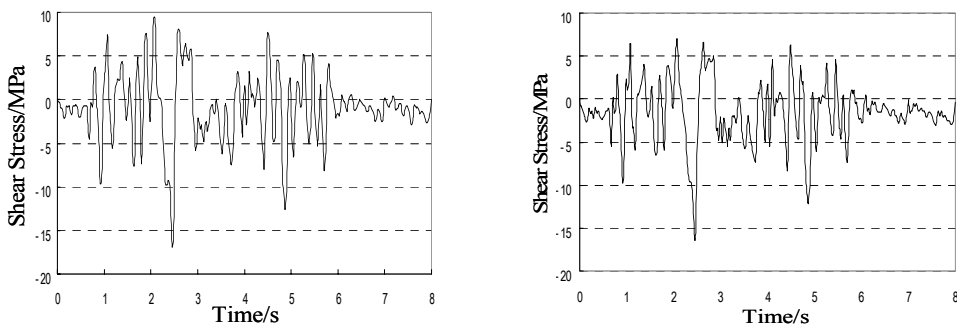
4 Time History Response Analysis

For this cable-stayed bridge, the intensity of ground earthquake is 7 degree. There is no liquefiable soil layer. The soil in this field belongs to middle hard soil. The sort of building field belongs to II class. El-centro ground motion acceleration record is used to calculate the response of the bridge under seldom occurred earthquake along longitudinal input (Cremona C., 2003).

4.1 Response of Lower Structure

The damage of bridge during earthquake often occurs from lower structure. Especially, the damage of bridge piers may lead to the drop of the beam. The damage model of high pier often presents bending form. The damage model of short pier often presents shear form. The height of this bridge is 8m, and the core of piers is solid. So the piers do not belong to high pier. The time history curves of shear stress for tower pier and the base of No.2 bridge pier are shown in Figure 4.



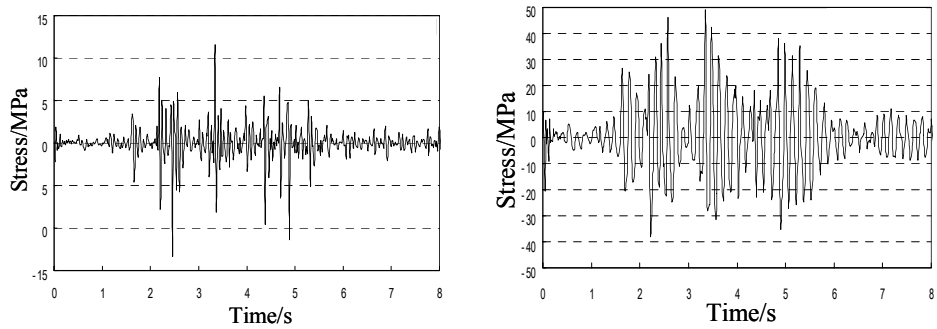
(a) Tower pier (b) No.2 Bridge pier

Figure 4. Time history curves of shear stress.

It can be seen from Figure.4, time history curves of shear stress for tower pier and the base of No.2 bridge pier are similar, and their peak values are nearly equal. The maximum shear stress is about 17MPa, which is far less than the design stress. The results demonstrate that lower structure meets the seismic acquirements.

4.2 Response of Upper Structure

The time history curves of acceleration for the middle of bridge deck and the middle of tower are shown in Figure 5. It can be seen that the acceleration of the middle of bridge deck is enlarged with 3 times, and the acceleration of the middle of tower is enlarged with 10 times, which are both in the normal range.

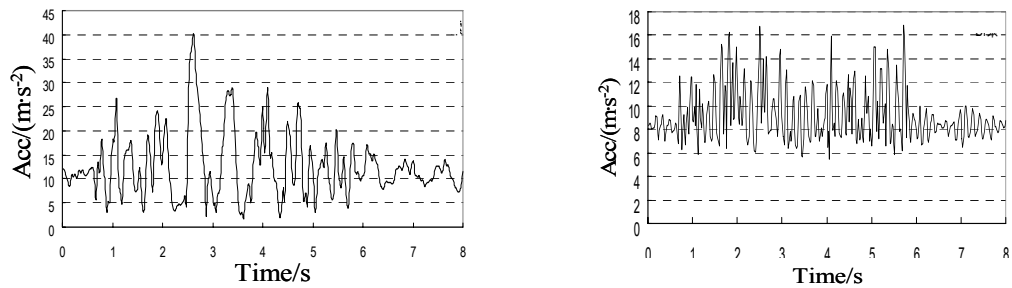


(a) Middle of bridge deck (b) Middle of tower

Figure 5. Time history curves of acceleration for middle of bridge deck and middle of tower.

4.3 Response of Cables

Because the bridge is symmetric along longitudinal direction and the earthquake is also input along longitudinal direction, the analysis for cables only focus on one side. The time history curves of cable stress for several representative cables, A1 and B1, are shown in Figure 6.



(a) Cable A1 (b) Cable B1

Figure 6. Time history curves of cable stress for cable A1 and B1.

Through the analysis for cables A1 to A11 and B1 to B3, it can be seen that the time history curves of cable stress for all 14 cables are nearly consistently, the amplitude values all fluctuate up and down the initial cable stress, and the peak

values nearly emerge at the same time. The maximum of cable stress emerges on cables A6 and A7, the cable stress of which are 41.0MPa and 42.2MPa, respectively, but both of them are far less than the standard strength of 1,670MPa.

5 Conclusions

The finite element model for a practical cable-stayed bridge is set up. The time history response analysis under El-centro earthquake excitation is carried out. Some analysis results, including time history of shear stress for lower bridge piers, time history of acceleration for upper bridge deck and time history of cable stress are obtained. Some conclusions are summarized as following:

(1) The shear stress curves of tower pier and bridge pier under longitudinal earthquake excitation present correspondence, and the difference of values is minimal. It shows that tower pier and bridge pier bear the earthquake response averagely, the design of which is reasonable.

(2) The damage model of upper structure is the failure of the dropped beam. The maximum displacement of bridge deck is in the safe range. The enlarged multiple of acceleration is normal. The maximum of cable stress is far less than the standard strength.

(3) This cable-stayed bridge will be safe under seldom occurred earthquake.

ABSTRACT

The paper suggests a new mode of public transportation system, called "One Road One Line with Straight Driving", in order to save residents' travel time and improve bus agencies' operation efficiency. After analyzing the implication and characteristics of the "One Road One Line with Straight Driving" mode, this paper develops the framework for the new mode. It also discusses the key technologies of the framework, including the analysis of passenger flow, the technology integrating the layout of network and bus stops, the technology integrating intelligent public transportation dispatching and bus priority signal control among others.

Keywords: public transportation system, One Road One Line with Straight Driving Mode, key technology

INTRODUCTION

Practices in China show that the strategies of public transportation priority are in line with the actual conditions of urban and transportation development in China. The traditional public transportation modes in China have some shortcomings, which lead to relatively low share of public transportation as indicated in Table 1 and Table 2.

In this context, the paper suggests a new mode of public transportation system, called "One Road One Line with Straight Driving." The key technologies involved in this new mode include the technology integrating the layout of network and bus stops, the technology integrating intelligent public transportation dispatching and bus priority signal control, among others.

IMPLICATION OF ϴNE ROAD ONE LINE WITH STRRAIGHT DR IVING" MODE

In the new public transportation mode called "One Road One Line with Straight Driving", in principle, only one bus line will be assigned to one road or street, and the bus is operating along the road without turning at intersections, which makes the bus network consistent with road network. In this new mode, bus stations are set near the stop lines of intersections to improve the efficiency and convenience of the transfer system: on one hand, it facilitates the seamless connection between bus lines with different directions; on the other hand, it ensures that passengers can arrive anywhere with no more than one time transfer. Meanwhile, the technologies of intelligent public transportation dispatching and transit signal priority are used to coordinate the signal plans in a way that that the signal lights switch to red when buses make stops on the corresponding approaches, and thus improve the efficiency of the overall system.

Comparing with the tradition mode called "central urban area focus mode", the new mode has the following characteristics:

Firstly, there is only one bus line set assigned to one road or street, and the buses run along each road without turning at intersections in the new mode (in particular cases, two bus lines may be assigned to the same segment of a road). Therefore bus line overlap factor is near one, and the transit network is consistent with the road network. The configurations of bus lines depend on the demand of transit users, and the layout of transit network that covers basically all roads and streets in the city. The resulting new mode decreases the bus line overlap factor, and thus reduces bus queues, which advances the efficiency of road utilization.

Secondly, all bus stops on one road serve only one bus line, and the arriving

interval of the bus is constant. Therefore, compared to the traditional modes, the new mode will help to reduce bus queues, the corresponding waiting time and transfer time of passengers on bus stops, and thus improves level of service.

Thirdly, there are several available paths with one time transfer for transit passengers to make the flow distribution more balanced. As a result, the phenomenon existing in the traditional mode, in which routes in arterial road are crowed while others are smooth, will be avoided.

Fourthly, buses run along roads without turning at intersections in the new mode. This characteristic helps to eliminate the conflicts between the buses and the other vehicles, and ensure that the buses will arrive evenly at intersection. Meanwhile, traffic management strategies that improve transit efficiencies, such as transit signal priority and arterial coordination control, can be easily implemented under this new mode.

Fifthly, bus delays due to signal control can be significantly reduced in the new mode. Stochasticity of transit travel is then decreased and one could expect more accurate travel time prediction. Moreover, it is much helpful for developing advanced passenger information system and dynamic bus assignment system.

THEORETICAL FRAMEWORK OF ϴNE ROAD ONE LINE WITH STRAIGHT DRIVING'MODE

The theoretical framework of the new mode includes the following components: (1) the adaptability of the new mode, (2) analysis of passenger flow, (3) layout of network and bus stops, (4) transit signal priority, (5) intelligent public transportation dispatching, etc.

Facilitated by the research on the network layout and design models of bus traffic systems, the adaptability analysis is intended to construct the new bus traffic network mode called "One Road One Line with Straight Driving" based on urban form and road network. The new pattern provides technological support to macroscopic decisions. By SP investigation, the passenger flow analysis of the new pattern is fundamental to design the layout of network and bus stops, and the security operations. The layout design of network and bus stops is the key work in the urban public transportation system of the new pattern. While the design of facilities for transit signals priority and intelligent public transportation dispatching ensure the efficient operation of the system. The theory framework of the new mode is shown in Figure 1.

THE KEY TECHNOLOGIES OF ϴNE ROAD ONE LINE WITH STRAIGHT DRIVING'MODE

The adaptability and match analysis technology of the new mode.

Research on adaptability and match analysis technology of the new mode includes the following three aspects:

(1) Based on the implication of the new mode and the requirements for road transport infrastructure, a matching model that deals with the urban form, typical

road network structure and the new mode of public transport system is established, and its adaptation is evaluated. Moreover, the level of implementing the new mode (e.g., full, local or single-line operation) is explained.

(2) Based on the idea of "active public transit", research includes: a) to ensure the efficient and equitable bus trips, a double-layer optimization model of urban road network density is developed, and the technology and method to analyze road network density for typical network layout (Grid, radiation ring) are studied; b) in the new mode, road planning and design technologies which meet the needs of public transport network and stop layout(e.g., the layout of the road section and the geometric design), are studied.

The passenger flow analysis technology of the new mode.

(1) The SP survey method and the data analysis technology are used to understand individual travel behavior. These methods and technologies include the investigation report and form design, survey methods, database establishment, and the analysis of statistical characteristics of residents' trip chaining behavior.

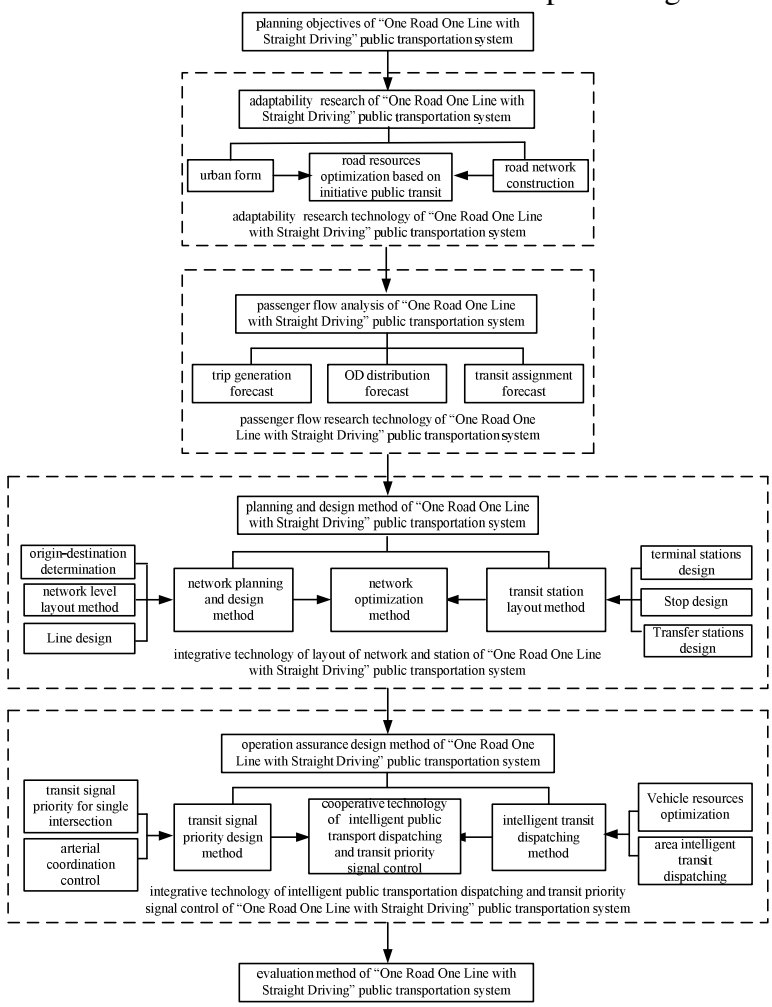

Figure1. Theory research framework of the new mode

(2) The influence of the new mode on travel characteristics (such as trip purposes, modes used, and trip distribution) and their change patterns are studied given the conditions of a highly information based society. A forecasting method of urban travel demand is proposed as the basis to forecast travel demand for public transport.

(3) An activity-based demand forecast model of the new mode is developed, with the emphasis on individual travelers' behavior. The demand forecasting model is composed of the following elements:

a) The utility functions that are constructed as an activity-based generation-mode split model using the factors from the above studies;

b)The utility functions and the corresponding algorithms that are developed to capture the destination choice behavior as an activity-based distribution model (Nageswar 2001); and

c) The demand forecasting model for transfer passengers.

(4) Distribution technologies for bus passenger flows of the new mode are researched. The details are as follows:

a) A multi-path probabilistic distribution model of bus route choice with a single transfer is established to ensure efficient travel and convenient transformation, and a corresponding rapid algorithm is proposed. This distribution model is based on the demand forecast for bus passenger flows. The characteristics of bus passenger flows (e.g., destination, walk time, departure interval, transfer time, and line grading), and the route choice behavior for residents taking public transport are considered in the model; and

b) Meanwhile, to ensure efficient travel and convenient transformation, a model and the corresponding solution algorithm for transfer passenger flows are developed to minimize the transfer times, considering the travel choice behavior of public transport.

Integration of network layout and stop design.

The technologies developed include:

(1) Grading technology for bus lines. Based on the passenger flow allocation of public transport, the land use, road configurations and traffic conditions along lines are analyzed to establish a fuzzy-cluster analysis model of hierarchy evaluation for the bus lines of the new mode;

(2) The bus lane design. Based on the distribution characteristics of vehicles on different grades of bus lines, the models are developed to represent the speed-flow relationships for buses and social vehicles driving on different roads and under traffic conditions. In the new mode, the design techniques for bus lanes of different grades are studied, focusing on lane type, section layout, and geometric design.

(3) The integrative design of bus stop layout and intersection channelization. Based on the arrival and parking characteristics of vehicles at bus stops near intersections, collector-distributor characteristics of passenger flows, and the size and

channelization design of intersections, an integration technology of the location, type and geometric design of bus stops and intersection drainage are studied in order to reduce the transfer space of social vehicles and pedestrians when passing through intersections (Yang 2007).

(4) Optimization and design of transfer nodes. Based on the demand forecast of transfer passenger flows, the grade and road conditions of bus transfer routes, and the level and scale of transfer nodes for public transport are determined. The integrative design of transfer nodes and crossing facilities is proposed, and the corresponding technical standards for the transfer node design are developed.

Integration of bus priority and the scheming of operation.

(1) Bus Priority control technology. Bus Priority control technology is a key measure to improve the operational efficiency of public transport. The corresponding research includes:

a)The fuzzy self-adaptive signal control based on Agent technology for single intersection is studied (Wadjas 2003) to minimize the delay of buses with straight line;

b)The coordination control technology based on content control theory for main bus lines is studied in order to realize the "non-blocking" run of high-grade bus lines and the optimal efficiency of bus passenger flow,; and

c)The regional coordination control model and the algorithm for public transport are developed based on Multi-Agent technology.

(2) Intelligent technology of bus dispatching. The studies include:

a) Bus travel time prediction. Based on ITS, GIS, vehicle location, wireless communication etc, the real-time operating data of buses is collected. Then, a dynamic model for bus travel time prediction is developed;

b) The optimization model of start timetable for bus lines. An optimization model of start timetable is developed with the passenger demand as the input data. This model is to find the optimal solution of start timetable under the objective of maximizing the weighted average of bus passenger satisfaction and bus enterprise satisfaction. The start interval and the fleet size are used as constraints; and

c) The dispatching model based on demand analysis of bus passenger flows in the new mode. The optimization model of timetable with the largest consistency of bus lines (Ceder 2001) is studied to minimize the waiting time for transfer passengers. Dispatching optimization and regional coordination model of start time for bus lines are studied using game theory and an approximate global optimization algorithm.

(3) Active coordination of scheduling for main bus lines and signal control for intersections. In order to reduce the signal delay at intersections along the way, the active coordination of scheduling for main bus lines and signal control for intersections is studied according to the match degree of vehicle dispatching and

signal control synergies at intersections,. The green wave control for buses is implemented to ensure their accessibility.

CONCLUSION

With its high efficiency and service level, the new mode proposed in the paper is able to enhance the attractiveness of public transport and meet the travel demand of residents. Therefore, it demonstrates a bright future of application. The establishment of the proposed framework and the discussion of key technologies point out the direction for in-depth studies.

Abstract

Considering the complexity and uncertainty of urban public transit, a dispatching system based on real-time prediction and game theory is proposed in this paper. After the real-time passenger flow data is obtained, the vehicles' passenger load rate for several consecutive time intervals is predicted, the preliminary dispatching strategies for bus lines or subway lines will be proposed. Then game theory is applied to find the best dispatching strategies for different lines. Finally, the efficiency and flexibility of each station, line and whole urban public transit system can be improved to a higher level.

1. INTRODUCTION

In recent years, urban public transit problem has become one of the most important problems which have obvious impact in daily life. Urban public transit has shown such characteristics as complexity and uncertainty, and cannot make prompt response to time-variant passenger demand. In order to improve the adaptive capacity and operational efficiency of urban public transit system, some domestic experts and scholars have done a lot of research and presented some important results. But how to implement it in practical application is still not clear, and more research needs to be conducted.

2. PROJECT OF URBAN PUBLIC TRANSIT DISPATCHING SYSTEM

2.1. Dispatching targets of the system

The urban public transit includes bus, subway and taxi. Both bus and subway are operated regularly in time schedule and route, and they have large transport capacity,; taxies have no specified stations and fixed routes, and they only can carry a little proportion of passengers flow. The investigation about service capabilities of different transit tools shows that more than 90% passengers choose bus or subway. So, bus system and subway system are chosen as dispatching targets of this system.

2.2. Components and structure of the system

It is appropriate to use a multi-level structure to describe a urban public transit dispatching system. Dispatching center should be set up in the city's traffic management center; subway system and bus system should also set up their own management centers in order to operate and dispatch bus lines or subway lines in their levels（see Figure 1）.

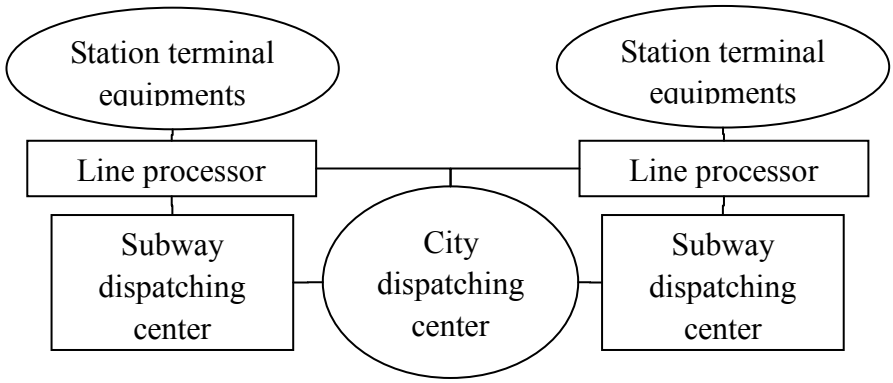

Figure 1. Structure of urban public transit dispatching system

2.3. Components of line processor and their function

Line processors are playing a key role in urban public transportation dispatching system(Xiangyong Yin et al. 2000). They compute rational strategies according to different goals, capacities and given data（see Figure 2）.

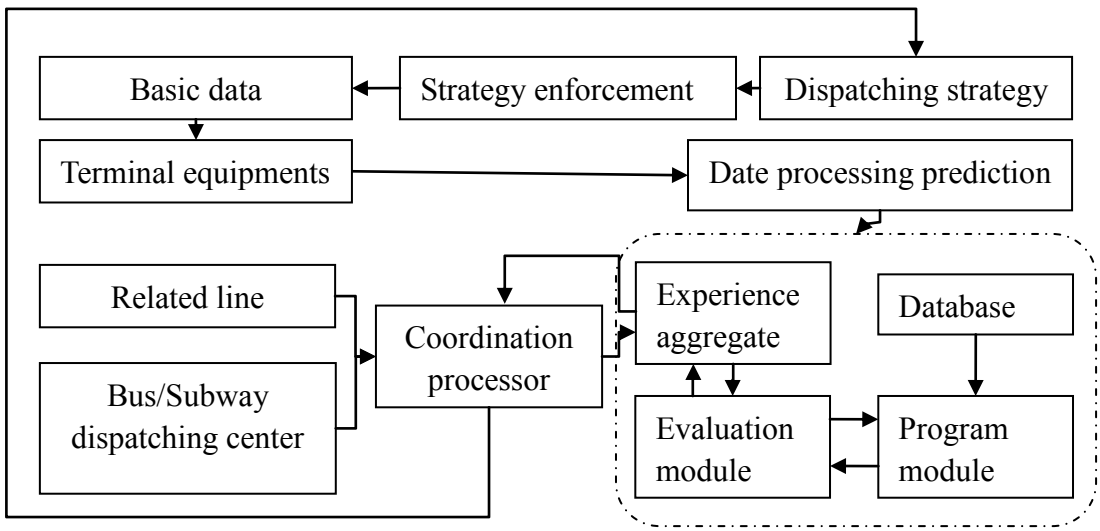

Figure 2. Structure of line processor

The passenger flow data are collected by the detectors installed in buses and stations, and the data are sent to the line processor. The processor makes a prediction based on the obtained data; the current adopted operating strategy can be updated. According to the processed data, program module processes all the data and calibrate a set of new parameters, thus a new optimal dispatching strategy of this line will be figured out.

3. GENERATING AND CO ORDINATING OF DISPAT CHING STRATEGY

3.1. Strategy targets and data obtaining

The goal of dispatching strategy is to find appropriate departure frequencies of bus or subway lines. The departure frequencies must be suitable for the different passenger transport requirements and capacities of stations.

The passenger flow data can be obtained by registered equipments or monitoring facilities which were installed in vehicles or at stations (Sun Zeyu et al. 2005). For buses, it's appropriate to install some radio-frequency radiation recorder sets near its front door and back door, so the number of passengers who get into and off the bus can be recorded easily at every service station.

3.2. Formulating process of line dispatching strategy based on real -time prediction

Considering that the passenger demand of a station is often reflected in the vehicles' passenger load rate when they are going to leave the station, a prediction of passenger load rate is conducted to provide the basis for finding the optimal strategy.

The passenger flow data of each station is detected by corresponding installed equipments and sent to line processor in real-time (HAN Yin et al. 2003). The processor uses the following method to deal with those obtained data and figure out an appropriate departure frequency for each line.

(1) Expression of passenger load rate. The passenger capacity of vehicles is termed as Z, number the stations is denoted as j (j=1,2,3,…,n) , and vehicle index is represented as i (i=1,2,3,…,n). U_{ij} and D_{ij} are used to denote the number of passengers who get into and get off the vehicle i at the station j. So the passenger load rate r_{ij} can be expressed as:

$$r_{ij} = \sum_{c=1}^{j} (U_{ic} - D_{ic}) / Z \qquad (1)$$

(2) Prediction of passenger load rate. In fact, it needs a period of time for one prepared vehicles to go into service. And passenger demands of each station changes with time, so a strategy achieved only based on the current situation does not work for the situation at the oncoming time intervals, therefore the procedure of strategy searching must be integrated with prediction.

The delay time of strategy is termed as T, and the passenger load rate r_j^* at T time later in station j can be predicted based on the recently obtained data of passenger load rate in station j. $Q(r_j)$ is adopted to represent the data aggregation j of the recently obtained passenger load rate, and the rate of station j after T time is:

$$r_j^* = g[Q(r_j), T] \qquad (2)$$

In the above equation, $g[Q(r_j),T]$ is a predicting function expression about passenger load rate r_j and time T.

(3) Computation procedure of departure frequency of a line

① It is supposed that the maximum allowed passenger load rate of vehicles is r_{max}. If $r_j^* \geqslant r_{max}$, the current departure frequency should be updated in order to make it adapt to passenger demands. $\overline{r_j}$ is used to denote the average passenger load rate of station j in the past Δt time, supposing that current departure frequency is H, and T time later the optimal departure frequency of station j is (LIU Chuang et al. 2008).:

$$H_j^* = f_1(r_j^*, \overline{r_j}, H) \qquad (3)$$

Here, $f_1(r_j^*, \overline{r_j}, H)$ is a function, and $r_j^*, \overline{r_j}, H$ are its parameters.

② If $\overline{r_j} \leq r_j^* \leq r_{max}$,then let $H_j^* = H$; If $r_j^* \leq \overline{r_j}$,then let $H_j^* = f_2(r_j^*, \overline{r_j}, H)$, $f_2(r_j^*, \overline{r_j}, H)$ is another function.

(4) Coordinating of different departure frequencies According to step (3), the obtained departure frequencies of different stations which belong to a same line are different from each other, so the frequency data must be coordinated and the more reasonable departure frequency of the whole line should be figured out.

$H_j^*(j = 1,2,3,\ldots, n)$ is the obtained frequencies of each station, and the importance of different stations can be considered by ordering different priority coefficients like $P_j(j = 1,2,3,\ldots, n)$ .Line processor coordinates a set of H_j^* until a rational frequency H^*can be computed, and the following should be met:

$$P_j^* \geq P_j(j = 1,2,3,\ldots, n) \mid H^* \qquad (4)$$

3.3. Holistic dispatching strategy based on Nash -balance of game theory

Optimization of one bus line or subway line doesn't mean higher efficiency and capability of the whole public transit system. A single station is often shared by several lines, and each station has one specified capacity limit; on the other hand, the number of spare vehicles has a limit as well. Because of these, it's possible that the departure frequencies of some lines can not be allowed in the same time.

Dispatching strategy of one line might have some impact on that of others and be affected by them, therefore, a line processor should consider other processor's possible strategies. So different processors exchange their information with each other and coordinate all strategies according to game theory, and a situation of Nash-balance might be reached.

3.3.1. Coordination model

The line processors are the main participators of coordinating process, the aggregate of them is termed as C; the aggregate of each processor's information is

denoted as I; S is the aggregate of all possible strategies; U is objective function. It means the efficiency and capability of the whole system and includes several targets such as reasonable departure frequencies of each line, moderate passenger load rate of vehicles, and acceptable schedule for each station.

The coordinating process can be defined as F={C,I,S,U}. During the process, each line processor chooses proper strategies from strategy space S according to its own information, and tests each other with strategies of other line processors. Through continuous coordinating, a Nash-balance can be reached and all parties' interests can be met in a accepted extent, the balance situation must be able to meet these conditions:

$$r_{min}^{k} \le r_{ij}^{k} \le r_{max}^{k} \qquad (5)$$

$$\sum_{1}^{k}\sum_{1}^{m} i \mid \forall t \le M \qquad (6)$$

$$\sum {}_{j} H_{k}^{*} \mid \forall t \le H_{j\max} \qquad (7)$$

r_{min}^{k}, r_{max}^{k} are the allowed minimum value and maximum value of passenger load rate of line K; $\sum_{1}^{k}\sum_{1}^{m} i$ is the sum of running vehicles of all lines, M is the number of all available vehicles; $\sum {}_{j} H_{k}^{*}$ is the sum of frequencies of all lines in station j, $H_{j\max}$ is the maximum service capacity of station j.

3.3.2. Coordination program

(1) Under normal situations, each line operates buses according to its normal schedule, line processor record the passenger load rate of vehicles which departs in a past T time period of time from each station, then the rate after in each station can be predicted;

(2) If some stations' predicted passenger load rates are out of the allowed range, then adjust the frequency of the line according to the established regulations. After figuring out a new strategy, the processor sends a coordination request to others who have close relations with it;

(3) Receiving the request, each of those processors makes response immediately, and a temporary coordination group is established and starts finding Nash-balance;

(4) If Nash-balance can be reached, coordinating strategy would be established based on the balance, each line could define its dispatching method, the coordinating process come to an end; if the balance can't be found out, processors will send coordination requests to dispatching center;

(5) Computers of different dispatching center make response, coordinate all the possible strategies, if Nash-balance can be reached, then each line determines its

frequency; if not, the coordination request will be sent to the city dispatching center;

(6)Computers in city dispatching centers coordinate different strategies and try to find Nash-balance, if it is reached, then lines of bus and subway will adjust their operation conditions; if not, a widely accepted sub-optimal dispatching order must be sent down directly.

4. URBAN PUBLIC TRANSPOR T DISPATCHING SYSTEM SIMULATION AND APPLICATION

In Figure 3, supposing that the number of passengers who get on buses in each station comply with passion distribution; the departure interval of each line is 15 T (30 minutes); the delay time capacity of each station is 30 vehicles per hour; the number of spare bus is big enough; the allowed passenger load rate is within the range (0.3, 1.3), and linear regression model is adopted to predict the passenger load rates. A simple computer program was written in order to simulate the dispatching system (Adamsli A et al. 1998;Moazzem Hossain et al. 2000).

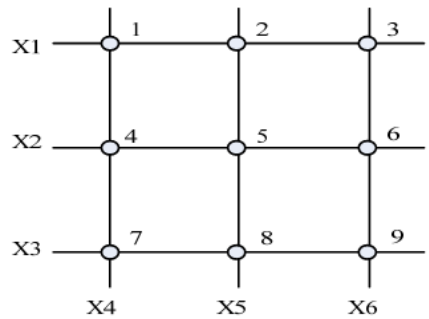

Figure 3. Bus lines and its stations

It's obvious that this urban public transit dispatching system can enhance the flexibility of lines and operation efficiency of vehicles, moreover, this system can also improve stations' capacity, and finally improves the service level of whole public transit system (see Figure 4).

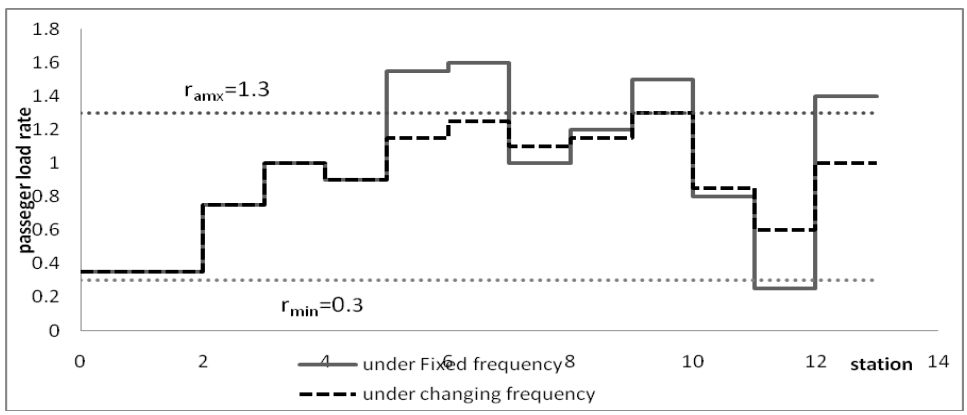

Figure 4. Comparison of passenger load rate

Through the investigation for one bus line which is dispatched by fixed frequency in Guangzhou, the passenger load rate is as follows(see Table 1); with the urban public transportation dispatching system, we adjusted the frequency and the

passenger load rate as follows (see Table 1):

Table 1. The data of passenger load rate

Station	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Fixed frequency	0.3	0.7	1.0	1.3	1.6	1.6	1.5	1.2	1.5	0.8	0.7	0.5	0.3	0.2
Changing frequency	0.3	0.8	0.9	1.1	1.2	1.3	1.2	1.3	1.3	1.2	1.1	1.0	0.8	0.5

From the data, the urban public transit dispatching system reduces the passenger load rate during the rush hour, and enhances the average passenger load rate (see Table 2). The system can enhance the flexibility of lines and operation efficiency of vehicles.

Tab le 2. Comparison of passenger load rate

Station	Fixed frequency	Changing frequency
Average load rate	0.94	1.01
Rush hour load rate	1.49	1.27

5. CONCLUSION

This paper proposes an urban public transit dispatching system based on real-time prediction and game theory. On the basis of the obtained passenger flow data, line processors are used to process the data and make predictions, and the elementary dispatching strategy is obtained. Then game theory is applied to coordinating the strategies and an optimized dispatching strategy for whole public transit system is obtained. The simulation result shows that the capacity and flexibility of each station, line and whole public transit system can be improved.

ABSTRACT

This paper carries out four sessions experiment upon drivers' route choice behavior, which aims to study drivers' decision rules under complete information and incomplete information, Historical (H) and No Historical (NH) conditions. With the theory of learning in games as a tool, this study compares experimental data across sessions, and proceeds to construct a population-level model and an individual-level model of the drivers' choice behavior based on a recursive and updated belief set. The paper also measures the influence of various information conditions and drivers' previous experience on their route choice behavior. It's found that learning is a prevalent phenomenon in the process of drivers' decision-making, and the effect of learning remarkably depends on payoff differences between alternative routes, even when a driver may not have a clear idea of travel time of other options. It has been shown by experiment that experience and information exert their important influence on drivers' choice behavior, although they fail to accelerate convergence to network equilibrium. A driver will become more sensitive to payoff differences when he gains experience and holds complete information of alternative routes. The experienced drivers can more accurately perceive traffic conditions, consequently the frequency of switch between routes is greatly reduced. There exist considerable differences in the effect of complete information among drivers due to their different learning rules. This paper classifies drivers in terms of their different learning rules, and explores the influence of a variety of information and traffic conditions on drivers' learning behavior.

KEY WORDS: *learning; games; experience; information; route choice behavior*

1 INTRODUCTION

Traffic network equilibrium should be interpreted as an idealized condition. The traffic flow of any route or the whole network could be calculated by traffic assignment theory and stochastic utility theorem if the traffic network can eventually converge to that equilibrium (Liu, 2001; Shao, 2004; Lu, 2006). However, it raises two questions of network equilibrium. Firstly, network equilibrium is based on the assumptions that the drivers hold complete information about traffic network, and

that drivers' choice behavior depend on full rationality and identical decision rules, while those assumptions may not be satisfied by actual conditions. Secondly, those traffic network equilibrium models can only show the final status of network equilibrium but not the whole process. In fact, network equilibrium arises as the long-term outcome of a learning process in which the drivers are influenced by incomplete information in addition to their bounded rationality. Therefore, it is essential to know drivers' learning processes and decision rules in actual conditions so as to understand traffic network equilibrium.

Games theory researchers have fruitfully studied the learning processes of bounded rational players over time. Cournot (1897) assumed that players will choose a best response to what they most recently observed; Maynard Smith, Price (1973, 1974) and Brown (1951) respectively developed evolutionary model and fictitious play model to explain learning phenomenon. Cross (1983), Roth and Erev (1995) proposed reinforcement model and the concept of cumulative payoffs to simulate players' choice behavior. Weibull (2006) systematically summarized and perfected evolutionary game theory. Crawford (1995) interpreted data from coordination games using player-specific belief sets. Cheung and Friedman (1997) estimated a weighted fictitious play model on individual-level data from four games, including hawk dove, stag hunt, buyer seller and battle-of-the-sexes. Boylan and El-Gamal (1992) explained learning behaviors in coordination games and dominance-solvable games with fictitious play model and cournot dynamics; they found fictitious play model fit data better. Camerer and Ho (1999) developed an experience-weighted attraction model on the basis of experiments. Stähl (2001) studied players' learning process on decision rules.

In these years, some researchers attempted to use the theory of learning in games to explain route choice behavior of drivers so as to improve traditional theory. Li Zhen-long (2003) made an analysis of route choice behavior of drivers under guide information based on evolutionary game model. Wu Bing and Li Lin-bo (2006) analyzed traffic congestion phenomenon using evolutionary game approach.

So far, there are few quantitative analysis of route choice behavior based on the theory of learning in games. This study carries out four sessions experiment upon drivers' route choice behavior. Comparing experimental data across sessions, the paper proposes a population-level model and an individual-level model of the drivers' choice behavior based on a recursive and updated belief set. This paper also discusses the influence of various information conditions and drivers' previous experience on their route choice behavior.

2 LEARNING MODELS

2.1 POPULATION-LEVEL LEARNING MODEL

At present, an extensively used approach in the analysis of population learning phenomenon is the evolutionary model. The basic idea of this model is based on the assumption that the percentage of a population that uses a strategy

changes proportionally with relative payoff advantage of that strategy. This paper proceeds to construct a population-level learning model of the driver's choice behavior also based on the evolutionary approach.

Suppose there are *n* independent routes between O and D in a traffic network. The user cost function of each route is defined as:

$$C_i = A_i + B_i v_i, (i = a, b, \cdots, n) \tag{1}$$

Where A_i = the minimum user cost of route *i*,

B_i = the traffic flow parameter. It's inversely proportional to the capacity of route *i*,

v_i = the traffic flow. The total traffic flow Q of the whole networks is calculated by adding together all v_i.

According to the evolutionary approach, let $Q_i(t)$ represent the number of drivers' choosing route *i* in period *t*, so the percentage of drivers' choosing this route in period *t* is $P_i(t)=Q_i(t)/Q$. In this time period, the payoff to using route *i* and the average payoff in the population are defined as $u_i(t)$ and $\bar{u}(t)$, respectively. The rate of the percentage changes of drivers choosing route *i* is:

$$\frac{dP_i(t)}{dt} = [u_i(t) - \bar{u}(t)] \bullet P_i(t) \tag{2}$$

If we allow the lagged relative payoff advantage of route *i* to affect the driver's choice in period *t*, we obtain the following equation:

$$\frac{dP_i(t)/dt}{P_i(t)} = \frac{P_i(t+1) - P_i(t)}{P_i(t)} \tag{3}$$
$$= \alpha_0 + \alpha_1(u_i(t) - \bar{u}(t)) + \alpha_2(u_i(t-1) - \bar{u}(t-1)) + \cdots + \alpha_k(u_i(t-k+1) - \bar{u}(t-k+1)), (k = 1, 2, \cdots)$$

Where, α_0 = a constant, it captures the drift toward route *i*,

α_k = the weight parameter placed on relative payoff advantage in period *t*-*k*+1.

Based on equation (3), we will discuss these questions about the population learning in the following sections:

1. Whether a significant correlation exists between the percentage changes of drivers choosing a route and relative payoff advantage of that route?
2. Whether historical relative payoff advantages have lagged effects on drivers' choice behavior, and how long is the duration of these effects?
3. How various information and traffic conditions influence drivers' population learning behavior?

2.2 INDIVIDUAL-LEVEL LEARNING MODEL

Different from population-level learning model, which places more emphasis on the tendency of population learning behavior, the individual-level learning model attempts to make some predictions about how specific individuals will change what they do. There are considerable differences in predictions about the choice behavior of individuals due to different explanations about cognitive and thinking processes.

The reinforcement model assumes a player always receives "reinforcements" which are proportional to his realized payoff. Cournot dynamics assumes the strategy played last period by others will be played again. The fictitious play model weights all previous observations equally. The weighted fictitious play model counts recent experiences more than distant ones. Because of the lack of study on individual driver's learning behavior, this paper attempts to measure the weights placed on current and lagged experiences directly, rather than using the above-mentioned models.

Suppose there are also n independent routes between O and D in a traffic network. The user cost function of each route is same as in equation (1):

$$C_i = A_i + B_i v_i, (i = a, b, \cdots, n)$$

The parameters are the same as the above.

Each individual makes decisions based on his perception of potential payoffs due to the lack of precise understanding about the choice of the others and the traffic conditions.

In this paper, the perceived payoff function $G_i(t)$ of route i before a driver makes a choice in period t is defined as:

$$G_i(t) = \beta_0 + \beta_1 u_i(t-1) + \beta_2 u_i(t-2) + \cdots + \beta_k u_i(t-k), (k = 1, 2, \cdots) \quad (4)$$

Where, β_0 = a constant, it captures the drift toward route i,

β_k = the weight parameter placed on lagged realized payoff of this driver in period t-k+1

According to stochastic utility theorem, the driver will choose routes with higher perceived payoffs more frequently. The probability of a driver choosing route i in period t is:

$$P_i(t) = \frac{e^{G_i(t)}}{\sum_{j \in N} e^{G_i(t)}}, (i, j \in N) \quad (5)$$

Based on equation (5), we will discuss these questions about individual learning behavior in the following sections:

1. Whether previous experiences can affect the choice of individual drivers?
2. Whether there are differences among drivers in effectively memory length and the attitude toward previous experiences?
3. How do various information conditions affect different types of drivers?

3 EXPERIMENTS

We ran four sessions experiment upon drivers' route choice behavior. Subjects were 22 undergraduates at Beijing University of Technology. The experimental traffic network are comprised of two independent routes, where route a is shorter with lower capacity, and on the contrary, route b is longer and having higher capacity. Subjects made choices between two routes and chose optimal decision based on their

realized payoffs until achieve network equilibrium. Table 1 contains the information and traffic conditions in each session:

Table 1 Information and traffic conditions in each session

session	information used to making a choice			traffic conditions	
	received payoff in last period	received payoffs in all period	unchosen payoffs (forgone payoffs) in last period	First BPR Function	Second BPR Function
1	√			√	
2	√	√		√	
3	√	√			√
4	√		√	√	

The first session experiment intends to simulate drivers' choice behavior in an unfamiliar traffic network. In this session, after each choice, subjects got feedback only about their received payoff in last period. The second and third session experiments attempt to explore drivers' decision-making in a more familiar traffic network. For this purpose, subjects were told their received payoffs in all periods of each session. The fourth session experiment aims to study drivers' choice behavior if they hold complete information about received payoffs and forgone payoffs. In addition, we set a different BPR function in session 3 in order to detect subjects' response under different traffic conditions, and moreover, the marginal cost caused by one unit vehicle in session 3 is higher than other sessions.

The experiments overcame the challenge which is how to transmit information to each subject respectively. We did this by using questionnaires on which the received payoff information in last period were provided. Based on this information, each subject made a decision about which route to choose in the next period. After that, subjects wrote their choices on the questionnaires and handed them in. We calculated payoff of each route according to the number of subjects' route choice, and then, we feedback this information to each subject by a new questionnaire again. In session 2 and session 3, besides the information from these questionnaires, subjects could also record their received payoffs in each period of this session on a paper. In session 4, subjects could get feedback about their received payoffs and forgone payoffs after each period through questionnaires.

4 MODELS SPECIFICATION

4.1 POPULATION-LEVEL MODEL SPECIFICATION

Because there are only two alternative routes in our experiments, we can calculate the change in the percentage of drivers choosing route a in period t to discuss the population-level learning process. According to equation (3),

$$\frac{P_a(t+1)-P_a(t)}{P_a(t)} = \alpha_0 + \alpha_1(u_a(t)-\bar{u}(t)) + \cdots + \alpha_k(u_a(t-k+1)-\bar{u}(t-k+1)), (k=1,2,\cdots) \quad (6)$$

Where, $P_a(t)$ = the percentage of drivers choosing route a in period t,

$u_a(t)$ = the payoff to choosing route a in period t,

$\bar{u}(t)$ = the average payoff in the population in period t, $\bar{u}(t)=P_a(t)u_a(t)+P_b(t)u_b(t)$,

k = the order of lags.

We use Ordinary Least Squares (OLS) to estimate equation (6) because it is a multiple linear regression model and $P_a(t)$, $u_a(t)$, $\bar{u}(t)$ in this equation can be derived from experimental data.

It is calculated as:

$$\min\sum_{t=1}^{T}\frac{P_a(t+1)-P_a(t)}{P_a(t)}-\left[\alpha_0+\alpha_1(u_a(t)-\bar{u}(t))+\cdots+\alpha_k(u_a(t-k+1)-\bar{u}(t-k+1))\right] \quad (7)$$

Allowing for the order of lags k is unknown, we estimate equation (6) at different value of k, and then select a reasonable model according to the estimated results.

4.2 INDIVIDUAL-LEVEL MODEL SPECIFICATION

Similarly, we can analyze the change in the probability of a driver choosing route a or b to explore the individual-level learning process. According to equation (5), the probability of a driver choosing route a or b in period t can be written as

$$P_a(t)=\frac{e^{G_a(t)}}{e^{G_a(t)}+e^{G_b(t)}}=\frac{1}{1+e^{G_b(t)-G_a(t)}}=\frac{1}{1+e^{\beta_0+\beta_1\Delta u(t-1)+\cdots+\beta_k\Delta u(t-k)}} \quad (8)$$

and

$$P_b(t)=1-P_a(t) \quad (9)$$

respectively. Where, $\Delta u(t)$ is a function of the payoff differences, $\Delta u(t) = u_b(t)- u_a(t)$.

The forgone payoff of a driver in period t is defined as his average payoff to choosing that route previously, except in the fourth session experiment. Furthermore, we classified the individuals into four groups in terms of their changes in frequency of switch (shown in table 2). We estimated an individual-level learning model for each group respectively.

Table 2 The changes in the frequency of switch across different groups

group	frequency of switch in session 2 or session 3 than the ones in session 1		frequency of switch in session 4 than the ones in session 1	
	reduce	almost unchanged or increase	reduce	almost unchanged or increase
1	√		√	
2	√			√
3		√	√	
4		√		√

We estimate equation (8) using Maximum Likelihood Estimation (MLE). The likelihood function for the sample is obtained from:

$$\max \quad L = \prod_{i=a} P_a(t) \prod_{i=b} (1 - P_a(t)) \tag{10}$$

Similarly, we estimate equation (10) at different value of *k,* and then select a reasonable model according to the estimated results and Akaike Information Criterion (AIC).

AIC is a function that is used to determine the order of lags *k*. The value of AIC function of equation (10) can be obtained as follows.

$$AIC(k) = -\frac{\ln L}{n} + \frac{k}{n} \tag{11}$$

Where, ln*L* = the value of maximized log-likelihood function, i.e. the logarithm of equation (10),

n = the size of calibration samples.

When the order of lags *k* is increasing, the first term in equation (11) will decrease because of the improvement of goodness-of-fit, whereas the second term will increase due to a more complicated model. According to AIC, the value of *k* that can minimize equation (11) is the reasonable order of lags.

5 RESULTS

5.1 RESULTS OF POPULATION-LEVEL MODEL

We estimated population-level learning model using EViews5.0. Table 3 contains OLS estimates of population-level learning model. P values are reported in parentheses.

Table 3 Estimates of population-level learning model

session	k				
		α_0	α_1	α_2	MA(1)
1	k=1	1.069 (0.0013)	0.153 (0.0005)	-	-

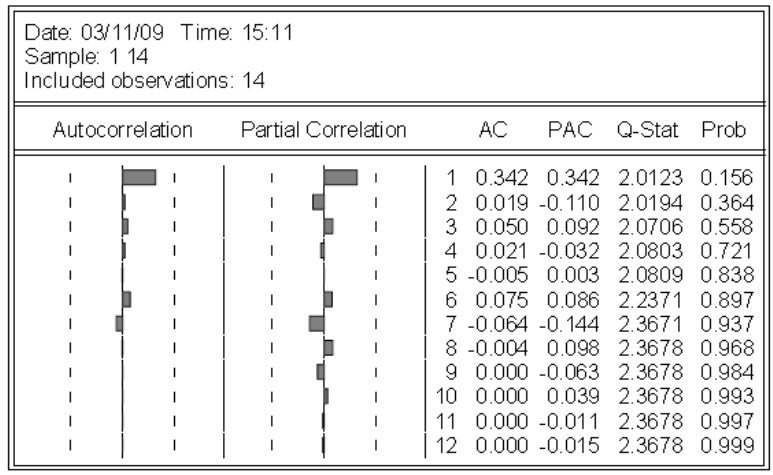
		0.869	0.847	1.898	39.795 (0.0000)

Durbin-Watson (DW) statistics is a measure, which is used to test for serial correlation in the residuals of a time series regression model under the classical linear model assumptions. The value of DW will be close to 2 when the assumption of no serial correlation is valid. However, when k=1, the values of DW derived from population-level data in session 3 and session 4 are 1.219 and 1.037 respectively, significantly less than 2. It means that, the residuals in these two sessions may suffer

from positive serial correlation. Then, we found that autocorrelation cutoffs after order one and partial correlation is trailing according to the correlogram of residuals (shown in Figure 1). Thus, we introduce moving average process of order one (MA(1)). Then, the more reasonable models are obtained.



Date: 03/11/09 Time: 15:11

Figure 1 The correlogram of residuals before introducing MA(1) into session 3 (k=1)

From Table 5, we can find that the percentage changes of drivers' choosing a route remarkably depends on the relative payoff advantage of that route, even when a driver may not have a clear idea of travel time of other options.

The increase in α_1 and the goodness-of-fit for experimental data in session 2 shows that subjects pay more attention to payoff differences as they become more familiar with the traffic network. Moreover, they also have a longer memory in this session. Their choice behavior is influenced by their received payoffs of last two periods. The aforementioned changes imply that the subjects tend to switch cautiously in general (shown in Table 4). The decrease in the frequency of "trembles" (the switch from the higher payoff route to the lower one) indicates that subjects can more accurately perceive traffic conditions in this session.

The decrease in α_1 as well as the increase in the frequency of switch in session 3 shows that the subjects adjust themselves to changed traffic conditions.

The estimators in session 4 embody the influence of complete information. The increase in α_1 reflects that subjects are more sensitive to the changes of payoff differences. However, the length of memory remains unchanged. In this session, the frequency of switches decreases, at the same time, the frequency of "trembles" remains practically unchanged. It indicates that the effect of complete information differs from individual to individual. In the following discussion, we can find considerable differences through the analysis of individual-level model.

Table 4
The speed of convergence and the frequency of switches in each session

session	the number of choices lead to convergence	total frequency of switch	frequency of "trembles"(wrong switch)
1	17	113	28
2	17	95	18
3	15	113	-
4	16	97	24

5.2 RESULTS OF INDIVIDUAL-LEVEL MODEL

We specified individual-level learning model using Gauss9.0. The results are given in Table 5 and P values appear in parentheses.

Table 5 Estimates of individual -level learning model

group	session	β_0	β_1	β_2	Hit Ratio	McFadden R-squared
1	1	-0.803	0.198	-	80.00	0.196
		(0.1150)	(0.0677)			
	2	-5.041	1.201	-	96.67	0.583
		(0.0318)	(0.0461)			
	3	-3.266	0.201	-	92.31	0.478
		(0.0005)	(0.0043)			
	4	-3.045	0.122	-	93.33	0.115
		(0.0503)	(0.4738)			
2	1	0.473	0.302	-	86.67	0.433
		(0.5310)	(0.1692)			
	2	0.177	0.141	0.055	57.14	0.151
		(0.7865)	(0.3335)	(0.6474)		
	3	0.625	0.068	0.030	75.00	0.268
		(0.4693)	(0.1722)	(0.6000)		
	4	1.048	0.015	-	73.33	0.006
		(0.0815)	(0.7498)			
3	1	-4.302	0.132	-	93.33	0.270
		(0.0955)	(0.2727)			

	2	-0.799 (0.3088)	0.159 (0.3736)	-	78.57	0.069
	3	-0.746 (0.2511)	0.005 (0.8050)	-	69.23	0.004
	4	-2.681 (0.0135)	0.017 (0.8563)	-	93.33	0.005
4	1	0.641 (0.4669)	-0.004 (0.9402)	-	66.67	0.000
	2	0.402 (0.4492)	-0.003 (0.9662)	-	60.00	0.000
	3	-0.139 (0.8056)	0.003 (0.8622)	-	46.15	0.002
	4	-1.053 (0.1006)	0.078 (0.2406)	-	60.00	0.100

From Table 5, we can find considerable differences between groups on their decision rules and their attitude toward information and previous experiences.

The individuals in group 1 can be regarded as strictly empiricists. They are highly sensitive to the changes of the payoff differences in all sessions. The frequency of switch can be greatly reduced when these drivers gain experience and hold complete information of alternative routes. Thus, the learning model fits their data fairly well.

The drivers in group 2 are counted as skeptical empiricists. They show sensitivity to payoff differences as well as a longer memory. However, they attach great more importance to realized payoffs of alternative routes than perceived payoffs. They will switch between routes more frequently once they get to know this information.

The subjects in group 3 are described as perverse players. They are slower in learning than former two groups even aware of the payoff differences. They tend to make a choice according to impressions on traffic network.

The drivers in group 4 prefer to make a decision randomly. They have frequent switches in all sessions due to their indifference to payoff differences. So the goodness-of-fit of the learning model is worse. Nevertheless, a steady decrease in β_0 reflects these subjects are less willing to choose route a which capacity is lower.

Table 6 The frequency of switch across different groups

session	the frequency of switch of			
	group 1	group 2	group 3	group 4
1	40	19	21	33
2	14	8	31	42
3	26	22	28	37
4	12	35	11	39

6 CONCLUSION

In this paper, we proceeds to construct a population-level model and an individual-level model of the drivers' choice behavior based on experimental data. These models succeeded in capturing some aspects of behavior observed in a variety of experimental environments. Specifically,

1. A significant correlation exists between payoff differences and drivers' choice. Therefore, the model based on the theory of learning in games can fit well with the data from population-level and individuals of some groups.

2. The payoffs of last two periods can exert their significant influence on drivers' choice behavior.

3. Although gaining experience and holding complete information of alternative routes fail to accelerate convergence to network equilibrium, the experienced drivers can more accurately perceive traffic conditions, consequently the frequency of switch between routes is reduced.

4. There are considerable differences between different types of drivers on their decision rules and their attitudes toward information and previous experiences.

Despite these successes, we do not believe that our models have captured all important aspects of learning process of drivers. This learning process is complicated and diversified, and we still know very little about it. We hope that we'll have a chance to improve our models some day so as to make it more reasonable.

ABSTRACT

This paper reviews the generalized cost model and analyzes the makeup of generalized cost, calculated as the monetary operating cost, travel time cost and externality cost, which together form a linked cost function. The transfer cost function was built by applying queuing theory. Finally, the model was applied to the case of Ningbo-Zhoushan port's optimization, testing the veracity and effect of the generalized cost model.

1. INTRODUCTION

Currently, many defects exist in the theory of optimization of ports' collecting and distributing systems. The primary problem is the lack of a cost model that accounts for different goods and transportation modes and the lack of a freight network optimization model that accounts for multi-modal transportation.

A cost model is key to traffic assignment. The narrowly-defined cost function considers only the journey time spent by vehicles; while the generalized cost function consists of various network-service-level related factors, such as travel expense, time value, and the degree of reliability of transport.

Most research on transport cost models has concentrated on urban transport networks, whose main research object is passenger transport. Therefore, the cost function of regional freight network has been paid less attention, and existing literature is mainly confined to highway networks, lacking cost function research on integrated transportation networks.

If the narrowly-defined cost function, with time as the only variable, is applied to urban traffic assignment, there would be no big error. However, if it is used in regional freight networks, the time alone can not accurately reflect the service level of a freight network; therefore, regional freight network assignment without consideration of generalized cost will cause a larger deviation.

2. GENERALIZED COST MODEL

Among all kinds of generalized costs, money and time spent are the two most important factors. Hence, the generalized cost model in this paper includes the monetary operating cost, travel time cost and other external costs.

2.1 Link Generalized Cost Model

2.1.1 Monetary Operating Cost

The unit operating cost is concerned with type of good, transport mode and distance. Once product type and the transport mode have been confirmed, the unit operating cost is a function of transport distance. There are usually two ways to calculate the monetary operating cost: a calculation can be based on a freight tariff or on a regression method. The latter is often used. Through a series of fittings, there is generally a linear relationship between the unit of freight T and the mileage of L. The regression equation is as follows:

$$T_{1i} = aL_i + b$$

Where T_{1i}: monetary operating cost of transport mode I (yuan/ton)
L_i: transport length (km), a,b: regression parameters

2.1.2 Travel Time Cost

Travel time cost is also a form of travel impedance that is usually applied in urban road networks. The most representative models are the BRP model, the TRRL model, and the Davidson model (Branston). The travel time cost model of a port's collecting and distributing system differs markedly from the traditional model of city roads.

Highway travel time cost model

In highway systems, BPR function (Bureau of Public Roads) is most commonly used. BPR function takes into account the impact of traffic load on travel time, but does not account for intersection delays, non-motorized vehicles and other factors. It is suitable for regional inter-city road network, such as the highway part of a port's collecting and distributing system. The highway travel time cost is given by the expression: $t = t_0\left[1 + \alpha(\frac{V}{C})^{\beta}\right]$

Where t_0 : the free flow time(hr), V: the traffic volume (pcu/hr)

C: the capacity of the highway (pcu/hr), α, β: model parameters.

Railway travel time cost model

Based on the assumption that no more than two trains can meet at the same time on a single-track railway line, the conditions of driving too close to the front train, or a conflict between opposite directions, does not exist; that is, there is no congestion effect. Double-track railway travel time cost is given by the expression:

$t = \frac{L}{Sp}$ where L: the railway length (km), Sp: railway's average speed (km/hr)

The operation of a train running on single-track railway is more complex than on double-track railway. To ensure safe train operation, some mandatory requirements such as station blocking and interlocking, must be met for single-track railway. This paper suggests a polynomial nonlinear function similar to BPR function (Guelat) to calculate the single-track railway travel time cost.

$\tilde{t} = t_0\left[a + bV + c(\frac{V}{Cap})^d\right]$ Where V : train carriages on single-track railway (carriage/ hr); *Cap*: the capacity of the railway section(carriage/ hr)
t_0: the free flow time of the railway section(hr), *a,b,c,d*: model parameters

Waterway travel time cost model

There is generally no congestion in water transport. As a result, the time spent depends on the ship's average speed. The waterway travel time cost is given by the expression: $t = \frac{L}{Sp}$

Where *L*: the navigation length (km), *Sp*: ship's average speed (km/hr)

2.1.3 Other External Costs

Presently there is no common method to calculate external costs of all transport modes. The most practical way is to combine the existing results of transport economics and use the empirical data.

Table 1. Unit External Cost of Railway and Highway.

External cost (units)	Railway	Highway
cents / tonne-kilometers	0.054	0.394
yuan / tonne-kilometers	0.004212	0.03073

2.2Transfer Generalized Cost Model

2.2.1 The Concept and Classification of Freight Transfer Hubs

Freight transfer hubs are the intersections of two more transportation routes and the integrated facilities offering transfer, store and clearance services (Shen 2005).

Table 2. The Classification of Freight Transfer Hub.

Freight transfer hub		Transfer way	Hub type	Physical infrastructure
Land-land transfer hub	Highway transfer hub	highway ↔ highway	Single-mode	Lorry changing station
	Railway transfer hub	railway ↔ railway	Double-mode	Railway marshal yards
	Highway-railway transfer hub	highway → railway railway → highway	Double-mode	Inland integrated transport hub
Land-water	Water transfer hub	waterway ↔ waterway	Single-mode	Inland and

Freight transfer hub		Transfer way	Hub type	Physical infrastructure
transfer hub		highway → waterway		coastal harbor
	Water-land transfer hub	railway → waterway waterway → highway waterway → railway	Double-mode	
Other transfer hub: Airport, special commodity transfer and so on				

This paper focuses on double-mode hubs, at which goods transfer between different transport modes (hubs with → in the above table).

2.2.2 Generalized Cost Model of Highway-railway Transfer Hub

According to system theory and queuing theory, as well as transport process in transfer hubs, a highway-railway transfer hub can be regarded as a complex queuing service system. Such a queuing service system is composed of three interrelated subsystems (an arrival, a detention and a departure subsystem).

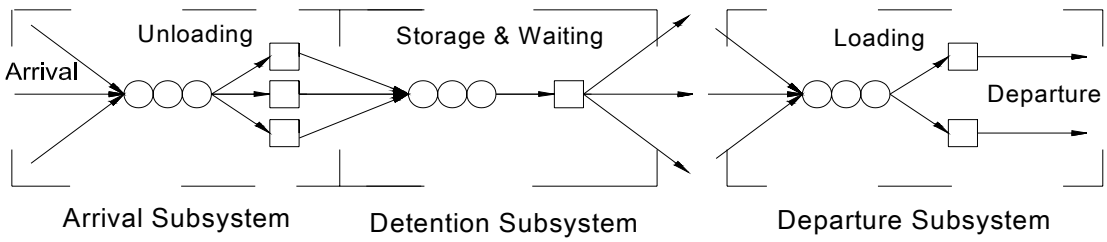

Figure 1. Highway-railway Transfer Hub Queuing System.

Monetary operating cost in a transfer hub includes handling and storage costs, while the travel time cost in a transfer hub is mainly the waiting time including unloading time, detention time and loading time.

For long-term freight network planning, residence time is much more than loading and unloading time. Thus at the strategic level, residence time can be only considered that the entire system as an approximate [M/M/1] queuing system. The generalized cost equation of a highway-railway transfer hub is as follows:

$$S_t = \theta_1 T_m + \theta_2 T_t = \theta_1 \times \rho + \theta_2 \cdot (VOT + \lambda) \cdot \left(\frac{Ser_t}{1 - V_t / CAP_t} \right), \quad Ser_t = \frac{lp}{CAP_t}$$

Where T_m: average monetary operating cost at transfer hub t

T_t: average residence time cost at transfer hub t

ρ : unload and load fee at transfer hub t (yuan/ton, yuan/TEU)

λ: storage fee at transfer hub t (yuan/ton·day, yuan/TEU·day)

V_t : throughput at transfer hub t, Ser_t : average service time at transfer hub t
CAP_t : the capacity of transfer hub t, l_p : the time length of the planning period

2.2.3 Generalized Cost Model of Land-water Transfer Hub

The process of a land-water transfer hub can be interpreted by Figure 2.

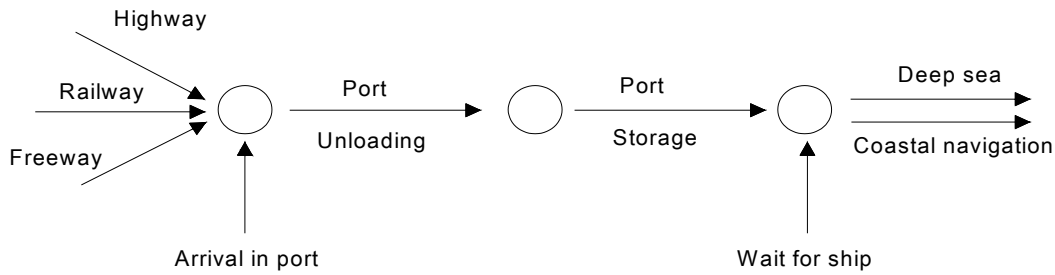

Figure 2. The Diagram of Land-water Transfer Hub.

The generalized cost of a land-water transfer hub consists of a port service fee and the delay time cost. The port service fee also contains the cost of customhouse and cargo survey besides cartage and storage charge, which have specific charge criteria at a port.

At the condition of **highway → waterway** and **railway → waterway**, the waiting time is more dominant than loading and unloading time and service time. Waiting time is determined by the frequency of carriers, and equal to half of headway. The average waiting time is given by the expression:

$$T_t = \frac{1}{2} \times \frac{L_p}{N} \times \max\left\{1, \left(\frac{V_{boat}}{N}\right)\right\}$$

where V_{boat} : port cargo carriers required, N: the ship sail frequency; l_p : the time length of the planning period

At the condition of **waterway → highway**, if sufficient cargo gathering, then time waiting for truck do not need. The total time cost at port are loading and unloading time and service time, that is $T_t = t_z + t_s$ where T_t : average residence time cost; t_z: loading and unloading time, t_s:other service time.

At the condition of **waterway → railway**, average residence time can be calculated according to ***five scheduled train*** plans (location-fixed, line-fixed, train-fixed, time-fixed, price-fixed).

$$T_t = \frac{1}{2} \times \frac{L_p}{N} \times \max\left\{1, \left(\frac{V_{train}}{N}\right)\right\}$$

where V_{train} : train carriages needed for port cargo; N : the ***five scheduled train*** frequency; l_p : the time length of the planning period.

3. OPTIMIZATION MODEL OF PORTS COLLECTING AND DISTRIBUTING SYSTEM

3.1 Multimode Multiproduct Network Optimization Model

A port's collecting and distributing system contains not only a transfer hub, but also a variety of transport modes. Generally speaking, optimization of a port's collecting and distributing system is a kind of multimodal multiproduct network optimization problem (INRO Consultants). The objective function is to minimize the cost of freight transportation on the port's collection and distribution network. The generalized cost contains both link cost and transfer cost, which have been modeled in chapter 2. The following objective function F(v) can therefore be formulated:

$$F = \sum_{p \in P} \left(\sum_{a \in A} s_a^p(v) v_a^p + \sum_{t \in T} s_t^p(v) v_t^p \right)$$

$$\text{S. T. :} \quad \sum_{k \in K_{od}^{m(p)}} h_k = g_{od}^{m(p)} \quad h_k \geq 0,\ k \in K_{od}^{m(p)} \quad o \in O,\ d \in D,\ p \in P$$

Where N: a set of modes, A: a set of links, T: a set of transfers, M:a set of transport mode; $K_{od}^{m(p)}$: a set of path conveying product p from O to D

v_a^p: the flow of product p on link a, v_t^p: the flow of product p on transfer t

s_a^p: generalized cost of product p on link a, s_t^p: generalized cost of product p on transfer t, g_{od}^p:the demand of product p from O to D, h_k: flow of link k, $k \in K_{od}^{m(p)}$

3.2 Application and Test

We applied the model to the Ningbo-Zhoushan port transportation optimization to check the veracity and effect of optimization in the near future. If the test is in line with the accuracy requirements, then it can be applied to future multimode multiproduct network analyses.

Table 3. Transport Flow Distribution on Collecting and Distributing System.

Transport mode & link			Traffic flow		error (%)
			Calculated	Observed	
Highway	Trunk network	Hangzhou-Ningbo	33846	36590	7.5%
		Ningbo-Wenzhou	20997	19734	6.4%
	Channel for port	Luoxia Road	21450	24000	10.6%
		Jiangnan Highway	14300	18215	21.5%
		Tongtu Highway	31250	27000	15.7%
		National Highway 329	19250	17610	9.3%
Railway	Trunk line	Xiaoshan-Ningbo	40301	36712	9.8%
	Branch line	Zhenhai branch railway	8055	8493	5.5%
		Beilun branch railway	12343	12877	4.1%

Through the traffic flow comparison between calculated volume and observed volume on some important network sections, the average error rate of the results is around 10%, which within the threshold for precision.

4. CONCLUSION

Based on previous research, this paper attached importance to the generalized cost model—the core content in multimode multiproduct network optimization. By analyzing the constitution and indicators of generalized cost, a new generalized cost function model was established. The application in a practical project verified the model's feasibility and precision.

ABSTRACT

Accessibility is a fundamental concept in transportation analysis and planning. Typically, accessibility refers to the 'ease' of reaching opportunities for activities and services can be used to evaluate the performance of a transportation system. In this paper, Utility-Based (UB) accessibility measures derived from the combined travel demand model are used to assess the performance of public transport network. Network-based accessibility measures using a combined travel demand model that is consistent with random utility theory are established. By using travel time and ticket fees via bus as the measures, accessibility between any two bus stops is described from the user's perspective. An example is provided in this paper to examine the effect of this method. The results indicate that the accessibility measures proposed in this paper are capable of measuring the degree of bus stop accessibility to assess the public service.

INTRODUCTION

To be accessible or not to be accessible seems to be the questions these days. Public transport network plays a crucial role in providing persons with sufficient access to their destinations via bus. Yet, traditional public transport planning often neglects this important role the public transport networks play and limits its focus on the efficiency of the public transport system itself. In future, accessibility should be given more weight in land use and transport decisions. Accessibility planning is a key area of transport policy. However, accessibility is often misunderstood, poorly defined and poorly measured construct. Finding an operational and theoretically sound concept of accessibility is quite difficult and complex (Karst, 2004; Thomas, 2008). Indeed improved access to bus services is a major aspect of integrated transport strategy. The importance of access to public transport in order to access local services has been identified by several studies (Zhao, 2005; Cheng, 2007).

This paper makes a review of UB accessibility measures; this is followed by the introduction of accessibility based measure that used to analysis public transport network. Then, an example is provided to examine the effect of this method.

Conclusions and future research are given in the final section

UB ACCESSIBILITY MEASURES REVIEWED

Accessibility is frequently measured as a function of the available opportunities moderated by some measure of impedance. Despite the popularity of the concept, accessibility has historically been measured in different ways depending on the context of the applications. UB accessibility measures interpret accessibility as the outcome of a set of transport choices. Utility theory addresses the decision to purchase one discrete item from a set of potential choices, all of which satisfy essentially the same need, and can be used to model travel behaviors and the (net) benefits of different users of a transport system.

An initial approach is based on random utility theory using the denominator of the multinomial logit model, also known as the logsum, as an accessibility measure, assuming that an individual p assigns a utility to each possible destination j in a specific choice set and chooses the alternative that maximizes his/her utility. The logsum serves as a summary measure, indicating the desirability of the full choice set (Ben-Akiva and Lerman, 1979):

$$A_i = \frac{1}{\lambda} \ln \sum_{j \in J_p} e^{\lambda u_{pj}} \tag{1}$$

where λ is a travel cost sensitivity parameter and u_{pj} is measured utility.

Utility is derived at the individual or homogeneous population group level, and travel costs (i.e. travel time and ticket fee) can be regarded as the index.

MEASUREMENT OF NETWOEK-BASED ACCESSIBILITY

Description of the public transport network. In general terms, the role of public transport planning is to ensure the satisfaction of a certain demand for person movements with different trip purpose, at different times of the day, given a public transport system with a certain operation capacity. The public transport network itself can be seen as made up of nodes (stop locations) and lines (bus lines).

Consider a set of stop locations N ($n \in N$), a set of bus lines L ($l \in L$), and a set of bus routes S ($s(l) \in S$). Following Ren (2007), bus route is defined as a section between every two bus stops of one bus line in this paper. In very general terms the public transport network can be represented by: $G = (N, S, L)$.

In this section, we illustrate a simple public transport network (two bus lines: L1 has 5 stop locations from 1 to 5; L2 has 3 stop locations from 1 to 3) to make the concept of bus route understandable as depicted in Figure 1.

As can be seen from Figure 1, every two stops can only have 1 bus route from one line, while it is feasible to have more than 2 bus routes from different bus lines. We can get 10 bus routes from Line 1 and 3 bus routes from Line 2. Based on the definition of bus route, if there are n stops in a line, the number of the bus route can be calculated by: $n(n-1)/2$.

When passengers aboard the bus they can only get off at their destination, viz. they should not get off half-way. Therefore, after determining the number of transfer times, the set of passenger routes (bus route or the combination of bus routes) K between any two bus stops can be got, such as the set of passenger routes between stop1 and 4 include $S_3(L_1)$ and $S_{13}(L_2)-S_8(L_1)$.

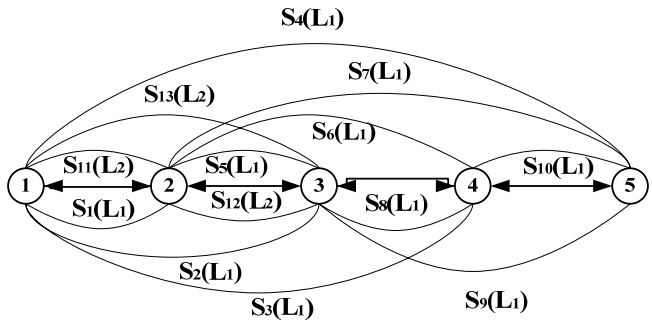

Figure 1. A simple public transport network with two bus lines.

Model formulation. This section introduces the model of UB accessibility. In terms of conceptualization, the model considers accessibility a property of stop locations, based on detailed measurements of UB accessibility derived from random utility theory. In this paper, we assume that different individuals value the attractiveness of the bus stop locations differently and no more than 1 time of transfer via bus.

Given the number of potential travelers taking passenger route from origin i to destination j per unit time d_{pij}. The probability expression can be derived as follows:

$$\frac{d_{pij}}{d_{ij}} = P_{p|ij} = \frac{e^{\beta_k U_p}}{\sum_{k \in K} e^{\beta_k U_k}} \qquad \forall i, j, p \tag{2}$$

Where d_{ij} is the amount of passengers from stop location i to j; β_k is the parameter in the combined travel demand model; U_k is the expected received utility of passenger route choices.

In this paper, the utility measure is adopted to quantify the accessibility between any two bus stop locations that is consistent with random utility theory used in the combined travel demand model described above. Ben-Akiva and Lerman (1979) defined the accessibility measure derived from random utility theory as follows:

$$A = E\left(\underset{k \in K}{Max}\, U_k\right) \tag{3}$$

For an individual, accessibility was defined as the expected value of maximum random utility of alternative k in choice set K. Moreover, two

important properties for accessibility were proved: a. monotonicity with respect to choice set size; b. monotonicity with respect to the systematic utilities. The first property implies that any addition to a person's choice set leaves the individual no worse off than before the addition. The second property implies that the measure of accessibility does not decrease if the systematic utility of any of the alternatives in the choice set increases.

With the two important properties, accessibility measures can be determined to assess the performance of public transport network. For example, under a certain abnormal event, the capacities of bus routes in the network may be significantly degraded, making them not attractive to some bus users. This will reduce the size of the choice set (i.e., smaller number of alternative passenger routes). Under the first property, the accessibility measure for route choice should not increase due to the unattractiveness (or unavailability) of some degraded routes. Furthermore, due to congestion caused by the reduced number of available passenger routes, according to the second property, the accessibility measure should not increase.

In addition, if the random variable is assumed to follow a Gumbel distribution, the accessibility measure will have a closed-form expression. Let $V_k = U_k + \varepsilon_k$ and $U_k = E(V)$, where ε_k is a Gumbel random variate. The measure defined in Eq.(3)becomes:

$$A = E\left(\underset{k\in K}{Max} U_k\right) = \frac{1}{\beta}\ln\sum_{k\in K} e^{\beta U_k} \tag{4}$$

Thus, by using the expected received utilities given in Eq.(2), the accessibility measure of any two bus stops is defined as follows:

$$A_{ij} = \frac{1}{\beta_k}\ln\sum_{k\in K} e^{\beta_k U_k} \tag{5}$$

Assessment procedure. In this section, a assessment procedure is provided to compute the accessibility measures and to perform the bus stop accessibility analysis. The steps are briefly summarized as follows:

Step1: Numbered bus stops, bus lines, bus routes.

Step2: Confirming the set of K of any two bus stops.

Step3: Using Eq.(2) to obtain the utility of passenger route choices.

Step4: Using Eq.(5) to get the accessibility measures of any two bus stops.

Step5: Report the results of the assessment analysis.

AN EXAMPLE

Taking the public transport network shown in Figure 2 as an example, this paper examined the effect of this method on assessing the performance of public transport network.

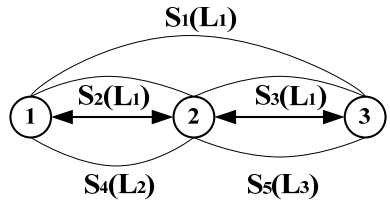

Figure 2. A simple public transport network with three bus lines.

The amount of passengers from stop location i to j (d_{ij}) were listed in Table 1.

Table 1. Bus OD matrix of public transport network.

OD	1	2	3
1	0	45	15
2	45	0	25
3	15	25	0

The travel time t_s of five bus routes were listed in Table 2. The waiting time t_w was assumed to be 2.5 minutes in this paper. The travel time t_k of a bus route k can be calculated by $t_k = t_w + \sum_m t_s$. The fixed travel cost c_k on a bus route k can be calculated by $c_k = m \times 1$ ￥, where m is the number of bus routes (1 or 2).

Table 2. The travel time of bus routes.

S	S_1	S_2	S_3	S_4	S_5
t_s (min)	5	3	2	2.5	2

Accessibility measures of any two bus stops can be computed using Eq.(2) and Eq.(5). Table 3 shows the results of accessibility measures.

Table 3. Accessibility measures for any two bus stops.

A_{ij}	1	2	3
1	0	0.56	0.78
2	0.56	0	0.64
3	0.78	0.64	0

As can be seen from Table 3, the value of accessibility has a positive relationship with the number of passenger routes and the amount of travel time. The higher value of accessibility, the more attractive of the bus service to the passengers. It is indicated that the accessibility proposed this paper can be used to assess degree of bus accessibility and evaluate the performance of the public transport service.

CONCLUSIONs AND FUTURE STUDY

This paper has presented a network-based accessibility measures for

assessing the degree of bus accessibility to evaluate the public service. The method employed a combined travel demand model formulated. Taking a simple public transport network as an example, this paper examined the effect of this method. It is indicated that accessibility has a positive relationship with the number of passenger routes and the amount of travel time. Improving the accessibility of public transport will be an effective policy to improve the public transport service and increase the passenger volume. In this paper, we just present the method of assessing the degree of bus stop accessibility to evaluate the public service. A case study may be needed to verify the effectiveness of the method.

ABSTRACT

For a long time, mismatched distribution has spatially existed between the production and consumption of coal resources in China. The current situation of allocating and transporting coal from the northwest of China to the rest of the country to meet demand will continue for a long period of time. In this paper, the example of the allocation and distribution (A&D) of coal in Shanxi Province is presented, and a model is set up for research. Since coal transport is particular and the parameters in the transport process are hard to quantify, a model based on fuzzy theory was used to get the primary A&D plan. Then, the relevant coal A&D network was built by using graph theory, and a detailed coal transport network was set up through non-linear programming modeling. Finally, a numerical example is provided to validate the effectiveness and advantage of the proposed model using MATLAB.

Keywords: Allocation; graph theory; fuzzy model; non-linear programming

INTRODUCTION

For a long time, coal, as China's basic energy source, has accounted for more than 70% of the production and consumption of disposable energy. It is predicted that China will require 2 to 2.6 gigatons of coal until 2010. Even up to 2020, coal consumption will account for about 60% in the energy consumption structure. However, mismatched distribution has always spatially existed between the production and consumption of coal resources in China. The current situation of allocating and transporting coal from northwest China to the rest of the country to meet demand will continue for a long period of time. Coal from Shanxi Province has a very important position in China. According to authority statistics, over the past 30 years, Shanxi has cumulatively produced over 9 gigatons of coal, which accounts for 30% of the total output of coal in China, and has cumulatively allocated and distributed 7 gigatons of coal, which accounts for 80% of amount of

coal traded in the national inter-provincial network. The export of Shanxi coal accounts for 70% nationwide as well. To solve the issue of national energy consumption, the allocation and distribution of coal from Shanxi to the rest of China appears essentially significant. Although rapid and drastic changes are taking place in vehicles for railway and road, coal allocation and distribution are still very severe and difficult problems. Meanwhile, economic development calls for more resources and short-term solutions. Therefore, it appears extremely important to transport coal faster and more safely at less cost. As indicated in some studies of the distribution status quo of coal in China (Gao 2008), coal transport is the key to the whole national economic development.

FUZZY MODEL OF COAL ALLOCATION AND DISTRIBUTION

Suggestions on Modeling

The establishment of a coal transportation network requires the collaboration of the entire coal supply chain. Coal mining enterprises should build cooperative relationships among various transport companies, especially railway transport departments. Coal mining enterprises should consider railway transport capacity when drawing up supply and marketing plans, and then determine coal supply and production plans. Meanwhile, transport departments should consider the supply plans of the coal mining plants as well to ascertain transport A&D plans. Information sharing set up by this means can guide the modeling of a coal A&D plan. With the rapid development of the global market and economy, flexibility has to be considered as important to competitiveness in an increasingly intense competitive environment (Pujawan 2004). Effective control of supply chain flexibility can enhance the business performance of a company (Kumar et al. 2006).

Fuzzy Model

As for the influencing factors in the transport process, it is difficult to quantify these factors and obtain precise data. For instance, the parameters of road capacity should be expressed by using fuzzy numbers to truly reflect the actual road transport capacity. As a result, fuzzy analysis on road networks and fuzzy classification of roads are of very important and practical significance for transport optimization decision-making in both peacetime and during disasters, especially for coal bulk cargo, which has more uncertainty. The concept of a fuzzy set was introduced (Zadeh 1965) as a mathematical method of representing vagueness and imprecision in actual problems. An interactive fuzzy goal programming technique was presented (Abd et al. 2006) for multi-objective transportation problems (MOTP). Li and Lai (2000) improved a fuzzy approach to MOTP. Pramanik and Roy (2006) solved the fuzzy goal programming approach with crisp and fuzzy coefficients for MOTP .

Assume $\widetilde{G}(V,E)$ denotes the entire fuzzy transport network; $f(v)$ denotes

the matrix of traffic flow through the transport network; $\widetilde{\mu}_D(f(v))$ denotes membership function of $f(v)$; R denotes a collection of all accesses from one coal supply point to one demand point in Shanxi; $\widetilde{F}$ and $\widetilde{C}_{ij}$ respectively denote target value and degree of membership of road capacity; V denotes the definite value of maximal flow; $\mu_F(v)$ denotes the degree of membership of demand quantity. According to fuzzy decision principle, the fuzzy transport model was proposed as following:

$$\max \mu_D(f(v)),\ \widetilde{\mathrm{D}} = \bigcap_{\forall r_{ij} \in R} \widetilde{C}_{ij} \cap \widetilde{F}$$

i.e., $$\widetilde{\mu}_D(f(v)) = \wedge \widetilde{\mu}_{r_{ij}}(C_{ij}) \wedge \mu_F(v) \quad \forall r_{ij} = R$$

Assume G(V,E) denotes the basic network abstracted from the coal transport network. The solving model of fuzzy transport optimal flow was obtained as the following:

$$\begin{cases} \max f(v) \\ \max \widetilde{\mu}_D f(v) \end{cases},\ \sum f_{ij} - \sum f_{ji} = \begin{cases} 0 & i \neq s,t \\ v & i = s \\ v & i = t \end{cases} \qquad i \to j, i \leftarrow j$$

$$0 \le f_{ij} \le \widetilde{c}_{ij},\ D = \bigcap \widetilde{C}_{ij} \cap F,\ \forall r_{ij} \in R$$

where R denotes one route from s to t, and F denotes fuzzy constraint of the maximal flow.

The optimal flow of the fuzzy problem can be solved according to the proposed model. The model can sufficiently reflect uncertainty in practice because it more realistically abstracts the coal transport system.

NON-LINEAR MODEL OF COAL ALLOCATION AND DISTRIBUTION

Streamlined-Formed Network Based on Graph Theory

Assume there is a directed network *G(V,E)*, as shown in Figure 1.

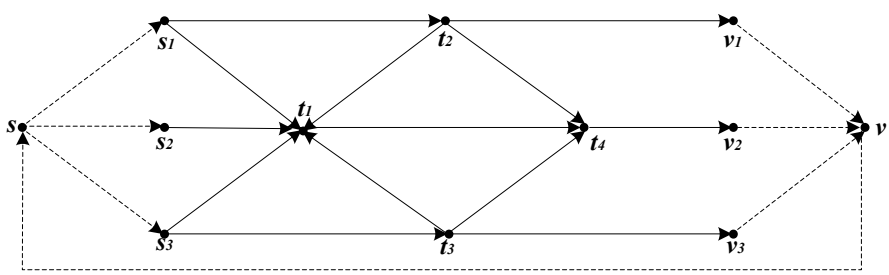

Figure 1. Coal A&D network.

To clearly denote the function of every node in the figure, s_i is used to denote each coal-producing area in Shanxi; t_i denotes each coal transfer stop or transport hub; and v_i denotes each coal demanding area. The directed arcs indicate the transport capacity of railway, highway, or waterway. In terms of coal nature and the practical situation, coal is transported to the provinces and cities mostly by railway in China. In the network, two virtual nodes (i.e., source and convergence) are set, and s denotes the coal source point; v denotes the coal convergence point. The directed arc ss_i is assumed to denote the process of transferring coal from underground to ground; arc v_iv denotes the coal consumption process; arc vs is a nominal one that makes the whole transport network connected. The cost is different according to different ways of transport; thus, assume that the transport costs of railway, highway, and waterway are definite in different areas.

The network constraint conditions are as follows:

1) Coal supply constraint: $s(s,s_i)$ denotes coal output in the producing area in the research year, and then freight quantity $f(s,s_i)$ meets $f(s,s_i)\geq 0$, $f(s,s_i)\leq s(s,s_i)$.

2) Coal demand constraint: $v(v_i,v)$ denotes the coal demand quantity in the demand area, which meets $0 \leq v(v_i,v) \leq f(v_i,v) \leq s(v_i,v)$.

3) Through-capacity constraint of coal transfer stop: Assume coal transport capacity of the existing line remains unchanged, and $t(ij)$ denotes through-capacity of existing coal on the transfer line, so the constraint of transport capacity $f(ij)$ at transfer stop is: $0 \leq f(ij) \leq t(ij)$.

Parameters Setting

T the T year of planning period, $T \in [1,15]$, let T=0 denote the year of 2000

S the supplying area, $S \in [1, \mathrm{M}]$, M is a definite integer

D the demand area, $D \in [1, \mathrm{N}]$, N is a definite integer

A the number of general road sections

B the number of coal road sections, $B \in [1, \mathrm{K}]$, K is the sum of the coal road sections

β transport effectiveness

L(B) the length of Section B

P(T,B) the coal transport cost (yuan/ton-km) of Section B in the T year; for instance, P(0,1)=0.15 denotes the coal transport cost of Section 1 in the year of 2000 is 0.15 yuan per ton-km

C(T,A) the coal through capacity (million ton) of Section A in the T year; for instance, C(0,1)=10 denotes the coal through capacity of Section 1 in the year of 2000 is 10 million ton

BS(B,S) the matrix of coal road Section B with the beginning of supply area S, BS(B,S)=1 when B is related to S; else BS(B,S)=0

BD(B,D) the matrix of coal road Section B with the end of demand area D, BD(B,D)=1 when B is related to D; else BD(B,D)=0

BA(B,A) the matrix of coal road Section B related to general road section A, BA(B,A)=1 when B passes through A; else BA(B,A)=0
$MX_1(T,S)$ the output of soft coal in supply area S in the T year
$MX_2(T,S)$ the output of blind coal in supply area S in the T year
$MY_1(T,S)$ the consumption of soft coal in supply area S in the T year
$MY_2(T,S)$ the consumption of blind coal in supply area S in the T year
$NY_1(T,D)$ the demand of soft coal in demand area D in the T year
$NY_2(T,D)$ the demand of blind coal in demand area D in the T year
$LQ_1(T,B)$ the freight quantity of soft coal in coal Section B in the T year
$LQ_2(T,B)$ the freight quantity of blind coal in coal Section B in the T year
$DF_1(T,D)$ the gap of soft coal in demand area D in the T year
$DF_2(T,D)$ the gap of blind coal in demand area D in the T year
$PVD_1(T,D)$ the penalty coefficient of soft coal in demand area D in the T year
$PVD_2(T,D)$ the penalty coefficient of blind coal in demand area D in the T year

Function Determination

The objective function of minimizing the total cost was given as follows:

$$\min\ f(T) = \sum_{B=1}^{K} \mathrm{L}(B)\mathrm{P}(T,B)\left[\mathrm{LQ}_1(T,B) + \mathrm{LQ}_2(T,B)\right]$$
$$+ \sum_{D=1}^{K}\sum_{B=1}^{K}\left[\mathrm{PVD}_1(T,D)\mathrm{DF}_1(T,D) + \mathrm{PVD}_1(T,D)\mathrm{DF}_2(T,D)\right]$$

where the supply constraints are $\sum_{B=1}^{K} \mathrm{BS}(B,S)\mathrm{LQ}_1(T,B) \le \mathrm{MX}_1(T,S) - \mathrm{MY}_1(T,S)$

and $\sum_{B=1}^{K} \mathrm{BS}(B,S)\mathrm{LQ}_2(T,B) \le \mathrm{MX}_2(T,S) - \mathrm{MY}_2(T,S)$; the transport constraint is

$\sum_{B=1}^{K} \mathrm{BA}(B,A)\left[\mathrm{LQ}_1(T,B) + \mathrm{LQ}_2(T,B)\right] \le \mathrm{C}(T,A)$; the demand constraints are

$\sum_{S=1}^{M}\sum_{B=1}^{K} \mathrm{BS}(B,S)\mathrm{BD}(B,D)\cdot\beta\mathrm{LQ}_1(T,B) + \mathrm{DF}_1(T,D) \le \mathrm{NY}_1(T,D)$ and

$\sum_{S=1}^{M}\sum_{B=1}^{K} \mathrm{BS}(B,S)\mathrm{BD}(B,D)\cdot\beta\mathrm{LQ}_2(T,B) + \mathrm{DF}_2(T,D) \le \mathrm{NY}_2(T,D)$; another constraint is $\mathrm{LQ}_1(T,B), \mathrm{LQ}_2(T,B), \mathrm{DF}_1(T,D), \mathrm{DF}_2(T,D) \ge 0$.

Numerical Example

Taking T=1, for instance, select 3 coal supply areas, 6 demand areas, 6 coal road sections, and 4 general road sections. Statistical value was given in the following matrices and Table 1.

$$BS(B,S)=\begin{bmatrix}1&0&1&0&1&0\\0&1&1&0&0&0\\1&0&0&1&0&1\end{bmatrix},\ BA(B,A)=\begin{bmatrix}1&0&1&1&1&0\\1&1&0&1&0&1\\0&1&1&0&1&1\\0&0&1&0&1&0\end{bmatrix},\ BD(B,A)=\begin{bmatrix}1&1&0&1&0&1\\0&1&1&0&1&0\\1&0&0&1&0&1\\1&0&1&0&1&0\\0&1&1&0&1&0\\1&0&0&1&0&1\end{bmatrix}$$

Table 1. Value of Each Parameter (mt: millon ton).

mt \ S	1	2	3
$MX_1(1,S)$	20	10	5
$MX_2(1,S)$	15	10	5
$MY_1(1,S)$	4	1	0.8
$MY_2(1,S)$	2	1	0.4

mt \ D	1	2	3	4	5	6
$NY_1(1,D)$	3	4	5	4	2	1
$NY_2(1,D)$	2	3	1	2	4	3

mt \ A	1	2	3	4
$C(1,A)$	10	8	12	9

D	1	2	3	4	5	6
$PVD_1(1,D)$	-0.01	-0.012	-0.01	-0.008	-0.005	-0.006
$PVD_2(1,D)$	-0.01	-0.011	-0.009	-0.007	-0.008	-0.005

The optimal result calculated by MATLAB is shown in Table 2.

Table 2. Optimal Result Calculated by MATLAB (mt: millon ton).

mt \ B	1	2	3	4	5	6
$LQ_1(1,B)$	3.15	3.48	2.52	4.33	2.67	2.85
$LQ_2(1,B)$	1.78	2.41	1.78	2.73	4.32	2.22

CONCLUSION

This paper proposes the fuzzy model, which primarily solves the problem of optimizing decision-making of the fuzzy transport network. The model reflects uncertainty of the transport process when it was actually operated. A further A&D network model was set up using correlative graph and non-linear theory. Since the model results in several matrix relationships and relevant data related to coal transport, a transport plan can be optimized by using relevant mathematical software to calculate the transport amount of each coal road section only if above-mentioned data are available. Finally, the feasibility and effectiveness of the proposed simple-operated model were validated. The paper concentrates on initial modeling, referring less to algorithms used in later calculations. The model will integrate with detailed algorithms to develop a more complete and practical coal A&D plan in further study in the future.

A Comprehensive Bus Line Evaluation Method Based on Fuzzy C -means Cluster ing Algorithm

Chen Suping, Chen Xuewu, Yang Min

School of Transportation, Southeast University; Room 1513, QunYingLou, No.35, JinXiangHe Road, Nanjing 210018, China; email: csp1983@163.com

ABSTRACT

Analyzing and appraising the operational situation of bus lines is an important basis on which bus companies can adjust bus lines and establish operation schedules. However, at present, the assessment of bus lines lacks accurate and scientific methods. This article proposed to use a Fuzzy C-means clustering algorithm to comprehensively analyze the structural difference and operational effects of bus lines. By comparing the evaluation indexes of each line, those with similar structure and operational effects were classified into one category, each with its own unique structural and operational characteristics. Based on this, the algorithm was applied to the operational situation of the public transit system in Changzhou city. As a result of the evaluation process, suggestions to optimize the transit system are proposed.

Key words : Fuzzy C-means Clustering; cluster factor; comprehensive evaluation

INTRODUCTION

The evaluation of the operational effects of bus lines is important to bus companies. Through compiling, analyzing, and researching daily operations data, representative content can be obtained, providing a basic understanding of the bus lines' management state and operational quality, which can provide a reliable basis for determining policy orientation. However, the kinds of data to be analyzed and the evaluation of bus lines still lack scientific and accurate methods.

Clustering analysis means classifying things according to the similarity degree of their properties. Individuals in same class have high homogeneity and individuals in different classes have high heterogeneity (Bezdek 1976). In recent years, clustering analysis method obtained a widespread application in public transportation domain, Liu Xiao; Li Mohan (Xiao, 2004) evaluated the public transit network's service level of the residents' zones in Dandong city using Fuzzy clustering analysis method. Li Yuhua(Yuhua 2004) applied grey clustering analysis to evaluate the service level of the public transit system in Qingdao city. In its master degree thesis, Li Hong Tao (Hongtao 2005) proposed a GIS based Clustering Analysis of Urban public traffic network service level. The above clustering methods mainly focus on the entire transit network, stressing in evaluation to the entire transition system, but lacking evaluation of concrete bus lines.

This paper presents the use of the Fuzzy C-means clustering algorithm on the appraisal of concrete public bus lines. First, the bus lines' evaluation index system was determined, and then the clustering algorithm was used to classify the bus lines into different categories. Each line's operational characteristics were analyzed separately, and scientific suggestions were provided for the bus companies' operations dispatch.

BASIC PROCESS OF PUBLIC BUS LINES' SYNTHETIC EVALUATION

In the evaluation of the public bus line, three levels were involved: line layout level, line facility level, and line operation level. The layout level includes line alignment, etc., and must be considered unified in the road network's construction. The facility level includes bus allocation and stop locations of each line; this is mainly related to passenger flow distribution and can be reflected from indexes such as the line's passenger flow volume, average stop spacing, etc. The operation level is related to service level indexes such as average travel speed, punctuality rate, and passenger comfort. A synthetic evaluation of bus lines should include indexes from the above three aspects; the appropriate evaluation methods were used to conduct omni-directional analysis of the lines.

PRINCIPLE AND STEP OF FUZZY C -MEANS CLUSTERING ANALYSIS

Principle of Fuzzy C-means Clustering Analysis

Clustering analysis is a method based on "like attract like." Input samples' classified attributes are not known beforehand, but an automatic classification is applied to the samples using the "similarity" or "distance." between them. The fuzzy clustering analysis method, which was proposed by Bezdek (1981), considers the boundary's fuzzy characteristics between different classes. Its computed result is superior to other taxonomic approaches (Wei 2002). The principle of Fuzzy C-means clustering analysis is as follows (Xinbo 2004):

(1) The input sampled data set for X, $x_{ij} \in X$ is the sample attribute data value, $1 \leqslant j \leqslant p$. n is the sample number, and p is the sample attribute number. Fuzzy C-means clustering's goal is to make the objective function J_m the smallest.

$$J_m(U,V) = \sum_{k=1}^{n}\sum_{i=1}^{c}(u_{ik})^m(d_{ik})^2 \qquad (1)$$

Where c is the clustering number; n is the sample number; $U=[u_{ik}]$ is the fuzzy classification matrix; $V=(V_1, V_2, \ldots, Vc)$, V_i is the clustering center of the ith class. $(d_{ik})^2=(X_k-V_i)^2$, which (X_k-V_i) is the distance between vector X_k and V_i. It is generally taken the Euclidean distance as the distance of (X_k-V_i), that is $\| X_k - V_i \| = \left[\sum_{j=1}^{p}(x_{kj} - V_{ij})^2\right]^{1/2}$, $m \in (1, \infty)$ is the weight of the index.

(2) Seeking the minimum of J(U,V) according to the clustering criterion, so

$$\begin{cases} \min\{J(U,V)\} = \min\left\{\sum_{k=1}^{n}\sum_{i=1}^{c}(u_{ik})^m (d_{ik})^2\right\} = \sum_{k=1}^{n}\left\{\min[\sum_{i=1}^{c}(u_{ik})^m (d_{ik})^2\right\} \\ \sum_{i=1}^{c} u_{ik} = 1 \end{cases} \tag{2}$$

(3) Solving the problem by using the Lagrange multiplier method,

$$F = \sum_{i=1}^{c}(u_{ik})^m (d_{ik})^2 + \lambda\left(\sum_{i=1}^{c} u_{ik} - 1\right) \tag{3}$$

(4) Optimality conditions are as follows:

$$\begin{cases} \dfrac{\partial F}{\partial \lambda} = \left(\sum_{i=1}^{c} u_{ik} - 1\right) = 0 \\ \dfrac{\partial F}{\partial u_{ik}} = \left[m(u_{ik})^{m-1}(d_{ik})^2 - \lambda\right] = 0 \end{cases} \tag{4}$$

(5) According to step (4), we get:

$$u_{ik} = 1 / \left[\sum_{j=1}^{c}\left(\frac{d_{ik}}{d_{jk}}\right)^{2/(m-1)}\right] \tag{5}$$

$$V_i = \sum_{k=1}^{n}(u_{ik})^m X_k / \sum_{k=1}^{n}(u_{ik})^m \tag{6}$$

From the above inferential reasoning process, if the data set X, clustering number c, and the weight of the index m are known, we can determine the best fuzzy classified matrix and the clustering center by (5) and (6). Therefore, the optimized questions can be solved by using an iterative algorithm.

Steps of Fuzzy C-means Clustering

According to the principle of fuzzy C-means clustering, the concrete steps for carrying on fuzzy C-means clustering analysis by iterative algorithm are as follows:

Step 1: Assign the clustering number c, $2 \leqslant c < n$; choose the form of d_{ik}; assign the weight of the index m, $1 \leqslant m < \infty$.

Step 2: Initializing $U^{(0)}$, the sum of the elements in each column should be 1; set the iteration number l=0.

Step 3: Compute the c clustering centers $\{V_i^{(l)}\}$ by using formula (6).

Step 4: Update $U^{(l)}$ to $U^{(l+1)}$ by using formula (5) and $\{V_i^{(l)}\}$.

Step 5: Compare $U^{(l)}$ and $U^{(l+1)}$, if $\| U^{(l+1)} - U^{(l)} \| \leqslant \varepsilon_L$, , then stop the iteration; otherwise, return to step 3, l=l+1.

SYNTHETIC EVALUATION OF BUS LINES IN CHANGZHOU CITY

Choosing the Clustering Factors of Bus Lines

The following factors should be considered when choosing the public bus lines' clustering factors: The chosen indexes should be representative and can reflect the structural properties and operational effects of the research objects (JPTC 2008). To guarantee that this method has strong versatility, the chosen indexes should be able to be collected and computed easily. Based on the above principles, all the bus lines' evaluating indicators were classified and analyzed. Deferring to the principles of generality, coordination, comprehensibility, objectivity and usability, six indexes in three aspects were considered as the bus lines' evaluation indexes, as shown in Figure 1.

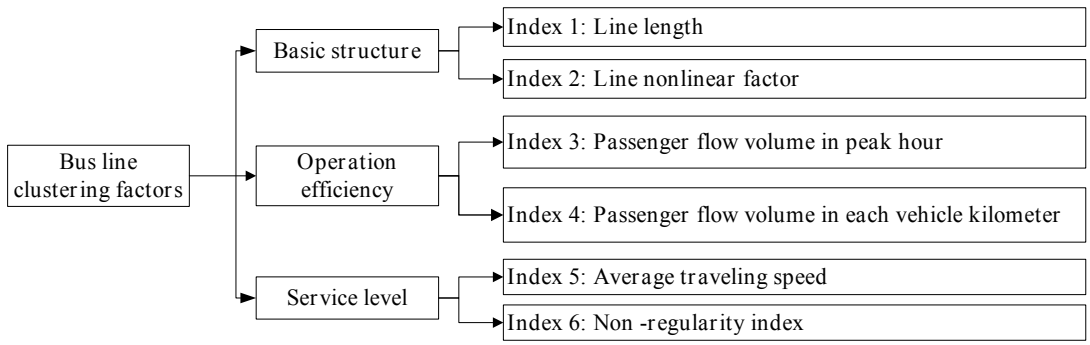

Figure 1. Bus line clustering factors .

After designating the clustering factors, statistical data for 35 bus lines were analyzed and computed. The value of the clustering factors is shown in Table 1.

Table1. Value of Clustering Factors of Surveyed Lines.

Bus Lines	Index 1	Index 2	Index 3	Index 4	Index 5	Index 6
1	10.50	2.52	1737	7.39	13.59	0.33
…	…	…	…	…	…	…
901	12.10	1.65	1273	5.26	18.82	0.25
902	6.80	1.30	918	6.75	13.51	0.20
B13	12.90	1.49	3195	6.72	21.19	0.20

Normalization of Bus Lines Clustering Factors

As shown in Table 1, the differences in dimension and magnitude of the clustering factors are very large, so the data must first be normalized. Otherwise, it is easy to highlight the indexes with high magnitude, but this reduces, even neglects, indexes with small magnitude (Zhouyang 2005). Therefore, the indexes were normalized; the results are shown in Table 2.

Table2. Normalized Bus Line Clustering Factors .

Bus Lines	Index 1	Index 2	Index 3	Index 4	Index 5	Index 6
1	0.10	1.00	0.13	0.66	0.12	0.50
…	…	…	…	…	…	…
901	0.13	0.42	0.08	0.45	0.33	0.37
902	0.02	0.19	0.04	0.60	0.11	0.30
B13	0.15	0.32	0.29	0.60	0.43	0.30

Fuzzy C-means Clustering Analysis

After the clustering factors were determined, the appropriate index weight m and cluster number c were selected. Bezdek (2002) determined that m=2 was the most meaningful from the physical interpretation, so we let m=2. For cluster number c, c=2, c=3 and c=4 were selected to classify the bus lines. After computation, the results were compared with the public bus lines' actual operation situation in Changzou city, and it was found that dividing into four categories was most appropriate. The classified members and distance matrix are shown in Table 3 and Table 4.

Table 3. Classified Members .

Category	Bus Lines
1	14, 23, 25, 56, 902, 812, 813, 81
2	1, 5, 7, 8, 16, 20, 29, 30,33, 38, 201, 259, 302, 901, 811
3	15, 17, 18, 35, 57, 68, 328
4	3, 6, 9, 11, 12

Table 4. Distance Matrix .

Category	1	2	3	4
1	0	0.993	0.957	0.303
2	0.993	0	0.804	1.156
3	0.957	0.804	0	0.944
4	0.303	1.156	0.944	0

Clustering Analysis Results

The Category 4 bus line operation efficiency is best; passenger flow volume is large, and line length is generally short, so this kind of bus line is most efficient in all categories. After investigation, it was found that this kind of bus line was located in the passenger flow corridor of Changzhou city, so the passenger flow volume of these lines is the largest. However, for the Category 4 lines, the service level is bad, and the average traveling speed is slow.

As is shown in Table 4, the Category 1 lines are closest to the Category 4 lines, so it has something in common with the Category 4 line, for example, large passenger flow volume and high efficiency. The Category 1 lines mainly connect the central urban area and the adjacent districts, and their service level is much higher than the Category 4 lines. The main reason is that the line nonlinear factor is smaller and alignment is smoother.

The Category 2 lines' length and passenger flow volume are moderate, and their efficiency is inferior to the Category 1 and Category 4 bus lines. The primary cause is because the Category 2 lines are generally built on collector streets and belongs to inferior skeleton bus lines.

Category 3 bus lines' length is generally much longer; the average line length is usually more than 30 kilometers, and their operation efficiency is lowest. The alignment of these lines usually starts from the center of the city and extends to the urban marginal areas. Their main task is to satisfy the travel demand of the city boundary residents who need to travel to the downtown area.

Through the above analysis, unified with each kind of line alignment, some pertinence measures were proposed, as shown in Table 5.

Table 5. Optimization Measures of Bus Lines.

Measures	Concrete Contents
1	Reduce the line overlap factor on main streets to avoid too many bus lines competing for passengers and disturbing each other.
2	Try to establish as many stops as bus bays to reduce the delay of vehicles in and out of the stops.
3	Shorten or cut lines that are too long to improve operation efficiency.
4	Enhance transit priority measures in center districts to reduce delay and improve vehicle traveling speed.

CONCLUSION

In view of the problem that current public bus line evaluations lack scientific and accurate methods, this article proposed to use a fuzzy C-means clustering algorithm principle to appraise and analyze bus lines. Concrete evaluation steps and key questions were presented. The method was applied to evaluate 35 bus lines' operations situation in Changzhou city. Each category of lines was analyzed, and optimized suggestions were given. The article proposed some reference meanings for bus companies to adjust bus lines and establish a dispatch schedule.

A Nonlinear Model for Decision-Making for Container Slot Chartering & Allocation under Liner Shipping Alliance

Ji-hong Chen and Hong Zhen

College of Communications and Transport, Shanghai International Shipping Institute, Shanghai Maritime University, P.O. Box 1290, Shanghai, China, 200135; PH (86) 21-65853850 ext. 8038; email: cxjh2004@163.com

ABSTRACT

The development of strategic alliances is very important to the liner industry. Liner shipping companies can benefit significantly from cooperating with shipping alliance members. This paper proposed a nonlinear model for container slot chartering & allocation under liner shipping alliance, which can help planners make better scheduling decisions for their fleets and routes under alliance agreement, and estimate shipping system costs more accurately. The proposed model pursued an optimal scheduling strategy for liner shipping company under shipping alliance agreement. The results showed that slot chartering under shipping alliance has outstanding advantages for shipping companies to lower their system costs, offset route capacity, and ensure the completion of freight tasks among others.

INTRODUCTION

Liner shipping alliance has been developed particularly rapidly these years. Alliance members can cooperate in the form of slot chartering, to take advantage of economies of scale. Slot chartering (Phties M. Panayides 2003) is a specific way for the shipping alliance members to share their shipping resources (Ji-hong Chen et al. 2008). It means that according to the alliance agreement, both parties cooperate by the sale of container slot and in a way that one party is to sell while another is to buy. In this way, shipping companies do not completely rely on their own ships (Hua-An Lu et al. 2006). Instead, they do their shipping business by leasing certain number of container slots from other shipping alliance members.

Many linear optimization models have been developed to identify the liner shipping routes (Phties M. Panayides 2003), fleet planning (Ji-hong Chen et al. 2008), transportation network (Hua-An Lu et al. 2006), etc in the literature. However, there are some defects in the models in terms of their practical applications. This paper is intended to develop a nonlinear model as a decision-making tool to determine slot chartering and allocation under containerized liner shipping alliance. Moreover, the paper uses LINGO software to solve the optimization model for a sample problem.

TRADITIONAL LINEAR OPTIMIZATION MDEL FOR LINER SHIPPING FLEETS & ROUTES (Model Ⅰ)

The optimization model is developed as below:

$$\text{Min} \quad Z_0 = \sum_i \sum_j c_{ij} x_{ij} + \sum_j \delta_j u_j \tag{1}$$

s.t.

$$\sum_j \frac{1}{n_{ij}} \le m_i \tag{2}$$

$$\sum_i N_i x_{ij} + u_j = Q_j \tag{3}$$

$$x_{ij} \ge 0; \quad u_j \ge 0; \text{ integer} \tag{4}$$

Model Ⅰ is a linear model developed for route planning and slot allocation for liner shipping company (Gang Zhao 1997), without considering shipping alliance agreement. The explanation for the model and parameters can be referred to model Ⅱ.

NONLINEAR OPTIMIZATION MODEL FOR SLOT CHARTERING (MODEL Ⅱ)

$$\text{Min} \quad Z = \sum_{\forall i \in S} \sum_{\forall j \in R} c_{ij} x_{ij} + \sum_{\forall j \in R} \delta_j u_j + \sum_{\forall k \in H} \sum_{\forall j \in R} \omega_{kj} e_j q_{kj} \tag{5}$$

s.t.

$$\sum_{\forall j \in R} \frac{1}{n_{ij}} x_{ij} \le m_i \qquad \forall i \in S \tag{6}$$

$$\sum_{\forall j \in R} \frac{1}{p_{kj}} \omega_{kj} \le l_k \qquad \forall k \in H \tag{7}$$

$$\sum_{\forall i \in S} N_i x_{ij} + \sum_{\forall k \in H} q_{kj} \omega_{kj} + u_j = Q_j \qquad \forall j \in R \tag{8}$$

$$\omega_{kj} \ge \omega_{kj}^d \quad \forall k \in H; \forall j \in R \tag{9}$$

$$\omega_{kj} \le \omega_{kj}^u \quad \forall k \in H; \forall j \in R \tag{10}$$

$$q_{kj} \ge q_{kj}^d \quad \forall k \in H; \forall j \in R \tag{11}$$

$$q_{kj} \le q_{kj}^u \le M_k \quad \forall k \in H; \forall j \in R \tag{12}$$

$$\omega_{kj} \le M Y_{kj} \quad \forall k \in H; \forall j \in R \tag{13}$$

$$q_{kj} \le M Y_{kj} \quad \forall k \in H; \forall j \in R \tag{14}$$

$$\omega_{kj} q_{kj} > M(Y_{kj} - 1) \quad \forall k \in H \; ; \forall j \in R \tag{15}$$

$$Y_{kj} \in \{0,1\} \tag{16}$$

$$x_{ij} \, , \; \omega_{kj} \, , \; q_{kj} \, , \; u_j \geq 0 \;\; \text{and integer} \;\; \forall i \in S \; ; \forall k \in H \; ; \forall j \in R \tag{17}$$

DESCRIPTION OF THE MODEL

In model Ⅱ, formula (5), (8) and (15) show that the model is a nonlinear model. Explanation of the parameters and formulas for model Ⅰ is almost the same as model Ⅱ. Explanation for the models is as follows.

Symbols and sets. i: symbol for the ships of the shipping company ; k: symbol for cooperative ships; j: symbol for liner shipping routes; S: a set for all the ships of the liner shipping company; H: a set for all the cooperative ships; R: a set for all the liner shipping routs.

Decision variables. x_{ij}: the number of consecutive voyages for ship i on route j in the planning period; ω_{kj}: the number of cooperative consecutive voyages for cooperative ship k on route j in the planning period; q_{kj}: the number of slots (TEU) for chartering, from cooperative ship k on route j for each consecutive voyage; u_j: un-carried TEU of the shipping company on rout j in the planning period; Y_{kj}: binary variables ($Y_{kj} \in \{0,1\}$).

Parameters. c_{ij}:transportation cost of ship i on route j for a consecutive voyage; δ_j:opportunity cost for each TEU(twenty equivalent unit) on route j; e_j: slot charting cost of one TEU for cooperation, paid to the cooperative company; m_i: the number of ship i; l_k : the number of cooperative ship k; n_{ij}:maximum consecutive voyages for ship i on route j in the planning period; p_{kj}:maximum consecutive voyages for cooperative ship k on route j in the planning period; N_i:capacity (TEU) of ship i; M_k: capacity (TEU) of cooperative ship k; Q_j: forward shipment (TEU) of the shipping company in route j in the planning period; M: a very big number ($M \to \infty$).

Formulas. Formula (5) means the total system cost for the shipping company should be minimized; formula (6) and (7) show that number of ships or cooperative ships assigned should be no more than the number of available ships; formula (8) means the ships and the cooperative ships assigned for slot chartering should finish the carrying tasks; formula (9) and (10) show minimum & maximum limits for cooperative consecutive voyages of cooperative ship k on route j in the planning period; formula (11) and (12) show the range of the available slots for chartering for each cooperative consecutive voyage of cooperative ship k on route j; with the help of Y_{kj} (binary variables), formula (13) through (15) show, if there is

or no cooperative voyage, there will be or no container slots for chartering; formula (16) and (17) show the ranges for decision variables.

ALGORITHM FOR THE MODEL

Much effective algorithm for the nonlinear models has been offered by the scholars. A particle swarm optimization algorithm for nonlinear integer programming (Shang Gao et al. 2007) and a penalty interior-point method for nonlinear programming (Yi-rong Yao et al. 2008) were effective and helpful. When the model involves many variables, we often deal with it with the help of the related computer software, such as MATLAB and LINGO. The paper will process the example with the help of LINGO software.

APPLICATION OF THE MODEL

We assume two shipping companies (company A and company B) in a shipping alliance will cooperate in form of slot chartering. According to the alliance agreement, shipping company A can rent container slots from company B for each voyage in 4 container shipping routes, and for each cooperative voyage, the largest number of slots for chartering from each ship of company B is 1000TEU. Company A has three types of ships: 5 Ship1 (6000TEU), 8 Ship2 (3400TEU), and 8 Ship3 (2000TEU). For cooperation, company B offers three kinds of ships: 6 Ship Ⅰ (6000TEU), 6 Ship Ⅱ (5000TEU), and 8 ShipⅢ(4000TEU). The planning period is a quarter of a year. Other specific data can be got from Table1~3.

Table 1. Largest number of voyages for each ship in each route.

Company/Ship/Route		Route 1	Route 2	Route 3	Route 4
	Ship1	3	2	3	1
Company A	Ship2	4	3	3	2
	Ship3	5	5	5	2
	Ship Ⅰ	3	2	1	3
Company B	Ship Ⅱ	3	4	2	3
	ShipⅢ	5	5	5	2

Table 2. Largest number of cooperative voyages for ships of company B in each route (ω_{kj}^{u}).

Ship/Route	Route 1	Route 2	Route 3	Route 4
Ship Ⅰ	2	3	2	3
Ship Ⅱ	4	3	3	4
ShipⅢ	6	5	7	7

Table 3. Costs for one consecutive voyage or one TEU for company A (ten thousand USD).

Cost/Ship/Route		Route 1	Route 2	Route 3	Route 4
Transportation Cost for a Consecutive Voyage	Ship1(6000TEU)	100	110	120	140
	Ship2(3400TEU)	80	90	100	100
	Ship3(2000TEU)	60	80	80	90
Slot Chartering Cost (per TEU)		0.08	0.05	0.07	0.06
Opportunity Cost (per TEU)		0.3	0.125	0.2	0.175

Planning and routing without slot chartering. For the situation with no cooperation under shipping alliance, the results of planning and routing ships of Company A with model Ⅰ were obtained from LINGO software as shown in Table 4.

Table 4. Total number of consecutive voyages & total cost (ten thousand USD) of shipping system for Company A in the planning period.

Ship/Route	Route 1	Route 2	Route 3	Route 4	Total cost
Ship1 (6000TEU)	6	2	3	1	
Ship2 (3400TEU)	0	0	0	16	9110
Ship3 (2000TEU)	2	34	1	1	

Decision-making for slot chartering. With model Ⅱ and the help of LINGO software, the optimization results of Decision-making for slot chartering for Company A are in Table 5 and Table 6.

Table 5. Number of consecutive voyages and total cost of shipping system ($1,000) for Company A under shipping alliance

Ship/Route	Route 1	Route 2	Route 3	Route 4	Total cost
Ship1 (6000TEU)	7	3	3	0	
Ship2 (3400TEU)	0	0	0	16	6885
Ship3 (2000TEU)	0	26	0	9	

Table 6. Total number of cooperative voyages & number of slots for chartering

Ship/Route		Route 1	Route 2	Route 3	Route 4
ω_{kj}	Ship Ⅰ	0	3	0	3
Total Number of	Ship Ⅱ	0	4	0	4
Cooperative Voyages	ShipⅢ	0	3	0	7
q_{kj}	Ship Ⅰ	0	1000	0	1000
Number of Slots(TEU) for	Ship Ⅱ	0	1000	0	1000
Chartering for each Voyage	ShipⅢ	0	609	0	1000

Comparing Table 5 with Table 4, we can see that the total cost of the shipping system of Company A decreases significantly. System cost was reduced to 6885 from 9110, which represents 24.4% of decrease. These results indicate that slot chartering under shipping alliance has outstanding advantage for shipping companies to reduce their system costs.

CONCLUSION

Integration of global logistic systems has already had a significant impact on international shipping services (Chin-Shan Lu et al. 2007). Strategic alliances between liner shipping companies provide a whole new stage along with a flexible managing method for the carriers (Hua-An Lu et al. 2006). Co-operative activities such as joint fleet, slot exchange, slot charter, share of port usage etc., have been widely operated in the contemporary liner industry. Slot chartering is the fundamental and also the most effective form of cooperation for shipping alliance.

This paper proposed a nonlinear optimization model for ship scheduling and slot chartering under shipping alliance. The proposed method can help planners make better scheduling and routing decisions under alliance agreement constraints. Meanwhile, it can make more accurate estimates system costs, freight voyages, and cooperative voyages in liner service route planning. The proposed model pursues an optimal scheduling strategy to reduce system cost. Moreover, the experimental results of a case study show that the proposed model can perform as a good decision support tool to improve the management performance for liner shipping alliance members.

ABSTRACT

Hubs play a significant role in the transport of emergency supplies after earthquakes. To ensure that transport and incident management operate efficiently under earthquake conditions, this paper presents a model for hub location suitable for the conditions of earthquakes. Taking the characteristics of road networks and freight transportation under the condition of earthquakes into account, the minimum of total supplies' reliable transit time under the service time constraints of kinds of supplies is the objective function of hub location under earthquake conditions. A surcharge is introduced in the cost function for those o/d pairs that were not being delivered to on time. The cost of waiting time due to congestion and the cost of reliable traveling time are considered. A Simulated Annealing algorithm was developed to solve the model. The algorithm has been tested in randomly-created networks. The results show that when a situation of congestion occurs, the proposed algorithm enables better solutions to be found.

Key words: model of hub location under the condition of earthquake; operations research; reliable transit time; surcharge overtime; waiting time due to congestion

INTRODUCTION

The catastrophe of a destructive earthquake put tremendous pressure on the urban transportation hub. On one hand, great damage is caused to the transportation infrastructure; on the other hand, the transportation of emergency rescue teams and supplies into the affected areas put tremendous pressure on the hub. Hub location can satisfy the demands of people and material transportation in the relief effort, and determine the operation of emergency rescue, evacuation, and withdrawal, as well as urban renewal.

Therefore, in urban development construction, taking special traffic demand under earthquake conditions into consideration for hub location should be synchronized with overall urban planning.

HUB LOCATION RESEARCH

Since O'Kelly (1986) presented the findings of his studies on hub location, many researchers have centered their efforts on the hub location problem. Campbell (1994) presented a linear model for the p-hub location problem. Later, Skorin-Kapov et al. (1997) developed an expression to simplify the problem. Aykin (1995) proposed an algorithm to solve the problem of locating p hubs. O'Kelly et al. (1998) developed a model called FlowLoc. Ebery et al. (2000) studied the hub location problem of multi-distribution and capacity constraints. Kara and Tansel (2002) studied the p hub location problem of mono-distribution. The research of domestic hub location can be classified into two categories: the two-stage method of hub location (Zhang et al. 2001; Yuan et al. 1991), and the application of AHP (Yan and Wang 1999 Guo and Yan 1997) and Fuzzy Theory (Liu and Yan 2006) to hub location evaluation.

The research of hub location domestically and abroad addressed normal situations, but did not take into consideration the needs of special transportation under earthquake conditions when they discuss the problem of hub location.

DEFINING THE PROBLEM

The traffic-attracting nodes in emergency relief are affected regions and planning refuges; traffic-generated nodes include designated relief supplies reserve centers and posts of rescue teams. Transportation of emergency relief supplies have a weak economy and are strongly time-sensitive; thus, hub location under earthquake conditions is a problem of optimizing the hub sites to minimize total supplies reliable transit time under the service time constraints of the kinds of supplies. In this paper, the following assumptions are made:

Cargo passes through one or two hubs to complete its transport.

- Economies of scale are taken into account.
- Supply delivery under earthquake conditions has time constraints.
- When cargo arrives at a busy hub, a queuing phenomenon can occur.
- A devastating earthquake causes serious damage to the connectivity of road networks. Reliable transit time is corrected by the connectivity reliability of road networks.

OPTIMAL LOCATION OF HUBS UNDER EARTHQUAKE CONDITIONS

This paper presents a model for hub location based on Aykin's model (1996). The specific model is:

$$\sum_{i}^{Min}\sum_{k}\sum_{t}\sum_{j}\sum_{a}(W_{i,j}^{a}+C_{f}^{a}WT_{i,j}^{a})(\beta T_{i,k}+\alpha T_{k,t}+\beta T_{t,j})V_{i,k,t,j} \tag{1}$$

$$C_{f}^{a}=\begin{cases}0, & if\left(T_{i,k}+T_{k,t}+T_{t,j}+\omega_{k}+\omega_{t}\right)\le T_{Max}^{a}\\ C_{f}^{a}, & if\left(T_{i,k}+T_{k,t}+T_{t,j}+\omega_{k}+\omega_{t}\right)>T_{Max}^{a}\end{cases}$$

$$s.t. \quad \sum_{k}\sum_{t} V_{i,k,t,j} = 1 \quad \forall i,j \tag{2}$$

$$\sum_{k} Y_k = \sum_{l=l_1}^{l_4}\sum_{k} Y_k = p_1 + p_2 + p_3 + p_4 = p \tag{3}$$

$$\sum_{i\neq k}\sum_{\substack{l\neq k \\ h\neq k}} \left(V_{i,l,h,k} + V_{k,l,h,i}\right) \le M\left(1 - Y_k\right) \quad \forall k \tag{4}$$

$$\sum_{\substack{l\neq k \\ h\neq k}} (V_{k,k,h,t} + V_{t,h,k,k} + V_{t,t,h,k} + V_{k,h,t,t}) + \sum_{\mathrm{h}} (V_{k,h,h,t} + V_{t,k,h,k}) \le M(2 - Y_k - Y_t) \quad \forall k \neq t \tag{5}$$

$$\sum_{k} Z_{i,k} = 1 \quad \forall i \tag{6}$$

$$\sum_{t}\sum_{j} V_{i,k,t,j} \le \left(N - p + 1\right) Z_{i,k} \qquad \forall i,k \tag{7}$$

$$\sum_{i}\sum_{k} V_{i,k,t,j} \le \left(N - p + 1\right) Z_{j,t} \qquad \forall t,j \tag{8}$$

$$V_{i,k,t,j}(T_{i,k} + T_{k,t} + T_{t,j}) \le T_{Max} \quad \forall i,k,t \tag{9}$$

$$\begin{aligned} &\sum_{i}\sum_{t}\sum_{j} \left(V_{i,k,t,j} W_{i,j}\right) \le CHub_k \quad \forall k \\ &\sum_{i}\sum_{t\neq k}\sum_{j} \left(V_{j,t,k,i} W_{j,i}\right) \le CHub_k \quad \forall k \end{aligned} \tag{10}$$

$$Z_{i,j}, V_{i,k,t,j}, Y_k \in \{0,1\} \quad \forall i,k,t,j \tag{11}$$

Where,

$W_{ij} = \sum_{a=1}^{q} W_{i,j}^{a}$ - cargo flow from *i* to *j*, $WT_{i,j}^{a}$ is load of cargo *a* from *i* to *j* which is not on time

C_{f}^{a} - surcharge of cargo *a* due to not on time

$\omega_k = \dfrac{1}{\mu_k - \lambda_k}$ - queuing time spent in hub *k*, λ_k、μ_k are arrival rate and service rate of *k* hub

T_{Max}^{a} - maximum delivery time of cargo *a*

α / β - factor of scale economy between hubs/between hub and non-hub

$T_{m,k} = t_{m,k} \cdot \psi_{m,k}$ - reliable transit time between node *m* and node *k*, $\psi_{m,k}$ is connectivity reliability

$V_{i,k,t,j}$ - when the cargo going from *i* to *j* passes through hubs *k* and *t*, $V_{i,k,t,j}=1$; otherwise, 0

$Z_{i,k}$ - if the *i*-node is assigned to hub *k*, $Z_{i,k}=1$； otherwise, 0

Y_k^l - when the k-node is a l tape hub, $Y_k^l=1$; otherwise, 0

$Y_k = \sum_{l=l_1}^{l_4} Y_k^l$ - when the *k*-node is a hub, $Y_k^l=1$; otherwise, 0

p - number of hubs
M - a very high number
$CHub_k$ - capacity of hub k

SOLUTION ALGORITHM

To solve the problem of hub location, a simulated annealing algorithm based on Aykin's1995 was developed.

Initial Solution

When seeking the initial solution, all nodes in the network are considered hubs. Therefore, each node is assigned to itself. The total cost is calculated with this solution. In each loop, the cost of the solution of closing down one of the hubs in the network is calculated, and the hub that represents the least increase in cost is closed.

Improvement of the Initial Solution

In this stage, exchanges are made between those nodes that are hubs and those that are not. Finally, the greatest money-saving changeover is selected in accordance with the following equation for estimating savings:

$$U_{t,r} = \max_{k \in H} \left\{ R_{k,r} \right\} \tag{12}$$

Where

$R_{k,r}$ - estimated saving when substituting hub k for node r.

The amount of cargo goes from hub k to l:

$$I_{k,l} = \sum_{\{i/Z_{i,k}=1\}} \sum_{\{j/Z_{j,l}=1\}} \left(W_{i,j} + \mathrm{C}_f W T_{i,j} \right) \tag{13}$$

The savings achieved when hub k is replaced by the node r is:

$$R_{k,r} = \sum_{\{i/Z_{i,r}=1\}} O_i (T_{i,k} - T_{i,r}) + \sum_{\{i/Z_{i,r}=1\}} O_i (T_{k,i} - T_{r,i}) + \sum_{\substack{q \in K \\ q \notin r}} (I_{r,q}) \alpha (T_{k,q} - T_{r,q}) + \sum_{\substack{q \in K \\ q \notin r}} (I_{q,r}) \alpha (T_{q,k} - T_{q,r}) \tag{14}$$

Where

O_i - total cargo originating at node i
D_i - total cargo arriving at node i,
$Z_{i,k}$ - if node i is assigned to hub k, $Z_{i,k}$=1; otherwise, $Z_{i,k}$=0

Since $U_{t,r}$ is an estimate of the savings involved and is its lower limit, in some cases the result could be a negative value. However, on updating the assignation of nodes to hubs, the switching of node r to a hub is a good choice. Because of this, the algorithm calculates the probability of acceptance. The exchange between r and t is calculated in the following function:

$$P(accept \quad at \quad \Delta) = \begin{cases} e^{-\Delta/T}, & if \quad U_{r,t} \geq 0 \\ 1, & if \quad U_{r,t} < 0 \end{cases} \tag{15}$$

$\Delta = U_{t,r}/$ evaluation of the objective function for the best known solution (16)

If $U_{t,r}<0$, it is always recommendable to make this change; once $U_{t,r} \geq 0$, a random number ω is generated, which is compared with the value of the probability of accepting the change. If $\omega < P(accept \quad at \quad \Delta)$, the switchover between *r* and *t* will be made. The cooling function is

$$T_n = T_{n-1}{}^{v} \tag{17}$$

Where

T_n - temperature value for the loop *n*

v - cooling parameter

To relax congestion in the hub, the flow of cargo in the network is balanced. First, the quantity of cargo that passes through each hub is calculated using Eqs. (10) and (11). Next, the hubs where the nominal capacity is exceeded and those where the amount of cargo is not below their nominal capacity are identified. The necessary re-assignations are made to reduce the cargo going through those hubs where the nominal capacity is being exceeded. To reduce congestion in an *h* hub, the ($Z_{i,h}$=1) *i*-node nearest to a non-congested *k* hub is selected from all the *h* hub's assigned nodes, and the *i* assignation is changed using ($Z_{i,h}$=0; $Z_{i,k}$=1).

COMPUTATIONAL RESULTS

The model was evaluated in 10 randomly-created networks of 52 nodes each. The load matrices and the distance were also generated at random. The problem of locating three hubs was solved for each situation. The delivery time was 24 hours, and 10 hours were available for transporting and handling the cargo at hub. The tests conditions can be seen in Table 1.

Table 1. Characteristics of the Hubs.

Capacity	Rate of Service	Under Capacity		Over Capacity	
		Rate of Arrival	Time in Hub	Rate of Arrival	Time in Hub
10	13	12	1	12.44	1.8
10	13	12	1	12.7	3.4
15	19	18	1	18.44	1.8
15	19	18	1	18.7	3.4

It is assumed that the cargo that is not delivered within the delivery time has an additional cost of 20% over that which is delivered in time. The results obtained with Aykin's algorithm were compared with the results obtained from the same problems but introducing the task of balancing the assigning of nodes. The results are compared in Table 2.

Table 2. Results for Problems of Different Time Consumed at Hub.

ω = 3.4	Improvement %				ω = 1.8	Improvement 改善%			
	CHub＝10		CHub＝15			CHub＝10		CHub＝15	
Experiment	*PSIT*	*LSIT*	*PSIT*	*LSIT*	Experiment	*PSIT*	*LSIT*	*PSIT*	*LSIT*
1	10.2	9.8	27.2	28.3	1	-2.1	-2.3	6.1	6.7
2	2.1	1.7	10.4	10.2	2	0.4	-0.2	3.9	3.3
3	4.2	4.3	12.4	12.4	3	-2.2	-2	6.8	6.9
4	0.8	1.1	10.5	11.1	4	-2.4	-2.2	3.6	3.7
5	2.5	3.1	23.2	23.7	5	2.8	2.5	5	5.1
6	46.3	46.8	46	46.5	6	11.6	12.1	13.9	14.5
7	1.3	1.2	16.7	17	7	-1.7	-2	5.9	5.7
8	6.3	6.5	16.8	16.8	8	-0.8	-1.1	0.1	-0.1
9	5.3	5.5	38.2	39.2	9	-8.4	-8.3	-2.6	-2.9
10	8	8.6	17.4	17.9	10	0.6	-0.1	3.8	3.4

$PSIT_b$ and $PSIT_0$ are the number of pairs served in time with and without balancing nodes assignation separately. $LSIT_b$ and $LSIT_0$ are the load served in time with and without balancing nodes assignation separately.

$$\%\ improvement\ PSIT = \left(\frac{PSIT_b - PSIT_0}{PSIT_0} \right), \%\ improvement\ LSIT = \left(\frac{LSIT_b - LSIT_0}{LSIT_0} \right) \quad (18)$$

It can be seen that when the additional waiting time at the hub due to congestion is long, balancing the assignation of node offers very satisfactory results, because the increase in the distance the cargo travels is compensated for by the decrease in the time spent waiting at the hub.

To study the consequences of balancing out the assignation of nodes, the total cost of the solution was broken down into travel cost, distance surcharge, and congestion surcharge .These values were calculated for each of the problems. Table 3 shows the averages for the 10 problems in each case.

Table 3. Change in Components of Cost Controlling Overload in Hubs.

Test	% Mean Improvement			
	Capacity	Cost Due to Distance	Cost Due to Congestion	Total Cost
△	10	-1.51	2.06	0.55
ω=2.4	15	-1.53	4.71	3.18
△	10	-1.41	0.48	0.48
ω=1.8	15	-1.19	1.15	1.15

It can be seen from the results that, in all cases, the cost of late deliveries due to distance increases on balancing the assignation of nodes, while the cost of late delivery through congestion is reduced. It can also be seen that, on average, the total cost of the solution improves.

CONCLUSIONS

This study takes the standard of service into account when locating hubs under earthquake conditions and considers that each hub has limited capacity. The standard of service is measured according to the amount of cargo to be served within the delivery time and to the number of o/d pairs to be served on time. The objective function considers three factors: (1) the cost of transport between each o/d pair and the cost arising from not delivering the goods within the agreed time limit; (2) the surcharge generated when cargo makes too long a journey; and (3) the cost created by cargo that is delivered late because it spent too much time at the hub. The model introduces a delivery time restriction to solve the issue of urgent delivery characteristics under earthquake conditions, which controls the waiting time due to congestion at the hub effectively; in this way the model allows the problem of hub location under earthquake conditions to be solved by reducing congestion at the hubs and ensuring delivery on time.

The methodology used to improve the initial situation is simulated annealing. The cooling function used is the traditional one. By testing in randomly created networks, when a situation of congestion occurs, the proposed algorithm enables the total delivery time to decrease, and the number of pairs and supplies served in time to increase. The proposed algorithm enables better solutions to be found, thereby fitting the problem of hub location under earthquake conditions.

ABSTRACT

To improve the effects of urban parking facilities' management and control, this paper collected 10 hours data consecutively on parking arrival and departure rates from one off-street park in central Nanjing city in China and sets the time series marshal as an interval of 15 minutes. Autocorrelation functions and partial correlation functions are set up to describe the relationship among the parameters such as parking arrival rate, parking departure rate, and parking actual occupancy. A Granger causality test model was used to analyze the three characteristics mentioned above. Conclusions were drew that, in specific time sections, the lagged parking arrival rates can affect the value of the current parking departure rate and occupancy rates of valid parking berths distinctly, while the lagged parking departure rates can greatly affect the value of current occupancy rates of valid parking berths. Finally, forecasting models of parking arrival and departure rates were set up based on correlation analysis, and the results show that these models demonstrate promising performance for modeling parking arrival and departure rates.

Keywords: parking arrival rates, parking departure rates, correlation analysis, forecasting model.

INTRODUCTION

With the rapid development of the Chinese economy and car ownership, the problem of the supply-demand imbalance of parking facilities in urban centers has become severe. Parking arrival and departure rates reflect dynamic parking demand, which is of important guiding significance for the optimal setting and management for parking facility. The existing literature (Chen Jun et al. 2007; Jeffrey F.Paniati. 2007; Guan Hongzhi et al. 2005; Yan Hai et al. 2005) on parking

arrival and departure rates emphasize influencing factors and behavior characteristics of drivers; the correlation between arrival and departure rates and the utilization ratio of parking facilities are rarely researched, which are important research issues of this paper.

EXPERIMENTAL INVESTIGATION APPROACH OF SHOT-TIME PARKING ARRIVAL AND DEPARTURE RATES

To get shot-time variation characteristics of parking arrival and departure rates, this study investigates the Bai-nao-hui underground parking located on Zhujiang Road in the city centre of Nanjing. The approach is to record the parking arrival and departure rates from the electronic toll systems of parking lots and statistically analyze each 15 minutes to meet the research precision. In Figure 1, the time series is set as the x-coordinate and the arrival and departure rates (veh/15min) are set as the y-coordinate.

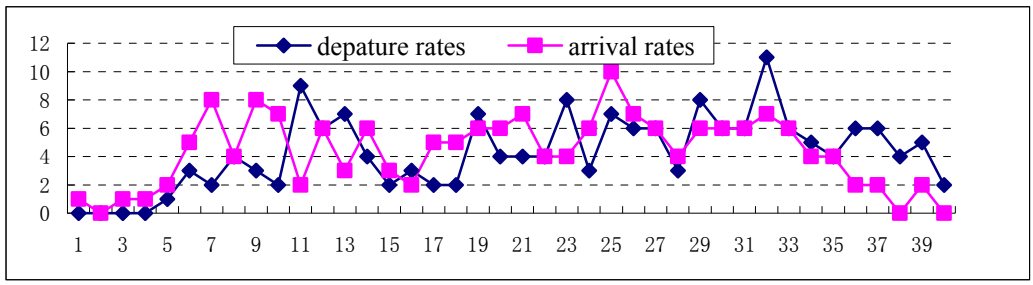

Figure 1. Distribution of parking arrival and departure rates at 15 minute intervals.

EXPERIMENTAL DATA AND CORRELATION ANALYSIS OF SHOT-TIME PARKING ARRIVAL AND DEPARTURE RATES

This paper treats the trend of parking arrival and departure rates as a set of random variable $\{y_t\}$ depending on time period t. The autocorrelation functions and partial correlation functions (William H.K et al. 2006) are expressed as:

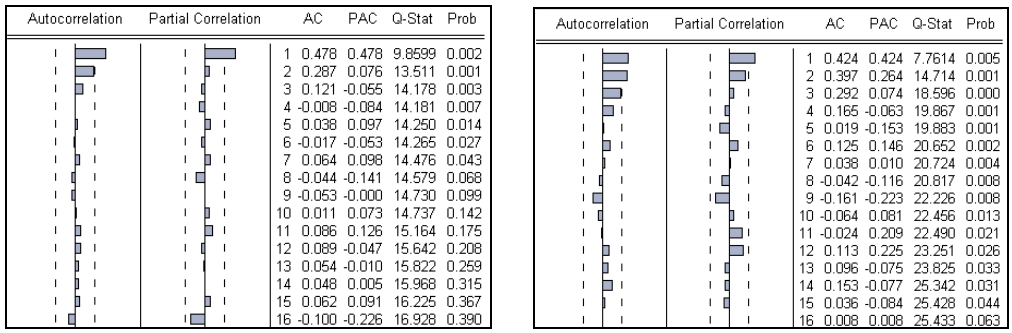
$$r_k = \frac{\sum_{t=k+1}^{T}(y_t - \bar{y})(y_{t-k} - \bar{y})}{\sum_{t=1}^{T}(y_t - \bar{y})^2} \tag{1}$$

$$\phi_k = \begin{cases} r_1, & k = 1 \\ \dfrac{r_k - \sum_{j=1}^{k-1}\phi_{k-1,j} r_{k-j}}{1 - \sum_{j=1}^{k-1}\phi_{k-1,j} r_j}, & k > 1 \end{cases} \tag{2}$$

where r_k is the autocorrelation coefficient of the current value of parking arrival rates (departure rates) and the value before time k; ϕ_k is the partial correlation coefficient of the current value of parking arrival rates (parking departure rates) and the value before time k, the partial correlation of lagging k

steps is the coefficient of y_{t-k} when regression of $y_{t-1} \ldots y_{t-k}$ by y_t; T is value of the time series (for the 10-hours investigation, the time interval is 15 minutes, so T=40); $\bar{y}$ is the sample mean; $y_t, y_{t-1}, \ldots y_{t-k}$ is the variable set based on time series t.

Based on the time series data, the results of the autocorrelation coefficient and the partial correlation coefficient of parking arrival and departure rates in 15min analyzed by software Eview5.0 (Yi Danhui. 2002) are shown in the figures below.



(a) **(b)**

Figure 2. Autocorrelation coefficient and partial correlation coefficient of parking arrival rates (a) and departure rates (b).

Several explanations are necessary: (1) If the value of the autocorrelation (partial) coefficient lies within the boundary of two dashed lines marked in Figure 2, there would be no significant difference between significance level reached at 95% and that of 0; (2) AC and PAC denotes, respectively, the result of the autocorrelation coefficient and the partial correlation coefficient; Q-Stat and Prob denote the Q statistic and the probability of series independence test.

As a result, there is notable correlation between the arrival and departure rates at 15min and in the adjacent time interval than that in the other time interval.

For the further study of variation characteristics of parking arrival and departure rates, three indexes were selected to study the correlation characteristics, which are parking arrival rates, parking departure rates, and occupancy rates of valid parking berths. The correlation characteristic formula can be expressed as:

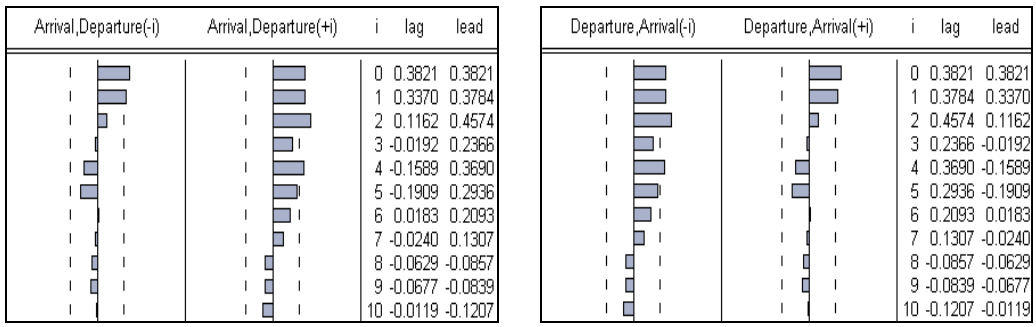
$$r_{xy}(l) = \frac{c_{xy}(l)}{\sqrt{c_{xx}^2(0) c_{yy}^2(0)}} \quad l = 0, \pm 1, \pm 2 \cdots \tag{3}$$

$$c_{xy}(l) = \begin{cases} \sum_{t=1}^{T-l} (x_t - \bar{x})(y_{t+l} - \bar{y}) / T & l = 0,1,2,3 \cdots \\ \sum_{t=1}^{T+l} (y_t - \bar{y})(x_{t-l} - \bar{x}) / T & l = 0,-1,-2 \cdots \end{cases} \tag{4}$$

where $r_{xy}(l)$ is the cross correlation coefficient of time series $\{x_t\}$ $\{y_t\}$ under

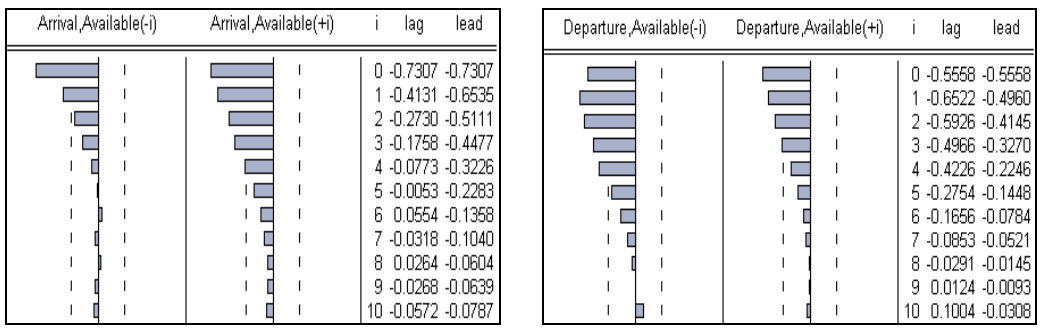
lagging time l; $\{x_t\}$ and $\{y_t\}$ are the values of pair wise correlation coefficients among parking arrival rates, parking departure rates, and occupancy rates of valid parking berth. The other parameters are the same as above.

Based on the time series in Figure 1, the results of cross correlation among parking arrival rates, parking departure rates, and occupancy rates of valid parking berths analyzed by software Eviews5.0 are shown as follows.



(a) **(b)**

Figure 3. Cross correlation of parking arrival-departure rates (a) and departure-arrival rates (b).



(a) (b)

Figure 4. Cross correlation of parking arrival rates- berth available rates(a) and parking departure rates- berth available rates(b).

Note: -i presents lagging time i; +i presents leading time i.

As shown in the figures, (1) there was a positive correlation between parking arrival rates at time t and parking departure rates form time t-1 to time t+5; (2) parking departure rates at time t are positively correlated with parking arrival rates from time t-1 to time t-5 and that in time t+1; (3) significant negative correlation was observed among parking arrival rates at time t and occupancy rates of valid parking berths at time t-1, and from time t+1 to t+4; (4) there is a negative correlation between parking departure rates at time t+1 and occupancy rates from t-4 to t+3.

CAUSALITY TESTS OF RELATED CHARACTERISTICS

The literature (Jenkins 1968; Jian 2004) shows that causality cannot be determined, although there is a certain correlation between two series. If series $\{x_t\}$

is useful to the series $\{y_t\}$ prediction, there is a remarkable Granger causality relationship from series $\{y_t\}$ to $\{x_t\}$, which means it meets the causality test. The test formula for whether series $\{x_t\}$ causes series $\{y_t\}$ is expressed as follows:

$$y_t = \alpha_0 + \alpha_1 y_{t-1} + \cdots + \alpha_l y_{t-l} + \beta_1 x_{t-1} + \cdots + \beta_l x_{t-l} \quad (5)$$

where α_0 , α_1 …, α_l are the regression coefficients; F statistics is Wald statistics with joint hypothesis. The joint hypothesis is $\beta_1 = \beta_2 = ...\beta_l = 0$, which means there is no causality relationship between $\{x_t\}$ and $\{y_t\}$ according to the Granger causality test.

Using the test equation above, the causality relationship of parking arrival rates and parking departure rates Lag=1~40 is tested separately. The results show that when lag=1~9, the variety of parking arrival rates can cause changes in parking departure rates, and changes in parking departure rates can cause changes in parking arrival rates. This means that parking arrival rates in the past 1~9 periods affect the current parking departure rates.

FORECASTING MODEL OF PARKING ARRIVAL AND DEPARTURE RATES BASED ON CORRELATION ANALYSIS

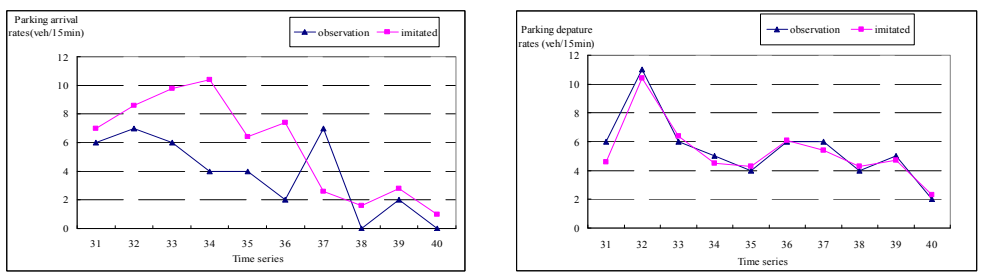
Based on the 30 samples of 40 pieces of 15-minute periods in Figure 1, the prediction time series model can be made by regression, expressed as follows:

$$y_t = -4.5281x_{t-1} + 7.5985 - 0.4584y_{t-1} + \varepsilon_t - 0.5088\varepsilon_{t-2} - 0.9851\varepsilon_{t-4} \quad (6)$$

$$z_t = -6.6854x_{t-1} + 0.2565y_{t-6} + 6.8123 - 0.7925z_{t-5} + \varepsilon_t - 0.9777\varepsilon_{t-9} \quad (7)$$

where y_t is parking arrival rates at time t (pcu/15 min); z_t is parking departure rates at time t (pcu/15 min); x_{t-1} is occupancy rates of valid parking berths at time t-1; y_{t-1} is parking arrival rates at time t-1; y_{t-6} is parking departure rates at time t-6; z_{t-5} is parking departure rates at time t-5; and ε_t is the random disturbance at time t .

Using the prediction model from formulas (6) and (7), the comparison between the prediction value and the actual value can be obtained by predicting the parking arrival rates and departure rates from periods 31 - 40 as follows.



(a) **(b)**

Figure 5. Comparison between prediction value and actual value of parking

arrival rates (a) and departure rates (b).

The results shown in Figure 5 indicate that the prediction model based on correlation analysis can reflect the trend of parking arrival rates and fits well to the departure rate in different periods at actual parking lots.

CONCLUSION

By investigating parking arrival and departure rates on work days, the time series was set as intervals of 15 minutes and then autocorrelation, cross correlation, and causality of the time series were analyzed. The main conclusions are as follows:

(1) Current parking arrival and departure rates are distinctly autocorrelated with the two adjacent parking arrival and departure rates and are distinctly partial correlated with one adjacent parking arrival and departure rate.

(2) The parking arrival rate of the previous time can evidently affect the parking departure rate, while the parking departure rate does not influence the parking arrival rate.

(3) The parking arrival rate of the previous time evidently affects the occupancy rate of valid parking berths, while the occupancy rate of valid parking berths has little influence on the parking arrival rate.

(4) The parking departure rate of the previous time can evidently affect the occupancy rate of valid parking berths, and the occupancy rate of valid parking berths can also affect the parking arrival rate.

(5) Prediction models based on correlation analysis demonstrate promising performance for modeling parking arrival and departure rates. Results mentioned above provide technical support for the association study of parking arrival and departure rates.

Transit Network Optimization Method Based on BRT Attracting Region: A Case Study of Changzhou

Zimu Li, Xuewu Chen, and Xiaoqing Liu

School of Transportation, Southeast University; No.35, JinXiangHe Road, Nanjing, Jiangsu Province, PRC, 210008; PH: (86) 15850552234; email: mzzm414@163.com

ABSTRACT

There are two approaches in common transit network optimization (TNO) research: if only adjusting routes, the network may lack integration; otherwise, network adjusting would reduce the operability. To overcome these problems, this paper proposed a TNO method based on research in City of Changzhou. First, bus routes in BRT attracting regions were found and classified according to their position relationship, influence extent and function split. Then optimal schemes of each route were generated using some optimization methods. Second, the concept of key nodes was proposed for the first time. The network was rebuilt by expectation line search. Optimal schemes were established after schemes were screened. Finally, schemes comparison was conducted according to the optimal objective function and the optimum solution was determined. The method was applied for BRT No.2 in City of Changzhou. The results show that the passenger flow volumes are greatly increased.

1 INTRODUCTION

Due to serious urban traffic congestions in China, public transportation systems become increasingly important. Normal bus systems have several disadvantages, such as the limited capacity, slow speed, poor accuracy, etc. Thus, the normal bus systems cannot provide enough capacity and level of service for urban transportation needs. MRT and LRT are now being built in some cities. BRT becomes an important option because it can be the skeleton of public transportation and fill the incapability of MRT and LRT. However, the normal bus network and the BRT system are interrelated. Thus, the normal bus network needs to be optimized in order to increase the benefit of BRT. In addition, the convenience of transit passengers needs to be maintained

2 MAJOR BACKGROUNDS IN THIS PAPER

(1) BRT attracting region

BRT attracting region is a continuous public transit attracting region based on each station of BRT, where passenger collecting-distributing and flow volume are

high. The immediate service radius may range from 500m to 800m. A median value of 650m is suitable according to its function and level of service (Zhang, 2007).

(2) Overlap station and overlap section

An overlap station has the same name with a normal bus stop or nearby stops (e.g. less than 100m). The number of overlap stations is noted as T. We define the section of normal bus route between the first and the last overlap station as one overlap section of this normal bus route with $T \geq 2$. Number (N) is a classification parameter. An example can be seen in Figure 1.

(3) Node, key node and node expectation line

Nodes include (i) road network intersections, (ii) transit stations and stops, and (iii) original stations and destination stations of BRT and normal buses. Key nodes are locations where a route must pass. They are usually near important passenger collecting-distributing areas such as traffic hubs, residential areas, schools, hospitals, etc. The basic location of a bus route can be obtained by linking its key nodes according to their spatial locations. A node expectation line is a line that connects key nodes and some optional nodes of a route, and represents the expectation location of this route.

3 TRANSIT NETWORK OPTIMIZATION METHOD

3.1 Summarization of transit network optimization method

The TNO Method has three parts. The flow chart of it is shown in Figure 2.

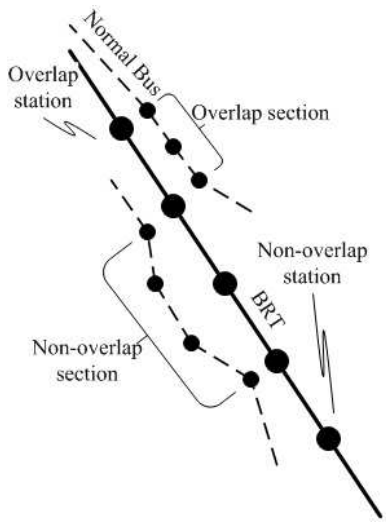

Figure 1. Overlap stations and overlap sections

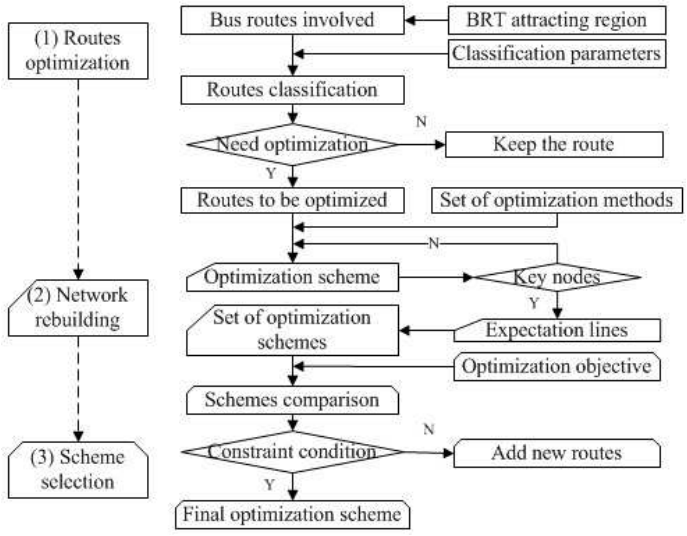

Figure 2. Flow chart of TNO method based on BRT attracting region

3.2 Routes Optimization

3.2.1 Routes classification

(1) Classification by position relationship

There are three types of routes (see Table 1) after classification. The parameters are amount of overlap stations (N) and overlap sections (T). An overlap route usually has some similar sections with BRT and needs more improvements. A cross route usually crosses the BRT corridor and needs less improvements. The other routes are usually unnecessary to be improved.

Table 1. Classification by position relationship

Classification	Name	Parameters
I	Overlap-route	$N \geq 1$, and $T \geq 2$
II	Cross-route	$N = 0$, and $T \geq 1$
III	Other-route	$N = 0$, and $T = 0$

(2) Classification by influence extent

The classification parameters are p and T (see Table 2). $p = \sum l_N / l_{BRT}$, where l_N is the length of an overlap section and l_{BRT} is the total length of BRT route. A competition route may impact operations and passenger collecting-distributing of BRT. An assistant route has benefits for BRT and needs optimization to release their capacity and increase transfer volume.

Table 2. Classification by influence extent

Classification	Name	Parameters
A	Competition-route	$p \geq 20\%$, or $T \geq 4$
B	Assistant-route	$0.5\% \leq p < 20\%$, or $2 \leq T < 4$
C	Unrelated-route	$p < 0.5\%$, or $T \leq 1$

(3) Classification by function split

Routes after optimization have different functions for BRT, which are the basis of the classification (see Table 3). A branch route is a part of BRT system that serves important areas which are insufficiently serviced by the BRT corridor. A feeder route has origin or destination stations in BRT attracting regions.

Table 3. Classification by function split

Classification	Name	Function
a	Branch-route	Supporting the BRT mainline
b	Feeder-route	Normal bus connected to BRT
c	Generic-route	The other independent routes

3.2.2 Optimization judgment

The judgment parameters are *P*, *L*, and *S*. *P* is the overlap stations' proportion in all stops of a normal bus route whose number is *t*, i.e. $P = T / t$; *L* is the length of the longest overlap section; and *S* is the distance between normal bus stops and BRT stations which are in the same overlap station. *S* should be compared with the average riding distance of BRT, which is noted as *D*. Values in Table 4 are for cities where BRT is the main skeleton of public transportation. Once one parameter is not optimal, the route needs to be optimized.

Table 4. Critical values of optimization judgment parameters

Parameters	Values need optimization	
	Urban district	Suburban district
L	$L > 0.5\ D$	$L > 0.8\ D$
S	$S > 50$m	$S > 80$m
P	$P > 60\%$	

3.2.3 Set of optimization methods

I-A, I-B and II-B (there is no II-A routes) routes' optimization are usually easier than the other types. The methods are shown in Table 5. Every route that needs to be optimized has been processed by several optimization methods, where each method includes several optimization schemes. The methods can also be used together. For example, we can extend a route's original station while adjusting its destination station.

Table 5. Set of optimization methods

Method	Explanation	Route types
Adjusting	Adjusting stop spacing and route location	I-A, I-B, II-B, others
Extending	Extending certain operation section	I-A-a, I-A-c, I-B, II-B
Truncation	Cutting off certain operation section	I-A, I-B, II-B-c
Revocation	Cancelling the operation of a route	I-A-c

3.3 Network rebuilding

3.3.1 Determination of key nodes

Key nodes play a crucial role in determining a bus route's direction and location. The methods to determine key nodes include Manual Approach, System Analysis and Market analysis Project (Chua and Silcock, 1982, and Chua, 1984), which focus on the existing routes and emphasize the application of experience. Otherwise, the final scheme will greatly vary from the present network and will be difficult to be implemented.

3.3.2 Establishment of node expectation lines

The establishment of node expectation lines is based on route searching, in an attempt to obtain optional nodes that can connect contiguous key nodes. The set of node expectation lines is determined using searching results and needs to satisfy the following conditions:

$$l_{min} \le l \le l_{max}$$
$$= l / d \le \ _{\max}$$

where l is the length of expectation lines; l_{min} and l_{max} are minimum and maxinum values of length of bus routes (km); and d is the straight distance between the origin and destination of expectation lines. Usually, l_{min} = 5km, l_{max} = 15km, and $_{\max}$ = 1.4 (Urban road traffic planning and designing standard, 1995).

3.3.3 Set of optimization schemes

Each optimization scheme of a route to be optimized should be compared with the nodes expectation lines of this route. Then screening schemes that can meet the constraint conditions is taken to establish set of optimization schemes.

3.4 Scheme selection

3.4.1 Optimization objective

The objective is to decrease competition routes, optimize assistant routes and increase BRT passenger flow volume (PFV). The PFV of BRT mainline and branch routes and transfer volume need to be increased.

$$\max f = \sum_{i \in R} f_{\mathrm{m}}(i) + \sum_{\in R} f_{\mathrm{a}}(i) + \sum_{\in i \ R} f_{\mathrm{b}}(i) + \sum_{\in \ i \ R} f_{\mathrm{c}}(i)$$

s. t.

$$X \le X_{\max}$$
$$e(i) \le e_{\max}(i)$$
$$q(i) \le q_{\max}(i)$$
$$r_a \ge r_b$$

$f_{\mathrm{m}}(i)$ is the PFV of the ith BRT mainline (person/day); $f_{\mathrm{a}}(i)$ is the PFV of the ith BRT branch route ; $f_{\mathrm{b}}(i)$ and $f_{\mathrm{c}}(i)$ are the transfer PFV from the ith feeder route and the ith generic route; X and X_{max} are transfer ratio and maximum transfer ratio; $e(i)$ and $e_{max}(i)$ are PFV of the ith cross section of BRT (Chen, 2002) and the maximum value of it (person/hour); $q(i)$ and $q_{max}(i)$ are PFV of the ith node of BRT and the maximum value of it (person/hour); r_a (r_b) is the covered area rate after (before) the optimization process; and r_a needs to be higher than r_b to avoid service blank.

3.4.2 Schemes comparison and selection

Set of route optimization schemes (R) was obtained after routes optimization and network rebuilding are finished. Steps of schemes comparison and selection are as follows.

Step1. Select the first route optimization scheme of each route from *R*, and establish original optimization scheme M_0;

Step2. Input related data (include OD matrix, route information, time value, etc.), and calculate M_0 to obtain the original solution;

Step3. Select the *j*th route optimization scheme of the *i*th route to establish optimization scheme M_{ij}; and

Step4. Calculate M_{ij} to find the optimum solution.

4 CASE STUDY OF CHANGZHOU

The length of mainline of BRT No. 2 is about 21km, and there are 2 origin and destination stations and 23 couples of stops. The classification of the routes to be optimized in BRT attracting region are shown in Table 6.

Table 6. Classification of routes to be optimized

Classification	I-A-a	I-A-b	I-A-c	I-B-a	I-B-b	I-B-c	II-B
Counts	2	2	1	1	2	4	9

A BRT network with one mainline and three branch routes was established by using the TNO method based on BRT No. 2 attracting region (see Figure 3). Nine routes were mainly optimized with one route truncation. Other routes were optimized mainly by adjusting the distance from BRT overlap stations to assistant operation of BRT (see Figure 4). With appropriate operation dispatching, the daily PFV of the mainline of BRT No. 2 after the optimization process was 80,000 persons by forecasting in TransCAD. The PFV is increased by about 25%. The optimization's benefit is significant.

Figure 3. Optimization BRT network

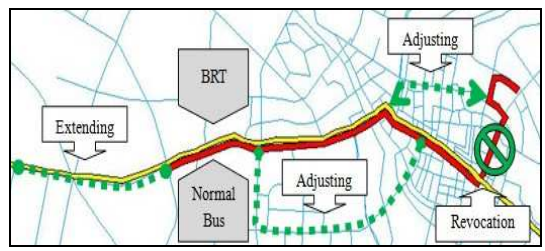

Figure 4. Optimization schemes

5 CONCLUSIONS AND RECOMMENDATIONS

The method proposed in this paper conducts the optimization step by step, increasing the optimization flexibility. The comparison and selection of scenario analysis can be done for different optimization objectives. Disadvantages, such as difficult to implement caused by many theoretic optimization and inconvenient trip of residents, can be avoid. of the current transit network and operation efficiency are increased which has been confirmed by Changzhou Public Transport Company. The convenient and safety problem caused by the increasing of transfer times can be solved by seamless integration of stations.

The method focuses on BRT network with single mainline. The parameters in

classification of routes are usually physical facilities. In future research, we will analyze large transit networks with multiple BRT mainlines. The structure of the method and the parameters of classification need to be adjusted. The algorithm will be improved for the application in cities with more complex circumstances.

Abstract：The urban transit terminal plays a significant role in urban transportation system for passenger distribution and transfer. Transfer efficiency is regarded as a key factor of urban transit terminal operational performance which reflects level of service. Thus, efficiency evaluation of urban transit terminal is important to measure the level of service improvement. First, influence factors of terminal transfer efficiency are analyzed and the corresponding evaluation index system is proposed. Then, based on the cloud model, a comprehensive evaluation model for the transfer efficiency of urban transit terminal is investigated. In this evaluation model, fuzzy and random qualitative concepts are integrated; uncertainty expressions are mapped to different cloud particles; variations of the weight are mapped to mathematical expectation of clouds; and the efficiency of urban transit terminal transfer is evaluated synthetically. Finally, an applicative example is used to show that the evaluation model is efficient and effective.

Key words: urban transit terminal, transfer efficiency, evaluation, cloud model

1. Introduction

An urban transit terminal is part of very large urban transportation service systems. The transit terminal plays an important role in urban transportation system for passenger distribution and transfer.

Kwon and Kwon (2003) studied the impact of the effective use of the coefficients in park and ride facilities. Beimborn et al. (2003) investigated public transport services on coefficients, such as accessibility and connectivity. Shih et al. (1997) developed a synchronous transfer Interval travel design model. Bates(1978) treated the existing transport system to improve the transfer facilities, and he suggested that transfer facilities must be more efficient to encourage passengers to use the transfer. Ye and Tan (1998) analyzed the problems of urban rail transit transfer and made some suggestions. Wang and Li (2003) analyze and deduce the

mean transfer time formula, present some measures on other transportation transfer, and keep track of them in full coordination to attract more passengers. Many other studies also examine urban passenger transfer problems (Qin, 2003; Du, 2005; Wu, 2005). The research of urban transit terminal is mainly concentrated on the choices of transfer modes and transfer facilities planning. Evaluation of urban transit terminal transfer efficiency did not receive enough attentions. At present, researches focus on transfer facilities' effectiveness and many issues impact transfer facilities in major cities, including transfer facilities, location, size and configuration.

Transfer efficiency is regarded as a key factor of urban transit terminal operational performance which reflects level of service. Thus, measuring the efficiency of urban transit terminals is very important. In this paper, a cloud-model-based method is introduced to evaluate efficiency of urban transit terminals.

2. Cloud model and uncertainty illation

2.1 Concept of cloud model

The cloud model is an uncertainty conversion model between some qualitative concepts expressed with linguistic words and their relative quantitative values. Let U as a domain comprising accurate numbers, whose accorded qualitative concept is $\tilde{A}$. For any given element X in the domain, there is a random number having stable tendency $y = \mu_{\tilde{A}}(x)$, which is called certainty degree of x for $\tilde{A}$. The distribution of y in domain is called the cloud model, or the cloud in a simpler name. The cloud consists of a number of cloud drops, each of which presents one point projected from qualitative concept to numeral domain. For its every realization, the cloud model can denote the certainty degree of the point, reflecting some qualitative concept.

The cloud is identified by three digital characteristics, E_x (expected value), E_n (entropy) and H_e (hyper entropy), which express the quantity feature of qualitative concept.

The algorithm of generating the cloud is called the cloud generator, which includes forward cloud generator, condition X cloud generator, condition Y cloud generator and backward cloud generator. When the cloud drops are produced by the digital characteristics of cloud, the cloud generator is called forward cloud generator; when cloud's three digital characteristics (E_x, E_n, H_e) and the special value x_0 are given, the cloud generator is called condition X cloud generator; when cloud's three digital characteristics(E_x, E_n, H_e) and the special value μ_0 are given, the cloud

generator is called condition *Y* cloud generator; if a group of cloud drops(x_i , μ_i) satisfying normal distribution to be specimen is given and the three digital characteristics(E_x , E_n , H_e) of cloud model are known, we call this backward cloud generator. Condition *X* cloud generator and condition *Y* cloud generator are the basis of conducting uncertainty illation by cloud model. By integrating the forward cloud generator and the backward cloud generator, the conversion between qualitative words and quantitative values can be achieved at any moment.

2.2 Uncertainty illation based on cloud model

The formal description of a qualitative rule is: if *A* then *B*. *A* and *B* are cloud objects, denoting language value. The cloud generator is the basis of conducting uncertainty illation by cloud model. Connecting a condition *X* cloud generator and a condition *Y* cloud generator can yield a single rule generator. Figure1 presents the schematic diagram about single rule generator. In the figure, CG_A denotes condition *X* cloud of the input language value *A*. CG_B denotes condition *Y* cloud of the output language value *B*. When we input some special value x_0 to activate CG_A, CG_A produces a group of figures μ_i (μ_i reflects the corresponding qualitative rule's activation intensity), and pipes into CG_B, this figure μ_i controls CG_B to produce a group of random drops (y_i , μ_i). It needs a brief account that the cloud drop and output produced by generator are not only one and uncertain, so it can achieve uncertainty illation.

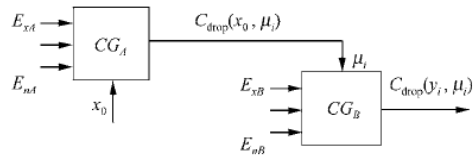

Figure1. Single rule generator

3. Description of evaluation factors with cloud model

3.1 Evaluation factors

Three criteria are taken into account in the evaluation: convenience, comfort and safety. Each criterion consists of several factors, which are shown in Table 1.

3.2 Description of evaluation factors

The evaluation standard of every evaluation factor is according to the knowledge of experts respectively. A qualitative and fuzzy language is used to express a certain numerical range.

Table 1. Evaluation factors

Convenience	Comfort	Safety
Total walk time	Climate control	Police protection
Total time in system	Area per person	Emergency response
Route travel times	Rest room facilities	Entry control
Total delay	Avoid crowding	Emergency egress
Queue length	Waiting areas	Safe walking
Flow conflicts	Cleanliness, sanitation	Surfaces
Connectivity	Esthetic design	Lighting
Directional information		
Service reliability		
Consumer services		

For example, the evaluation standard "shorter, short, common, long, longer" in factor "total walk time" is according to the time spend by walk in the transfer process. The evaluation standard of the factor "queue length" is according to the length of queue. So do others.

The five qualitative concepts of the evaluation standard of the factor "total walk time (unit in second)" are expressed with cloud model in time field as follows:

$$D_{A_1} = \begin{cases} 1, & x \in [0,60] \\ D(60,60/3,0.05), & \text{others} \end{cases}$$

$$D_{A_2} = D(120,60/3,0.05)$$

$$D_{A_3} = D(180,60/3,0.05)$$

$$D_{A_4} = D(240,120/3,0.05)$$

$$D_{A_5} = \begin{cases} D(360,120/3,0.05), & \text{others} \\ 1, & x \in [360,\infty) \end{cases}$$

4. Evaluation based on the cloud model and correlation analysis

4.1 Data preparation

First, we use the cloud model to express the factor's evaluation standard of transfer efficiency. The cloud model was discussed in Section 2.

Before analyzing the relation between transfer efficiency and evaluation factors, we can translate the uncertain factor conditions into quantitative impact.

By using the factor "total walk time" as an example, we can establish the qualitative illation rule by the knowledge of expert as follows:

1) if total walk time is "shorter", then impact value is "higher";

2) if total walk time is “short”, then impact value is “high”;
3) if total walk time is “common”, then impact value is “common”;
4) if total walk time is “long”, then impact value is “low”; and
5) if total walk time is “longer”, then impact value is “lower”.

The five qualitative concepts of the rule’s rear are expressed with the cloud model in impact value fields as follows:

$$D_{B_1} = D(90,15/3,0.05)\,; D_{B_2} = D(70,15/3,0.05)\,; D_{B_3} = D(50,15/3,0.05)\,;$$

$$D_{B_4} = D(30,15/3,0.05)\,; D_{B_5} = D(10,15/3,0.05)$$

Using the cloud of the rule’s front to drive forward cloud generator, we can obtain a group of distance figures, then determine theirs average to be the input of condition X cloud generator, and count the certainty degrees of the five qualitative concepts of the rule’s front respectively. Finally, we can determine the maximum μ_i.

If the *i-th* rule in rule-base is activated, the activation intensity is μ_i. After using the single rule generator to generate output, we select the output to be this factor’s impact value. When calculating the output by using the algorithm of condition Y cloud generator, we choose the plus or the minus by corresponding whether the input is of up or down. When $x < E_{xA}$, we choose the minus, while if $x > E_{xA}$, we choose the plus. According to survey data we can get samples to establish the rules. The form of samples data is shown in Table 2.

Table 2. Samples data

Factors	Terminal 1	Terminal 2	Terminal 3	Terminal 4	Terminal n
Total walk time	97.20	76.73	63.25	86.26	…
Total time in system	87.52	80.34	70.80	68.43	…
Route travel times	96.13	87.38	76.15	91.43	…
Total delay	85.08	84.70	80.43	72.99	…
Queue length	96.12	95.26	86.98	68.10	…
Flow conflicts	96.24	93.99	95.99	79.30	…
Connectivity	73.78	70.36	84.69	66.04	…
Directional information	94.54	91.28	91.55	69.39	…
Service reliability	73.78	70.36	84.69	52.29	…
…					…

4.2 Calculating weights by correlation analysis

First, we must normalize the reference data, compare data, then calculate weights of transfer efficiency factors according to the following formula:

$$\zeta_i(k) = \frac{\min_i \min_k |x_0(k) - x_i(k)| + \zeta \max_i \max_k |x_0(k) - x_i(k)|}{|x_0(k) - x_i(k)| + \zeta \max_i \max_k |x_0(k) - x_i(k)|}$$

$$r_i = \frac{1}{n}\sum_{k=1}^{N} \zeta_i(k)\,; w_i = \frac{r_i}{\sum_{k=1}^{n} r_i} \times 100$$

where x_i is impacting value; $\zeta_i(k)$ is the correlation coefficient x_i to x_0 in moment *K*; ζ is distinguished coefficient, usually chosen between 0 and 1; r_i is the correlation degree of each transfer efficiency factors; and w_i is the weight of each transfer efficiency factors.

After calculating, the weight of transfer efficiency evaluation factors is shown in Table 3.

Table 3. Weight of transfer efficiency evaluation factors

Index	Weight	Index	Weight	Index	Weight
Convenience	**47.62%**	**Comfort**	**19.05%**	**Safety**	**33.33%**
Total walk time	11.22%	Climate control	15.51%	Police protection	14.75%
Total time in system	10.10%	Area per person	13.20%	Emergency Response	16.39%
Route travel times	7.86%	Rest Room Facilities	14.85%	Entry control	11.48%
Total delay	12.35%	Avoid crowding	16.50%	Emergency egress	13.11%
Queue length	13.47%	Waiting Areas	14.03%	Safe walking	18.03%
Flow conflicts	8.98%	Cleanliness, sanitation	14.36%	Surfaces	13.93%
Connectivity	7.86%	Esthetic Design	11.55%	Lighting	12.30%
Directional information	7.63%				
Service reliability	10.66%				
Consumer services	9.88%				

By analyzing the weight of factors, we can find which factors effect transfer efficiency significantly and must be improved. With the weight of factors, the comprehensive evaluation of transfer efficiency also can be obtained.

5. Conclusion

The analysis of the variability of factors which impact on the transfer efficiency of urban transit terminals may provide useful insights on the strengths and weaknesses of a given transportation terminal service and recognize qualitative attributes that need special attention. This research focused on the transfer efficiency of urban transit terminal performance and employed the cloud model to assess the

quality implications of the variability of the efficiency with respect to the transit terminal systems.

In conclusion, this research demonstrates how factor analysis and cloud model may be used to analyze the variability of transfer efficiency and how the results and findings of this process may contribute to policy and decision making. The urban transit terminal operators and authorities may include these methods in their quality-control programs in order to facilitate the formulation of short- and medium-term action plans. Depending on the aim and nature of a survey and the level of detail of the collected data, this proposed approach may assist in operational adjustments related to service frequencies, network expansion, facilities configuration, network coverage and many others.

Abstract

Public transportation priority development is a basic policy to solve the problem of travel of Chinese people. Firstly, the author Analysis the means of urban traffic and their characteristics in China, then point the factors affecting their choice and the method professors used to study. Secondly, using the traffic survey analysis, prepare the questionnaire to determine factors which are important to the choosing of travel mode. Thirdly, construct the main factors related variables and passenger travel will of the asymmetric response model with multiple linear regression method. Finally, through the analysis of the status quo of China's urban traffic and passengers will travel model of asymmetric response, and from policy implementation, technical standards and the law-making, give some suggestions improve urban transportation system structure, improve the urban living environment, and ease urban traffic.

1. Introduction

With the steady development of the national economy, urban traffic development is rapid in our country, the large and middle scale cities have had a complete transportation system basically. However, the growth of vehicle's quantity and the increase of road course are uncoordinated, so residents' normal journey is difficult and discommodious seriously (Benartzi et al. 1995).

Li Linbo and Wu Bin (Li Linbo et al, 2003) pointed travelers can make their own choice from time, expense and environment, traffic modes can be chose and so on. And they make a quantitative analysis on factors influenced residents' travel choice. Li Min's (Li Min, 2004) activity-based behavioral analysis mainly studied on people's travel behavior characteristics and the choice characteristics. Zhou Xuemei(ZHOU Xuemei et al, 2007)based on Stated Preference Survey, individual characteristic and travelers intentions criteria are discussed and the effects of public transit choice are derived, Travel mode choice model is established on the basis of the surveyed data of Cixi in China. Zong Fang(Zong Fang et al, 2007) built a travel mode choice model based on the Logistic model and analyzed the effect of the policy of encouraging application of the

public traffic system on the travel modes of the inhabitants. Abdellaoui (Abdellaoui et al. 2007) analyzed mode choice behavior for suburban trips in the Grand Canary island using mixed revealed preference (RP)/ stated preference (SP) information.

2. Travel Mode Categories in Large Cities and Their Affective Factors

Researching on urban traffic travelers' choices makes an extremely vital role in grasping the present situation of urban traffic (Tversky et al. 1992), forecasting the trend of mass transit development and proposing effective measure for public transportation priority.

At present stage of our country, there are five urban travel modes as followed: the public transportation, the urban rail traffic, the taxi, the sedan and other travel mode such as the motorcycle, the bicycle as well as the ambulation. The large-scale city has a complete municipal transportation system generally.

The transportation characteristic influence mainly means in a journey intrinsic property, factors influenced to travelers' travel mode selection (Bateman et al. 1997). There are the trip purpose, the running time, the distance, the expense, comfortableness, the security, the time reliability as well as transfers the number of times and the waiting time and so on.

The paper chooses the price, the time reliability, the travel time, the security and comfortable as essential factors. And based on this, a questionnaire is established, uses 5-point Likert-type scale. The analysis obtains, the journey expense, the time reliability, the travel time are the most important factors The concrete information as the ***Table 1*** shows.

Table 1.Questionnaire survey second partial information statistics

	The least important(1)	The less Important(2)	Indefinite(3)	The more Important(4)	The most Important(5)
Price	0	0	0	46.03%	53.97%
Punctuality	0	1.02%	1.97%	46.01%	51%
Travel time	0	4.88%	12.07%	43.25%	39.80%
Safety	0	9.89%	13.74%	39.01%	37.36%
Comfortable	2.20%	25.82%	39.01%	18.68%	14.29%

3. Empirical Analysis of Travel Mode Choice in a Large City

3.1. Model Assumptions

According to the actual situation, in order to simplify the model, the assumptions are as follows:

- Within the research period, residents' travel modes are fixed.
- City has a Sound urban transport system.
- No considering of short-distance travel.
- Personal attributes do not affect travel mode.

3.2. Model Specification

We use the following set of variables to specify the function: price (P_i), schedule (S_i), time(T_i). These variables represent attractiveness of a transport mode and, as shown in previous empirical studies, all of them affect residents' choice directly. The price (P_i) is the representative of the amount of costs of a certain transport mode passengers choose, such as fares, prices, parking fees and other costs; schedule (S_i) represents the on time character of a certain transport mode, such as bus, subway Operation plans in accordance with the time running on time; time (T_i) represents the time of a transport mode need to reach their destinations, to compare different means, we assume that each mode is exactly the same travel routes.

Assuming passengers only choose one mode of transportation, the v_i Function can be written as follows:

$$\begin{aligned} v_i = \alpha_i &+ \beta_1 (PGAIN_i + \lambda_P PLOSS_i) \\ &+ \beta_2 (SGAIN_i + \lambda_S SLOSS_i) \\ &+ \beta_3 (TGAIN_i + \lambda_T TLOSS_i) \end{aligned} \quad (1)$$

P_i is the price or cost of one mode of transportation i at present, S_i is punctuality of the mode of transportation, T_i is the time need of the mode of transportation. P_r represents market price. If $P_i \leq P_r$, $PGAIN_i = P_i - P_r$, and $PLOSS_i = 0$; If $P_i \geq P_r$, $PLOSS_i = P_r - P_i$, and $PGAIN_i = 0$. Similarly, if the punctuality of the mode of transportation i equal to or exceed (better than) the reference point ($S_i \geq S_r$), then $SGAIN_i = S_i - S_r$, and $SLOSS_i = 0$. On the other hand, if the punctuality of the mode of transportation i is lower (inferior to) than the reference point ($S_i < S_r$), then $SLOSS_i = S_i - S_r$, and $SGAIN_i = 0$. So does the T_i.

3.3. Model

According to the statistical data of survey questionnaire, 182 valid, we select the bus, subway, taxi, car and other transport to study(the number of people were 58,51,33,26,14 respectively). Other type of transport is only 0.77 percent, and various factors affects loss aversion.

Because a market share of any transport mode can theoretically range from zero to one only, we utilize the following binary logit function to model a transport mode's market share as

$$S_i = \frac{1}{1 + e^{-v_i}} \quad (2)$$

According to the survey data, we get four functions respectively as follow. Here we take ***bus*** as an example.

$$\begin{aligned} v_{BUS} = -0.727 &+ 0.695(PGAIN + 1.889 PLOSS) \\ &+ 0.344(SGAIN + 3.279 SLOSS) \\ &+ 0.788(TGAIN + 1.346 TLOSS) \end{aligned} \quad (3)$$

According to (3), $\beta_1 = 0.695$, $\lambda_P = 1.889$.

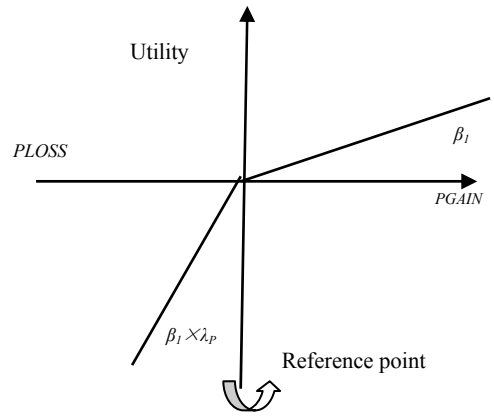

Figure1. Slopes reflecting loss aversion of the price of bus

The relationship can be draw from the price impact of the loss aversion slope map as shown in ***Figure 1***.

Taking into account of the definition of punctuality of any transport mode, subway is always punctual. No punctuality loss aversion effect on subway (the loss is neutral). Therefore, $\boldsymbol{\beta_2 = 0}$. Parameters of other functions, such as the relationship of subway, taxi and car with the loss aversion of the price, schedule and time are list in ***Table 2***, with there test results.

Table2. Parameters of functions

v_i	α_i	β_1	λ_p	β_2	λ_s	β_3	λ_T
bus	-0.727	0.695	1.889	0.344	3.279	0.788	1.346
	0.000	0.018	0.000	0.042	0.001	0.001	0.001
subway	-0.904	1.144	1.767			0.785	1.912
	0.000	0.043	0.000			0.048	0.011
taxi	-1.403	0.344	2.587	0.477	3.071	0.232	5.134
	0.000	0.027	0.000	0.000	0.000	0.037	0.000
car	-1.724	0.448	2.083			0.352	2.946
	0.000	0.448	2.083			0.024	0.000

3.4. Model Testing

To judge the goodness of the models, we use the adjusted R2 values. Its value obtained directly from the computer output with software SPSS15.0 (Yoshinori Suzuki et al. 2001), we calculate the adjusted R2 for each model by the following formula:

$$Adjusted R^2 = 1 - \frac{\sum_i \left(S_i - \hat{S}_i\right)^2 / (m-p)}{\sum_i \left(S_i - \overline{S}_i\right)^2 / (m-1)}$$

Where $\hat{S}_i$ is the predicted value of $\overline{S}_i$, the arithmetic mean of S_i, m is the total number of sample size used for parameter estimation, and p is the number of parameters estimated. The results can be seen in ***Table 3***.

Table3. Test results of functions

model	R	R Square	Adjusted R Square	Std. Error of the Estimate
bus	0.970	0.940	0.912	0.18162825
subway	0.897	0.805	0.753	0.42499817
taxi	0.987	0.973	0.960	0.09447970
car	0.976	0.953	0.932	0.11959297

3.5. Estimation and Analysis

We learn from the attractive function of every travel mode that the loss parameters of loss is larger than that of gain, with price, time and schedule (that is ***PLOSS>PGAIN***, ***SLOSS>SGAIN***, ***TLOSS>TGAIN***). According to the concept of loss aviation in Behavioral Economics (Köbberling et al. 2005), it shows that residents more sensitive with loss than gain. Take bus transport mode for example, if the price (mainly referring to the fare) fell 75 percent, according to calculation formula related above the number of bus travel up to 85, an increase of 46.55 percent; if travel time and punctuality and in the 75 percent, the choice may be drawn bus number 89 and 84 respectively, an increase of 53.45 percent and 44.83 percent. These shows that price, travel time and punctuality are all important to residents who choose bus to travel. In turn, more than 50 percent price increase will cause more residents travel by bus originally change to by subway.

To sum up, passengers who choose bus are more sensitive to punctuality, travel time and the gain of price. However, the price of subway is more sensitive to its punctuality and travel time. Though fast is the main advantage of taxi, when traffic become worse, the choice of taxi passengers will change to travel by subway possibility. Those who travel by car are sensitive to the loss aviation of price significantly. These tell us that we can take various strategies with different transport mode respectively to help passengers choose public transportation.

4. Strategies to Improve Public Transport Attractive

According to the model we point out strategies from three aspects as follows.

4.1. Policy measures

- Increase the social promotion; raise the traffic awareness of all the people.
- Improve the public transport system and its internal level. Improve the public
- Continue to develop urban rail transport vigorously.
- Improve public transport service quality.
- Control the use of cars.

4.2. Technology Strategies

- Public transport Operation priority
- Pricing Scientifically.
- Pricing in accordance with the law.
- Establish a rational mechanism of price subsidies.

5. Conclusions

In the use of the concept of loss aversion in economics, in light of China's large city transport development status and characteristics of the existing mode of travel, the article analysis the affecting factors and their role, and then point out that price is an important factor for every choice, the increase of travel time and the on time loss aviation will decrease the attraction of subway severely, also worse the traffic, worse the car's attraction, in the face of high prices its advantages would not exist. Sound public transport system is a major factor for residents to choose it. Besides strengthening the transportation infrastructure construction, government also can put forward some policies from the implementation of policies, technical standards and the law-making, to improve urban public transport to attract residents, and promote public transportation into a priority situation, and eventually achieve a high ratio of public travel, optimize urban transportation system structure, improve the urban living environment, ease city traffic.

ABSTRACT

In this paper, we present an empirical analysis of the topological properties of PTN based on the bus networks data of Shijiazhuang from 1996 to 2008. As a result, we find that the PTN is a small-world, accelerated growing network and a hybrid between a scale-free and a random network. To explain the results, we propose a simulation model based on accelerated growth and nonlinear preference rules to show a possible evolutionary mechanism for PTN. Numerical simulations show that the model performs well in reproducing basic topological properties of the real-world PTNs. The results can help us to understand the evolution mechanism of PTN as well as other evolving transportation networks.

INTRODUCTION

Recent years have witnessed an upsurge in the study of complex systems that can be described in terms of networks (Boccaletti et al. 2006). Public transport networks (PTN) can be mentioned as an important example of these evolving complex networks. There has been a substantial amount of interest in the topological properties and evolutionary processes of PTNs among researchers in different scientific fields (Sienkiewicz and Holyst 2005; Gao et al. 2005; Lu and Shi 2007; Xu et al. 2007; Ferber et al. 2009). These studies made careful analysis of various PTN instances using empirical, simulational, and theoretical tools and revealed the general features of PTN such as small-world, scale-free, and hierarchically-organized. However, most of these studies viewed networks from a static perspective, so it was difficult to capture and explain the evolution mechanism of PTN.

In this paper, we will use complex network theory to analyze the topological properties of PTN from a temporal perspective. An empirical analysis

of PTN based on the bus networks data of Shijiazhuang from 1996 to 2008 is presented first. The results indicate that the PTN is a small-world, accelerated growing network, and its evolution is governed by both random and preferential attachment. Based on the empirical survey, we propose a simulation model that captures the PTN's time evolution. Finally, numerical results are presented to demonstrate the effectiveness of our model.

The set-up of the paper is as follows: in the next section we provide an empirical analysis of the topological properties of the PTNs in Shijiazhuang; in the third section we describe our model for PTN evolution; in the fourth section we compare the major topological properties of simulated and real-world PTNs; discussion and conclusions are given in the last section.

EMPIRICAL ANALYSIS

The empirical study object in this research is the historical data of bus networks of Shijiazhuang from 1996 to 2008, which is provided by the Shijiazhuang Public Transport Corporation. As the bus network is appreciably changing in one-year intervals, we expand interval for 4 years and chose 4 sets of data, which are 1996, 2000, 2004 and 2008.

Usually the PTN can be described by three different topological representations: space L, space P, and space C (Sienkiewicz and Holyst 2005; Ferber et al. 2007). In space P, the network consists of nodes representing bus stops, and an unweighted edge between two nodes exists if there is a direct bus route that links them. In our analysis, we are interested in features of the PTN as measured when represented in space P, because it can better describe the accessibility and convenience of PTNs (Xu et al. 2007). Using this topological representation, the main statistical topological properties of PTNs are calculated and shown in Table 1.

Table 1. Statistical Topological Properties of PTNs of Shijiazhuang in 4 Years.

Year	R	N	E	M	$<k>$	$<l>$	$<C>$	u
1996	44	500	6472	18.23	25.89	2.24	0.86	0.23
2000	70	696	12326	20.39	35.42	2.30	0.80	0.32
2004	86	899	18341	21.24	40.80	2.35	0.78	0.39
2008	104	1033	22027	21.96	42.65	2.38	0.77	0.42

R: number of routes; N: number of nodes; E: number of edges in Space P; M: mean number of stops per route; $<k>$: average degree of nodes, a node's degree k in space P is the number of its neighbors; $<l>$: average path length; $<C>$: average clustering coefficient, the clustering coefficient C is defined as the probability that two neighbors of any given node are also neighbors of each other; u: parameter of the stretched exponential distribution.

To get a deeper understanding of the topological properties of PTNs, we give a detailed analysis of their degree distributions. The degree distribution $p(k)$ gives the probability that a selected node has exactly k links. Another way of presenting degree data is to make a plot of the cumulative distribution function $P(k)$, which can reduce the noise in the degree data (Boccaletti et al. 2006). Figure 1 shows the cumulative node degree distribution of PTNs.

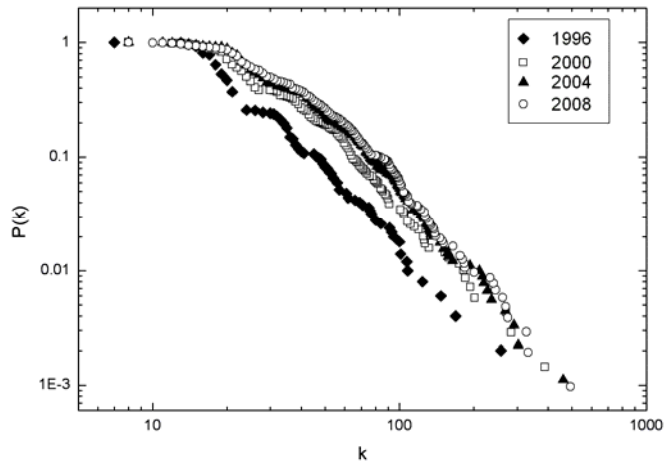

Figure 1. Cumulative degree distribution in log-log scale.

From Table 1 and Figure 1, we can find at least three nontrivial characteristics of PTN:

1. PTN is a small-world network. The high average clustering coefficient and small average path length show that PTN has small-world features. This has been revealed by many previous researchers (Sienkiewicz and Holyst 2005; Gao et al. 2005; Xu et al. 2007).

2. PTN is an accelerated growing network. The average degree <k> of PTN increases with time, which means that the number of edges grows faster than the number of nodes. This is a main characteristic of an accelerated growing network and has been found in some social networks of collaboration (Barabási et al. 2001).

3. PTN is a hybrid between a scale-free and a random network. The degree distribution of PTN represents a transition from power-law to exponential decay with time and can be well fitted with the stretched exponential distribution (Zhou et al. 2005). The cumulative distribution function of stretched exponential distribution is $P(k) = \exp(-(k/A)^u)$, in which u is a nonnegative parameter smaller than one. The borderline u=1 corresponds to the usual exponential distribution and u=0 to the power-law. It is well known that the exponential distribution can occur for evolving networks when nodes are attached completely randomly and power-law when attached preferentially to nodes with high degree (Barabási and Albert 1999). The increasing parameter u reveals that the PTN is evolving from scale-free network to a random one.

SIMULATION MODEL

To reproduce the major topological properties of empirical PTNs mentioned above, we propose a simulation model in this section. In our model, the PTN is built in an iterative fashion, each time repeating and reusing the elements generated in the previous steps as follows:

Step 1: The simulation PTN starts from an initial route with m stops which are fully connected. Set t=0.

Step 2: A new route with (m-1)q(t) new stops and m-(m-1)q(t) "old" stops which are chosen from the existing stops is added to the PTN. Here we define $q(t)=t^{-a}$, in which a is a parameter and determines the speed of growth of new stops. The rule of selecting the old stops is using a nonlinear preference rule with probability $p \propto k^b / \sum_i k_i^b$, where k denotes degree of an old stop, i denotes all existing stops, b is a parameter and b>0. Similarly, all of the stops in this route must be fully connected.

Step 3: Set t=t+1 and repeat Step 2 until R routes are created.

This model is very similar as compared with some evolution models of collaboration networks (Ramasco et al. 2004; Chang et al. 2007). The principal difference of our model is that the ratio of new stops declines with time and the selection of old stops follows a nonlinear preference rule. This can be explained as follows: When the PTN's scale is small, the main aim of developing a new route is to enlarge the service area of PTN, so most stops of the newly-developed routes are new. On the other hand, a few "old" stops be connected directly each other to ensure the convenience of PTN. As a result, the small-scale PTN usually has a star-like structure with a tiny number of stops, called hubs, which have a large number of links. New routes connect preferentially to these hubs and the PTN appears to be scale-free. But with increase in network size, there are a large number of routes crossing in more than one hub to enhance the accessibility and efficiency of the PTN and it evolves to a more random network. We think this model should be capable of capturing the key evolution mechanism of real-world PTNs.

NUMERICAL RESULTS

To check the validity of our model, we present a numerical experiment to compare the simulation results of the model with the empirical data on PTNs of Shijiazhuang. Table 2 and Figure 2 show some of the results.

Table 2. Numerical Results of the Simulation Model.

R	*N*	*E*	*M*	<*k*>	<*l*>	<*C*>
44	453	7038	19.97	31.07	2.07	0.85
70	717	12884	20.05	35.94	2.14	0.81
86	901	17763	20.88	39.43	2.18	0.80
104	1073	21910	21.74	40.84	2.25	0.79

The model's parameters: a=0.17; b=1.3; m is a random number with a Gaussian distribution centred at 20.

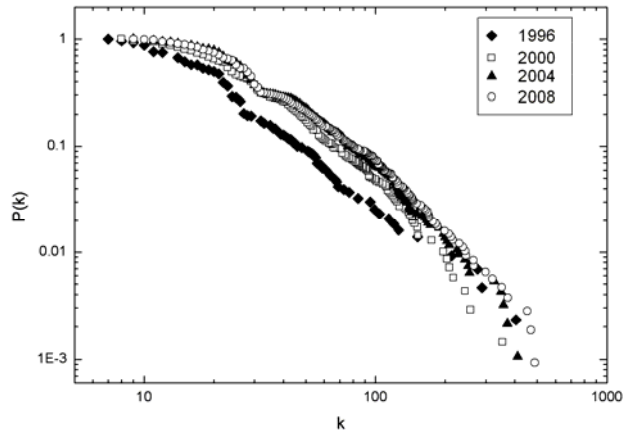

Figure 2. Cumulative degree distribution of simulation PTNs.

From Table 2, we can see that the simulation PTN also has a high average clustering coefficient, a small average path length, and a gradually increasing average degree. Figure 2 shows that the degree distribution of simulation PTNs represents a transition from power-law to exponential decay with time. Comparing Table 1 and Figure 1, it is apparent that the simulation results of our model are capable of reproducing the major topological properties of empirical PTNs.

CONCLUSION

The PTN represents a prototype of complex evolving networks. By mapping the PTNs of Shijiazhuang from 1996 to 2008, we infer the dynamic and structural mechanisms of this complex system. The empirical measurements allow us to uncover the time evolution of the topological properties of PTN. The results indicate that the PTN is a small-world, accelerated growing network and that the network evolution is governed by both random and preferential attachment. Also, we propose a simple model that captures the PTN's time evolution based on accelerated growth and nonlinear preference rules. The numerical experiments show that the model is capable of reproducing the major topological properties of real-world PTNs. The results and methodologies presented in this paper could be useful for a systematic study of other complex evolving transportation networks as well, such as railway, airport and logistics networks.

ABSTRACT

Congestion often occurs at bus stops during peak hours, since traffic flow and service frequency are very high near bus stop. Based on research of road traffic flow, the capacity model of bus stop is built in two steps after analyzing the operation rules in-out bus stop during peak hours. First, the formula of bus stop physical facility capacity is established. The formula of maximal arriving rate (bus stop capacity) is then solved based on obtaining the state equation's parameters by the analysis method of birth-death process. The numerical capacity tables of different berths anddwell time are calculated using Matlab. In addition, curve fitting formula is deduced from the table for application convenience, which provides a preference for the bus stop building and planning. Finally, a numerical example in City of Nanjing is presented to describe the method.

OVERVIEW

The importance of developing public transportation systems was widely realized by most cities in world. However, some problems still exist when the bus routed network is planned, such as underestimation of bus stop capacity during peak, hours. Bus stops are often operated normally in light traffic, while the congestion in bus stop will occur during peak hours due to the increasing bus frequency, road traffic flow and limitation of in-out bus stop. These problems result in inefficient use of buses and influence the traffic in adjacent lanes. Therefore, it is beneficial to study the bus stop capacity during peak hours.

The current literature on the bus stop capacity has two problems. First, the studies emphasize on network and route volumes, while the single bus stop capacity is not sufficiently investigated. Second, although the bus flow is lower than the capacity, the queue congestion often occurs around the bus stop during peak hours. The research on the bus stop capacity is studied in a TCRP (Transit Cooperation Research Program) report and other references (Bai and Li, 2007; TCRP, 2003; Hamdouch and Lawphongpanich, 2008; Zhao et al., 2008). Although the model parameters and estimation values are found in these references, the stop capacities during peak hours and light traffic are not appropriately addressed. The calculated capacity of bus stop is often smaller than factual one during peak hours, which results in congestions even if the bus flow is lower than the capacity. Thus, an appropriate approach needs to

consider the traffic flow characteristics during peak hours. Under the condition of analyzing the bus operational characteristics at out-line stop and on-line bus stops, this paper establishes the birth-death formula of vehicle operations at bus stop. Additionally, the formula of conventional bus stop capacity during peak hours is proposed..

MODEL ANALYSIS OF CONVENTIONAL BUS STOP

Conventional bus stops can be classified out-line and in-line bus stops. The advantages of out-line bus stop include lower influence to vehicles on adjacent lanes and lower probability to form bottleneck near bus stop. However, the capacity of the out-line stop is smaller than one of the in-line stop. Because of the stochastic dwell time, the phenomemon of in-out bus stops in advance complicates the stop operations. But during peak hours, there is little different operational characters between on-line and out-line bus stop. Considering the limitation of *M/M/1* and *M/M/S* queue system, this paper models bus stop as a birth-death process (Zhu and Shu,2006). We first discusss bus stop as a whole birth-death system and then discuss the birth-death status parameters.

The delay of buses are very slight in the case of no queue in bus stop when the arriving rate is lower than capacity. When the queue occurs in bus stop, the bus flow will increase to physical facility capacity. There is little probability for bus to change lane during peak hours when the passed bus number is close to the physical facility capacity. Assum that k berths in bus stop and k buses are coming in bus stop immediately after it is clear. The passed bus number will be stable in physical facility capacity as queue occurring. However, the delay of stop operations will be increased because of queue. The longer the queue is, the greater the delay is . The bus stop is the key location of delay on bus line, which must be restricted in an appropriate range. The bus arriving rate is lower than the capacity in reference (Bai and Li, 2007) whose value is close to the physical facility capacity. However, the bus queue is often long, which influences the service level of bus stop and operation efficiency of line. Therefore, it is not suitable for physical facility capacity or capacity of ideal condition as evaluation criterion. The queue delay must be considered in capacity evaluation criterion. This paper proposes a method to calculate the conventional bus stop capacity in given delay level during peak hours. The bus arriving rate in this condition just embodies the service level of the bus stop.

We can adopt in-line bus stop as prototype to deduce the formula of conventional bus stop capacity during peak hours. Based on the analysis of bus stop operations, physical facility capacity formula is constructed. Physical facility capacity is the output rate when the bus arriving rate is input rate. The state equation of birth-death is established. The queue probability of buses is selected as the congestion index of bus stop. The inequality, is deduced in order that bus arriving rate in different berth bus stop needs to meet in condition of given delay index. The maximum bus arriving rate equals the conventional bus stop capacity during peak hours.

MODEL OF CAPACITY DURING PEAK HOURS

Assuming k berths in the bus stop, the bus arriving rate of a line to the bus stop is λ, which is input rate of birth-death system. Then let deceleration time of incoming bus be t_j, average service time of boarding and alighting be t_d, bus safe reflecting time-headway be t_a. g and c indicate the green time and cycle next intersection respectively, B_f be physical facility capacity, B_c be bus stop capacity during peak hours. The physical facility capacity can be established using formula (1) according to the operation analysis of bus stop.

$$B_f = \frac{3600 \cdot k \cdot (g/c)}{t_j + t_d(g/c) + (k-1)t_a} \tag{1}$$

Where, $(k-1)t_a + t_j$ represents the whole deceleration time of k buses; Hence, the output rate of birth-death system is formula (2).

$$\mu_i = \begin{cases} \dfrac{3600 \cdot i \cdot (g/c)}{t_j + t_d(g/c) + (i-1)t_a} & i = 1,2,\ldots k \\ \dfrac{3600 \cdot k \cdot (g/c)}{t_j + t_d(g/c) + (k-1)t_a} & i = k+1, k+2,\ldots \end{cases} \tag{2}$$

The state equations of birth-death can be deduced as following (3-4). When no buses are in bus stop ($i = 0$), the state equation is:

$$\mu_i P_1 = \lambda P_0 \tag{3}$$

If there are i buses in bus stop, the state equation is:

$$\lambda P_{i-1} + \mu_{i+1} P_{i+1} = (\lambda + \mu_i) P_i \tag{4}$$

where P_i = probability of i buses coming simultaneously， $i = 0, 1, 2\ldots$.

According to formula (3-4), formula (5) can be deduced.

$$P_i = \begin{cases} \dfrac{\lambda^i}{\prod_{j=1}^{i} \mu_j} P_0 & i \le k \\ \dfrac{\lambda^i}{B^{i-k} \prod_{j=1}^{k} \mu_j} P_0 & i > k \end{cases} \tag{5}$$

where $\sum_{i=0}^{k} P_i + \sum_{i=k+1}^{\infty} P_i = 1$.

We can establish the formula of P_0 at k berths bus stop as following (6-8).

$$P_0(1) = \frac{B_f - \lambda}{B_f} \tag{6}$$

$$P_0(2) = \frac{(B_f - \lambda)\cdot \mu_1}{u_1 \cdot (B_f - \lambda) + B\lambda} \tag{7}$$

$$P_0(k) = \frac{(B_f - \lambda)\cdot \prod_{i=1}^{k-1} \mu_i}{(B_f - \lambda)\cdot \sum_{i=0}^{k-2} \lambda^i \prod_{j=i+1}^{k-1} \mu_j + B_f \cdot \lambda^{k-1}} \qquad k = 3,4,5,6... \tag{8}$$

where $P_0(k)$ indicates the probability of 0 bus arriving rate in k berths bus stop. Let the allowed bus queue probability be α, formula (9) is:

$$P_i(i \le k) \ge 1 - \alpha \tag{9}$$

By the corresponding formula (5-8) with different number of berths into formula (9), we can obtain the bus arriving rate inequality as following formula (10-12).

$$1 - \left(\frac{\lambda}{B_f}\right)^2 \ge 1 - \alpha \qquad k = 1 \tag{10}$$

$$\frac{\left(B_f \mu_1 + B_f \lambda + \lambda^2\right)\cdot (B_f - \lambda)}{{B_f}^2 \mu_1 + B_f \cdot \lambda \cdot \left(B_f - \mu_1\right)} \ge 1 - \alpha \qquad k = 2 \tag{11}$$

$$\frac{\left(B_f \cdot \sum_{i=0}^{k-1} \lambda^i \prod_{j=i+1}^{k-1} \mu_j + \lambda^k\right)\cdot (B_f - \lambda)}{B_f \cdot \sum_{i=0}^{k-2} \lambda^i \prod_{j=i+1}^{k-1} \mu_j \cdot \left(B_f - \lambda\right) + {B_f}^2 \cdot \lambda^{k-1}} \ge 1 - \alpha \qquad k = 3,4,5,6... \tag{12}$$

Choosing the corresponding formula in (10-12) according to given number of berths, we can calculate allowed maximum of bus arriving rate, which corresponds to bus stop capacity in peak.

CALCULATION RESULTS AND CURVE FITTING FORMULA

According to formula (2), physical facility capacity is calculated as follows. Tables 1 and2, with *g/c*=0.5, compare with capacity in TCRP. The suggested values of related parameters are calculated as follows: number of berths is 1~7, dwell time is 20~90*s*, $t_j = 5s$, and $t_a = 3s$.

Table 1 （*g/c*=0.5）Conventional bus stop physical facility capacity （*bus/h*）

Dwell time	20	25	30	35	40	45	50	55	60	65	70	75	80	85	90
1	120	103	90	80	72	65	60	55	51	48	45	42	40	38	36
2	200	176	157	141	129	118	109	101	95	89	84	79	75	71	68
3	257	230	208	189	174	161	150	140	132	124	117	111	106	101	96

4	300	272	248	229	212	197	185	173	164	155	147	140	133	127	122
5	333	305	281	261	243	228	214	202	191	182	173	165	158	151	145
6	360	332	309	288	270	254	240	227	216	206	196	188	180	173	166
7	382	355	332	311	293	277	263	250	238	227	217	208	200	192	185

It is reasonable to select bus queue probability α=15% according to the research of bus operation state in TCRP. Conventional bus stop capacity during peak hours, B_c, is determined from formula (10-12) by MATLAB 7.0, as following Table 2 and Figure 1.

Table 2 （*g/c*=0.5）Conventional bus stop capacity in peak（*bus/h*）

Dwell time	20	25	30	35	40	45	50	55	60	65	70	75	80	85	90
1	35	31	28	25	23	21	20	19	17	16	15	15	14	13	13

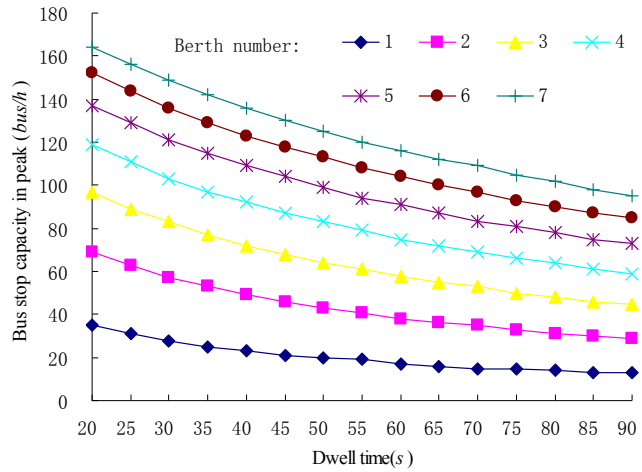

Figure 1. Bus stop capacity curve in peak in different dwell time (*g/c*=0.5)

Formula (10-13) is very complicated. Hence, a curve fitting formula 13 is obtained according to table 2. The correlation coefficients are over 0.9.

$$B_c\left(g/c=0.5\right)=\begin{cases}0.1114t_d^{\,2}-3.2435t_d+37.07, & k=1\\ 0.1701t_d^{\,2}-5.4178t_d+72.815, & k=2\\ 0.2017t_d^{\,2}-6.7769t_d+101.94, & k=3\\ 0.2059t_d^{\,2}-7.387t_d+124.54, & k=4\\ 0.2121t_d^{\,2}-7.833t_d+143.53, & k=5\\ 0.2081t_d^{\,2}-8.0017t_d+158.74, & k=6\\ 0.1878t_d^{\,2}-7.7902t_d+170.73, & k=7\end{cases} \tag{13}$$

A NUMERICAL EXAMPLE

The example station is located at Beijing East Road in City ofNanjing named Beijihuitang station. Investigation was conducted during the period of 5:30 to 6:30. The basic data is following. The example station is 25 meters to next intersection. 13 lines park in the bus stop, which has 4 berths. g/c=80/154=0.519, and t_d=32s. The mean bus arriving rate is 138 *bus/h.* First of all, physical facility capacity B_f=244 *bus/h* can be calculated by formula (1). Then we can obtain capacity in peak B_c=106 *bus/h* by formula (6-13). Observe that the actual bus volume is lower than physical facility capacity because of 244>138. Also observe that the bus queue probability is over 60%. Then we compare capacity during peak hours to actual bus volume, 106<138. Saturation is 138/106=1.3>1. Bus stop is supersaturated, which is confirmed by actual status of the station.

The authors believe that frequent congestion will occur if the physical facility capacity in alighting traffic is used as the design basis of bus stops. The congestion will result in lower service level of bus lines and influence the vehicles of adjacent lanes seriously. Then capacity in existing method is close to physical facility capacity. It is not suitable to take capacity in existing method as a criterion during bus stop planning and designing. This paper proposes a numerical model based on the given probability, which is close to actual capacity of bus stop during peak hours and is suitable to be reference in planning and designing of bus stop. However, the research of different between in-line stops and out-line stops is insufficient in the new capacity model, which will be investigated in the future.

ABSTRACT
Trip mode transfer is a behavior of inhabitant in the process of adjusting their trip mode. The behavior is similar to the transition of quantum. In this paper, trip mode transfer and quantum transition were compared. According to the quantum transition theory, three linear imitation models and a polynomial imitation model were built. The models were applied via 1990 NPTS (Nationwide Personal Transportation Survey) data from U.S. and 2001 CCTS (Changchun Trip Survey) data from the city of Changchun, China. The results indicate that the relations between income difference and number of transferring levels, trip distance difference and number of transferring levels, and trip distance difference and income difference are all linear and the function between trip distance difference and income difference fits quadratic and higher polynomials of which the constant items are zero when one trip mode transfers to others. The proposed models can reveal the rules of change of trip mode sharing rates.
Key Words: trip behavior; trip mode transfer; quantum transition; energy level

INTRODUCTION
Inhabitant reorganization is a universal phenomenon arisen from inhabitant adjusting their travel behavior when economy developing, land use changing or level of living improving etc. The phenomenon sometimes brings on recombining trip distributions. Adjusting travel behavior is usually adjusting trip modes. The adjusting mostly relies on inhabitant income. Generally speaking, inhabitant will adjust trip mode properly when choosing it with income increasing, such as converting bicycle into motorcycle or bus, transforming bus into taxi or diverting taxi to private car etc. The behavior often makes trip distance increase accordingly. In addition, with increase of income, people are pursuing life quality with high standard, such as capacious space, neat surrounding or trip comfort etc. However, the restriction of city planning and land use and the discommodity of layout of old city zones make the standard difficult to realize at the city center. According to the rules of city construction, the kind of zones commonly locates at the periphery of city. When inhabitant income increases to a certain value, it is possible to choose dwelling place renewedly. When choosing

dwelling place, inhabitants have tendency to choose the areas away from the city center. That is to say, trip distance of inhabitant increases. This is one major cause of city extension ceaselessly, which is also related to trip mode transfer.

A topic relative to trip mode transfer is modal split or mode choice. It is an important part of the traditional four-step procedure for transportation planning applications. Many researchers developed various models based on random utility maximization theory or maximum simulated likelihood method to analyze individual or household travel behavior, such as the logit model (Bhat 2000; Li et al. 2002), the mixed logit model (Bhat and Sardesai 2006), and the nested logit model (Dissanayake and Morikawa 2002) etc. Lately, some scholars described travel mode choice via neural network (Xie et al. 2003; Celikoglu 2006). The achievements have significant influences on predicting trip distributions or traffic assignment. They pay attention to individual or household behaviors of not adjusting but choosing trip mode.

Some scholars presented the macroscopic descriptive model of inhabitant distribution based on the probability density model of electron occurring out of nucleus (Wang et al. 1996; Wang et al. 2007). In the model, an inhabitant is regarded as an electron, and a household, work location or shopping center is looked upon as a nucleus, inhabitants go the motion round the nucleus with a certain radius. Since the factor of income was rarely considered in the conventional trip distribution models, some researchers gave the electron energy model of trip distribution by comparing the similarity of energy level transition in the quantum mechanics theory and the increase of inhabitant trip distance (Qu et al. 2003). These results have an important significance to trip distribution prediction, but the subject of trip mode transfer did not be referred. However, the applied quantum mechanics theory has a referenced value to studying trip mode transfer. The theory indicates that quantum transition will occur when electron energy increases to a certain value; that is, electron transfers from a lower energy state to a higher energy state and the radius of motion of electron going round the nucleus increases accordingly. The characteristics of quantum transition are very similar to the characteristic of trip mode transfer. That is to say, the inhabitant behavior of adjusting trip mode is similar to quantum transition.

In the paper, the similarity of trip mode transfer and quantum transition is analyzed in detail. The trip mode transfer models are given on the basis of energy level transition theory. The models are explained by 1990 NPTS (Nationwide Personal Transportation Survey) data from U.S. and 2001 CCTS (Changchun Trip Survey) data from the city of Changchun, China.

Basic Principle

Similarity of Phenomena. The quantum transition theory assumes that an electron will transit to the final state with higher energy level from the original one with lower one after absorbing a photon; it will release a photon after transiting to the final state with lower energy level from the original one with higher one. For trip mode transfer, an inhabitant will change his trip mode with lower quality (e.g. slower speed) to higher quality (e.g. quicker speed) after his income increases; he will have to alter his trip mode with higher quality (e.g. quicker speed) to lower quality (e.g. slower speed) after his income decreases.

The similarity between trip mode transfer and quantum transition is as follows (Yao and Wang 2007). The first is income and electron energy. The chosen trip mode by an

inhabitant lies on his income. This is similar to the one that the chosen movement track by an electron depends on its energy. The second is the trip distance and track radius. A great deal of statistical data showed that the reachable trip distances are different for various trip modes. Then the trip distance can be a token of relevant trip mode. Similarly, the radius is a token of electron movement track. The third is trip mode quantization and electron track quantization. The category of trip modes is limited and discrete. Trip modes can be numbered by using natural number according to energy (e.g. speed) order. This is similar to the quantum characteristic of electron track. The electron only moves in some discrete tracks. The last one is trip mode transfer and quantum transition. When the income of an inhabitant increases, he/she will choose a trip mode with higher quality (e.g. quicker speed) to realize further trip distance. On the contrary, when the income decreases, he/she will have to choose a trip mode with lower quality (e.g. slower speed) and only realize closer trip distance. Similarly, when the energy of an electron increases, it will transition to a track with higher energy and movement radius is also longer; when its energy decreases, it will transition to a track with lower energy and movement radius is also shorter.

Trip* Mode *Transfer Model. Based on the quantum mechanics theory, electron energy is composed of the kinetic energy of motion of electron going round the nucleus in a circle and the potential energy of the system. Let us only consider the potential energy and suppose that trip distance (regarding household, work location or shopping center as trip origin or destination) is a token of the potential energy. For a average sense, trip distance is farther when inhabitant income is higher.

In the Bohr theory of hydrogen atom (Zhou 1998), a basic equation is

$$E_n = E_1 / n^2 \tag{1}$$

where n is primary quantum number and an integer, and E_1 and E_n are energy of electron which locates at the first and nth stationary state trajectories, respectively.

The relation between the primary quantum number and radius of electron away from the atomic nucleus is $n^2 = r_n Z / \alpha_1$. For hydrogen atom, $Z = 1$, and Eq.(1) becomes

$$E_n = \alpha_1 E_1 / r_n \tag{2}$$

where r_n is the radius of the nth stationary state orbit at which electron locates, and α_1 is the radius of the first Bohr orbit which is a stationary state orbit of electron in hydrogen atom away from the nucleus nearest.

According to Eq.(2), we have

$$r_n - r_m = \alpha_1 E_1 (E_m - E_n) / (E_n E_m) \tag{3}$$

In the Bohr theory, the zero (maximum value) of potential energy locates at infinite away from the atomic nucleus;the potential energy of electron at each energy level is negative. When the potential energy of electron is greater, the attraction power between electron and nucleus is less, namely the ability of electron escaping the nucleus is larger. But trip distance and inhabitant income are all positive in the process of trip mode transfer. In Eq.(3), α_1 and E_1 are constants, then

$$\Delta r = \beta \Delta E / (E_n E_m) \tag{4}$$

where $\Delta r = r_n - r_m$ is the radius difference between two energy levels; $\Delta E = E_n - E_m$ is the energy difference between two energy levels; $\beta = -\alpha_1 E_1$ is a

positive parameter.

In Eq.(4), the radius difference is directly proportional to the energy difference, and inversely proportional to the product of the energies. It is a ternary nonlinear function. The parameter β is difficult to be calibrated. In fact, the three variables are not unattached. Furthermore, the radius difference depends more on the energy difference. As a result, Eq.(4) can be rewritten as a unitary nonlinear function:

$$\Delta r = f(\Delta E) \tag{5}$$

According to the above similarity, the trip mode transfer model is

$$\Delta D = f(\Delta I) \tag{6}$$

where ΔD is trip distance difference; ΔI is income difference.

MODEL REVISION

Energy Level Analysis. Table 1 lists the income and trip distance for the different trip modes obtained from 1990 NPTS and 2001 CCTS data. From Table 1, the energy levels of trip mode in U.S. and Changchun city are walk, bike, school bus, private vehicle, rail/subway and bike, bus, autocycle, car from the lowest to the highest.

Table 1. Income and trip distance for different trip modes

	Trip Mode	Walk	Bike	School Bus	Private Vehicle	Rail/Subway
NPTS	Income ($10^4\times$dollars)	2.501	2.9741	3.0659	3.2658	3.3393
	Trip Distance (miles)	2.5522	3.1472	5.2837	7.735	12.7907
	Trip Mode	Bike	Bus	Autocycle	Car	
CCTS	Income ($10^3\times$yuans)	1.1616	1.3734	1.6	2.076	
	Trip Distance (km)	2.0544	3.9679	4.4962	5.8674	

Linear Imitation Formulas. Table 2 lists the number of transferring levels, income difference and trip distance difference obtained from 1990 NPTS and 2001 CCTS data. From Table 2, any two of the income difference, trip distance difference and number of transferring levels follow a linear relation, namely:

$$\Delta I_n = \gamma_1 n + \varphi_1 \tag{7}$$

$$\Delta D_n = \gamma_2 n + \varphi_2 \tag{8}$$

$$\Delta D_n = \gamma_3 \Delta I_n + \varphi_3 \tag{9}$$

where ΔI_n and ΔD_n are income difference and trip distance difference when transferring n levels; $\gamma_1, \varphi_1, \gamma_2, \varphi_2, \gamma_3, \varphi_3$ are constants.

Table 2. Number of transferring levels, income difference and trip distance difference

	Number of Transferring Levels	1	2	3	4
NPTS	Income Difference ($10^4\times$dollars)	0.2096	0.3767	0.565	0.8384
	Trip Distance Difference (miles)	2.5596	4.9421	7.4131	10.2384
	Number of Transferring Levels	1	2	3	
CCTS	Income Difference ($10^3\times$yuans)	0.3048	0.5705	0.9144	
	Trip Distance Difference (km)	1.271	2.1707	3.813	

Polynomial Imitation Formula. Eq.(6) is a nonobjective function and its concrete expression is not clear yet. However the trip distance difference can be imitated as a polynomial of the income difference, namely

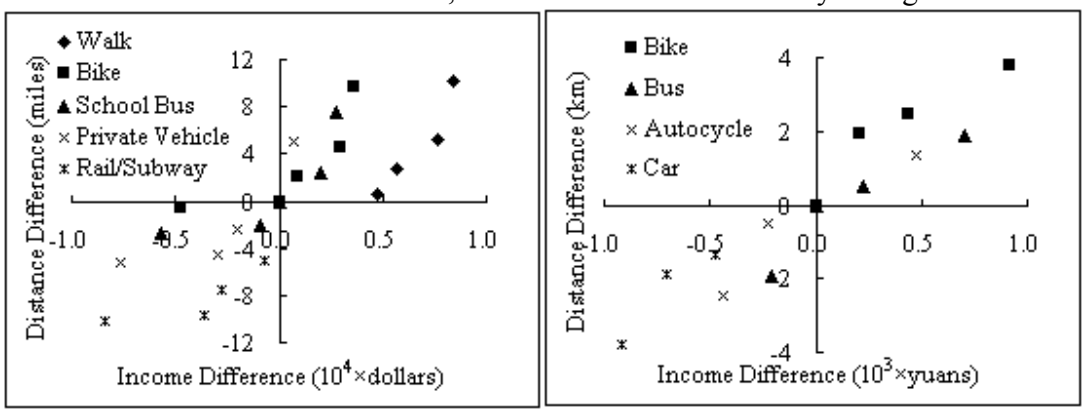
$$\Delta D = a_0 + a_1 \Delta I + a_2 \Delta I^2 + \cdots + a_n \Delta I^n \tag{10}$$

where $a_0, a_1, a_2, \cdots, a_n$ are unknown coefficients.

Figure 1 illustrates the relations between the trip distance difference and the income difference for one trip mode transferring to others obtained from 1990 NPTS and 2001 CCTS data. From Figure 1, the curves all traverse the origin of coordinate and are all nonlinear, namely $a_0 = 0$ and $n \geq 2$ in Eq.(10).

MODEL APPLICAION AND RESULTS

Linear Models. Table 3 indicates the correlative coefficient of the linear trip mode transfer model via 1990 NPTS and 2001 CCTS data. From Table 3, the correlation coefficients of the linear imitation models are all greater than 0.98. It is showed that the income difference and the trip distance difference are linearly correlated to the number of transferring levels; and the trip distance difference is linearly correlated to the income difference. Furthermore, their linear correlation is very strong.



(a) NPTS (b) CCTS

Figure 1. Curves of one trip mode transferring to others

Table 3. Correlative Coefficient of Linear Imitation

Relations	Number of Levels and Income Difference		Number of Levels and Distance Difference		Income Difference and Distance Difference	
Data	NPTS	CCTS	NPTS	CCTS	NPTS	CCTS
Correlative Coefficient	0.9930	0.9973	0.9992	0.9861	0.9970	0.9957

Polynomial Model. Table 4 indicates the correlative coefficient of the polynomial trip mode transfer model via 1990 NPTS and 2001 CCTS data. From Table 4, the correlation coefficients of the quadratic and cubic polynomial imitation models are all greater than 0.90 and 0.96 respectively; and the correlation coefficients of the biquadratic polynomial imitation models are all equal to 1.00. It is showed that the function relation between the trip distance difference and the income difference fits the quadratic and higher polynomials of which the constant items are zero; the imitation effects of the biquadratic and higher polynomials have no difference.

CONCLUSIONS

The quantum mechanics theory describes the quantum transition behavior in the microscopic world. The trip mode transfer is a behavior of inhabitants adjusting trip modes in the macroscopic world. The two phenomena are similar. In this paper, their common points were analyzed. Based on the quantum transition principle, the trip mode transfer model was presented. The linear and polynomial imitation formulas were given via the NPTS and CCTS data. The results showed that the relation of any two among income difference, trip distance difference and number of transferring levels is linear; the function between trip distance difference and income difference fits quadratic and higher polynomials of which the constant items are zero for one trip mode transferring to others.

The contribution of this paper is to reveal the similarity between trip mode transfer and quantum transition, to describe the trip mode transfer rules via survey data, to establish the trip mode transfer models according to the quantum transition theory, and to explain the micro-phenomenon in the macroscopic world. It is valuable for trip distribution and modal split, and useful to explain inhabitant reorganization phenomena. Therefore, it may provide new perspectives to urban planning and urban traffic planning of developing cities.

[1] MOE Key Laboratory for Urban Transportation Complex Systems Theory and Technology, Beijing Jiaotong University, 100044, Beijing, China; PH (010) 51687138; Fax (010) 51688344; Email: zhangxingqiang@jtys.bjtu.edu.cn

ABSTRACT: Interferences between vehicle flow and non-vehicle flow at a grade intersection are mainly induced by the crossing behavior between bicycles and vehicles. In this paper, according to the conflict danger degree, vehicle-bicycle conflicts at a 4-leg intersection are classified into 3 groups using the fuzzy cluster theory; the behavior of through bicycles crossing right-turn motor vehicles on neighboring lanes is used as the case study. The factors affecting the crossing behavior are analyzed, including the bicycle speed before crossing and the acceptable Gap. Then a decision-making model describing bicycle crossing behavior is built by the logistic regression model. Finally, based on the model, the Multi-Agent simulation system of the through bicycle crossing right-turn motors is built, the simulation results show that the behavioral decision-making model is reasonable, and the simulation system is validated.

Keywords: bicycle; intersection; crossing behavior decision-making model; simulation

1 INTRODUCTION

In Chinese urban traffic, vehicle-bicycle conflicts at intersections are one of the most important factors to traffic jam and safety. So analyzing bicyclist microscopic behaviors and establishing the bicycle-motor interaction model are necessary to study the mixed traffic characteristics and to find an effective method for resolving the mixed traffic problem. Based on the boundary gap theory, Wu (2004) established the acceptable gap probability model when a bicyclist passing through vehicles at a signalized intersection. Xu (2006) studied the distributed rules of left-turn bicycles passing through vehicles and established models between left-turn bicycles and through vehicles. Researchers pay more attention to the bicyclist behaviors, but bicyclist behavior simulation is sparse at signalized intersections. In this paper, various bicycle behaviors are examined based on data collected at two typical intersections in Beijing: the Ganjiakou intersection and the Fuchengmen intersection. According to the conflict danger degree, the vehicle-bicycle conflicts at a 4-leg intersection are classified using the fuzzy cluster theory. Then speed distribution and cyclist acceptable gap at signalized intersections are analyzed in order to establish microscopic behavior model of bicyclist passing through motor. Finally, using the software NetLogo, an agent based microscopic model is established to simulate the

behavior of bicyclists passing through vehicles.

2 FUZZY CLUSTER ANALYSIS OF VEHICLE-BICYCLE CONFLICT

Based on the quantity and danger degree, the vehicle-bicycle conflicts at intersections are classified using the fuzzy cluster theory. Fuzzy cluster target function can be expressed as:

$$\min F(U,V,W) = \sum_{\mathrm{h}=1}^{c}\sum_{j=1}^{n}\{u_{hj}^{2}[\sum_{i=1}^{m}[w_i(x_{ij}-v_{ih})]^2]^{\frac{a}{2}}\} \quad , \qquad (1)$$

where: $X=(X_1,X_2,\cdots X_n)$ is the value swatch set; $V=(V_1,V_2,\cdots V_n)$ is the cluster center matrix; $W=(W_1,W_2,\cdots W_n)$ is the characteristic weight sector of V; $U=(u_{kj})$ is the subordinate grade membership matrix; $\alpha=2$ is the least squares optimized rule. The matrix U and the sector W should accord with the restriction conditions, respectively:

$$0\le u_{hj}\le 1;\ \sum_{\mathrm{h}=1}^{c}u_{hj}=1;\ 0<\sum_{j=1}^{n}u_{hj}<n \ \text{ and } \sum_{\mathrm{i}=1}^{m}w_i=1;\ 0\le w_i\le 1 \qquad (2)$$

The vehicle-bicycle conflicts at intersections may be divided into 5 types (see Figure 1). Based on the statistical vehicle-bicycle conflict quantities TC and the equivalent weight traffic amount of vehicle and bicycle MPCU at the Ganjiakou intersection (see Table 1), the vehicle-bicycle conflict ratio TC/MPCU is regarded as the evaluated index. Ten conflict points are regarded as the

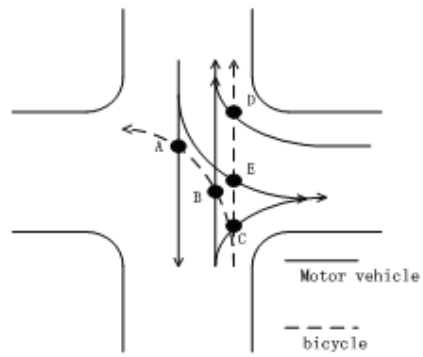

Figure 1. Vehicle-Bicycle Conflict Types

evaluation set X=(X_1、X_2、X_3……X_{10}), the conflict danger degree XK is divided into three kinds of type: lower danger, danger, higher danger.

Table 1. Vehicle-Bicycle Conflict Ratio TC / MPCU at Ganjiakou Intersection

Ganjiakou Intersection	7:30-7:50	7:50-8:10	8:10-8:30
1. North A	0.0155	0.0185	0.0312
2. North B	0.0127	0.0157	0.0097
3. North C	0.323	0.3072	0.2315
4. North D	0.753	0.2389	0.1913
5. North E	0.471	0.2253	0.2321
6. West A	0.102	0.0105	0.0061
7. West B	0.135	0.0150	0.0103
8. West C	0.461	0.3890	0.2042
9. West D	0.911	0.0795	0.0673
10. West E	0.795	0.0673	0.0541

Using Matlab, the fuzzy cluster results showed that the higher danger conflict types are 3, 4, 5, 8 (see Table 1), which indicates that the conflicts between through bicycles and right-turn vehicles on the adjacent lane are the most dangerous and representative. So the conflicts between the through bicycles and the right-turning motors are the main focus in this paper.

3 PASSING THROUGH DECISION-MAKING MODEL

Based on the collected data, the average bicycle speed is 3.47m/s and follows a normal distribution. The speed is clearly affected by the intersection type: 4.18m/s at the Fuchengmen intersection and 3.14m/s at the Ganjiakou intersection. Speed is less affected by sex of the bicyclist. The bicycle acceptable also follows a normal distribution and the average value is 2.71s (see Figure 2).

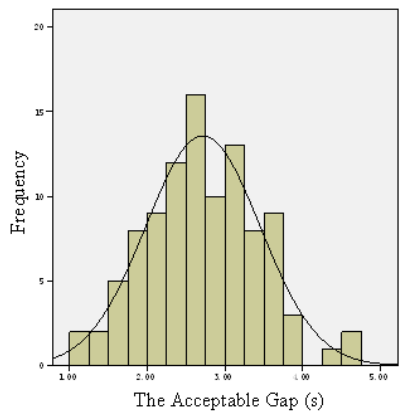

Figure 2. Distribution of the Accepted Gap

In this paper, we assume that each bicyclist independently selects the acceptable gap. Furthermore, bicycles will not affect each other. As a result, 4 factors: the front motor type, the following motor type, sex of the bicyclist, and whether the bicycle is parked or not, are selected to check the relation of the acceptable gap by the Levene's method (see Table 3). The results show that the primary factor of the acceptable gap is the following motor type; the other factors are subordinate.

Table 3. Levene's Test

Levene's Check		Cyclist sex	Front motor	Following motor	Parking or not
Equal variances test	*F* value	0.936	0.577	0.760	0.631
	P value	0.336	0.449	0.385	0.429
T test	*T* value	1.400	-0.798	0.641	-0.072
	P value	0.165	0.427	0.523	0.943

The logistic regression theory is adopted to establish the decision-making probability model. Assuming that the acceptable gap is 1 and the refused gap is 0. A hundred groups of passing through data and 44 groups of refusing data are analyzed. The acceptable Gap model of the through bicycles passing through the right-turn motors may be expressed as:

$$P = \frac{1}{1 + \frac{1}{\exp(\beta_0 + \beta_1 * v + \beta_2 * Gap + \beta_3 * l)}}. \qquad (3)$$

Here: $\beta_0, \beta_2, \beta_3, \beta_4$ are regression coefficients; Gap is the gap distance; v is the followed motor speed; l is the type of followed motor, 0 is car and 1 is truck.

Variables are imported into the model using the step regression method based on the score test. The resulting acceptable probability model can be expressed as:

$$\mathrm{P} = \frac{1}{1 + \frac{1}{\exp(1.157 - 1.233 * \mathrm{v} + 0.556 * Gap - 1.724 * l)}} \qquad (4)$$

The actual frequencies and the forecast frequencies are compared with the "Hosmer –Lemeshow" parameters which are obtained using the Pearson Method. The compared results show that the statistical parameters follow the "g-2" distributing, which indicates that the decision-making model is reasonable. The forecast results and the actual results are shown in the Table 4. The correct ratio is 76.2%, in which the correct ratio of the accepted passing through samples is 90.0% and the refused passing through samples is 44.2%. The decision-making model may well forecast the crossing behavior of through bicycles and right-turning motor vehicles on the neighbor lane.

Table 4. Classification Tab. of Gap Choice Model

		The forecasted results		
		Passing through or not		Correct ratio
		0	1	
Passing through or not	0	19	24	44.2
	1	10	90	90.0
Totally				76.2

4 MULTI-AGENT SIMULATION

In this paper, intersection traffic agent's hierarchy consists of two layers: traffic unit agent and traffic environment agent (see Figure 3). The traffic unit agent is further divided into three layers: the motor agent, the bicycle agent and the pedestrian agent. The bicycle agent and the motor agent include 6 sub-structures; each sub-structure has separated behavior and interact each other in order to simulate traffic conditions realistically.

In communicating information among sub-structures, the bicycle roadway shift decision is defined as that front bicycle's speed is lower than the following bicycle and the following bicycle's speed is lower than 50% of the maximal speed. A Bicyclists selects randomly one roadway and judges whether there are other bicycles in front of him/her. If this is not the case, a roadway shift will appear.

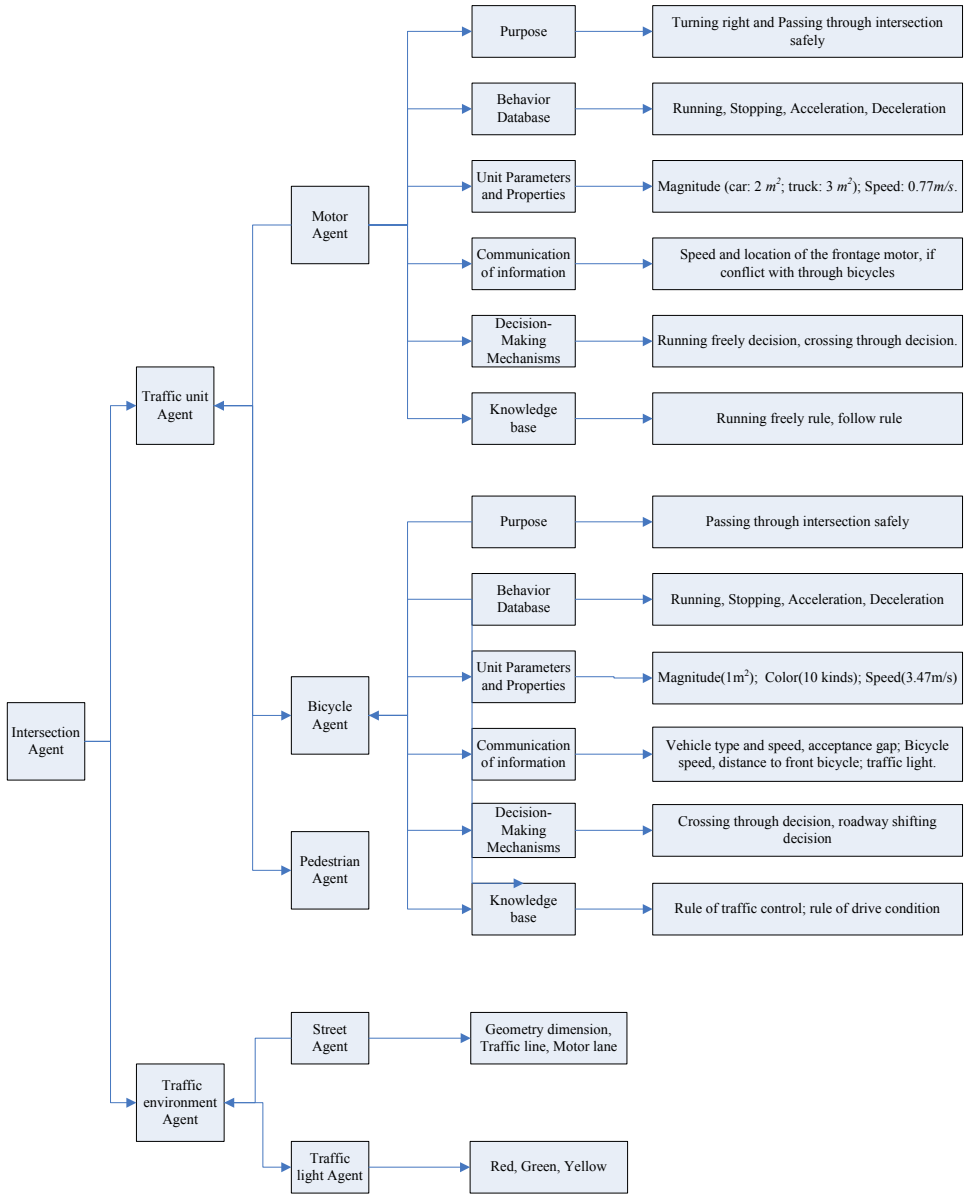

Figure 3. Structure of the intersection Agent

The bicycle passing through decision is made according to the decision-making probability model. If the probability is less than P, the bicyclist will refuse to pass through motor vehicle. Otherwise, the bicyclist will pass through.

By establishing the intersection agent model, the simulation for through bicycles passing right-turning vehicles is implemented based on the software called NetLogo (see Figure 4 for the simulation interface). The simulation interface is shown in Figure 5. In total, 109 observed samples were used to analyze the frequency distribution; the results show that the bicycle average speed is 2.77m/s, which is consistent with the former data.

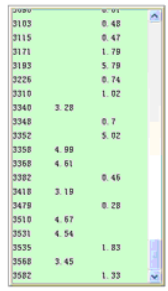

Figure 4. Simulation Interface

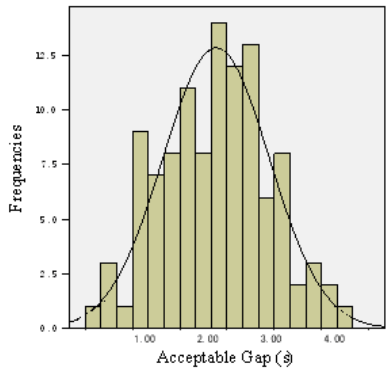

Figure 5. The Accepted Gap

5 CONCLUSIONS

(1) At intersections, bicycle speeds follow a normal distribution. The mean speed is 3.47m/s and the variation is 0.99. Intersection type plays an important role to the speed distribution. The acceptable gap also follows a normal distribution. The mean gap is $\mu = 2.71$ s and the standard deviation is $\sigma = 0.73$ .The following vehicle type plays an important roles to the acceptable gap.

(2) The decision-making model of through bicycles passing right-turn vehicles is established and validated; the forecast accuracy rate reaches 76%.

(3) The micro-simulation model for the through bicycle passing the right-turn vehicles is established based on multi-agent; the simulation results show that the model proposed in this paper works properly.

AN OPTIMIZATION MODEL FOR BUS RAPID TRANSIT

Bo Yan[1], Yonglei Jiang[1], Bin Yu[1], Zhongzhen Yang[1]
[1]College of Transport Management, Dalian Maritime University, Dalian, 116026, China; TEL/FAX (411) 8472-6756; email: yangzhongzhen@263.net

Abstract: This paper develops a new model, aiming to maximize the efficiency of bus rapid transit (BRT) system (i.e. maximize direct-through travelers on unit length of BRT route). Since the problem is NP-hard, a heuristic algorithm, based on ant colony optimization, is developed. With a numerical test from Dalian City, China, the effectiveness of the model and the algorithm is examined.

Keywords: BRT; optimization; ant colony optimization

1 Introduction

High-quality transit service is considered as an effective way to attract travelers away from private car trips toward the transit use in congested metropolitan areas. Bus Rapid Transit (BRT) is an innovative transportation system, which combines the quality of rail transit and the flexibility of buses. BRT often operates on exclusive transit ways with high-capacity and high-speed vehicles. Since many features of BRT are similar to light rail transit (LRT), BRT may be considered to be able to improve transit service through incorporating favorable operational characteristics of rail-based transit systems. Referring to rail transit route planning, BRT routes need to cover large transit demand corridors which can provide enough travelers.

Planning BRT routes is similar with arterial transit route network design. Transit network design has been an important problem in urban transportation planning. There have been many successful studies on transit network planning over the past several decades. Ceder and Wilson (1986) introduced three-step method (trip assignment, planning routes and departure interval) into the design of network of public bus routes. Hasselstrőm (1981) presented a two-step model to optimize routes and frequency simultaneously. Wang (2001) developed a model aiming to maximize direct travelers. Yang et al. (2007) presented an optimization method of public bus network, which can efficiently obtain the trade-off between route length and the number of direct travelers and improve the efficiency of optimization. Recently, some studies have been completed on BRT route planning. Bai et al. (2007) optimized the BRT routes using tabu search algorithm and tested the model and the algorithm by simulation. Fan and Pan (2007) study the application of genetic algorithm on intelligent transport systems scheduling of vehicles. Sun et al. (2007) focus on BRT headway and scheduling combination optimization with genetic algorithm. An et al. (2008) employed particle swarm optimization to solve a set of

bi-level programming models to find a feasible solution for the BRT network design problem. All the aforementioned studies stimulated us to develop a heuristic algorithm to optimize the routes of BRT.

The purpose of this paper is to extend the model of Yang et al. (2007) to design BRT routes. The objective of this study aims to maximize direct transit trip density, which is related to the direct transit demands and the length of the route. Some network optimization problems are NP-hard, which is difficult to be solved using traditional techniques. In this paper, ant colony algorithm is used to solve the optimization model.

1 Optimization Model

Among existing studies, the direct traveler approaches are practical and convenient. They aim to maximize the number of the direct travelers under the length constraint or set the route along the shortest path. Maximization of the number of direct travelers may cause the bus routes in the network to be extremely long, whereas the latter limits the number of alternative routes and then damages the optimizing quality. Moreover, in both cases mentioned above, the route directions might not coincide with travelers flow directions. To overcome these problems, we choose the maximum direct traveler density as the optimal objective, that is, the maximum number of travelers per unit length. As a bus route is composed of the stops and the road segments it covers, the optimization problem is hereby equivalent to finding the corresponding stops and road segments. Here, N denotes the stop collection; and A denotes the collection of road segments. All of the alternative bus routes, the sub collections of A, are denoted as S = {SOD}. Then, if not considering the loop route, the bus network optimization model is as follows:

$$\max \quad D_{od} = \frac{P_{od}}{L_{od}}$$

$$s.t. \quad \begin{cases} L_{min} \le L_{od} \le L_{max} \\ od \in F \\ q_{od}^{x} \le 1.5 \\ m \ne n \qquad \forall m, n \in S_{od} \\ \forall l_{gh} > 0.8km \end{cases} \tag{1}$$

where

$$x_{ij} = \begin{cases} 1 & \text{i, j are consecutive on Planning BRT routes;} \\ 0 & \text{else.} \end{cases}$$

D_{od} = direct traveler density of the route starting from O and ending at D;

o= origin stops;

d=destination stops;

F=collection of origin and destination stops;

pi j = the number of direct travelers between stops i and j

$P_{od} = \sum_{g \in N} \sum_{h \in N} p_{gh} x_{gh}$ =the number of direct travelers from original stop i to destination stop j;

l_{gh} = length of the road section between g and h, usually l_{gh}=0.8~1.2km;

$L_{od} = \sum_{g \in N} \sum_{h \in N} \Delta_{gh} l_{gh} x_{gh}$ =if the length of BRT routes is too short, it will add the turnover time and affect the speed advantage of BRT. Hence, the length constraint of BRT routes is relaxed as $10km \le L_{od} \le 25km$;

$$\Delta_{gh} = \begin{cases} 1 & \text{g, h are consecutive on Planning BRT routes;} \\ 0 & \text{else.} \end{cases}$$

q_{od}^{x} = nonlinear rate, because usually buses with large capacity is adopted in BRT routes, if the value of nonlinear rate is too large, the operational speed will be affected.

m, n= the middle stops of candidate routes. This constraint aims to control the route trend, which means one route should pass through the one stop twice or more.

2 Algorithm Design

2.1 *Ant Colony Optimization introduction*

The ant colony optimization (ACO)algorithm is a probabilistic technique for solving computational problems which can be reduced to finding good paths through graphs. ACO was firstly introduced by Dorigo (1992) and has been used to find the solutions for many difficult combinatorial optimization problems. In ACO, artificial ants build solutions by moving on the problem graph. During the process they deposit artificial pheromone on the graph in such a way that future artificial ants can build better solutions. Due to positive feedback rule, the ACO possesses powerful ability in searching better solutions for combinatorial optimization problems.

2.2 *Transition rules*

The moving of ants is according to certain rules instead of unconscious. First, ants can only move through feasible neighbor nodes, which suggest that many nodes are unavailable for the ant moving. For example, the nodes which have been visited are unavailable in the optimization problem of BRT routes. The transition rules are as follow: the ant chooses available nodes according to the probability of each available node. The method of choosing probability of node j for the ant k at the node i is as follows:

$$P_{ij}(k) = \begin{cases} \dfrac{\tau_{ij}^{\alpha} \times \eta_{ij}^{\beta}}{\sum_{h \notin tabu_k} \tau_{ih}^{\alpha} \times \eta_{ih}^{\beta}} & j \notin tabu_k \\ 0 & others \end{cases} \tag{2}$$

Here, ： the intensity of which reflects the prior experience of the ants at this searching, and also means the total pheromone which cumulated during the running process of the ants; ： visibility, the value of which is obtained by solving a greedy

algorithm of an original problem; it only considers the local and encourages the ants to search for the local optimized routes; , : the pheromone heuristic factor and the visibility heuristic factor; $tabu_k$: the setting of unavailable nodes of the ant k.

2.3 *Pheromone Refreshing Strategy*

According to the transition rules, an ant can construct a solution of an original problem. For example, a solution means that the ant has searched a BRT route between original node and destination one. Then, the quantity of pheromone of each segment will be refreshed by the formula (3):

$$\tau_{ij}(t+1) = \rho \times \tau_{ij}(t) + \sum_{k=1}^{p} \Delta \tau_{ij}^{k} \tag{3}$$

Where is the remaining coefficient of pheromone (0, 1); p: the scale of ants; $\Delta\tau_{ij}^{k}$: The pheromone increment when the ant k is on line (i, j) in one loop.

To improve the efficiency of updating pheromone, ant-weight strategy (Yang et al. ,2007) is used to compute the pheromone increment, which can integrate the global and local information of the search. Specifically, the updating strategy of the increased pheromone is as follow:

$$\Delta\tau_{ij}^{k} = \begin{cases} \dfrac{Q}{f^{k}} \times \dfrac{f^{k} - f_{ij}}{(n-2)f^{k}} & \text{if link}(i,j) \text{ on the } k_{th} \text{ route} \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

where Q= a constant, f^{k} = the direct traveler density of route k, f_{ij} = the direct traveler density on link (i, j), n = the number of the stops along route k (n>2).

The strategy for updating the increased pheromone consists of two components: the first is global pheromone increment Q/f^{k} related to the direct traveler density of route k; and the second one is local pheromone increment $(f^{k} - f_{ij})/((n-2)f^{k})$ based on the contribution of link (i, j) to route k. Thus, the update strategy ensures that the assigned pheromone increments are directly proportional to the direct traveler density. The more favorable of the link/route, the more pheromone increment is allocated to, and the more accurate directive information is provided to the later search. Meanwhile, by adjusting the pheromone assigning method for the links of current optimal path automatically, the algorithm can facilitate more delicate searches in the next cycle in a more favorable area. This helps to improve the learning capacity of the algorithm from past searches, and enhance the efficiency.

3 Case Studies

In order to examine the feasibility and validity of our model and algorithm, the main urban zone of Dalian City is used in our case study. The area of Dalian City is 180 km^2 with 89 bus routes and 3004 bus stops. ACO is implemented to search the routes with largest direct traveler density for BRT routes and the result is shown in Figure 1.

To validate the designed BRT route, transit passenger assignment is

implemented on the networks with or without BRT routes, respectively. The result is shown in Figures 2 and 3.

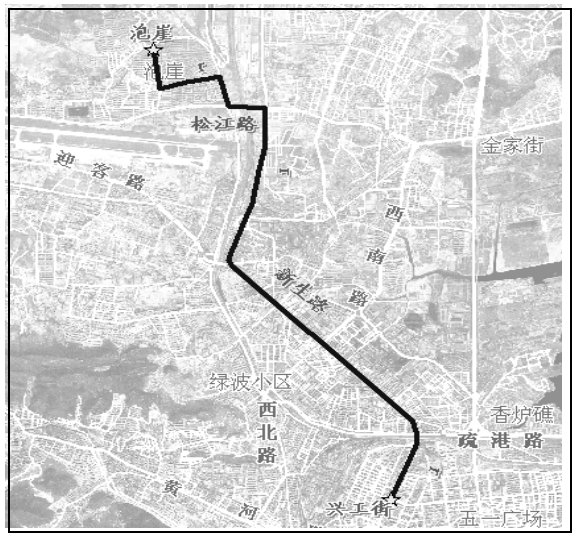

Figure 1. the Resulting BRT Routes

Figure 2. Distribution Result without BRT Routes

Figure 3. Distribution Result with BRT Routes

Because of its advantages such as the speediness, large capacity and so on, travelers flow is collected on the BRT route; and the flow of the bus routes near the BRT route is decreased significantly. It is necessary to change the public bus routes in the service area of BRT routes. With BRT routes, the total time of trip of residents decreases from 10.08 to 9.98. This is because that the BRT route is built along the public corridor, where the dense travelers flow is collected. Moreover, it employs public special bus lane to ensure fast operating speed. All these attribute to the decreased trip time.

4 Conclusions

This paper presents an optimization model of BRT routes which aims to maximize the density of direct travelers flow. This model has the objectives of minimizing transfer times and maximizing traveler flow of unit, by satisfying the constraints of the length of routes and nonlinear coefficient. An ACO based on the coarse-grain model is designed to solve the model. Finally the validity of the model and algorithm is examined in the case study. The result indicates that the model developed here can be used to optimize the routes of BRT effectively.

ABSTRACT

Due to the drawbacks of existing trip production forecasting model, this paper develops a model of mixed land use and trip production using back-propagation neural network, which has the advantages of non-linear relation mapping. In the first place, contemporary researches on the relationship between mixed land use and trip production in China and oversea countries are reviewed to provide helpful groundwork. Then, based on the theory of neural network, the major mixed land-use factors and network structure are proposed. Furthermore, the model is verified and applied using existing data. The result shows that the forecasting model has relative high precision, which proves its good maneuverability as well as theoretical advantages. At last, the future research directions are discussed.

Key Words: mixed land use; land use index; trip production; BP neural network

INTRODUCTION

In recent years, academics and engineers worldwide have paid special attention on traffic demand forecasting as the basis and core content of transportation planning. The traditional travel demand forecasting method, well known as the four-stage planning method, is composed of trip production, distribution, model split and traffic assignment. In this method, the reliability of the trip production forecasting method, the first stage of the four-stage method, will directly affect the precision of the following three stages (Zheng et al. 2007). In addition, urban land use and traffic are linked and mutually affect each other (Yang et al. 2006). From the viewpoint of transportation planning, traffic demand results from land use and different land-use patterns determine trip production, forms of distribution, and to some extent, transportation structure. The capacity of road facilities cannot satisfy demand when land use is unreasonable or exploited too intensely. On the other hand, from the perspective of land use, transportation development would change urban structure and land-use patterns (Chen et al. 2004; Zheng et al. 2007).

Contemporary researches on the bearing between urban mixed land use and trip production in China and oversea countries could be divided into two categories, namely the mathematical models and artificial experience models (Lu, et al., 2008). Mathematical models, such as the trip generation rate models, classification generation rate models, regression analysis models, and classification regression analysis models, forecast trip production by setting up a mathematical model to represent the correlation between land-use influence factors and transportation (Badoe and Miller, 2000; Chen, et al., 2004; Yang, et al., 2006). However, the issues of mathematical models lie in: (1) the process is too complicated since practical operation requires large amounts of data; (2) the ways to calibrate weight parameters cannot be unified; and (3) the accuracy of prediction is limited.

Furthermore, the artificial neural network method, which has been successfully applied in various fields and Back-Propagation network (for short, BP network) in particular, is the most suitable method to predict trip production among other network models (Dougherty, 1995). The advantage of BP network in trip production forecasting include: (1) its non-linear mapping between input and output aggregate with a simple realization process; (2) no need to be aware of the internal structure of the system; (3) what is necessary to do is to simulate the system by studying existent samples; and (4) it can significantly cut the precision caused by inaccuracy of data and parameters (Pei et al. 2004). Meanwhile, trip production of mixed land use has its own characteristics and there are disparities in different land-use combinations. Hence, BP network as a simple and high precision method can be used in this field.

The work demonstrated in this paper starts with the discussion of the major mixed land-use factors. Then, a model of mixed land use and trip production is developed using the BP network. In summary, this paper is aimed to improve the performance of traditional prediction methods, to simplify the planning process and to enhance the prediction efficiency and accuracy of original models.

MIXED LAND-USE INDICES

The chief land-use indices factors and social economical character factors are the main elements that impact trip production (Lu et al. 2008). In a mixed land use area, the former includes different characteristics and combinations of land use, and the latter includes level of population, level of economic development, accessibility of transportation, vehicle population, etc (Clay et al. 2006). This paper mainly discusses major mixed land-use indices (e.g., the characteristics of land use, the intensity of land exploiting, the degree of mixed land use and the location factor), since they are the main influential factors of trip production and all other indices could be indicated by them.

Character of land use. Land use with different characteristics can lead to different trip production patterns (Yang et al. 2006). For instance, trip production patterns deriving from ten major categories of land-use forms in China vary from

each other. Characteristics of land use can be digitized as the indicator of functional community, which is described by the largest proportion of land area code of the community.

Intensity of land exploiting. The intensity of land exploiting directly determines the volume that urban traffic system could support. Regardless of the characteristics land use (e.g., residence or commercial space), it is believed that the higher the intensity is, or the greater the occupancy is, the larger travel demand would be generated (Chen et al. 2004).

Floor area ratio (FAR), also known as building density, is an important technology index that reflects intensity of land exploiting. FAR equals the building area divided by land area. It is widely believed that the greater the FAR the more intensive the land use is.

Degree of mixed land use. This index refers to a particular region with a variety of land uses. Trip production of a mixed land use community should not be taken as the summation of the productions from every single characteristic of land use simply because mixed land use has its own characteristics and varies by different land-use combinations. Therefore, this paper uses diversity index (H), dominance index (D), and evenness index (E) referred to definition in biology to describe this index as follows.

(1) Diversity index H describes the quantity and complexity of land use types and also reflects the proportion of each type. This index will increase when the differences between the ratios of land-use types are minimal. The formation of Shannon-Weiner diversity index function, which is a commonly used expression, is stated as follows:

$$H=-\sum_{k=1}^{n} P_k \ln(P_k) \tag{1}$$

Where: P_k represents the proportion of kth type of land from the total area; n represents number of types. For a given n, diversity index number will reach maximum as $H_{max}=\ln(n)$; if the proportion of each type is equal, $P_k=1/n$.

(2) Dominance index D demonstrates discrepancy of maximum and actual value of diversity index, and illustrates the degree of one or several other types that dominate the whole extent. The formation, Simpson's index function, is as follows:

$$D = H_{max} + \sum_{k=1}^{n} P_k \ln(P_k) \tag{2}$$

(3) Evenness index E, also known as Pielou index, describes even degree of distribution of types and the formation is as follows:

$$E = \frac{H}{H_{max}} \tag{3}$$

Location factor. The advantages of urban land use largely depend on the

location characteristics. Since travel will be greatly affected by it, location factor index is recommended to reflect the impact (Shi et al. 2005). Location factor is composed of the aggregated economic benefits, transport accessibility and the standard of infrastructure and environmental quality. Therefore, in the process of evaluation, we should consider the geographical locations, the level of economic development and the transport accessibility of a mixed land use area as whether it empnasizes on the development of industrial zones or the approach to the edge of bloc, highways, large shopping malls, hospitals, schools, tourist attractions, car parks, public transportation hub, the station, railway stations, etc., and then give different levels to communities.

Take Beijing as an example, areas that approach to "two axis, two band and multi-center "can be digitized as 3; area that approach to six high-ranking industrial function districts, including Zhongguancun Technology Zone, CBD, Beijing Economic Technological Development Area (Yizhuang), Shunyi Near the Airport Industrial Park, the Olympic Center Area and Beijing Financial Street, can be digitized as 2; area that approach to hospitals, shopping malls, parks and parking lots can be digitized as1; and others as 0.

MODELLING

Model structure. In order to develop a model with both operability and theoretical value, this paper sets up a three-layer BP network model which is a one-way transmission of forward network including input, hidden and output layers (Shmueli et al. 1996).

Based on the analysis above, the indicators of functional community, FAR, diversification index (H), dominance index (D), evenness index (E) and location factor are selected as input neurons.

In the process of model development, the symbole p, which is defined as the number of neurons in hidden layer, is crux since it will directly affect the effectiveness of the model, but there's no accurate theoretical or methodological explanatation. Some researchers use formations: $\sum_{i=0}^{n} c_p^i \rangle k$ or $p = \sqrt{n+q} + a$, where n represents the number of input neurons, q represents the number of output neurons and a represents a constant between 1 and 10, to calculate p (Feisi Technology Research and Development Center 2005).

Output neurons are trip production of community in morning and evening peak hours. The corresponding proposed analysis model is shown as Figure 1.

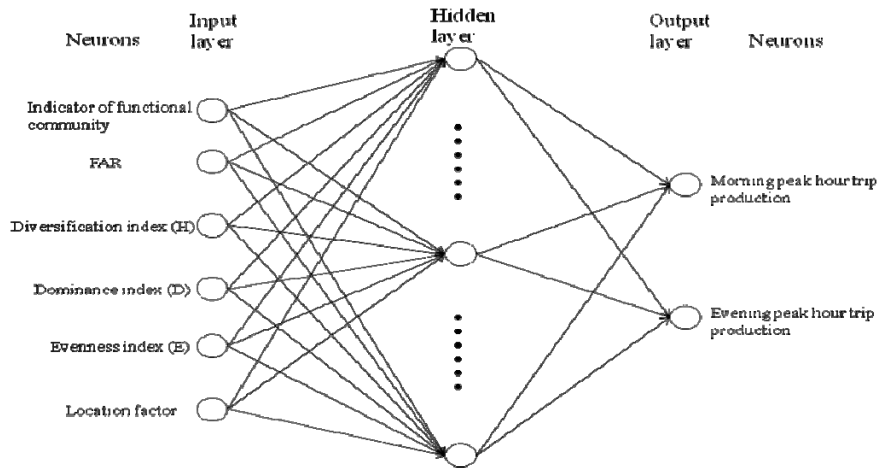

Figure 1. Model of mixed land use and trip production by proposed model

BP neural network model can be realized through many programs. This paper uses toolbox of Matlab to accomplish it.

Firstly, the model is trained by using the 30 existing samples of mixed land use areas in Beijing, which include residence land use Wangjing region, business land use CBD, industrial land use Jiuxianqiao and foreign affairs land use embassy region since these blocks are typical representatives of mixed land use.

Secondly, select 50% of data randomly as training samples and the remaining 50% as test samples. Set the number of input neurons to 6, training frequency to 10000, training error goal to 0.1, and suitable number of hidden layer to 5. Training error curve is shown in Figure 2.

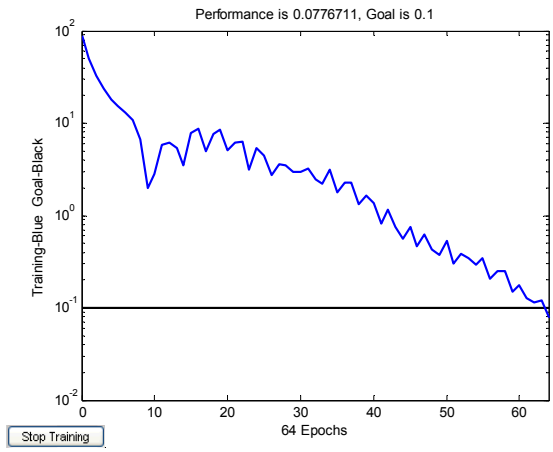

Figure 2. Training error curve of the BP neural network

According to practical operation, the speed of convergence for this model is relative fast. The model is repeatedly trained and modified until the precision results meet the requirement. The output and the estimation errors are shown in Table 1. The results indicate that the prediction error of the trip productions in mornings and evenings are 1.86% and 2.82% respectively, which is acceptable.

Table 1. Model Application Results

Peak hours	Model output (frequency/hour)	Actual value (frequency/hour)	Absolute error (frequency/hour)	Relative error (%)
7:00-8:00	2576	2625	-49	1.86
18:00-19:00	2207	2146	61	2.82

CONCLUSION

The bearing between mixed land use and trip production is a complicated non-linear mapping which BP network is skilled in. The work in this paper analyzes the indices that impact trip production directly and summarizes the major indices that are relevant to mixed land-use ones. Meanwhile, the model is developed to integrate the advantages of BP network and correlation between mixed land use and trip production. According to the characteristics of neural networks, there are some improvable aspects in this paper. One of the most important respects lies in the black-box operation of network that restrains the modification of hidden layer number, training algorithm and studying frequency. Therefore, future study will need to focus on ameliorating model structure and parameters automatically according to the input parameters and output results in order to improve operability and precision of the model.

ABSTRACT

Travel time reliability is considered as an important index on the reliability of a road network. The objective of this article is to study the impact of ice and snowfall on the travel time reliability. For this purpose, the link travel time ISB-BPR (Ice and Snowfall Based- Bureau of Public Roads) model is proposed, which is based on the conventional BPR (Bureau of Public Roads) model and scale functions are added to the corresponding parameters of BPR. To follow the characteristics of route choice, SUE (stochastic user equilibrium) is adopted in this study. We develop an assessment methodology, which integrates sensitivity analysis of SUE and Monte Carlo simulation to evaluate the travel time reliability. The ISB-BPR model and the algorithm are applied to a hypothetical small road network and results are presented. The results show that travel time level of service and intensity of ice and snowfall have the most significant impact on the travel time reliability.

Keywords: road network, travel time reliability, ice and snowfall, ISB-BPR model

INTRODUCTION

Road network has always been regarded as the lifeline of human beings. Especially the recent earthquakes in Sichuan province and the ice and snowfall disaster in the south of China are vivid reminders of the severe impacts on the transportation network and people life. Road network stability and reliability is a subject of great practical importance to traffic planners and engineers involved in network design and traffic management and control（Al-Deek and Emam, 2006）. Travel time reliability is one of the important parameters of road network reliability. It plays an increasingly important role in effectively describing the traffic operation performance and environmental protection concerns in urban areas, as expressed by the traffic flows, LOS and other attributes (Chen et al. 2002, Chen and Skabardonis, 2003). The travel time reliability information may be spread to travelers and commuters to help them decide on departure time and provide them with possible optimal alternative routes.

At present, the reliability research is mainly directed against the day to day recurrent traffic congestion. A classic example of nonrecurring congestion study is the network reliability under adverse weather conditions of rains (Lam et al. 2008). Although numerous accomplishments have been achieved in this area, so far, few studies have focused on road network reliability under ice and snowfall conditions, which will be studied in this research.

LINK TRAVEL TIME MODEL

In previous research, the BPR model was widely used in travel time reliability estimation. With the influence of ice and snowfall, the visibility and pavement friction will be reduced. As a result, the BPR model is not applicable to this condition. To calibrate and capture the actual functional relationship between the adverse effects and link travel time, a new link travel time model is proposed on the basis of the conventional BPR model. This is named as Ice and Snowfall Based-Bureau of Public Roads (ISB-BPR) model. It can be written as:

$$T_i(x_i, I) = g_{it}(I)t_i + \beta t_i(\frac{x_i}{g_{iC}(I)C_i})^n .$$

Here x_i and C_i , respectively, are the traffic demand and capacity on link i; t_i is the free-flow travel time on link i, which is a deterministic parameter; T_i is the travel time on link i; β and n are parameters in the conventional BPR function; $g_{it}(I)$ and $g_{iC}(I)$ are the scaling functions on free-flow travel time and link capacity, respectively, where *I* denotes the intensity of ice and snowfall. The scaling functions should satisfy the following conditions:

(1) $g_{it}(I)$ is a monotonous increasing function;

(2) $g_{iC}(I)$ is a monotonous decreasing function;

(3) When $g_{it}(I) = 1$ and $g_{iC}(I) = 1$ implying that there is no ice and snowfall, ISB-BPR will be BPR.

In this study, the ISB-BPR model is adopted. Since C_i is a random variable, so is T_i . For simplicity, let $g'_{iC}(I) = 1/\ g_{ic}$, $g_{it}(I)$ and $g'_{iC}(I)$ follow normal distributions expressed as:

$$g_{it}(I) \sim N(\mu_i^t, (\delta_i^t)^2)$$
$$g'_{iC}(I) \sim N(\mu_i^c, (\delta_i^c)^2)$$

It should be pointed out the actual distributions should be calibrated by observed field traffic data. The link travel time forms a probability distribution. Its mean can be determined as:

$$E[T_i] = t_i E[g_{it}(I)] + \beta t_i x_i^n E[g'_{ic}(I)]E\left(\frac{1}{c_i^n}\right)$$

The link capacity of each link forms different probability distributions, which can be obtained by Mellin transformation. In this study, the link capacity adopts normal distribution. The mean of the travel time on link *a* can be determined as:

$$E[T_i] = t_i \mu_i^t + \beta t_i x_i^n \mu_i^c \frac{\left(1-\theta_i^{1-n}\right)}{\overline{c}_i^n (1-\theta_i)(1-n)}, n \neq 1,$$

$$E[T_i] = t_i \mu_i^t + \beta t_i x_i \mu_i^c \frac{\ln \theta_i^{-1}}{\overline{c}_i (1-\theta_i)}, n = 1.$$

Here θ_i denotes the capacity use efficiency of link *i* on the worst ice and snowfall

conditions, $0 < \theta_i < 1$. In the theoretical research, the link capacity lower bound is $\theta_i \bar{c}_i$. The value of θ_i is different for each link; $\bar{c}_i$ is the design capacity of link *i*.

TRAVEL TIME RELIABILITY

Link Travel Time Reliability. Travel time reliability is the probability that a trip will arrive at its destination within a given period at a certain level of service. In this article, link travel time reliability is defined as the probability that the expected travel time at degraded capacity caused by ice and snowfall is less than the link free-flow travel time plus an acceptable threshold. It can be written as:

$$R(T_i) = P(T_i < t_i(1+\delta))$$

Where, δ is acceptable travel time threshold. For example, the parameter β in the ISB-BPR function is 0.1, hence the upper travel time threshold will be the free-flow travel time plus the acceptable time or 110% of the free flow travel time.

Path Travel Time Reliability. The road network is composed of links. Its reliability depends on all links reliability and how they are connected. For example, the following statement is false: "If all of the links in a system have 95% reliability at a given time, then the reliability of the system is 95% for that time."（Al-Deek and Emam, 2006）.

Generally, path is composed of links with the connection in series. Reliability of links connected in series can be written as:

$$P_k = \prod_{i \in A} P_i \quad , \quad \forall k \in K_{st}$$

Where , A is the links set of path k between OD pair *st.* In fact, OD pair *st* has one more paths; P_i and P_k, respectively, are the travel time reliability of link *i* and path *k*. If there are *m* paths between OD pair *st,* then OD pair reliability can be written as:

$$P_{st} = 1 - \prod_{k=1}^{m} (1 - P_k)$$

Where , P_{st} is the travel time reliability of OD pair *st*.

TRAFFIC ASSIGNMENT MODEL

As the network complexity and randomness of the traffic conditions , road users can not be fully aware of the real-time information. The path choice is stochastic. Consequently, Stochastic User Equilibrium (SUE) may be applied to modeling the traffic assignment as follows:

$$\min Z(f) = \frac{1}{\theta} \sum_{s,t} \sum_{k} f_k^{st} \ln\left(f_k^{st}\right) + \sum_{i \in A} \int_0^{x_i} t_i(w, y_i) dw$$

$$s.t. \qquad \sum_k f_k^{st} = q_{st}, \forall s, t$$

$$f_k^{st} \geq 0, \forall s, t$$

$$x_i = \sum_{s,t} \sum_{k} f_k^{st} \cdot \delta_{i,k}^{st}, \forall i$$

Where, k is the set of paths; f_k^{st} is the traffic volume on path k between OD

pair st; A is the set of links; x_i is the traffic volume on link i;

$$\delta_{i,k}^{st} = \begin{cases} 1 & if \quad i \quad belongs \quad to\ path \quad k \\ 0 & otherwise \end{cases}$$

SOLUTION ALGORITHM

Sensibility analysis and Monte Carlo simulation are adopted in this paper. Sensibility analysis is used to solve SUE. Monte Carlo as a test tool is used to simulate the traffic condition and calculate the reliability. The link capacity C_i and demand pattern parameters q_{st} are all random variables. Due to the absence of observed field data, it is assumed that they all follow the normal distributions. Here, the random variety generation (RVG) proposed by Chang (Chang et al. 1994) is used to generate the distribution. The flowchart of the algorithm is shown in figure 1.

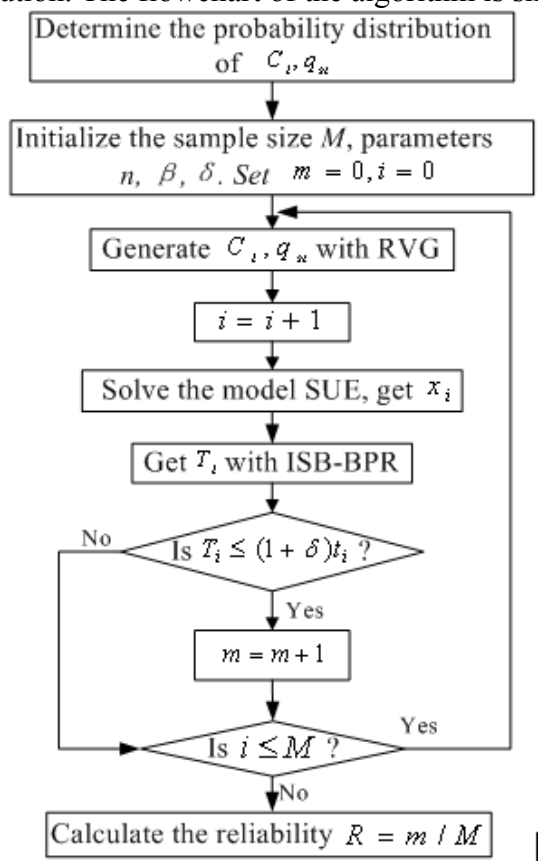

Figure 1. The flowchart of algorithm

NUMERICAL EXAMPLE

Simulation Settings. The purposes of the numerical example are to illustrate the ice and snowfall effects on road reliability and the application of the proposed model and solution algorithm. An example of a small hypothetical road network is studied as shown in figure 2. This network consists of four zones, six nodes and eight links, where zones 1, 2 are trip origin zones and zones 5, 6 are destination ones. The link data is shown in table 1. The forecast levels of hourly average snowfall intensity

are: light snowfall ($\leq 2.4mm/24hour$), normal snowfall ($\leq 4.9mm/24hour$), amber snowfall ($\leq 9.9mm/24hour$) and red snowfall ($\geq 10.0mm/24hour$). Therefore, the snowfall intensity may be assumed as depth of snowfall. The base traffic demands are respectively $q_{15}=20$ pcu/min, $q_{16}=30$ pcu/min, $q_{25}=20$ pcu/min and $q_{26}=20$ pcu/min. The link travel times are calculated from the ISB-BPR formula with $\beta=0.15, n=4$.

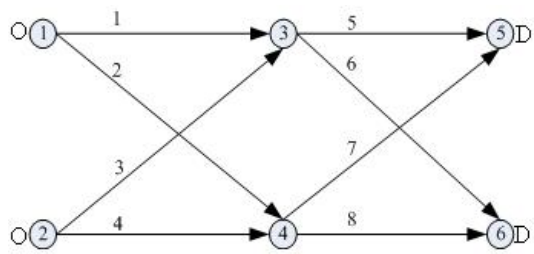

Figure 2. The test road network

Table 1. The link data of network

Link	t_i	C_i	$g_{it}(I)$	$g_{iC}(I)$
1	7	45	exp(0.09I)	exp(-0.04I)
2	8	45	exp(0.09I)	exp(-0.04I)
3	8	45	exp(0.09I)	exp(-0.04I)
4	7	45	exp(0.09I)	exp(-0.04I)
5	8	45	exp(0.09I)	exp(-0.04I)
6	9	45	exp(0.09I)	exp(-0.04I)
7	9	45	exp(0.09I)	exp(-0.04I)
8	8	45	exp(0.09I)	exp(-0.04I)

Monte Carlo simulation method and the software of Matlab7.0 are used to develop a procedure to estimate the reliability of travel time under different level of service, traffic demand and link capacities degradation. The procedure is shown in Figure 1.

Simulation Results and Analysis. In simulation, we assume that random variables c_i and q_{st} follow norm distributions. Table 2 and table 3 show that the estimated means and standard deviations of random variable resulting from the 4000 Monte Carlo simulations are very close to the theoretical values.

Table 2. Statistical value of capacities

Link	Theoretical		Estimate	
	Mean	Std.	Mean	Std.
1	45	8	45.0698	8.0321
2	45	8	44.9471	7.9864
3	45	8	45.1261	7.9646
4	45	8	44.9801	8.0932
5	45	8	45.0429	8.0165
6	45	8	44.9714	8.0619
7	45	8	45.1254	8.0441
8	45	8	44.9953	7.9269

Table3. Statistical value of OD demand

OD pair	Theoretical		Estimate	
	Mean	Std.	Mean	Std.
1-5	20	5	20.0292	4.9496
1-6	30	5	29.9282	5.0449
2-5	20	5	20.1187	4.9907
2-6	30	5	29.9233	4.9793

To illustrate the effects of level of services on the reliability, the following scenarios are simulated. For simplicity, we set the snowfall intensity $I=2.4$. Due to

space limitations, only portions of the tables are listed here. Table 4 is the reliability of link 1 at different service levels of travel times. Table 5 is the reliability of OD pair 1-5.

Table 4. Reliability of link 1 at different δ

δ	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
R	0	0	0.7610	0.9460	0.9765	0.9898	0.9938	0.9965	0.9965	0.9968

Table 5. Reliability of OD 1-5 at different δ

δ	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
R	0	0	0.9563	0.9980	0.9997	0.9999	1.0000	1.0000	1.0000	1.0000

To illustrate the effect of the snowfall intensity on the reliability, four scenarios of OD pair 1-6 under different snowfall intensities are simulated and the results are shown in Figure 3. From the figure, it can be seen that both travel time level of service and snowfall intensity are important factors in reliability analysis of a road network. The higher the snowfall intensity, the lower the travel time reliability. With the decrease of travel time requirements (i.e. δ increases), the reliability becomes higher. On the other hand, higher service levels result in lower reliability.

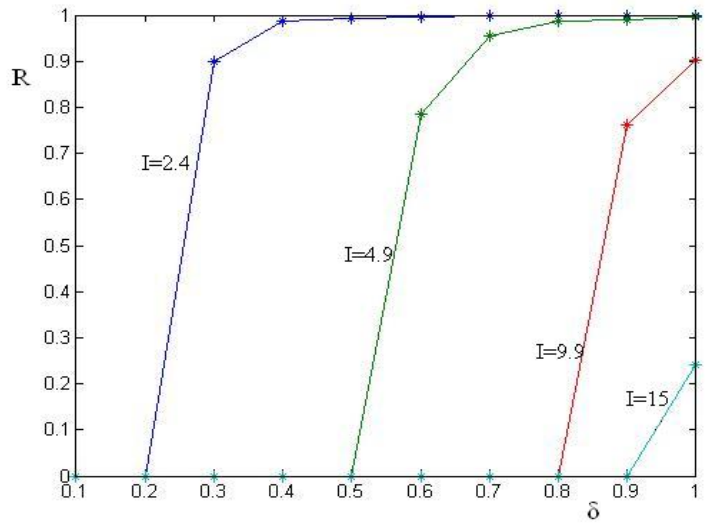

Figure 3. The effect of the snowfall intensity on the travel time reliability

CONCLUSIONS

This paper proposed the link travel time model of Ice and Snow Based- Bureau of Public Roads (ISB-BPR) model, which is based on the classical Bureau of Public Roads (BPR) model. SUE is used for the traffic assignment. We developed an assessment methodology, which integrates sensitivity analysis of SUE and Monte Carlo simulation to evaluate the travel time reliability. A numerical case study was also provided to demonstrate the practicality of the proposed model and the efficiency of the solution algorithm. Although only a small size road network was tested and normal probability distributions were adopted in this paper, the method has potentials to be extended to large-scale networks and other adverse weather conditions. It is useful for the planning and performance improvements of a road network.

ABSTRACT

Time series has already been widely utilized in the field of traffic flow prediction from the viewpoints of both theoretical exploration and practical implementation; however, the current research mostly limited to the one-dimensional time series and single section predictions. The objective of this paper is to use the multi-dimensional time series to forecast the multi-section short-term traffic flow. The correlation analysis of the multi-section traffic flow parameters (e.g. traffic volume) is firstly conducted to identify several sections with high correlation. Then, these road sections are treated as a whole to perform the threshold regression multi-dimensional time series short-term traffic flow forecasting. Finally, Comparative analysis between the multi-section and single section (ARIMA model) scenarios is presented to demonstrate the efficacy and robustness of the proposed methodology. Computational results indicate that applying the multi-dimensional time series to forecast the multi-section short-term traffic flow is more precise and robust than the single section approach.

KEY WORDS: Short-term Traffic Flow Prediction; Multi-Dimensional Time Series; Multi-section; Correlation Analysis; Threshold Regression

1 INTRODUCTION

Short-term traffic flow prediction is the key of the ITS, and it is also the major foundation of the traffic information service, traffic control and induction. While the current research of short-term traffic flow prediction is mostly focused on the filed of single-section, the research on the multi-section shot-term traffic flow prediction is very little involved. Many traffic detectors are installed on the highway and urban expressway, which can obtain the real time traffic information. Applying the dynamic analysis technology to the history and real-time data for the quick analysis, real-time prediction and judgment, it can improve the effectiveness of traffic control and induction. All these information can supply strong technical support for the traffic information service, travel induction, traffic incident detection, traffic management and the remission of traffic congestion of highway and urban expressway (Yiannis Kamarianakis et al. 2005). Therefore, the multi-section research on the short-term traffic prediction is of much practical significance. This paper is mainly on utilizing the multi-dimensional time series to forecast the multi-section short-term traffic flow.

2 TRAFFIC FLOW DATA CORRELATION ANALYSIS

Before the prediction, we utilize the correlation analysis to identify the study object of multi-section. The main propose of correlation analysis is to obtain the correlation degree of the multi-section's traffic data. According to the correlation degree, some of sections which have the relative strong correlation degree are divided into the same group. As a result, the whole road sections are divided into several groups. This paper introduces a method which is called Multidimensional Scaling (MDS) to analysis the multi-section data (Zhu Jianping et al. 2006).

2.1 The fundamental principle of MDS

The problem which MDS can be solved is following: Identify the expression in the low dimension space when the n objects' mutual similarity (or distance) is given. In order to minimize the change brought by the dimension reduction, the new expression should be "matching in gross". Every object in the multi-dimension space is a point, so the distance and similarity of the points are highly similar. That is to say two similar objects in the multi-dimension space have the relative closer distance; otherwise the dissimilar have further distance.

2.2 The application of MDS in correlation analysis of multi-section traffic flow data

In order to make the correlation analysis more accurate, it is essential to do some pretreatment for the raw data (identification, rejecting and restoration of error data), and then we obtain the processed data of Remote Traffic Microwave Sensor (RTMS) from RT008 to RT013 during the October 15th 2007 to October 29th 2007 between 7:30 ~ 8:30 interval 5-minute. The sections which are installed the RTMS are marked as Section 1, Section2,…,Section 6, which are shown in the **Figure 1**.

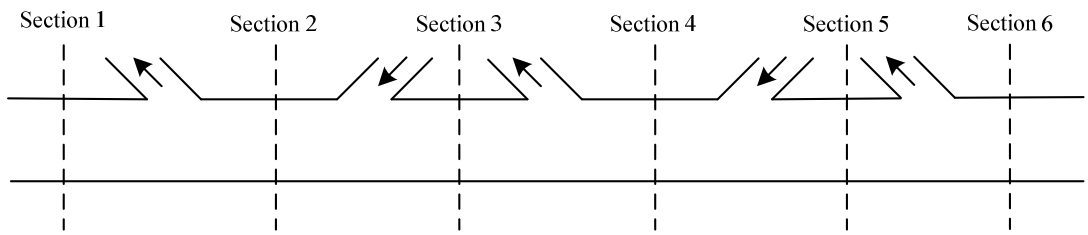

Figure 1. Chart of Road Cross-sections Where Traffic Sensors Locate

As the data of 6 sensors we get is during the 15 days, so firstly average the data of peak hour of the 15 days, thus we get the average value of the 15 days' value in peak hour. Utilizing these average value, the correlation degree of every section can be calculated, the larger of the degree, the stronger of the correlation. The original data matrix composed by these correlation degree can be adapted the MDS to make further study.

With the help of Multidimensional Scaling tool box in the software of SPSS, we can analyze the 6 sections' data with the method of MDS to determine their relevance. Confined to article length constraints, only two-dimensional perceptual mapping (coordinates perceptual mapping) is shown in **Figure 2**.,where Case1，case2，…，case6 are Section 1, Section2, …Section 6 respectively.

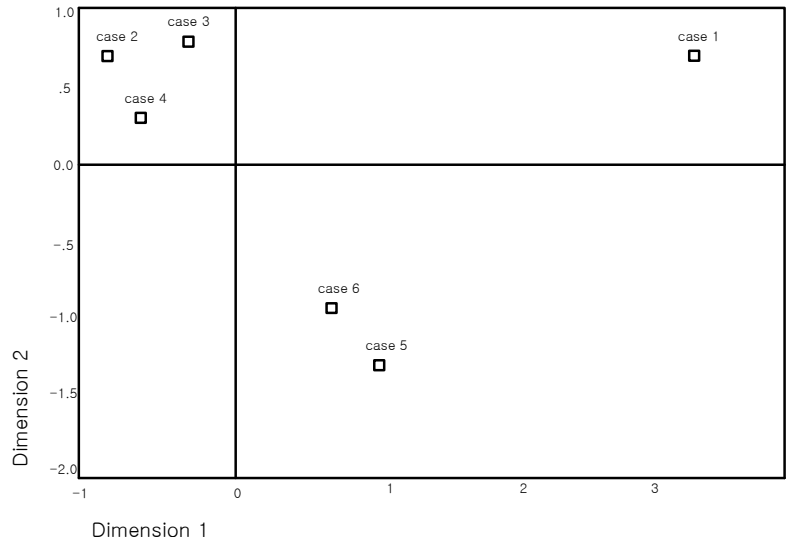

Figure 2. Derived Stimulus Configuration of Traffic Flow of 6 Road Cross-sections

From the figure above we can see that, among these 6 Sections, Section 2, Section 3, Section 4 are in the first quadrant, and the distance between each other is close, therefore, they will fall into one category, as a whole to be studied; Section 1 is more further form than the other sections, thus classified it as a separate category to be studied; and Section 5, Section 6 in the fourth quadrant, a relatively close distance between each other and therefore Section 5, Section 6 classify as a category to be studied. In that case, according to their degree of correlation, the original six sections will be divided into three groups: the first group is Section 1; second group is Section 2, Section 3, Section 4; the third group is Section 5, Section 6.

3 TRAFFIC FLOW PREDICTION MODEL AND METHOD

Assume that $X_{\mathrm{p}}(t)$ is p-dimensional time series, and it has n group of observations, marking it as:

$$X_{\mathrm{p}}(t)=\begin{bmatrix} x_{11} & \cdots & x_{1n} \\ \cdots & \cdots & \cdots \\ x_{p1} & \cdots & x_{pn} \end{bmatrix}$$

Yet the general, support that there are $m \cdot p$ threshold variables and any of these variables corresponds to l+1 threshold values, and m is order. There are $\sum_{ii=0}^{m \cdot p} C_m^{ii} \cdot p$ combinations for every group threshold values of $m \cdot p$ threshold variables, and thus m-order multi-dimensional time series of threshold auto-regressive model can be defined as (Jin Juliang et al. 2000):

$$X_{\mathrm{p}}(t)=\begin{cases} \sum_{i=1}^{m} B_1^{(i)} X_p(t-i)+ b_{1,0} & R\in (r_0, r_1] \\ \sum_{i=1}^{m} B_N^{(i)} X_p(t-i)+ b_{N,0} & R\in (r_{l-1}, r_l] \end{cases} \tag{1}$$

Where $X_{\mathrm{p}}(t)=\begin{bmatrix} x_1(t) \\ \cdots \\ x_p(t) \end{bmatrix}$, $B_k^i=\begin{bmatrix} b_{11,k}^{(i)} & \cdots & b_{1p,k}^{(i)} \\ \cdots & \cdots & \cdots \\ b_{p1,k}^{(i)} & \cdots & b_{pp,k}^{(i)} \end{bmatrix}$, $X_p(t-i)=\begin{bmatrix} x_1(t-i) \\ \vdots \\ x_p(t-1) \end{bmatrix}$, $r_j=\begin{bmatrix} r_{1,j} \\ \vdots \\ r_{m\cdot p,j} \end{bmatrix}$

$R=\begin{bmatrix} x_1(t-i) \\ \vdots \\ x_p(t-1) \end{bmatrix}$, $r_0<r_1<\cdots<r_l$, $N=l\sum_{ii=0}^{m\cdot p}C_{m\cdot p}^{ii}$, $i=1,2,\cdots,m$, $k=1,2,\cdots,N$

Sometimes it only uses p variables to predict the anterior g variables of multi-dimensional time series ($g \le p$), and this can be achieved by deleting p-g line of model (1) (Yang Weiqing et al. 1992), and the new model is:

$$X_{\mathrm{g}}(t)=\begin{cases} \sum_{i=1}^{m}B_1^{(i)}X_{p-q}(t-i)+a_{1,0} & R\in(r_0,r_1] \\ \sum_{i=1}^{m}B_N^{(i)}X_{p-q}(t-i)+a_{N,0} & R\in(r_{l-1},r_l] \end{cases} \tag{2}$$

For the equation (1), introducing the half polynomial:

$$\varphi_+=\begin{cases} \varphi & \varphi>0 \\ 0 & \varphi\le 0 \end{cases} \tag{3}$$

And thus the equation (1) can be transformed as:

$$X_p(t)=\sum_{i=1}^{m}B_1^{(i)}X_p(t-i)+c_{1,0}+\sum_{i=1}^{m}\sum_{j=1}^{l}A_j^{(i)}(X_p(t-i)-r_j)_+ \tag{4}$$

Correspondingly equation (2) can be transformed as:

$$X_g(t)=\sum_{i=1}^{m}B_1^{(i)}X_{p-q}(t-i)+d_{1,0}+\sum_{i=1}^{m}\sum_{j=1}^{l}A_j^{(i)}(X_{p-q}(t-i)-r_j)_+ \tag{5}$$

Where $A_k^{(i)}=\begin{bmatrix} a_{11,k}^{(i)} & \cdots & a_{1p,k}^{(i)} \\ \cdots & \cdots & \cdots \\ a_{p1,k}^{(i)} & \cdots & a_{pp,k}^{(i)} \end{bmatrix}$, $k=1,2,\cdots,N$

For the equation (1) (4) and equation (2) (5), it is not difficult to prove the equivalence between them (Yan Huasheng et al. 1994).

Introduce the screening technology of independent variable for the equation (4) and equation (5), and thus it can set up the threshold regression model of multi-dimensional time series. If the threshold variable's value is not selected in the final regression equation, that is to say to sub-merge the corresponding subsections, which indicates impact of the threshold variable and its value on the dependent variable is not significant. At this point, we have obtained the universal modeling program of threshold regression model of multi-dimensional time series.

4 EMPIRICAL RESEARCH

Peak-hour traffic volume is the most representative traffic volume of one-day, and it is also the most difficult prediction target, therefore chose the peak-hour as prediction research object, not only can test the prediction ability of threshold auto-regressive model of multi-dimensional time series, but also is full of practical significance. Select the second group of sections in correlation analysis, which is Section 2, Section 3 and Section 4, and take traffic volume data of these three

sections during the October 15, 2007 to 29 between 7:30 ~ 8:30 interval 5-minute as a study object; set order *m*=3, select the max and min value of the above estimating factors at one time. To each estimating factor, we could use the method of adding by 0.1 unit from the minimum value until it reach the max value of the related estimating factor, so that we could finish the conformation of threshold variable and the related threshold value. We utilize the method of 4 factors optimal subset regression to establish the multi-dimensional time series threshold auto-regressive model of peak hour traffic volume (take time period of 7：45~8：00 as an example):

$$x_{2,t} = 1.2(x_{2,t-1} - 13)_+ - 0.3(x_{3,t-2} + 5)_+ + 0.7(x_{3,t-3} - 6)_+ - 0.6(x_{4,t-2} + 7)_+ + 3 \quad (6)$$

$$x_{3,t} = -1.3(x_{3,t-1} - 5)_+ + 0.9(x_{3,t-2} - 2)_+ + 0.5(x_{4,t-1} - 4)_+ - 0.8(x_{4,t-2} - 9)_+ + 8 \quad (7)$$

$$x_{4,t} = -1.3(x_{3,t-1} - 14)_+ + 1.2(x_{3,t-3} - 13)_+ - 0.8(x_{4,t-1} - 9)_+ - 0.3(x_{4,t-2} - 5)_+ + 5 \quad (8)$$

In equation (6) to (8), $x_{2,t}$ 、 $x_{3,t}$ and $x_{4,t}$ separately represent the peak hour t moment's value of detector 2, detector 3 and detector 4. According to the definition of half polynomial, when the estimated factor is higher or lower than some threshold value, the relation between the estimated factor and the estimated object will be changed. In order to detect that whether the time series model is through the test of significance or not, we do the calculation of equation (6) to (8), and the F value is 5.8, 6.4 and 5.6 respectively, which all exceed the F significance text of $\alpha = 0.05$. These results indicate that the multi-dimensional time series threshold autoregressive model of the peak-hour traffic volume through a significant test.

Compared with the prediction and measured value of the peak hour, and the results are shown in **Figure 3**, where abscissa is time series, from 7:30-8:30 every five minutes for an interval time-series; ordinate is traffic flow, and lines are the measured and prediction traffic flow, and unit is vehicles per 5 minutes.

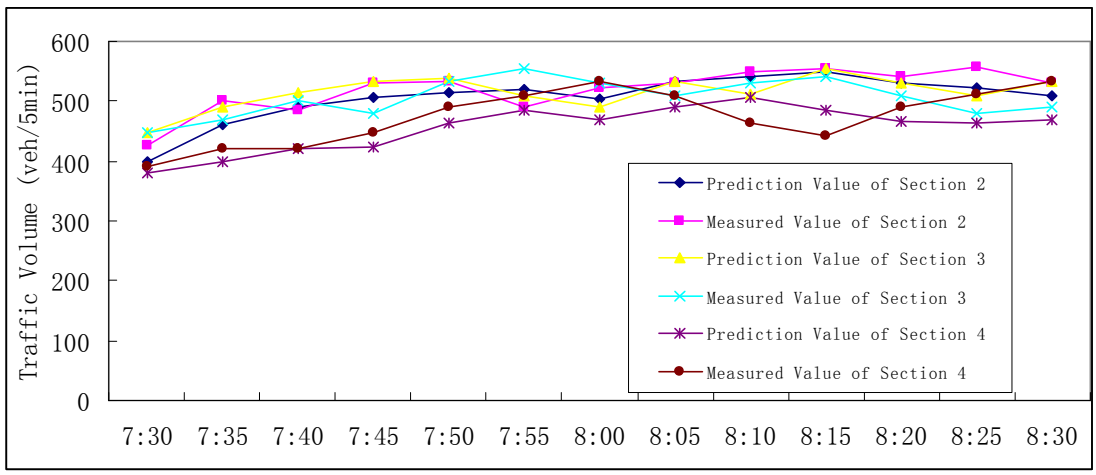

Figure 3. Prediction Values and Measured Values of Traffic Volumes from Road Cross-sections 2-4

From the fitting degree of prediction and measured values in figure 3, the cross-section values of prediction are consistent with the observed trend of traffic. Every moment's difference of the dashed line and solid line is the prediction error, and from the chart we can see the qualitative observation floating area of the each sectional predictive value is small.

In order to study quantitatively the effects of multi-section prediction, we do

the prediction of these 3 sections utilizing the single-section time series method (Autogression), and compared the results with this paper's. We adopt the Mean Absolute Percentage Error (MAPE) and Mean Absolute Percentage Error (MAD) as the comparative indicators of the prediction error, for these two indexes can reflect the difference between measured and prediction values more comprehensive.

Table 1. Error of Two Forecasting Methods of Time Series

		MAPE	MAD
Multi-section	Section 2	8.31%	11.27
	Section 3	9.75%	10.34
	Section 4	8.47%	11.16
Single-section	Section 2	15.36%	17.64
	Section 3	13.09%	14.68
	Section 4	16.56%	15.21

From the analysis results, compared with the single-section method, the multi-section method is more accurate than the single-section method, not only in the aspect of MAPE, but also the MAD.

5 CONCLUSION

This paper brings the thought of correlation analysis on multi-section traffic flow parameter, and utilizes the MDS to make the correlation analysis. It divides the road sections into several groups whose members are strongly related to each other, and determines the research object. Under the background of bringing the half multinomial, this paper conducts a new expression of threshold regression model of multi-dimension time series. What's more, according to the new expression, we put out a series new normal project of modeling. From the similarity of peak hour traffic measurement and test result, those three model all have several threshold, and the regression threshold model has a good capacity of similarity and estimating, and it has a broad application future and it is useful for further research and test.

ABSTRACT

Traffic flow shows unique characteristics in expressway weaving sections and time headway distribution is usually changed by traffic flow in weaving sections. In order to represent the inherent features of time headway distribution in expressway weaving sections, we use the advanced traffic detection instruments to collect the data of expressway weaving sections of type A in Beijing, Guangzhou and Shanghai. Based on the data processing and analysis with several commercialized tools such as Video Trace, MetroCount and NC-97, and applying probability theories to analyze those data by different lanes and sections, we found the practical distribution mostly obeys displaced negative exponential distribution and Cowan M3 distribution, shows dynamic rule of time headway distribution in expressway weaving sections, changing along with the traffic volume of passing certain section. Finally, this rule is proven by fitting technique of χ^2 and test of goodness.

INTRODUCTION

Weaving section is part and parcel of entire expressway system, and the characteristics of time headway distribution in weaving sections are also crucial to estimate capacity. The movements of vehicles on ramps and vehicles in mainline always lead to the turbulence of traffic stream, speed reducing, delay increasing and bottleneck. At the same time, because traffic volume of both mainline and ramp is higher on expressway, operation feature of traffic flow on expressway is different from that on freeway, such as merging, weaving and so on. So it is significant that we study the characteristics of time headway distribution on expressway weaving section.

It will lead to time headway redistributing in weaving location if

the number of entering vehicles from ramp changes (Li Wenquan et al. 2003). In order to obtain characteristics of time headway distribution in expressway weaving sections under conditions of different lanes and volumes, we conducted the regression analysis based on a large number of field data related to time headway statistic distribution of type A weaving sections which are typical in most of the cities.

DATA COLLECTION AND PROCESSING

Recently, we chose several typical expressway routes and collected a large number of practical data from all parts of expressway system in the cities of Beijing, Guangzhou, Shenzhen, Shanghai, Tianjin, Shenyang and Harbin. Here, several advanced traffic detection tools were used to collect data of weaving sections, and the tools include American NC-97 portable traffic counter, Australian MetroCount 5600 vehicle classification system, Chinese Video Trace™ VT2100R detection system and all weather digital video cameras. When put in practice, digital video camera was fixed so high that can easily observe the whole weaving area (Yan Baojie 1994). At the same time, according to their functions, other equipments were arranged in pairs or groups to collect data. The duration time of data collection for each site was 12 hours continuously, from 6:00a.m. to 6:00p.m., in order to fit the least demand number of statistic analysis and make the collected data more representative. The equipments installed in research site were shown as below (see Figure 1).

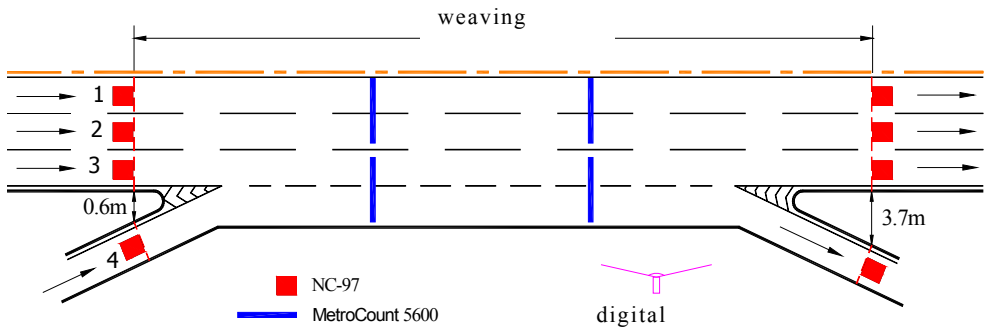

Figure 1. Sketch of equipments laying.

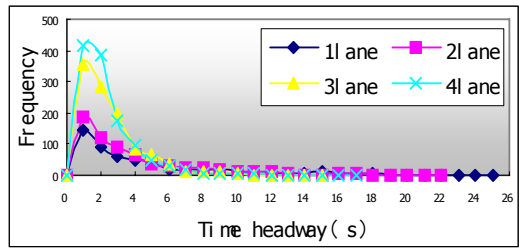
For the data processing, the data collected by MetroCount 5600 and NC-97 were preprocessed with the data processing systems themselves, and the Video Trace™ VT2100R calibrated the basic parameters required from the traffic flow data collected by digital video camera. Based on the observation and analysis, we found the current expressway traffic stream always arrived by the manner of motorcade and usually went and stopped when traffic volume was close to saturation, which implied that the state of traffic flow could have dramatic change within a short time period. Hence, 1 minute is adopted as data aggregation time period to represent the macroscopic characteristics of traffic flow,

operation state in different periods and LOS corresponding in expressway weaving sections.

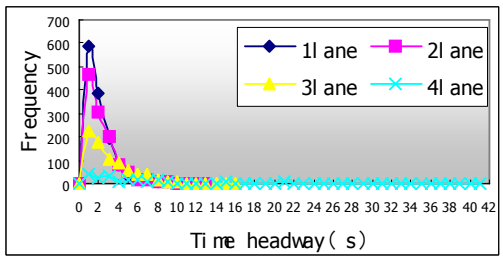
CHARACTERISTICS ANALYSIS OF TIME HEADWAY DISTRIBUTION

Time headway indicates a time interval when two continuous vehicles pass through a certain point in the same travel direction (China Academy of Highway and Transport 1998). The characteristics of time headway distribution in expressway weaving sections should be analyzed with befitting distribution models, then its distribution rule can be obtained. For modeling, a number of studies have been done by researchers throughout the world. At present the representative models mainly include negative exponential distribution, displaced negative exponential distribution, Cowan M3 distribution and K-rank Erlang distribution (Nathan Gartner et al. 1998).

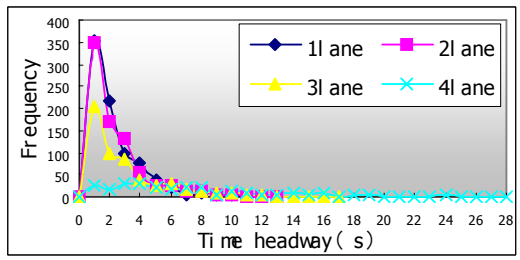
Due to the close correlation between time headway distribution and traffic volume, we made time headway data regressed by different lanes and volumes with several distribution models mentioned above. Now one weaving section on the North third Ring Road in Beijing was taken as an example. The actual time headway distributions of different lanes and three segments, entrance sites, interweaving sites and exit sites were shown in the following (see Figure 2).



(1). Entrance site.



(2). Interweaving site.



(3). Exit site.

Figure 2. Actual time headway distributions of weaving sections.

As shown in Figure 2, actual time headway distributions of both lane 1 and lane 2 are closer at the same site, so are those of both lane 3 and lane 4. While, at different sites, changing trend of time headway distributions of both lane 1 and lane 2 is similar, so is that of both lane 3 and lane 4. The reason is that main stream vehicles which are going to exit to ramp will have to merge into the most-right lane of mainline

actually before they start to run into weaving section, the main stream vehicles which are not going to weave section mostly use middle lanes or most-left lanes. Only a few main stream vehicles exit to ramp from weaving section to most-left lanes by time after several times of lane changing.

Time headway distributions of each lane at different sites have been regressed nonlinearly. The regression quality of theoretic distribution to actual distribution was verified by the fitting method of χ^2 at the marked level of 0.05 (see Table 1).

Table 1. Time headway distribution and checkout every lane in weaving section.

(Note: χ_o^2 =the value of observation; χ_t^2 =the value of theory; ×=refuse; ✓=accept.)

The regression results indicate that time headway distributions in expressway weaving section of type A are as dynamic variation between displaced negative exponential distribution and Cowan M3 distribution with different traffic volumes. Moreover, dynamic distributions of time headway of both lane 1 and lane 2 are usually the same changing characteristics, so are those of both lane 3 and lane 4.

χ^2 TEST OF TIME HEADWAY DISTRIBUTIONS

It is required that there should be some methods to estimate the regression quality when theoretic distribution is compared to actual data distribution. χ^2 test is usually used in traffic engineering at present. Under the condition of the least data required, firstly, the method needs to estimate distribution parameters, then to determine theory frequency with the assumed theoretic distribution model and figure out χ^2 value of actual observation data, finally to verify whether the assumed theoretic distribution model is acceptable or not at the marked level of 0.05. The following example is to analyze time headway distribution of lane 1 at interweaving site in the weaving section mentioned above including 1346 samples.

Parameters of Actual Observation

$$M = \frac{\sum_{i=1}^{12} f_i t_i}{\sum_{i=1}^{12} f_i} = \frac{2246}{1346} = 1.6686$$

$$D = \frac{\sum_{i=1}^{12} f_i t_i^2}{N-1} - \frac{\left(\sum_{i=1}^{12} f_i t_i\right)^2}{N(N-1)} = \frac{7164.5}{1345} - \frac{2246^2}{1346 \times 1345} = 2.54$$

$$\lambda = \frac{1}{M} = \frac{1}{1.6686} = 0.5993$$

χ^2 Test

The assumed theoretic distribution models are negative exponential distribution, displaced negative exponential distribution, Cowan M3 distribution and K-rank Erlang distribution, which are verified respectively by the method of χ^2. The verified result is acceptable when Cowan M3 distribution is assumed. The test process is as follows:

Let the least time headway of traffic flow equal to one second,

t_m=1s, then the ratio of the vehicles whose time headway are bigger than t_m over all vehicles is:

$$\alpha = e^{-0.55(q\text{-}0.025)} = e^{-0.55(1347/3600\text{-}0.025)} = 0.8253$$

$$\lambda = \frac{\alpha q}{1 - t_m q} = \frac{0.8253 \times 1347/3600}{1\text{-}1 \times 1347/3600} = 0.4934$$

Where, q= average arriving rate of traffic flow (pcu/s), λ= shape parameter.

So the Cowan M3 distribution model is:

$$p(h \geq t_i) = 0.8253 e^{-0.4934(t_i\text{-}1)}$$

The theoretic frequency is $F_i = 1346\left[p(h \geq t_i) - p(h \geq t_{i+1})\right]$. According to the rule of χ^2 test, F_i of samples in each group must not be less than 5. If F_i is less than 5, those samples will not be merged into near groups until F_i of the new group is more than 5.

Then $$\chi_o^2 = \sum_{i=1}^{10} \frac{f_i^2}{F_i} + \frac{\left(\sum_{i=11}^{12} f_i\right)^2}{\sum_{i=11}^{12} F_i} - N = 1347.9824 + \frac{4}{6.41804} - 1346 = 2.606$$

DF=11-2=9, α=0.05, After looking up the distribution table of χ^2 we can get $\chi_{0.05}^2 = 16.919$.

$\chi_o^2 < \chi_t^2$. The assumed theoretic distribution model is accepted, and so the actual data at this site obey Cowan M3 distribution.

According to the same reason, others' time headway distributions of each lane at correspondence site are verified. The test results are shown in the above table (see Table 1).

CONCLUSION

Weaving operation of vehicles could lead to new distribution of time headway in weaving sections and form dynamic distribution characteristic. After analyzing the practical data in detailed, we found that time headway distribution in expressway weaving section of type A could be well regressed with displaced negative exponential distribution and Cowan M3 distribution. At the same time other actual data of the same type weaving sections, such as East third Ring Road south farming exhibition pedestrian bridge in Beijing and Inner Ring Road B near railway station in Guangzhou, were analyzed with the same methods. We draw the conclusion that time headway distributions in expressway

section are as dynamic variation as different traffic volumes at different sites. If volume is less than 250 veh/h, time headway will obey negative exponential distribution; if volume is between 250 veh/h and 750 veh/h, time headway will obey displaced negative exponential distribution; if volume is between 750 veh/h and 1500 veh/h, time headway will obey Cowan M3 distribution.

There are unique characteristics of traffic flow in expressway weaving sections. This analysis provides fundamental research for further study on capacity of expressway weaving sections, reasonable planning of expressway, and traffic management.

ABSTRACT. The key of placing-in and taking-out operations of wagons is how to select a rational sequence, which is hard to solve. According to the analysis of characteristics of placing-in and taking-out operations of wagons in branch-shaped private sidings, we construct Hamilton graph of this problem, and convert this problem into searching Hamilton loop of minimum weight. In this paper, we present an improved ant colony optimization (ACO) algorithm for such a problem. The proposed ACO algorithm has several features, including introducing upper and lower bounds to the values of pheromone trail, and applying local search and modified global search strategy. The improved algorithm is experimented on branch-shaped sidings problem with 6 nodes and shows its advantage over conventional ant colony algorithm. For the large scale branch-shaped sidings problems, this proposed algorithm can save much time.

1 Introduction

Placing-in and taking-out wagons operation is an important task in large railway freight stations and some technical stations. Selecting a rational procedure of placing-in and taking-out operation, nonproductive detention time of wagon in the railway stations can be reduced and wagon turn-round can be accelerated. Therefore, many earlier researchers have carried out research on problem of placing-in and taking-out of wagons. Gao and Yang (1981) solves the problem of optimization of the orders of placing and taking-out of wagons on station with the shortest route in graph theory. Wang (1996) proposes three optimized targets and gives an optimization method for taking-out after placing-in of wagons in non-through trains. Yu and Li (2002) consider the problem as a typical traveling salesman subject, and solve it with heuristics-saving algorithm. Yang et al. (2008) proposes a chromosome presentation and realizes the genetic algorithm for the problem.

This paper is concerned with the problem of placing-in and taking-out of

wagons in branch-shaped sidings. The objective is to minimize the total time that a locomotive spends going to every private sidings. We firstly construct Hamilton graph of the problem, then find the Hamilton loop with minimum weight by means of an improved ant colony algorithm, which introduces mutation and crossover operators of genetic algorithm into basic ant colony algorithm.

The remainder of the article is organized as follows. Construction of Hamilton Graph is described in Section 2. The proposed ACO algorithm is presented in Section 3. Computational results of test problems are provided and discussed in Section 4. Section 5 summarizes the conclusions of this study.

2 Construction of Hamilton Graph

In this paper, we mainly discuss placing-in and taking-out operations of wagons in branch-shaped private sidings. The key problem is how to minimize the time a locomotive spends going to every special line. To construct the model, we firstly simplify constraints that are shown as follows: (1) One locomotive; (2) Every special line has two turnouts; (3) The number of cars that will be placed-in and taken-out is known. (4)The time the locomotive spends going to every special line is determined.

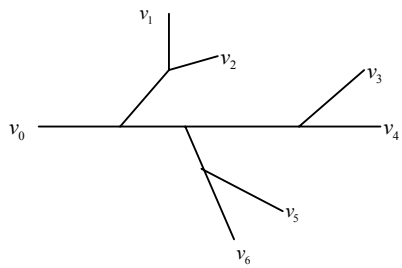

Figure 1. The special lines on branch-shaped sidings

As shown in Figure 1, v_0 which represents the station at the start node. $v_1 \sim v_6$ are leaves of the special line. In Figure 2, Hamilton loop of branch-shaped sidings is shown, the weight of edge (v_i, v_j) is equal to the time that the locomotive goes from v_i to v_j $(i, j = 0,1,2,3,4,5,6)$ .The problem of placing-in and taking-out of wagons is searching Hamilton loop with minimum weight.

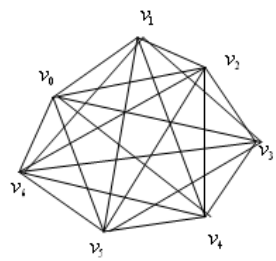

Figure 2. Hamilton loop of branch-shaped sidings

In fact, the problem of Hamilton loop is a well-known traveling salesman problem (TSP). TSP is a paradigmatic NP-hard combinatorial optimization problem, so it is hard to get an accurate result with traditional mathematical method. With the rapid development of computer, modern intelligent algorithms, such as genetic algorithm, simulated annealing algorithm, and ant colony algorithm, have successfully solved TSP. In this paper, we proposed the improved ACO algorithm for placing-in and taking-out operations of wagons in branch-shaped sidings.

3 The proposed ACO algorithm

Ant Colony Optimization (Dorigo M.,1997, ACO) is inspired by the foraging behavior of real ants, which can be described as follows. Real ants have the ability to find the shortest path from a food source to their nest without using visual cues. Instead, they communicate information about the food source by producing a chemical substance, called pheromone, laid on their paths. Since the shorter paths have a higher traffic density, these paths can accumulate a higher amount of pheromone. Hence, the probability of ants following these shorter paths will be higher than the longer ones.

ACO is one of the meta-heuristics for discrete optimization. It has been successfully applied to a large number of combinatorial optimization problems, including traveling salesman problems (Dorigo M.,1997), vehicle routing problems (Bullnheimer B.,1999) and quadratic assignment problems (Gambardella L.M.,1999), which have shown competitiveness with other meta-heuristics.

The ACO algorithm proposed in this paper is basically the ACS version (Dorigo M., 1997), but it introduces the feature of a minimum pheromone value and a maximum pheromone value from"max-min-ant system" (Stützle T., 2000, MMAS).

To make the algorithm more efficient and effective, we employ two distinctive features, including introducing mutation and crossover operators of genetic algorithm. Before elaborating on these features, we present our ACO algorithm as follows:

Step 1: Parameter initialization. Let the initial pheromone trail $\tau_{ij}(0) = C$ (C is constant); Let m be the ant number; Let n be the number of node, where m=n-1.

Step 2: Main loop. In the main loop, each of the m ants constructs a solution. This loop is executed for the maximum iteration $N_{c\max} = 100$.

Step 2.1: Constructing a solution by each ant. A set of artificial ants is initially created. Each ant starts with a node other than node v_0 and then successively appends a node to the partial solution until a feasible solution is constructed. In choosing the next node j , the ant applies the following state transition rule:

$$j = \begin{cases} \arg \max_{u \in allowed_k} \left\{ [\tau_{iu}(t)][\eta_{iu}(t)]^{\beta} \right\} & if \ q \le q_0 \\ S & otherwise \end{cases}$$

Where $\tau_{iu}(t)$ is the pheromone trail associated with node u to node i at time t; $\eta_{iu}(t)$ is the heuristic desirability at time t; β is the parameter which determines the relative importance of the heuristic information; $allowed_k$ is the set of feasible components, q is a random number uniformly distributed in [0,1], and q_0 is a parameter $(0 \le q_0 \le 1)$ which determines the relative importance of exploitation versus exploration. If $q \le q_0$, node j with maximum value is behind node i; otherwise, node j is chosen according to S. The random variable S is selected according to the probability:

$$p_{ij}^{k}(t) = \begin{cases} \dfrac{[\tau_{ij}(t)]\ [\eta_{ij}(t)]^{\beta}}{\sum_{u \in allowed_k} [\tau_{iu}(t)]\ [\eta_{iu}(t)]^{\beta}} & if \ j \in allowed_k \\ 0 & otherwise \end{cases}$$

Step 2.2: Local update of pheromone trail. To avoid premature convergence, a local trail update is performed. This is achieved by the following local updating rule:

$$\tau_{ij}(t+1) = (1-\xi)\tau_{ij} + \xi\tau_0 \qquad \text{where} \quad \xi \in (0,1]$$

Step 2.3: Local search. When each of m ants complete a solution, we select the best solution and suboptimal solution of this iteration. In our algorithm, we execute mutation and crossover operators of genetic algorithm into best solution and suboptimal solution of this iteration. Finally, we evaluate the best solution.

Step 2.4: Global update of pheromone trail. The global updating rule is applied after each ant has completed a feasible solution .The following rule is applied to the best solution which is found in Step 2.3. If edge (v_i, v_j) belongs to the best solution, then

$$\tau_{ij}(t+n) = (1-\rho)\tau_{ij}(t) + \rho\Delta\tau_{ij}(t)$$

where ρ ($\rho \in (0,1]$) is a parameter representing the evaporation of pheromone. The amount $\Delta\tau_{ij}(t) = 1/L_{best}$, where L_{best} is the global best solution. In order to prevent the solution from falling into a local optimum that results from the pheromone evaporating to zero, we introduce a lower bound and upper bound to the pheromone trail value by letting $\tau_{\max} = 5\tau_0$ and $\tau_{\min} = \frac{1}{5}\tau_0$.

Step3: When the cycle number $N_c \geq N_{c\max}$, the circulation is stopped and the results are put out; otherwise, turn to step 2.

4 Computational experiments

To verify the performance of the algorithm, the problem on branch-shaped sidings with 6 nodes is conducted. The running time that the locomotive goes from v_i to v_j is shown in Table 1 $(i, j = 0,1,2,3,4,5,6)$ .The algorithm is coded in MATLAB7.0 and implemented on a Pentium IV 3.0 GHz PC. The parameters are as follows: $N_{c\max} = 100$, $\xi = 0.1$, $\rho = 0.1$, $\beta = 5$, $q_0 = 0.9$ .The optimal route was v_0-v_3-v_2-v_1-v_4-v_5-v_6-v_0, and the total time is 190 min. In conventional ACO algorithms, the local search is executed once for every iteration，but our algorithm applies the local search whenever a better solution is found. Moreover, our approach requires only about 33% of the computation time as compared to the conventional approach. For the large scale branch-shaped sidings problems, this proposed algorithm can save much time.

Table.1 The running time between v_i to v_j

$d(v_i,v_j)$ v_j / v_i	v_0	v_1	v_2	v_3	v_4	v_5	v_6
v_0	-	35	20	25	40	30	35
v_1	35	-	15	50	45	65	70
v_2	20	15	-	25	45	50	55
v_3	25	50	25	-	65	45	40
v_4	40	45	45	65	-	35	45
v_5	30	65	50	45	35	-	10
v_6	35	70	55	40	45	10	-

5 Conclusions

In this paper, we have presented an ACO algorithm for placing-in and taking-out operations of wagons in branch-shaped private sidings. The developed algorithm has some distinctive features, including applying local search and modified global search strategy, and these features make the algorithm very effective and efficient. For the large scale branch-shaped sidings problems, this proposed algorithm can save much time.

ABSTRACT

Trip distribution is an important step of the four-phase method in transportation demand forecasting. It is affected by many factors. First, factors influencing vehicle trip distribution are analyzed and the results show that location potential, traffic impedance, trip production, and trip attraction play an important role. Second, an aggregation scale factor of the traffic zone is evaluated by fuzzy algorithm and the zone accessibility is calculated, and then, the location potential that is determined by the aggregation scale factor and zone accessibility is obtained. Third, traffic impedance based on travel time is determined based on analyzing the influences of traffic flow discontinuation, bicycles, pedestrians, and width of lanes. Finally, the trip distribution forecasting model based on the BP neural network which takes location potential, traffic impedance, trip production, and trip attraction as input parameters and the result of trip distribution as output parameters is established. The test shows that the forecasting result fits well with the survey data. Thus, the BP neural network model can be used for trip distribution forecasting with high prediction accuracy.

KEY WORDS: trip distribution; BP neural network; location potential; impedance function

FACTORS INFLUENCING VEHICLE TRIP DISTRIBUTION

The factors influencing vehicle trip distribution are complicated and various, so it is necessary to apply the modern technology which can supply an effective method for further improving prediction accuracy. Therefore, the BP neural network is used for vehicle trip distribution forecasting. For vehicle trip distribution, it is influenced by the location of the traffic zone, road condition, interference of non-motorized vehicles and so on. Trip production, trip attraction, the location potential of the traffic zone and traffic impedance are considered and finally determined as the factors influencing vehicle trip distribution. Among them, the trip production and trip attraction have been obtained in trip generation forecasting. Thus, it just needs to describe the location potential and determine the traffic impedance.

DESCRIBING LOCATION POTENTIAL OF TRAFFIC ZONE

The location potential refers to the attracting capability of people activity,

which is affected by economic and geographical position and the geographical position of traffic. The location potential of the traffic zone is determined and calculated by an aggregation scale factor and zone accessibility. An aggregation scale factor of the traffic zone is divided into seven grades (see Table 1) and evaluated by fuzzy algorithm. Zone accessibility is the attraction ability of the traffic zone, and can be calculated by the formula as follows:

$$A_i = \sum_{j=1}^{n} (P_j / d_{ij}) \tag{1}$$

Where, A_i is the accessibility of zone *i*; P_i is the local population of zone *i*; and d_{ij} is the distance between zone *i and* zone *j*.

Table 1. Aggregation Scale Factor of the Traffic Zone.

Grade	1	3	5	7	9	11	13
Description	Worst	Worse	Bad	Medium	Good	Better	Best

TRAFFIC IMPEDANCE FUNCTION OF VEHICLE TRIP BASED ON TRAVEL TIME

Traffic impedance reflects the convenience of travel between each pair of traffic zones. For vehicle trip distribution, travel time is chosen as the traffic impedance which can reflect not only the distance between two traffic zones but also the practical road traffic condition.

The characteristics of mixed traffic flow on urban roads determine that the travel time of a basic section is affected by many factors and needs to be corrected. First, the theoretical calculation of running speed is established based on the relationship among three parameters in traffic flow theory. Second, this theoretical model is modified according to the influences of traffic flow discontinuation, bicycles, pedestrians and the width of lanes. Finally, the calculation method of average running speed is proposed, and then travel time is obtained.

When the road facility condition is constant, the average running speed on a section is related to the traffic volume and traffic density on road. Travel time *t* is obtained by means of comparing the relationship among three parameters and calculated by the formulas as follows:

$$t = L / V \tag{2}$$

$$V = V_m / 2 \pm \sqrt{V_m{}^2 / 4 - Q V_m / K_m} \tag{3}$$

$$V_m = \eta_1 \eta_2 \eta_3 \eta_4 V_a \tag{4}$$

$$K_m = \eta_1 \eta_2 \eta_3 \eta_4 n / (l + l_0) \tag{5}$$

Where L is the length of the road; V is running speed; Q is traffic volume; V_m is the free flow speed; K_m is the jamming density; η_1 is the correction coefficient of discontinuous flow; η_2 is the correction coefficient of a bicycle; η_3 is the correction coefficient of a pedestrian; η_4 is the correction coefficient of lane width; V_a is design speed; n is the number of unidirectional vehicle lanes; l_0 is the average clear distance between two cars on a blocked section which can select 1.5m; l is the average vehicle length.

BP VEHICLE TRIP DISTRIBUTION FORECASTING

Selection of a neural network model. **A** neural network model mainly includes a perceptron neural network, linear neural network, radial basis function network and BP neural network. The factors influencing vehicle trip distribution are nonlinear mapping relationships with vehicle trip distribution, so a BP neural network and radial basis function network are suitable for the research object based on the characteristics of a neural network model. So a BP neural network is chosen for vehicle trip distribution forecasting, and the suitable model is established according to the forecasting precision.

Input and output of network. Input parameters of a network include vehicle trip production, vehicle trip attraction, location potential of a traffic zone, and traffic impedance. The output parameter is vehicle trip distribution of each traffic zone.

The study area is Liaoyang of Liaoning Province. Based on the 56 traffic zones divided in the World Bank loan project, the vehicle trip generation data of 20 relatively stable traffic zones during the year 2005 is selected as the data sample for building a network model. Network performance is determined by network generalization. The network generalization is not tested by data of a training set but by the other data. So in the experimental design, the vehicle trip generation data of 20 traffic zones is divided randomly into two parts. One part is used as a training sample and the other part is used as a testing sample. Based on the formula (1-5) and the collection date, vehicle trip production, vehicle trip attraction, location potential of a traffic zone and traffic impedance of the 20 traffic zones of Liaoyang city in 2005 can be obtained (show in Table 2 and Table 3 respectively).

Selection of network structure and learning parameter. **A** three-layer BP network can reflect any n dimensional to m dimensional mapping relationship, so this example adopts the three-layer BP network with one hidden layer. The number of input layer neurons is 4, namely vehicle trip production, vehicle trip attraction, location potential of a traffic zone, and traffic impedance. The number of output layer neurons is 1, namely vehicle trip distribution. The transfer function of the hidden layer adopts the bipolar tansig function and the transfer function of the output layer adopts the linear purelin function. The values of network

learning parameter are as follows: the target of prediction accuracy, the maximum training times, and the initial learning rate is 0.002, 20000 and 0.01, respectively.

Table 2. Location Potential and Trip Generation

The determination of hidden layer neuron and model training. The number of hidden layer neurons is determined by a trial calculation based on the consideration to the network's learning ability and learning rate. Considering the input layer neuron is 4, the forecasting result of the network is analyzed when the number of hidden layer neurons separately chooses 2 to 10. In this paper, the values

of hidden layer neurons are all carried out with repeated and large training, and finally the global optimal solution of a BP network is chosen. The network forecasting error of a training sample is seen in Table 4. The average absolute error mae and mean square deviation mse are referenced for comprehensive evaluation of a network forecasting result. The training method of each network structure is a LM algorithm.

Table 4. Comparing the Forecasting Errors of Different Neuron Hidden Layers.

Number of hidden layer neuron	Mae	Mse	Network convergence rates
2	0.0560	0.00199	205
3	0.0553	0.00198	23
4	0.0535	0.00192	13
5	0.0549	0.00195	8
6	0.0543	0.00193	7
7	0.0547	0.00198	4
8	0.0548	0.00193	4
9	0.0546	0.00195	5
10	0.0541	0.00193	7

The result of selecting the number of hidden layer neurons is that when the number of hidden layer neurons is 4, the network forecasting is the best with an average absolute error of 5.35％ and a mean square deviation of 0.0192. It meets the prediction accuracy after 13 steps of training. Thus, a three-layer BP neural network for vehicle trip distribution forecasting is established.

Model testing. The testing sample is the second group including ten traffic zones. Based on the established BP neural network, the vehicle trip distribution of the ten traffic zones is forecasted and compared with the survey date (see Figure 1).

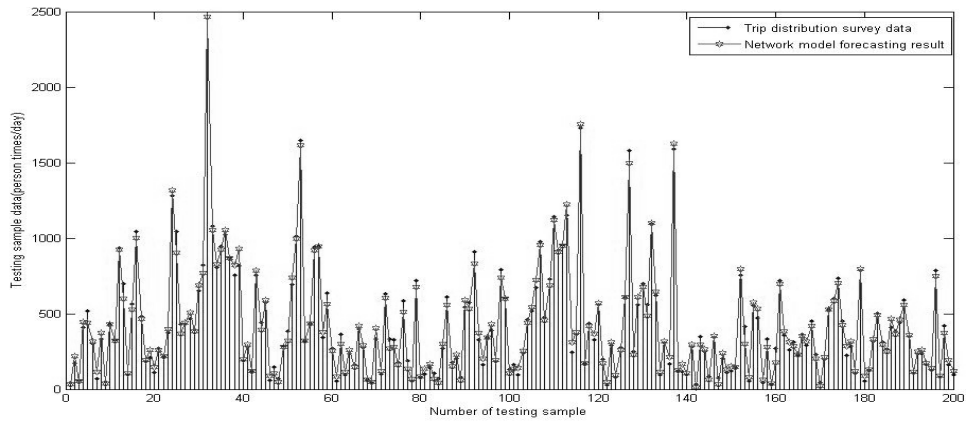

Figure 1. Comparison of model forecasting result with survey data.

Based on the comparison, it can be seen that the result of vehicle trip production and vehicle trip attraction forecasted by the established BP neural network are equal of 84824 person times/day, which is the same as the survey data. The established model meets the boundary condition that trip production and trip

attraction should be equal. The average absolute error of testing a sample forecasting result by a BP neural network is 4.91%, which shows that the prediction accuracy is high. Therefore, the established BP neural network has a high prediction accuracy for vehicle trip distribution forecasting and can be used for trip distribution forecasting.

CONCLUSION

Due to the complexity of data acquisition in the research process, only location potential of traffic zone and travel time are considered as the influencing factors of vehicle trip distribution model. More influencing factors can be taken into consideration in the subsequent research. The network model adopts the most widely used BP neural network, and other neural network models also have a wide scope of application, so other neural networks can be adopted in future research. Aiming at the study of vehicle trip distribution , other trip distribution patterns are the same and can be studied and discussed by similar methods in future research. In the process of establishing traffic impedance functions, travel time is influenced by many factors and local actual situations are suggested to be analyzed because cities with different grades are influenced by different factors. Besides, travel time is considered as traffic impedance in this paper, and traffic impedance is suggested to be calculated synthesizing the distance, expense, and other influencing factors.

ABSTRACT

A snowy day has a great impact on vehicles, road capacity, and drivers' behavior. Drivers may drive at slower speeds to obtain the longer perception times and stopping distances. Snow can reduce bus ridership, lengthen bus driving times, and dwell time, and increase bus operation costs and ridership's waiting time. Public transit service frequency determines passenger waiting times, and thus the time exposed to snow. This paper analyzes the passenger waiting time cost, in-vehicle time cost, fuel consumption cost, and bus vehicle cost, then takes the minimal bus line total system cost as the goal, establishing a bus service frequency multi-objective optimization model. Analysis of the relationship between frequency associated with the vehicle average running speed and financial subsidy, using examples to verify the effectiveness of the multi-objective optimization model, can optimize the bus frequency on a snowy day and improve bus service satisfaction.

1 INTRODUCTION

A snowy day will increase the city road network performance variability, to a large extent determining the city's road traffic conditions and road safety situation. In general, snow influences almost every aspect of transit service, such as reducing transit ridership, increasing vehicle running and dwell times, and increasing operation costs. In Zhan Guo et al. (2007) analysis, bus service frequency determines passenger waiting times and the time exposed to adverse weather. Total travel time might be lengthened due to slower speed and longer dwell time at stations. Hofmann and O'Mahony's (2005) study considered the impact of adverse weather on bus performance such as ridership, frequency, and travel time variability.

This paper first analyzes the passenger's time cost, and company operation costs, then takes the minimal bus line total system cost as the goal, establishing the bus service frequency multi-objective optimization model, and using examples to verify the effectiveness of the model. The relationship between frequency associated with the vehicle average running speed and financial subsidy is analyzed.

2 BUS SERVICE FREQUENCY OPTIMIZATION MODEL

Bus frequency optimization is a complex process. Providers (companies) want a longer frequency to reduce variable costs, and passengers request a more efficient service (i.e. high frequency) to reduce the waiting time cost. Therefore, to reduce companies' cost means increasing passengers' cost, and vice versa. This will only minimize the cost of companies and passengers to gain the greatest social benefits. Based on this idea, this article has taken into consideration the passengers' time value and companies' operating costs. Minimizing the bus line system's total cost (including passenger's time cost and company's operation cost) as the optimization goal establishes the bus service frequency multi-objective optimization model.

2.1 Model assumption. It is necessary to carry out the following assumptions:

1) At the optimization time period, all buses on the road drive at the same average speed;
2) Ignoring occasional accidents causes traffic jams on the bus lines;
3) All buses are not allowed to transcend and overtake bus station;
4) All buses operating on the line are the same models, and the capacity is sufficient;
5) Passengers at station will not wait too long to leave.

2.2 The analysis of bus running time

The bus running time $t_{k,k+1}$ from station k to $k+1$ can be stated as follow:

$$t_{k.k+1} = \frac{l}{v_b} + \frac{v_b}{2}\left(\frac{1}{a_a} + \frac{1}{a_d}\right) + t_s = \frac{l}{v_b} + t_{sd} \tag{1}$$

Here l is the distance between stations (this paper uses average distance, m); v_b is the average speed of bus drive on road (m/s); a_d is the deceleration speed (m^2/s); a_a is the acceleration speed (m^2/s); t_s is the average bus stop time (s); t_{sd} is the delay of bus dwell at bus station (s). Here the impact of intersection factors on bus running is ignored.

2.3 The analysis of passenger's time cost

Anthony A. Saka (2001) focused on the bus running time and divided it into acceleration and deceleration time, stop time, the waiting time at the signal intersection, smooth run-time, and other delays. Martin Lowson (2004) divided passenger trip time into walk time, wait time, in-vehicle time and transfer time. Based on the above research, this paper divides passenger time cost into passenger waiting time cost and in-vehicle time cost (including bus running time and the delay due to bus stations). According to passengers' psychological characteristics, passengers prefer stay a few minutes in the bus than to wait one minute at bus station; therefore, passengers waiting time value and in-vehicle time value are different.

2.3.1 Passenger waiting time cost

Each passenger has a different waiting time, but waiting time is closely related to bus departing interval. With random passenger arrivals at the station, the average waiting time can be assumed to be half of the departing interval, which is the average waiting time of passengers:

$$t_1 = L_b \cdot P \cdot (h/2) \tag{2}$$

Here h is the bus departing interval under optimization interval (s); L_b is the length of bus line (m); P is the bus passenger demand at unit length (person/m).

Supposing bus passenger waiting time per unit time value is λ_1 (Yuan/s), and then passenger waiting time cost under optimization time interval is:

$$C_1 = \lambda_1 \cdot t_1 = \lambda_1 \cdot L_b \cdot P \cdot (h/2) \tag{3}$$

2.3.2 Passenger in-vehicle time cost

Passenger in-vehicle time cost including passenger in bus running time and the delay due to bus stations. Passenger in bus running time t_{21} is determined by the average distance and the average vehicle speed, which can be expressed as:

$$t_{21} = L_b \cdot P \cdot (L_c/v_b) \tag{4}$$

The delay due to bus stations t_{22} can be expressed as:

$$t_{22} = L_b \cdot P \cdot \frac{L_c}{l} \cdot \left[\frac{v_b}{2} \left(\frac{1}{a_a} + \frac{1}{a_d} \right) + t_s \right] = L_b \cdot P \cdot \frac{L_c}{l} \cdot t_{sd} \tag{5}$$

Here L_c is the average distance of passenger (m).

Supposing passenger inner-bus time per unit time value is λ_2 (Yuan/s), and then passenger in-vehicle time cost is:

$$C_2 = \lambda_2 (t_2 + t_3) = \lambda_2 \cdot L_b \cdot P \cdot \frac{L_c}{l} \cdot \left(\frac{l}{v_b} + t_{sd} \right) \tag{6}$$

2.4 The analysis of Bus Company's operating cost

In the analysis of bus passenger's time cost in this section, consider Bus Company's interests and analyze Bus Company's operating cost, which includes the bus fuel cost C_3 and bus vehicle cost C_4.

Fuel consumption is different when the bus drives in the normal status and stops at the station, and therefore divides bus fuel cost C_3 into two parts: bus normal driving fuel consumption costs and bus stops fuel consumption costs. Supposing bus normal driving fuel consumption per unit time value is λ_{31} (Yuan/s), each time bus stops fuel consumption per unit time is λ_{32} (Yuan per unit time).

$$C_3 = \lambda_{31} \cdot \frac{L_b}{v_b} \cdot \frac{t}{h} + \lambda_{32} \cdot \frac{L_b}{l} \cdot \frac{t}{h} \tag{7}$$

Bus vehicle cost C_4 includes vehicle depreciation, maintenance, driver wages, and other costs; bus vehicle cost per vehicle is λ_4 (Yuan per vehicle)

$$C_4 = \lambda_4 \cdot (t/h) \tag{8}$$

2.5 The foundation of bus service frequency optimization model

Bus line total system cost can be divided into passenger's time cost and company's operation cost. This section takes the minimal of passenger's time cost and company's operation cost as the goal, establishing bus service frequency multi-objective optimization model. The optimization model's objective function is:

$$\min C = \min\left(C_1 + C_2 + C_3 + C_4\right) \tag{9}$$

Here C is the bus line total system cost, which can be expressed as follows:

$$C = C_1 + C_2 + C_3 + C_4 = \lambda_1 \cdot L_b \cdot P \cdot \frac{h}{2} + \lambda_2 \cdot L_b \cdot P \cdot \frac{L_c}{l} \cdot \left(\frac{l}{v_b} + t_{sd}\right) + \lambda_{31} \cdot \frac{L_b}{v_b} \cdot \frac{t}{h} + \lambda_{32} \cdot \frac{L_b}{l} \cdot \frac{t}{h} + \lambda_4 \cdot \frac{t}{h} \tag{10}$$

When the distance between stations is larger than the acceleration distance and the deceleration distance, the expression is as follows:

$$l \geq \frac{v_b^2}{2a_a} + \frac{v_b^2}{2a_d} \tag{11}$$

To gain the best service frequency $f = t/h$, and minimize the bus line total system cost, taking order partial differential on h:

$$\frac{\partial C}{\partial h} = \frac{1}{2}\lambda_1 \cdot L_b \cdot P - \frac{t}{h^2} \cdot \left(\frac{L_b \cdot \lambda_{31}}{v_b} + \frac{L_b \cdot \lambda_{32}}{l} + \lambda_4\right) = 0 \tag{12}$$

$$\Rightarrow h = \sqrt{2t \cdot \left(\lambda_{31} \cdot l \cdot L_b + \lambda_{32} \cdot v_b \cdot L_b + \lambda_4 \cdot v_b \cdot l\right) / \left(\lambda_1 \cdot v_b \cdot P \cdot l \cdot L_b\right)}$$

From formula (12) can find the effect factors of bus service frequency, the average speed of bus drive on road v_b, the bus passenger demand at unit length P, the distance between stations l and the optimization time interval t. To analyze a bus line departing interval of working day, can divide the working day into different optimization time interval, considering the bus passenger demand at unit length P, to solve for corresponding departing interval.

If $t = 3600s$, $\lambda_1 = 0.025$ Yuan/s, $\lambda_{31} = 0.1$ Yuan/s, $\lambda_{32} = 3$ Yuan per unit time, $\lambda_4 = 8$ Yuan per vehicle, $P = 0.15$ person/m, $l = 600m$, $L_b = 12000m$, then find the relationship between bus departing interval h and the average speed of bus drive on road v_b is: $h = 418.2v_b^{-0.39}$.

If $t = 3600s$, $\lambda_1 = 0.025$ Yuan/s, $\lambda_{31} = 0.1$ Yuan/s, $\lambda_{32} = 3$ Yuan per unit time, $\lambda_4 = 8$ Yuan per vehicle, $v_b = 6m/s$, $l = 600m$, $L_b = 12000m$, then find the relationship between bus departing interval h and the bus passenger demand at unit length P is: $h = 253.65P^{-0.5025}$.

3 THE DISCUSSION OF BUS FREQUENCY OPTIMIZATION MODEL

3.1 The average speed of bus drive on road v_b

On snowy days, for the lower sliding friction coefficient, the braking distance is extended. It is necessary to increase the spacing and reduce the driving speed, which increases the traffic delay. Markku and Heikki (2007) in Finland's study found that vehicle speed will be 6-7 km/h (1.6-1.9 m/s) reduction under adverse weather; Joseph et al. (2001) found when snow begins, speeds decrease by 30%.

Vehicle speed is decided by the vehicle's dynamic performance and road conditions. According to the vehicle traction force formula $Z_\varphi \varphi = Ggf + Ggi + C\rho AV^2$

and vehicles structure formula $Z_\varphi = Gg\left(d + h_g i\right)/L$, Z_φ is the pressure between the driving wheel and ground surface; φ is the adhesive coefficient between tires and ground surface; G is car body weight; g is acceleration of gravity; f is rolling resistance; i is road gradient; C is car streamlined coefficient; ρ is air density; A is cars' windward area; V is cars' running speed; d is distance from car center of gravity to drive shaft; h_g is the height of car center of gravity; L is wheel base.

The maximum speed that a vehicle can reach is determined by car weight and the adhesive coefficient between tires and the ground surface. Under snowy conditions, the adhesive coefficient between tires and the ground surface decreases and the maximum traction force decreases as well. Meanwhile, the ratio of the free-flow speed in the two different conditions can be calculated as:

$$\frac{V_s}{V} = \left(\left(\frac{d + h_g i}{L}\varphi_s - f_s - i\right)\Big/\left(\frac{d + h_g i}{L}\varphi - f - i\right)\right)^{1/2} \tag{13}$$

Take the structural parameters of a certain type of bus as an example. $L = 5.7m$, $h_g = 0.6m$ and $d = 4.8m$. In normal conditions, $\varphi = 0.5$, and $f = 0.02$. If no measure is taken in snowy conditions, $\varphi_s = 0.2$, $f_s = 0.03$. Substitute all the data into the formula (12), and then obtain the ratio V_S / V =58.33%.

3.2 The discussion of government financial subsidy

However, on snowy days due to the impact of the adverse weather factor which extends passengers wait time and in-vehicle time, in formula (10) in order to achieve minimum bus line total system cost can only increase departing interval to reduce Bus Company's operating cost. This is contrary to the actual survey when passengers were complaining about longer departing interval. Peter Tisato (1998) suggested that bus subsidy is favorable for public transport's option value. Here considering financial subsidy, is how to optimize the bus frequency under snowy day, access better bus services and improve passenger's bus service satisfaction.

Supposing under optimization time interval t, the subsidy of a departing bus is λ_5 (Yuan per bus), then the government financial subsidy C_5 is:

$$C_5 = \lambda_5 \cdot (t/h) \tag{14}$$

Then formula (10) can be expressed as:

$$\begin{aligned} C &= C_1 + C_2 + C_3 + C_4 - C_5 \\ &= \lambda_1 \cdot L_b \cdot P \cdot \frac{h}{2} + \lambda_2 \cdot L_b \cdot P \cdot \frac{L_c}{l} \cdot \left(\frac{l}{v_b} + t_{sd}\right) + \lambda_{31} \cdot \frac{L_b}{v_b} \cdot \frac{t}{h} + \lambda_{32} \cdot \frac{L_b}{l} \cdot \frac{t}{h} + \lambda_4 \cdot \frac{t}{h} - \lambda_5 \cdot \frac{t}{h} \end{aligned} \tag{15}$$

And formula (12) becomes:

$$\begin{aligned} &\frac{\partial C}{\partial h} = \frac{1}{2}\lambda_1 \cdot L_b \cdot P - \frac{t}{h^2} \cdot \left(\frac{L_b \cdot \lambda_{31}}{v_b} + \frac{L_b \cdot \lambda_{32}}{l} + \lambda_4 - \lambda_5\right) = 0 \\ &\Rightarrow h = \sqrt{2t \cdot \left(\lambda_{31} \cdot l \cdot L_b + \lambda_{32} \cdot v_b \cdot L_b + \left(\lambda_4 - \lambda_5\right) \cdot v_b \cdot l\right) / \left(\lambda_1 \cdot v_b \cdot P \cdot l \cdot L_b\right)} \end{aligned} \tag{16}$$

If $t = 3600s$, $\lambda_1 = 0.025$ Yuan/s, $\lambda_{31} = 0.1$ Yuan/s, $\lambda_{32} = 3$ Yuan per unit time, $\lambda_4 = 8$ Yuan per vehicle, $P = 0.15$ person/m, $l = 600m$, $L_b = 12000m$, in

normal situation $v_b = 6m/s$, under snow situation $v_b = 4m/s$, under this situation keep the primary departing interval, it needs $\lambda_5 = 100$ Yuan per bus.

4 CONCLUSIONS

We can draw these conclusions:

1) The relationship between bus departure interval and the bus passenger demand at unit length is an inverse proportion. According to the increasing passenger demand, departure interval will diminish and frequency increase.

2) The relationship between bus departure interval and the average speed of the bus drive on road is an inverse proportion. With the decline of average speed, passenger in-vehicle time cost will increase; in order to reduce bus line total system cost, the departing interval must be increased.

3) For the impact of snow, extending passengers wait time and in-vehicle time, passengers complain about the vehicle delay and hope to increase the frequency. So to the solution is to introduce subsidy into bus line total system cost, to optimize the bus frequency on snowy days, reform public transport services and improve bus service satisfaction.

ABSTRACT

This paper first studied the relationship between vehicle arrival rate and loop flow of roundabouts and finally established the capacity linear model with vehicle arrival rate and proportion of left turn vehicles as the independent variable based on analyzing the change relation of roundabout capacity which varies with loop flow in gap-acceptance theory. Compared with the gap-acceptance theory model, the new model has the following advantages: model can easily be calculated, parameters can easily be obtained. In the last part, the roundabout maximum traffic capacity was defined according to the characteristics of its self-adjustment of traffic flow and was acquired by using the new model. Thus the new model can provide more practical references for planning design of roundabouts.

INTRODUCTION

Various calculating models of non-signal-controlled roundabout capacity are mainly based on three theories. One model is the blending theory model with the maximum capacity of interwoven section of the roundabout. The capacity model, which was established based on the blending theory, was widely applied in early periods. The second model which is currently widely used analyzed the largest number of vehicles entering the loop in various road and traffic conditions based on the gap acceptance theory. The third model is the regression model which reflects the relationship between the roundabout's capacity and the vehicle arrival rates. This model has poor adaptability, so different types of intersections model are difficult to unify.(Bo Chun-yu,2002; Ren Fu-tian;2001; Ruili Wang,2002;Xie Jun,2007)

The calculating model which was proposed by domestic experts (Xiang Qiaojun, 2000) for the capacity of the low channeling roundabout based on the theory of gap acceptance theory applied more widely. However, this model has some shortcomings in computation complexity and parameter determination, such as loop flow and the ratio of free vehicles flow at loop lane. Moreover the maximum capacity of the roundabout is not easy to compute. The roundabout has a self-adjustment function. The roundabout capacity depends on that the number of vehicles entering into the loop is equal to the largest number of vehicles entering into the loop. Therefore, it is crucial to solve the equilibrium points between the capacity

and the vehicle arrival rate for the calculation of the roundabout capacity. But the gap-acceptance model is very difficult to solve the equilibrium point. Hence, this paper tried to establish more practical model for the capacity formula of low channeling roundabout and solve the maximum capacity is very important based on the gap acceptance model.

CAPACITY MODEL BASED ON GAP-ACCEPTANCE THEORY

The models of gap-acceptance theory change with the number of loop lanes. The capacity calculating models of sub single-loop and double-loop lanes are separately established by domestic experts Xiang Qiaojun, etc.

The capacity of single-loop roundabout is:

$$C_e = 3600 \times \frac{\alpha q_r e^{-\lambda(t_c - t_m)}}{1 - e^{-\lambda t_f}} \tag{1}$$

Where, C_e is the capacity of the roundabout, *pcu/h;* t_m is the minimum headway, *s;* t_f is the follow up time of the vehicle at loop, *s*; t_c is the critical gap time (the minimum time of the vehicle passing through the loop and entering into the loop), *s*; q_r is the loop vehicle flow, *pcu/h;* α is the proportion when the headway of loop vehicles are greater than or equal to t_m (the proportion of free flow at loop); $\lambda = \alpha q_r /(1 - q_r t_m)$.

Left and right approach capacities are divided into by Double-loop roundabout capacity which are analyzed respectively. The right approach capacity is the same as the total single-loop roundabouts. The total capacity of double-loop roundabout is:

$$C_e = 3600\left[\frac{q_r e^{-\lambda'(t_c - t_m)}}{1 - e^{-\lambda' t_f}}\left(1 - \frac{2q_{r1}q_{r2}t_m}{q_{r1} + q_{r2}}\right) + \frac{\alpha_2 q_{r2} e^{-\lambda_2(t_c - t_m)}}{1 - e^{-\lambda_2 t_f}}\right] \tag{2}$$

Where, C_e is the capacity of the roundabout, *pcu/h;* q_{r1}, q_{r2} are respectively vehicle flow inside and outside the loops, *pcu/s*; α_1, α_2 are respectively free flow proportions inside and outside the loops; $\lambda' = \alpha_1 q_{r1} / (1 - t_m q_{r1}) + \alpha_2 q_{r2} / (1 - t_m q_{r2})$.

CAPACITY MODEL BASED ON VEHICLE ARRIVAL CHARACTERISTICS

The loop flow is the key factor for the roundabout capacity in the gap-acceptance theory model, so it is necessary to establish the relationship between the loop flow and vehicle arrival characteristics before establishing the capacity model based on vehicle arrival characteristics. The loop vehicle flow q_r is the mean flow in four conflict point sections (see Fig.1). Each section's loop flow is equal to the sum of its left side approach flow direction and its opposite approach left turn flow direction (It is assumed that all of the arrival vehicles can enter and through the intersection). Therefore, the mean flow in four conflict point sections is:

$$q_r = q(1/4 + \beta_L / 4) \tag{3}$$

Where, q is the total vehicle arrival rate of roundabout, *pcu/s*; β_L is the

proportion of vehicles which are turning to the left.

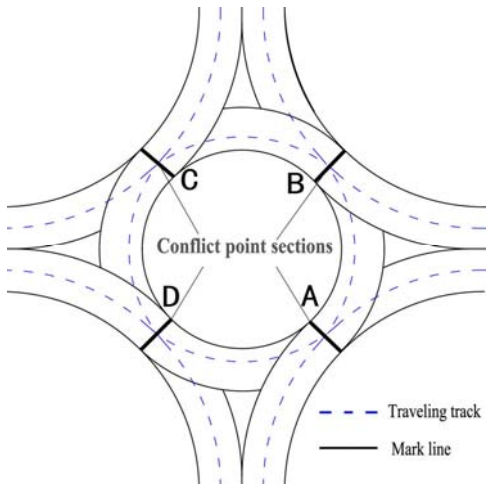

Figure 1. Schematic Diagram of Conflict Point Sections

From plenty of investigation and relating literature (Chen Kuan-ming, 2003), in Formula 1 and 2, the suggested values of related parameters are calculated according to the standard car as follows: $t_m = 2s$，$t_c = 6s$，$t_f = 3s$. In theory, various combinations of α and q_r can achieve, but α will constantly decrease with the increase of q_r. According to literature review and field investigation, the value range of α with change of q_r is given (see table 1，Xiang Qiaojun, 2000). Thus in the light of the Formula 1, roundabout traffic capacity can be calculated correspondingly at different loop flow.

Table 1. Value Range of q_r and α

q_r, *pcu/h*	<500	500～600	600～800	800～1000	1000～1200
α	1	0.9	0.8	0.7	0.6

The roundabout capacity can be calculated on the basis of Formulas 1 and 2. According to Formula 3, loop flow can be replaced by vehicle arrival rates and the proportion of left turn vehicles. Thus, we can calculate and acquire the roundabout capacity under the condition of different arrival rate and proportion of left-turn vehicles (see Table 2).

Table 2. Capacity at Different Arrival Rates and Proportion of Left Turn Vehicles

a. Single-Loop Roundabout （*q*, *pcu/h*）

	q=1000	q=950	q=900	q=850	q=800	q=750	q=700
β_L=0.05	826	843	861	879	897	915	934
β_L=0.10	809	827	846	865	883	902	921
β_L=0.15	792	812	831	850	870	889	909
β_L=0.20	776	796	816	836	856	877	897
β_L=0.25	759	780	801	822	843	864	885

β_L=0.30	743	764	786	807	829	851	873

b. Double-Loop Roundabout （*q* , *pcu/h*）

	q=1600	q=1550	q=1500	q=1450	q=1400	q=1350	q=1300
β_L=0.05	1525	1549	1573	1597	1622	1646	1671
β_L=0.10	1478	1502	1528	1553	1579	1605	1631
β_L=0.15	1431	1457	1483	1510	1537	1564	1591
β_L=0.20	1386	1413	1440	1467	1495	1523	1552
β_L=0.25	1341	1369	1397	1426	1454	1483	1513
β_L=0.30	1298	1326	1355	1385	1414	1444	1475

According to calculation results of Table 2, we can calculate the difference between roundabout traffic capacity and vehicle arrival rate changes with vehicle arrival rates and the proportion of left turn vehicles. (see fig.2).

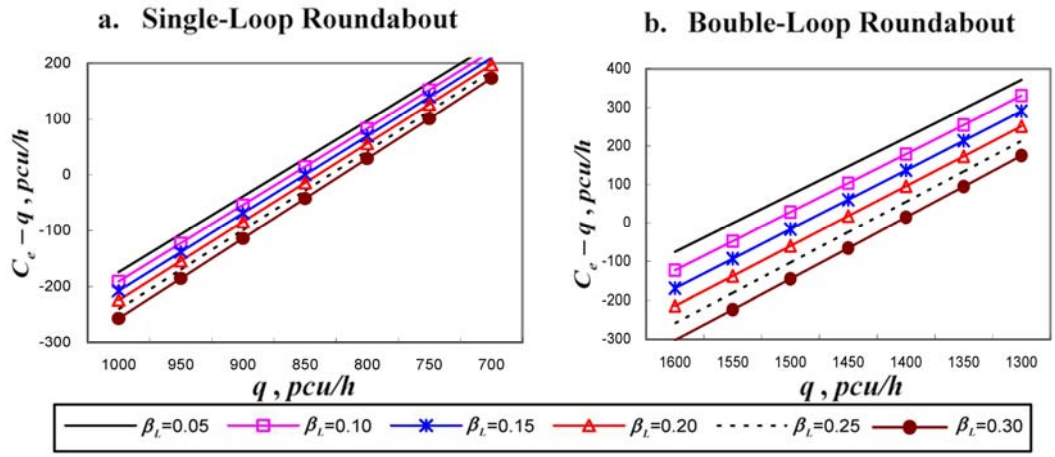

Figure 2. Relation Graph of q and $C_e - q$ about No-Signal Roundabout

The Fig. 2 can be drawn: A linear relationship holds between the q and $C_e - q$ about no-signal roundabout. The formula of the relationship between C_e, q and β_L can be established by using the linear regression method. Using the calculation data of Table 2, we obtain the fitting formulas 4 and 5, and the correlation coefficients of fitting formula are over 0.9.

The capacity of a single-loop roundabout is:

$$C_e = 1187.019 - 0.345q - 0.295q\beta_L - 36.076\beta_L \quad (4)$$

The capacity of a double-loop roundabout is:

$$C_e = 2319.063 - 0.468q - 0.315q\beta_L - 188.94\beta_L \quad (5)$$

Formulas 4 and 5 are acquired by regressive analysis of the formulas 1 and 2, but more simple forms of expression. Moreover, the change law of roundabout capacity with vehicle arrival rates and the proportion of left turn vehicles becomes more visual. In addition, the regression linear model is easier to solve.

THE MAXIMUM ROUNDABOUT TRAFFIC ROUNDABOUT CAPACITY

The new model can clearly reflect that the roundabout capacity depends on the vehicle arrival rate. The larger the vehicle arrival rate, the smaller the capacity

and vice versa. When the differences between capacity and vehicle arrival rate are positive, the capacity is still surplus. But the surplus carrying capacity has no practical significance because no more vehicles arrive and enter the loop. With the vehicle arrival rate increases, the surplus value of capacity begins to reduce to zero while the utilization ratio of the roundabout reached the maximum. If at this time the vehicle arrival rate increases further, the capacity becomes less than vehicle arrival rate, as well as the surplus value is negative while the roundabout begins to be crowded, or even blocked. Thus, when the capacity equals the vehicle arrival rate, the capacity value reached the maximum. The capacity which was obtained through the equilibrium point is defined as the roundabout maximum capacity. The maximum capacity is analyzed considering various roundabout correction coefficients.

The roundabout capacity model based on the gap-acceptance theory is modified properly in "Analysis on the Capacity of Urban Road" (Chen Kuanming, 2003). Correction coefficients and correction method are as follows:

$$F_L = 1.14 - 0.92\beta_L \quad (6)$$

$$F_R = 0.76 + 1.60\beta_R \quad (7)$$

Where, F_L, F_R are respectively the correction coefficients of left and right turn vehicles; β_R is the proportion of right vehicles turn.

Based on the above correction coefficients and Formulas 4 and 5, making the C_e equal to q, we can calculate the maximum roundabout capacity at different proportion of left and right turns (see table 3).

Table 3. Maximum Capacity at Different Proportions of Left and Right Turns

a. Single-Loop Roundabout （*pcu/h*）

	β_L=0.00	β_L=0.05	β_L=0.10	β_L=0.15	β_L=0.20	β_L=0.25	β_L=0.30
β_R=0. 00	669	661	653	645	637	629	622
β_R=0. 05	739	730	721	713	704	696	688
β_R=0. 10	810	800	790	781	771	762	753
β_R=0. 15	880	869	859	848	838	828	819
β_R=0. 20	951	939	927	916	905	895	884
β_R=0. 25	1021	1008	996	984	972	961	949
β_R=0. 30	1091	1078	1065	1052	1039	1027	1015

b. Double-Loop Roundabout （*pcu/h*）

	β_L=0.00	β_L=0.05	β_L=0.10	β_L=0.15	β_L=0.20	β_L=0.25	β_L=0.30
β_R=0. 00	1200	1183	1166	1149	1132	1116	1100
β_R=0. 05	1327	1307	1288	1270	1251	1234	1216
β_R=0. 10	1453	1432	1411	1391	1371	1351	1332
β_R=0. 15	1580	1556	1534	1512	1490	1469	1448
β_R=0. 20	1706	1681	1656	1632	1609	1586	1563
β_R=0. 25	1832	1805	1779	1753	1728	1703	1679
β_R=0. 30	1959	1930	1902	1874	1847	1821	1795

Table 3 can be drawn: no-signal roundabout capacity depends on its proportion of left and right turns. When the proportion of left and right turns lies between 0%~30% and the vehicle arrival rate of single-loop roundabout is more than 620~1090 *pcu/h*, its capacity would be less than the vehicle arrival rate. This will cause large delays and even traffic jams. Therefore, the single-loop roundabout is suitable for less than 620~1090 *pcu/h* vehicle arrival rates. The double-loop roundabout is suitable for less than 1100~1960 *pcu/h* vehicle arrival rates.

CONCLUSION

The paper first studies the relationship between vehicle arrival rates and loop flow of roundabouts. Then, based on the gap-acceptance roundabout capacity model, the simplified regression model is established on the basis of vehicle arrival rates and proportion of left turn vehicles as the independent variable. Compared with the gap-acceptance theory model, the new model has the following advantages: the model can easily be calculated and parameters easily be obtained. Finally, this paper obtains the maximum capacity and the adaptation range of traffic arrival rates by the use of the regression model.

The regression model is obtained based on the gap-acceptance model of the low channeling roundabout, and therefore only applicable to the low channeling roundabout. If the loop lane has a right turn lane, the right turn vehicles need not to drive intertwined with straight and turning left vehicles at the loop. Thus, the calculated maximum capacity is the maximum capacity of the straight and left turn vehicles. The roundabout capacity model needs to be further studied under the conditions of more than two loop lanes.

Abstract

The distance of midblock crosswalks directly influences traffic flow stability and operating efficiency. Considering the present situation of urban transportation in China, the reasonable distance of midblock unsignalized crosswalks was studied combined with the characteristics of vehicle traffic flow and pedestrian flow. In the peak hour traffic environment, eleven kinds of pedestrian crossing distance were designed (150m~400m, gap is 25m) in simulation model Vissim. Data of average speed time series, vehicular delay and pedestrian delay under time scales of 1s, 5s and 10s were obtained. The largest Lyapunov index of average speed time series was used to identify the influence of crosswalk distance over vehicle traffic flow stability. Vehicular delay and pedestrian delay were utilized to reflect the relationship among the distance of midblock crosswalks, vehicle flow efficiency and pedestrian crossing efficiency. This research takes the midblock management mechanism into consideration, balances the relationship among traffic flow stability, efficiency and pedestrian efficiency, and puts forward the recommended midblock crosswalk distance.

1 Introduction

Crossing is the main passage which pedestrians use to cross the street, and it also is an important component of Urban Transportation Facilities. It forms an Interaction System with the traffic flow and influence each other. Some scholars have studied the mutual interference between traffic flow and pedestrian on the crossing. Based on the behaviors of drivers and pedestrians crossing the street, Aronsson (2007) analyzed the impact of a single crosswalk on vehicle speed. Bastian (2007) set up the evaluation framework about the single crosswalk and vehicle traffic flow. Kaseko (2004) used Vissim to simulate the situation of pedestrian crossing on urban main roads, which reflected the influence of a single crosswalk on vehicle speed. But the above research all started from the angle of single crosswalk and did not get involve the distance of a continuous crosswalk. Research analyzed the effect of crosswalks on traffic flow from vehicular delay and pedestrian delay, which makes the evaluation lack all-sidedness. At present, confirmation about the distance of

crosswalks mainly depends on experience, some scholars(Yang, 2003 & Zhai, 2004) realized the tolerable walking distance of pedestrians according to different road functions, and then proposed the corresponding distance recommendation value. Only several researches had studied rational distance, such as the study of Lu(2002). In view of this, this paper plans to adopt the method of Computer Simulation, study the relationship between the distance of crosswalks and traffic flow from two aspects of traffic flow stability and efficiency, and finally confirm a rational value.

2. Traffic flow stability and efficiency

2.1 Definition and measurement of traffic flow stability

Traffic flow stability is an important index of measuring the running quality of traffic flow. If the traffic flow is stable, generally it is in an uncrowded and unblocked state of highway density section, speed fluctuations are orderly within the rational range. When it was interfered with by environment, it has a relatively strong ability to resume the original stable state. If the traffic flow is unstable, the density and speed at different times will be in disorder, which makes the efficiency of the traffic flow and traffic safety level reduced. Therefore, traffic flow stability is an important index of evaluating rationality of traffic facilities.

The paper uses the largest Lyapunov index λ_1 of average vehicle speed time series to reflect traffic flow stability. λ_1 is one of the common values reflecting chaos motion characteristic. λ_1 is a kind of index that can measure the average divergence and convergence of neighboring trajectory. Whether it is greater than zero or not can be regarded as a standard to judge whether the time series are in chaos(Lv, 2002), its value also indicates the system's chaotic degree. If $\lambda_1 > 0$, system is certainly chaos, an unstable condition(Zhu, 2008). When $\lambda_1 < 0$, the vector system in the direction of the movement is stable, the system's movement is in a certain predictable and orderly condition .The system is stable. This paper uses VISSIM simulation system to obtain average vehicle speed time series under different time scale, and then makes use of this sequence's largest Lyapunov index to distinguish the influence of crosswalk distance on vehicle flow stability.

2.2 Definition and measurement of efficiency

Pedestrians on crosswalks as an exterior interference will influence the operational efficiency of traffic flow. This paper uses vehicular delay and pedestrian crossing times to measure the influence of crosswalk distance on traffic efficiency. The equally lost time for vehicular delay and each vehicle passing the crosswalk is used to measure the influence crosswalk distance on the traffic efficiency. Pedestrian crossing time is the sum of time from the longitudinal sidewalk to the crosswalk and the time it takes a pedestrian to go through. Generally speaking, pedestrians will choose the crosswalk that is nearer them while conducting crossing behavior, usually the most disadvantageous crossing position is in the midpoint between two neighboring crosswalks. Here is an assumption that pedestrians uniformly distributed on both sides of road and pedestrian speed is constant. The paper approximately assumes that pedestrian embarks from the pedestrian crossing $d/4$ position moving toward this crosswalk, then street, and pedestrian crossing time is as follows:

$$t = t_1 + t_2 = d/(4 * v_p) + t_2 \qquad (1)$$

Where, t ——Pedestrian crossing time; t_1 ——Time of pedestrian along the longitudinal sidewalk arriving at the beginning of the nearest crosswalk; t_2 ——The time of pedestrian passing the crosswalk, can be provided from VISSIM simulation; d ——Distance of crosswalks, 150~400 m, gap is 25m; v_p ——Walking speed of pedestrian.

3. The simulate experiment of pedestrian flow and vehicle flow interaction

3.1 experiment scenes

The experiment adopts simulation software of VISSIM (4.1 edition) of Germany PTV Company. VISSIM is a discrete, random urban road micro-simulation software with (1/10) as time step long. It is based on the city traffic and the public transport simulation model, among them vertical sports of vehicles are adopted "psychology-physiology following model"; it can be set up with several parameters for example, vehicle parameter, traffic parameter, road parameter etc., also can imitate the reappearance the real road traffic conditions to the maximum extent. The simulation method can provide long time serial on different time scales, and avoid the restriction of surveying the data of traffic flow.

3.1.1 The characteristic of highway section

According to national standards of P.R.C.Code for transport planning on urban roads (GB-50220-1995), this paper adopts 1km long in total, six lanes of a two-way main road straight line sections as experiment section, and the width of the lane is 3.5 m, longitudinal slope for 0, width of crosswalk on lane are designed according to urban road design specification, priority rules of the crosswalk and lane are set up according to Mohamed S Kaseko(2004).11 kinds distance of crosswalk have been designed in the experiment (150m~400m, gap is 25m). In addition, in VISSIM, set up the corresponding data collector and road evaluation in order to get average speed, vehicular delay and pedestrian crossing time.

3.1.2 Parameter input

Choosing a model workday after field investigation, find the vehicle flow of peak hour in Peace Road in Wuhan city of China is 3000pcu/h, at the same time also survey traffic generation and attraction amount of crossing pedestrians are 800 persons/(hour*direction) in 1km of sections. According to the research of Wang(2007), we set up total cumulative frequency curve of pedestrian crossing. Vehicle speed on arterial highway is set up as 40~60km/h, the pedestrian average speed is 1.15m/s. The difference distance of crosswalks will cause its quantity to change; therefore under different distances the pedestrian flow on the crosswalk is different. The paper supposes that the pedestrian reaches the crosswalk equally, and the road section on both sides will establish the guard rail to force pedestrians to observe the traffic regulations, then under each distance of crosswalk, pedestrians flow on each are equal under every distance of crosswalk. According to the measured data, calculate the unidirectional pedestrian attraction quantity in each hour is 0.8 person /m, in view of crosswalk distance is different, obtains that crosswalks on the 1km main road can attract the length of D pedestrian crossing quantity, then calculate total pedestrian attraction quantity Q in the 1km section.

$$D=[\mathrm{int}(1000/d)+1]\square d \qquad (2)$$

$$Q = 0.8D = [\text{int}(1000/d)+1]\times 0.8d \text{ (person/(hour*direction))} \quad (3)$$

$$Q' = Q/\text{int}(1000/d) \text{ (person/hour/direction)} \quad (4)$$

Where, Q—The total attraction quantity of pedestrian,

Q'—The unidirectional crossing quantity of pedestrian on each crosswalk.

In VISSIM, the quantity of pedestrians crossing in the experimental section in VISSIM is in accordance with Q'.

3.1.3 Simulation parameter

At the initial stage of simulation, the vehicles are not distributed uniformly, vehicle flow parameters record are infidelity, so 400 seconds is regarded as the starting point of data recording. In the experiment, different simulation time-periods are selected, and different intervals are set up, thus output data under different time scales 1s, 5s and 10s are obtained. In each situation, four different random numbers are chosen, their averages are calculated in order to dispel the randomness of the experimental data after getting the data separately in simulations of each kind of situation.

3.2 Experimental results

3.2.1 Influence of distance on stability

From the simulation experiment, obtain time series of average vehicle speed under each distance of crosswalk and under different time intervals of 1s, 5s and the 10s, then get the largest Lyapunov index λ_1 through compiling programs in Matlab, see Figure 1.

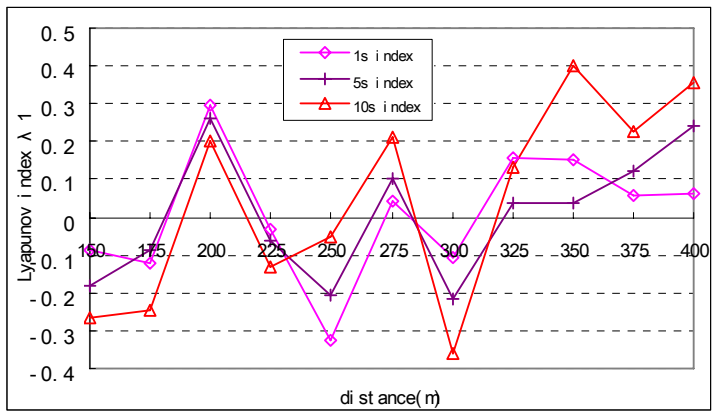

Figure 1. Lyapunov index λ_1 under different distance

It indicates that eleven types of distances are having remarkable effects on stability (p-value<0.01) to carry on variance analysis to data of Figure 1.As seen in Figure1, when the distance is 150m, 175m, 225m, 250m, 300m, λ_1 are negative, this shows that its traffic flow is stable; λ_1 of the remaining six types of distance are all positive, the traffic flow is in chaos. From Figure.1 also seen that λ_1 under different time scales is self-similarity, which indicates that it is reasonable to use chaos thought to judge crosswalk distance.

It indicates that eleven types of distances are having remarkable effects on vehicular delay and pedestrians crossing time of (p-value<0.01) after carrying on

analysis of variance to Figure 2 data. Seen from Figure 2, with the increase of crosswalk distance, the average speed shows the downward parabola trend change on the whole, when the distance is 250m, average speed is the largest, secondly are 275m and 300m. At the 150~250m, average speed increases with increased distance. Under the distances of 300~400m, average speed reduces with increased distance.

3.2.2 Influence of distance on efficiency

The vehicular delay and pedestrian crossing time have been shown in Figure 2, the vehicular delay of 250m is minimum. At the distance of 150~250m, vehicular delay reduces slightly with increased distance. Begin from 325m, vehicular delay increases sharply with increased distance, at distance of 350m~400m, the increasing degree slows down, delay at 400m is the maximum, and the whole curve presents the parabola with upward line. Pedestrian crossing time at 150m is the minimum, and at 400m is the maximum. It increases with the increased distance, and presents linear change on the whole.

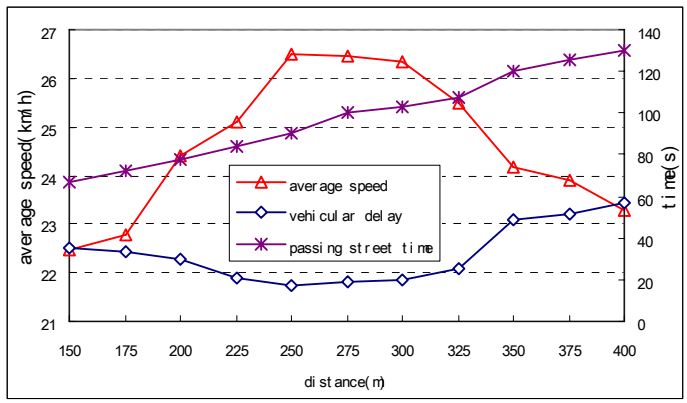

Figure 2.Average speed under different time scale and vehicular delays and passing street time of pedestrians under different distances

4 Discussion and analysis

The main road as an important component in urban road network and can be divided into two kinds: traffic and service. While studying crosswalk distance on main road, first analyze road management function of these two types of main roads, then based on the demand of traffic flow stability, vehicle operating efficiency, and pedestrian efficiency a reasonable value is determined.

The traffic main roads view the function of "passing" of a motor vehicle as the main purpose, give consideration to other traffic modes; generally speaking, it mainly relies on fast traffic. While confirming its distance of the crosswalk, should first make it meet the demand of traffic flow stability and vehicle operational efficiency, and then meet the demand of pedestrian efficiency, causes them to be most optimally balanced. The main service roads emphasize the function of "reaching", rely mainly on living service function, and pay attention to the services of different traffic modes. On the crosswalk of the service main road, the right of way of vehicles and pedestrians are equal; the distance should simultaneously meet stability, vehicle efficiency and pedestrian efficiency.

According to road management functions of traffic and service main roads, different weights of stability, vehicle efficiency and pedestrian efficiency of traffic

and main service roads are given respectively, they are 0.4:0.4:0.2 and 1/3:1/3:1/3. The stability index λ_1 and efficiency index (vehicular delay and pedestrian crossing time) are all cost indexes. Here stipulates that for each index the minimum value is 100 points, the maximum value is 0 point. According to different weights, the comprehensive scores under eleven types of distances are calculated separately, the results as shown in Figure 3.

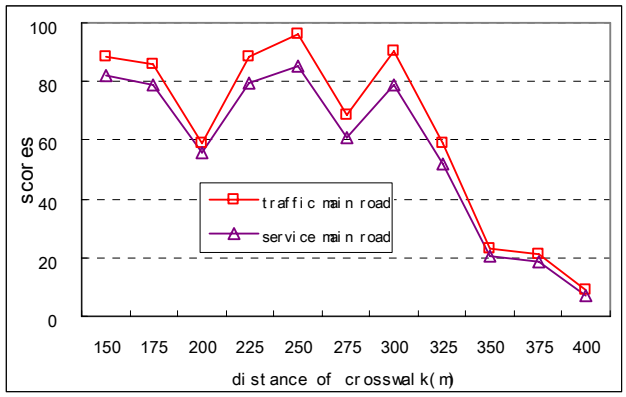

Figure 3.Weight ratios of stability vehicle efficiency and pedestrian efficiency of traffic and service main roads are respectively 0.4:0.4:0.2 and 1/3:1/3:1/3

In Figure 3, the comprehensive score of 250m is the largest. It can well meet the demand of traffic and service main road to stability and efficiency; therefore the recommended crosswalk distance on main road is 250m.

ABSTRACT

In this era of socialist countryside construction, lack of consideration for local residents, vehicles, and community roads in new rural community planning leads to unsustainable development. Green transportation systems that are appropriate for production and living should be developed for rural communities. Traffic Calming techniques can be used to optimize the road network and reduce the negative impact of motor traffic. By analyzing the case of Baodi, Tianjin, this study suggests how to build an appropriate scale, orderly, safe, comfortable and low energy consumption green transportation system and create a scientific, healthy, and sustainable new rural community development.

1. INTRODUCTI ON

Transportation is a key problem that can deeply affect the quality of human lives especially in residential communities. A new chapter was written in the 11th Five-Year Plan (China, 2006) with the major historic task of building and urbanizing the new socialist countryside. However, the theoretical study of transportation planning comparatively lags behind rapid construction. In designing and planning new-rural communities, lack of consideration of three elements of transportation, including local residents, traffic vehicles, and community roads (Boulter, 1999), leads to unsustainable development of the transportation planning system.

The purpose of this research is to build a green transportation system by means of using Traffic Calming techniques, such as reducing the turning radius, setting the bottleneck speed, and improving the road marks to optimize the road network in new rural communities and reduce the negative impact of motor traffic, creating a safe and pleasant environment.

2. BACKGROUND S

2.1 Green Transportation

Green transportation advocates that stress on the traffic organization should be put on the pedestrians in the road space, reducing the negative impact of motor traffic to the maximum limit to create pleasant, livable, and sustainable communities (Kallberg and Ranta, 2000). This idea is similar to the opinion of New Urbanism that encourages resolution of traffic problems on the basis of the comfortable distance of pedestrians in the neighborhoods (Yang dong-feng, 2007).

2.2 Traffic Calming

2.2.1 History of Traffic Calming

In the USA, traffic calming as a method to design roads and road networks to physically enforce lower driving speeds and to reduce traffic volumes, started as early as 1928 with an experimental neighborhood design in Radburn (Bagby , 1980). In the late 1960s, this idea was further implemented in Europe with the development of the SCAFT guidelines in Sweden, promoting the development of residential areas accessed by a system of ring roads. The technologies of traffic calming have been widely accepted in the neighborhoods of advanced countries (Webster, 1998, 2000).

2.2.2 Tendency of Techniques

Traditional traffic calming consists of four sections: (i) vertical deflections, (ii) horizontal deflections, (iii) volume deflections, and (iv) traffic signs deflections. The purpose of traffic calming schemes is to lower the speed of automobile into 30～40 kilometers per hour and achieve an enjoyable environment of safe streets. However, the studies in practice indicate that the traditional techniques have some flaws, such as averting the traffic pressure from one neighborhood to another, producing a limited effect on lowing transportation by a single technique (Silke, 1996). The tendency of techniques in the field is in the direction of regional and synthetic study.

3 METHODOLOGY

3.1 Site Selection

The study has been carried out in Majiadian which is located in the south district of Baodi in Tianjin. The distance is 8 kilos away from Baodi district and 60 kilos away from Tianjin city. The project of the new rural community is the promoter region for living, which be situated on east of one branch, south to the 5th Road, west to the 18th Road, north to the 4th and east to the 19th Road, the area of construction land is 7.51 hectares (Figure1).

Figure 1 Site Selection

3.2 Specific Schemes

3.2.1 Foundation of Green Transportation

The design of the community was aimed at building a green transportation system which is orderly, accessible, ecological, and low consumption. The road network adopted community-level "community-level road, group-level road, foot-level road", which is made of two cross roads-A and B, one ring road-C. The width and the form of the road-network is shown in Figure 2.

Figure 2 Scheme of Green Transportation

3.2.2 Improvement of Schemes

There are two more effective and acceptable traffic calming devices follow to optimize the schemes: Speed Bumps and Speed Humps.

(i) Speed Bumps

Speed bumps are raised pavement areas across a roadway and generally have a height of 3 to 6 inches with a length of 1 to 3 feet. These are typically found on private roadways and parking lots and do not tend to exhibit consistent design parameters from one installation to another. A bump causes a driver significant discomfort at typical residential speeds and generally results in vehicles slowing to 5 mph or less at the bump. At high speeds, bumps tend to have less overall vehicle impact because the suspension quickly absorbs the impact before the vehicle body can react (Bos and Dijkstra, 1998).

(ii) Speed Humps

Speed humps are raised areas in the roadway pavement surface extending transversely across the travel way. Sometimes called pavement undulations or sleeping policemen, speed humps normally have a maximum height of 3 to 4 inches with a travel length of approximately feet (Carsten, 1998). Within typical residential speed ranges, humps create a gentle vehicle rocking motion that causes some driver discomfort and results in most vehicles slowing to 15 mph or less at each hump and 25 to 30 mph between properly spaced humps in a system (Watts, Stait, Godfrey, Chinn and Layfield, 2002). At high speeds, the hump can act as a bump and jolt the vehicles suspension and its occupants or cargo.

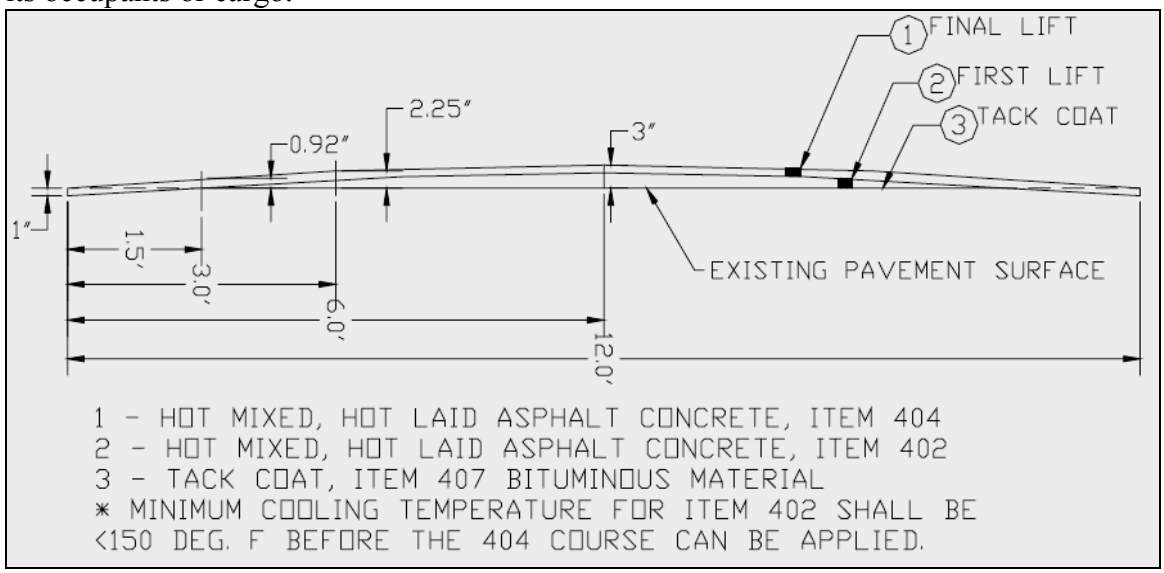

Figure 3 Speed Hump

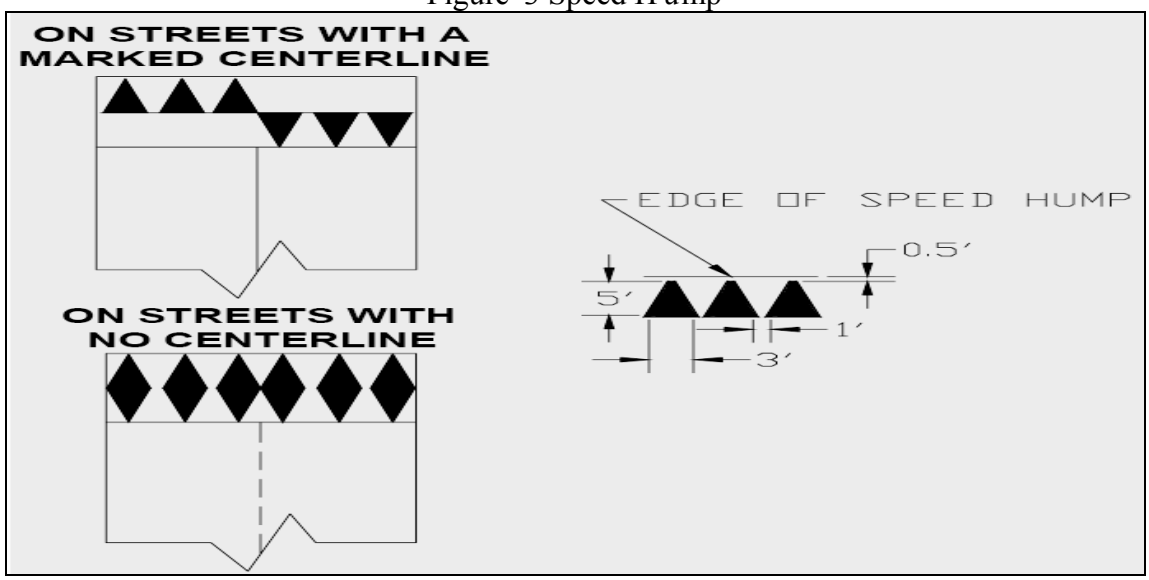

Figure 4 Speed Humps – Shark Teeth (Marking) Detail

4 ANALYSIS

Through simulated experiments, the results indicate that after using the traffic techniques the environment of the community has been greatly improved. The road network is constructed to very high standards, almost completely straight over more than 0.3 kilos, with pavement width in excess of 7 meters and with wide verges. Problem areas reported include: A relatively recent increase in traffic volumes; High speed on the road; A large percentage of heavy vehicles using the road; High noise levels emanating from the road; Accidents occurring on the road. The data below reveals that the important functions of speed bumps and humps applied in the scheme.

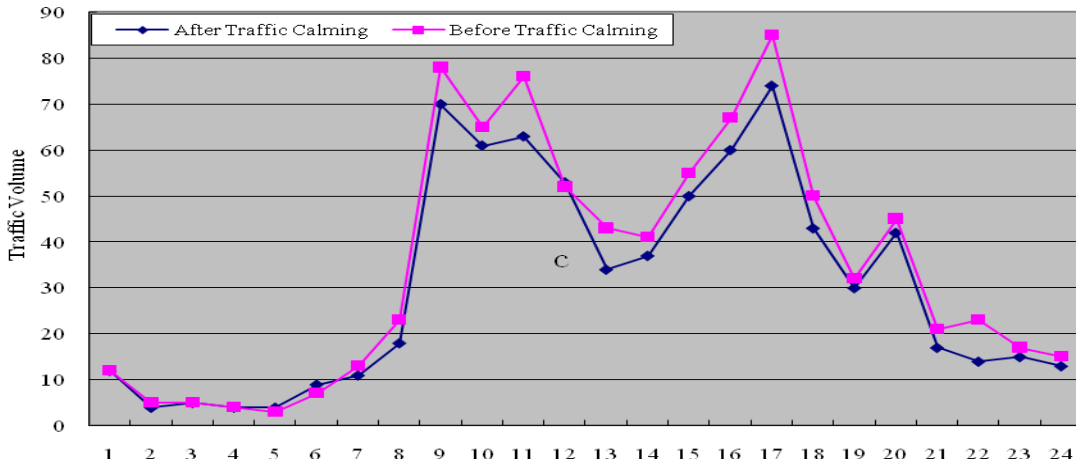

Figure 5 Total Traffic Volume

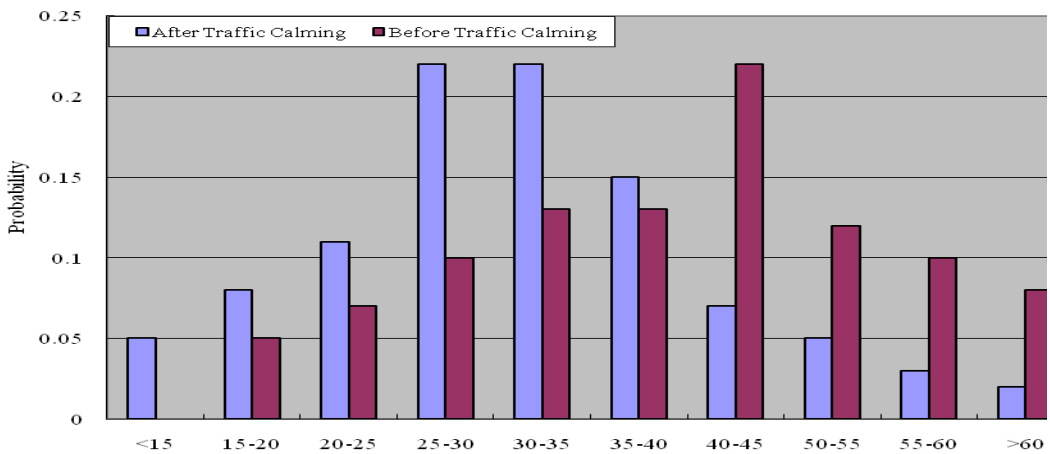

Figure 6 Percentage of Vehicles in Speed Classes

5. CONCLUSIONS

This literature review has shown that traffic calming is an effective and economical tool in planning green transportation in new rural communities to reduce vehicle speed, noise, and road accidents. It puts forward to build an appropriate scale, orderly, safe, comfortable, and low energy consumption of green system to realize the scientific, healthy, and sustainable development of new socialist rural communities.

[2]School of Transportation, Southeast University, Nanjing, 210096, China.

Abstract: The passenger traffic mode split is the result of the integrated effect among various factors, which are interrelated and mutually independent as well as interacted and mutual restrictive. In order to analyze the motivation of traffic structure, the influence mechanism of different factors should be analyzed comprehensively to figure out the basic caustic relationship between each factor. The structure model of system engineering modeling method will be applied to clarify the logical relationship between different factors. Furthermore, the mode split prediction method based on the structure model of various factors will be set up by fitting survey data. The result of the case analysis with less errors illustrates this method is easily applicable and of great value.

Introduction

The commonly forecasting model in trip mode split includes the diversion curve model, probability model, regression model etc. In the last few years, Chinese researchers placed an emphasis on trip mode split which meets the requirement of sustainable development, while the foreign study varies widely: Schmocker *et al.* studied modal split by the different attributes(gender, age, profession etc) of the travelers with different selection characteristics(Schmocker *et al.* 2008), Bergstrom *et al.* discussed the influence mechanism of external factors such as natural conditions, architectural environment, urban form and so on(Bergstrom 2003; Robert, 2002); in addition, Thogersen *et al.* analyzed the traffic mode structure in one certain city or area(Thogersen, *et al.* 2006; Goran, *et al.* 2006).

The inherent law of change in traffic structure would be ignored on the condition of only analyzing the regression equation between mode split and its related factors. The system structure model which was first introduced by Professor John N. Warfield (the United States, 1973), is widely used to analysis social, economic, environmental, management systems (Haijun, 2006; Benjamin *et al.*, 2006) for system planning. Transportation system involves many different elements. Consequently, some indirect relationship should be introduced to clarify the relationships between various elements, and the structural model should first be established, then forecast traffic modal split step by step.

Factors for mode split

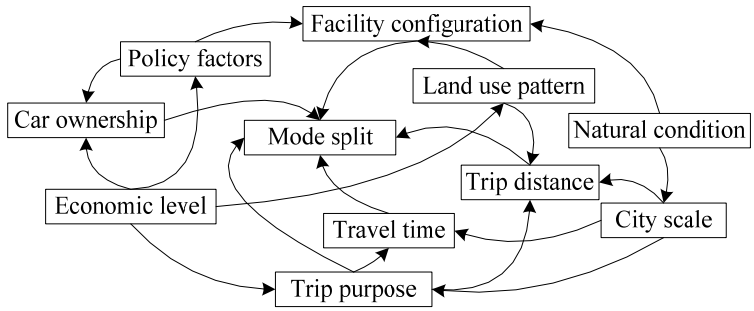

Fig.1 Causality among Influencing Factors of Trip Mode Split

Structural model building

The corresponding computation for the relationship between the influencing factors (in Figure 1) would be performed by establishing a multi-level hierarchy model (Dong, 2007; Shangyun, 2004).

0.1 Causal relationship matrix calculation

0.1.1 Adjacency Matrix building

First, define variable symbols and numbering as follows: V_1-mode split, V_2-trip distance, V_3-travel time, V_4-trip purpose, V_5-traffic facilities configuration, V_6-private vehicle ownership rate, V_7-policy factors, V_8-economic level, V_9-urban form, V_{10}-city scale, V_{11}-natural conditions.

Then set up the adjacency matrix, which is denoted by R, and describe the direct relationship between every two factors in the system. The elements of $\mathbf{R}$ is defined as:

$$\gamma_{ij} = \begin{cases} 1 & \text{accessible from } V_i \text{ to } V_j \\ 0 & \text{no route between } V_i \text{ and } V_j \end{cases} \quad (1)$$

0.1.2 Accessibility matrix calculation

Accessibility matrix, which describes the factors accessible degree of the system through a certain length of path, can be obtained by certain computing with the sum of adjacency matrix and unit matrix. Simplifying assumptions are:

$$\mathbf{R}_1 = (\mathbf{R}+\mathbf{I})^1, \quad \mathbf{R}_2 = (\mathbf{R}+\mathbf{I})^2, \quad \ldots \mathbf{R}_n = (\mathbf{R}+\mathbf{I})^n \quad (2)$$

It could be calculated to $(\mathbf{R}+\mathbf{I})^p = (\mathbf{R}+\mathbf{I})^{p+1}$ in turn with application of the rules of Boolean algebra. Take matrix $\mathbf{R}$ to operation in accordance with such rules to get:

$$\mathbf{R}^2=\mathbf{R}^3=\mathbf{M}=\begin{bmatrix} 1&0&0&0&0&0&0&0&0&0&0 \\ 1&1&0&0&0&0&0&0&0&0&0 \\ 1&0&1&0&0&0&0&0&0&0&0 \\ 1&1&1&1&0&0&0&0&0&0&0 \\ 1&0&0&0&1&0&0&0&0&0&0 \\ 1&0&0&0&0&1&0&0&0&0&0 \\ 1&0&0&0&1&1&1&0&0&0&0 \\ 1&1&1&1&1&1&1&1&1&0&0 \\ 1&1&0&0&1&0&0&0&1&0&0 \\ 1&1&1&0&1&0&0&0&0&1&0 \\ 1&1&1&0&1&0&0&0&0&1&1 \end{bmatrix} \quad (3)$$

0.1.3 Accessibility Matrix decomposition

Accessibility matrix decomposition consists of the following steps: first, demarcate the region, and then decompose inter-level. Decomposition algorithm can be described as follows: constitute an accessible set $X(V_i)$ with the factors relevant to V_i, the factors

which can arrive V_i will compose an antecedence set $Y(V_i)$. The mathematical relationship is stated as formulation (5):

$$X(V_i)=\left\{V_j \in W / m_{ij}=1\right\},\quad Y(V_i)=\left\{V_j \in W / m_{ji}= \right. \tag{4}$$

Where W is node set of all the factors, m_{ij} is the correlation degree of node i and j (value 1 or 0).

Set up a new set defined as the common set T, which contains all the factors V_i that the intersection of accessible set and antecedence set is equivalent to the antecedence set.

$$T=\left\{V_i \in X(V_i) \bigcap Y(V_i)=Y(V_i)\right\} \tag{5}$$

Then the accessible set, antecedence set, as well as the intersection of these can be found on the basis of known matrix M, as shown in Table 1. For inter-level decomposition, conditions can be seen in formulation (7):

$$X(V_i) \bigcap Y(V_i)=X(V_i) \tag{6}$$

Available from Table 1, only the element 1 satisfy this requirement, confirm $L_1=\left\{V_1\right\}$ being the first level, then remove the element 1 from the table, continue the calculation, the second level is educed to be $L_2=\left\{V_2, V_3, V_5, V_6\right\}$. Similarly, calculate the third level and the fourth level. Upon that, rearrange the row vector of the matrix according to the order of $\{1,2,3,5,6,4,7,9,10,8,11\}$, and then in accordance with the above order rearrange the column vector to obtain the shifted accessibility matrix $\mathbf{M}'$:

$$\mathbf{M}'=\begin{bmatrix} 1&0&0&0&0&0&0&0&0&0&0 \\ 1&1&0&0&0&0&0&0&0&0&0 \\ 1&0&1&0&0&0&0&0&0&0&0 \\ 1&0&0&1&0&0&0&0&0&0&0 \\ 1&0&0&0&1&0&0&0&0&0&0 \\ 1&1&1&0&0&1&0&0&0&0&0 \\ 1&0&0&1&1&0&1&0&0&0&0 \\ 1&1&0&1&0&0&0&1&0&0&0 \\ 1&1&1&1&0&0&0&0&1&0&0 \\ 1&1&1&1&1&1&1&1&0&1&0 \\ 1&1&1&1&0&0&0&0&1&0&1 \end{bmatrix} \tag{7}$$

0.2 Establish multi-level hierarchy model

We minus identity matrix from the shifted accessibility matrix $\mathbf{M}'$. From the definition of accessibility, knowing that: ①V_2, V_3, V_5, V_6 the second level only the first level V_1, namely $V_2 \to V_1$, $V_3 \to V_1$, $V_5 \to V_1$, $V_6 \to V_1$; ② then remove the column and row which V_1 is in to establish the relationship between the second and third level. We can see that the third level has V_4, V_7, V_9, V_{10}, whose mutual influence relationships are $V_4 \to V_2$, $V_4 \to V_3$, $V_7 \to V_5$, $V_7 \to V_6$, $V_7 \to V_5$, $V_9 \to V_2$, $V_9 \to V_5$, $V_{10} \to V_2$, $V_{10} \to V_3$, $V_{10} \to V_5$; ③ remove rows and columns which $V_2 V_2$, V_3, V_5, V_6 are in to know V_8, V_{11} existing in the fourth level, that is $V_8 \to V_7$, $V_8 \to V_9$, $V_{11} \to V_9$. Based on the foregoing analysis, can establish a four-level hierarchical model as Figure 2:

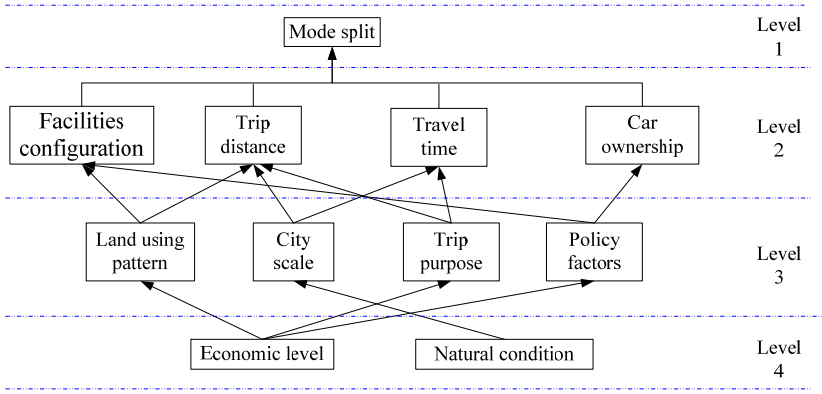

Fig.2 Structural Model for Influencing Factors of Trip Mode Split

1 The mode split prediction method

1.1 The indicators of variable factors

Based on the relevant research data (Crane 2000; Shangyun 2004; Haixiao 2005; Haifeng 2006), the variable factors indicators can be determined as follows:

①Urban form C: Urban form can be described by urban planning disciplines: select the compact degree as quantitative indicator for the urban form as formula (9).

$$C = A / \pi R^2 \tag{8}$$

Where A is the area of built-up section of the city. πR^2 is the area of the smallest circumcircle of the city.

②City scale S: With the view to integrity and comprehensiveness, the urban population is taken for indicator.

③Trip purpose I: In this paper, indicators for the trip purpose is defined as:

$$I = I_{\text{elastic}} / I_{\text{non-elastic}} \tag{9}$$

Where I_{elastic} and $I_{\text{non-elastic}}$ are proportions of elastic travel and non-elastic travel (work, school and backhaul) respectively.

④Policy factor P: We classifies policy in accordance with the strength for public transport priority shown in Table 1, demonstrating reference data of each type of cities for quantify.

Tab.1 Policy Intensity of Prioritize Public Transportation

Policy of prioritize public transportation	Very large	larger	general	little	none
value	0.75～1	0.5～0.75	0.25～0.5	0～0.25	0

⑤Transport facilities configuration R: Road network density as the analysis is selected as R indicator.

⑥Private vehicle ownership rate O

⑦Travel time T: Select the average travel time-consuming of the traffic survey data.

⑧Trip distance: Most of the domestic cities estimate the trip distance through the average travel time-consuming and travel speed of different traffic modes, as formulation (10).

$$D = \sum_i T_i V_i f_i \tag{10}$$

Where T_i is the average travel time-consuming of traffic mode i; V_i is the average travel

speed of traffic mode i(V_i of walking, bicycle, bus, car is 3.6, 9, 14.4, 27km/h respectively); f_i is the split rate of traffic mode i.

⑨Mode split rate M : Mode split rate could access from the trip survey data directly.

1.2 Mathematical modeling for all levels

The basic data in this paper is from transportation school of Southeast University, including different sizes and patterns cities. Taking into account that the complicated natural conditions is difficult to quantify, it started from the third level.

1.2.1 Relation between the second level and the third level

Set up the relationship between trip distance D and urban form C, city scale S, trip purpose I ; as well as between travel time T and city scale S, travel purpose, the relationship between transport facilities configuration R and urban form C, policy P; and between private vehicle ownership rates O and policy P.

① Data Fitting $D = F_1(C, S, I)$

$$D = 7.853\times10^{-2}\sqrt{S} + 0.157C - 0.208\exp(I) + 2.269 \quad (R^2 = 0.736) \tag{11}$$

Where, D is trip distance (km); S is city scale (million people).

We use the square of the adjusted correlation coefficient value (Adjusted R Square) to evaluate the model, which is known as model precision coefficient, namely, R^2 's closer to 1, the model's more accurate.

② Data fitting $T=F_2(S, I)$

To S, I, Use logarithmic and exponential function to fit respectively:

$$T = 3.580\ln(S) - 1.386\exp(I) + 7.676 \quad (R^2 = 0.853) \tag{12}$$

Where, T is travel time, other parameters are ditto.

③ Data fitting $O=F_3(P)$

$$O = -70.418P^4 + 127.3P^3 - 70.814P^2 + 14.661P - 0.1207 \tag{13}$$

④ Data fitting $R=F_3(C, P)$

Use composite exponential to fit to C, while to P, use the form of exponential function. Following formula reveals the fitting results:

$$R = -9.25\times10^{-2}\exp(\exp((C - 0.211)/0.432)) + 2.942\times10^{-2}P^{-1.974} + 5.987 \tag{14}$$

Where, C, P are the same as above.

1.2.2 Relation between the second level and first level

Set up relationship between mode split M and transport facilities configuration R, trip distance D, travel time-consuming T, private vehicle ownership rate O.

① Walk-split data fitting $M_\alpha = F_4(R, D, T, O)$

$$M_\alpha = -0.476R - 7.265D + 0.274T - 13.942O + 55.757 \quad (R^2 = 0.893) \tag{15}$$

Where, M_α is the walk-split rate (%),other parameters are ditto.

Judging form formulation (15), trip distance influences the walk-split rate most strongly, hence, it could be an important consideration to select the walk mode in microcosmic scale.

②Bicycle-split data fitting $M_\beta = F_4(R, D, T, O)$

$$M_\beta = 3.190R + 14.518D - 1.458T - 3.458O + 19.195 \quad (R^2 = 0.967) \tag{16}$$

Where, M_β is bicycle split rate (%).

③Public transport-split data fitting $M_\gamma = F_4(R,\ D,\ T,\ O)$

$$M_r = -2.694R - 5.682D + 1.126T + 6.247O + 12.540 \quad (R^2 = 0.926) \qquad (17)$$

Where, M_r is the public transport vehicles split rate (%).

The travel time plays most roles in public transport split.

④Car-split data fitting $M_\omega = F_4(R,\ D,\ T,\ O)$

$$M_\omega = 0.219R - 1.741D + 0.216T + 10.337O + 6.594 \quad (R^2 = 0.903) \qquad (18)$$

Where, M_ω is the car split rate (%).

1.3 Model validation

Model validation is to verify the goodness of fit of built model, reality system and testing whether the model can reflect the characteristics and changing rule of reality system or not. We used survey data from Weifang city to validate the built model, the good forecasting results in Table 2 show practical value of the proposed method.

Tab.2 Prediction accuracy of mode split forecasting results

	Predictive value	Survey data	Error rate		Predictive value	Survey data	Error rate
M_α	23.96	21.72	10.17%	M_r	8.94	8.08	9.62%
M_β	52.37	55.82	-6.18%	M_ω	14.76	14.38	2.64%

2 Conclusions

From the view of data analysis, factor contribution rate was used in the model to estimate the influencing effects of motor vehicle population, trip distance, road traffic facilities, travel time on trip mode split. The analysis results can provide theoretical basis for trip mode structure policy.

It is a new attempt to build the hierarchical structure model for modal split, which comprehensively considers all aspects of influencing factors in the transportation system. Moreover, calculation results which are the factual manifestation of traffic structure in this city, can be a great help for policymakers to grasp the traffic structure in a macro level and plan the further transportation more profoundly. However, accuracy decision coefficients (R Square) in parts of formulations are not as high as expected, indicating a certain gap with actual situations, so the pioneer work can be traced to solve these problems.

A Multi-class Multi-modal Combined Model for TDM Measures Evaluation in Large Scale Urban Transportation Network

ZHANG Tianran[1,2], YANG Dongyuan[1], YANG Chao[1] and ZHAO Yali[1]

[1]School of Transportation Engineering, Tongji University, Shanghai 201804, China
[2]Shanghai City Comprehensive Transportation Planning Institute, Shanghai 200040, China, PH (86) 21-62792285, email: zhangtianrantj@163.com

Abstract: A multi-class multi-modal combined modal split and traffic assignment model is formulated by variational inequality. It is used to evaluate the effects of Travel Demand Management (TDM) measures quantitatively in large scale urban transportation system. Three algorithms, i.e., Generalized Partial Linearization, Method of Successive Averages, and Constant Weight are compared. The convergence results show that the proposed algorithm is competent for practical application. Sixteen pure and combined TDM measures, such as cordon-based congestion charge, Park and Ride, fuel pricing, bus fares decrease, and bus exclusive lanes construction are tested quantitatively using the comprehensive transportation network of Huizhou, Southern China. The evaluation focuses on the sensitivity of public transport fares, the competition between taxi and rail transit, the effect of bus exclusive lanes, the different effects of cordon-based congestion charge and parking charge as well as the demand of Park and Ride under different parking charge.

1 Introduction

In recent years, with rapid economic and social development, metropolises in China are confronting difficulty balancing the restriction in road space resources and the increasing demand of motorization. The government realizes that great efforts should be made to develop public transportation and implement suitable TDM to construct sustainable urban transportation systems. To evaluate TDM, network model needs to have two critical capabilities, i.e. the capability to model the different behavior by heterogeneous travelers to the TDM in multi-modal transportation network and the capability to model various TDM measures simultaneously. The heterogeneity or multiclass means that people with different value of time (VOT) or different trip purpose will have different preferences of travel time and cost. Ignoring heterogeneity of VOT may cause serious errors in travel demand prediction and policy evaluation. On the other hand, combined models can reflect the interaction of multi-modal transportation system. Florian, Wu and He (2000) formulated the problem as a variational inequality, which is the most detailed multiclass, multimodal combined model. Kaneko, et al. (2001) estimated the impact of Area License Scheme with multi-class combined modal split and assignment model in the Bangkok Metropolitan Area. Boyce and Marshall (2002) had collaborated in the implementation and application of three combined models for the Chicago region for evaluating policy alternatives. There is much literature about this topic but we lack the space here to introduce the research. This paper concerns the travel behavior of multi-class users under TDM measures. Nine modes including pure modes, such as Private car, Taxi, Bus (with Bus exclusive lane), Rail, and combined modes, such as

P&R, Taxi & Rail, Bus & Rail are considered in the model. The interaction among different traffic flows, i.e., car, bus and freight, are modeled as asymmetric traffic assignment problem. The multi-modal vehicles such as trucks and buses are treated as vehicles instead of passenger car unit, As a result, the Jacobian of general cost is asymmetric. This is different with multi-modal traffic assignment model in current commercial software such as EMME/2 and TransCAD. The uniqueness of the asymmetric traffic assignment is guaranteed by special link travel time function. It works well in several large scale urban transportation networks.

2 Model formulation and algorithms

2.1 Travel behavior assumption

(1) Multiclass users

The mixed logit form directly corresponds to the situation, in which VOT and underlying utility coefficients for travel time and cost are assumed randomly distributed, rather than deterministic. We assume travelers have different VOT and submit to the lognormal distribution and classify it to the discrete set. The mean VOT of each class is calculated by

$$\overline{v}_i = \int_{v_{i-1}}^{v_i} vf(v)dv \Big/ \int_{v_{i-1}}^{v_i} f(v)dv,\ \forall i = 1,2,...,I \tag{1}$$

where v is the VOT, $f(v)$ is the VOT's probability density function of lognormal distribution.

(2) Route choice in multimodal network

The probability of choosing route k on condition that for user class i with their own VOT, from zone r to zone s by mode m, is given by

$$\Pr(k \mid i,r,s,m) = \exp\left(-\theta_1 C_{rs,k}^{i,m}\right) \Big/ \sum_k \exp\left(-\theta_1 C_{rs,k}^{i,m}\right) \tag{2}$$

where $C_{rs,k}^{i,m} = t_{k,rs}^{i,m} + p_{k,rs}^{m} / v_i$ is the general cost composed by time and monetary cost, $t_{k,rs}^{i,m}$ is the travel time of path k by mode m between OD pair (r, s) for user class i, $p_{k,rs}^{m}$ is the monetary cost of path k by mode m between OD pair (r, s) for user class i. v_i is the mean VOT of user class i. θ_1 is the diversion parameter of route choice.

(3) Modal choice

Probability of choosing mode m on condition that for user class i, from zone r to zone s, is given by,

$$\Pr(m \mid i,r,s) = \exp\left[-\theta_2\left(V_{rs}^{i,m} + S_{rs}^{i,m}\right)\right] \Big/ \sum_m \exp\left[-\theta_2\left(V_{rs}^{i,m} + S_{rs}^{i,m}\right)\right] \tag{3}$$

where $S_{rs}^{i,m} = -\ln\sum_k \exp\left(-\theta_1 C_{rs,k}^{i,m}\right)(1/\theta_1)$ is the inclusive cost of route choice, $V_{rs}^{i,m}$ is the component of mode choice cost except from travel cost between OD pair (r, s). θ_2 is the diversion parameter of mode choice.

2.2. Model formulation

The model is formulated as a variational inequality problem

$$\sum_{r,s,k,i,m}\left[C_{rs,k}^{i,m}(\mathbf{f}^*) + \frac{1}{\theta_1} f_{rs,k}^{i,m*} \ln\frac{f_{rs,k}^{i,m*}}{q_{rs}^{i,m*}}\right]\left(f_{rs,k}^{i,m} - f_{rs,k}^{i,m*}\right) + \sum_{r,s,i,m}\left[\frac{1}{\theta_2} q_{rs}^{i,m*} \ln\frac{q_{rs}^{i,m*}}{q_{rs}^{i*}} + q_{rs}^{i,m*} V_{rs}^{i,m}\right]\left(q_{rs}^{i,m} - q_{rs}^{i,m*}\right) \geq 0 \tag{4a}$$

s.t.

$$\sum_m q_{rs}^{i,m} = q_{rs}^{i}, \forall i, r, s \tag{4b}$$

$$\sum_k f_{rs,k}^{i,m} = q_{rs}^{i,m}, \forall r, s, i, m \tag{4c}$$

$$x_a^{i,m} = 1/voc_m \times \sum_{rs,k} f_{rs,k}^{i,m} \delta_{a,k}^{i,m,rs}, \forall i, m, a \tag{4d}$$

$$x_a^m = \sum_i x_a^{i,m}, \forall m, a \tag{4e}$$

$$q_{rs}^{i,m} \geq 0, f_{rs,k}^{i,m} \geq 0, x_a^{i,m} \geq 0, t_a^m(x_a^m) > 0, \frac{\partial t_a^m(x_a^m)}{\partial x_a^m} > 0, \theta_1 > \theta_2 > 0, \forall i, m, r, s, k, a \tag{4f}$$

where voc_m is vehicle occupancy (person-trip/vehicle-trip) for mode m, q_{rs}^{i} is OD trips of user class i sum of all mode. $q_{rs}^{i,m}$ is OD trips of user class i with mode m. $f_{rs,k}^{i,m}$ is the path flow(trips). $x_a^{i,m}$ is vehicle flows of user class i on link a of travel mode m. x_a^m is flows on link a of mode m. $\delta_{a,k}^{i,m,rs} = 1$ if path k between OD pair (r, s) by mode m user class i includes link a, and 0 otherwise. $C_{rs,k}^{i,m}(\mathbf{f})$ is route general cost function where $\mathbf{f}$ is the vector of flows of all physical vehicle type. We assume there are interactions between modes in this model. For different physical type of vehicles (multi-modal), the Jacobian of general cost function is asymmetric. The uniqueness of model solution is related to the form and parameters of link travel time function. We use a special type of link travel time function and the calibrated parameters can guarantee the uniqueness solution of x_a^m. For example, the route general cost of cars (private car and taxi) in class i is

$$\text{GCost(car,i)} = \sum_{a \in MiniPath} \left[t_a^{car}(\mathbf{x_a}) + (toll_a + fuel \times length_a)/(voc_{car} \times v_i) \right] \tag{5}$$

where

$$t_a^{car}(\mathbf{x_a}) = t_a^{car,0} \left[1 + \alpha_{car} \left(\left(x_a^{car} / C_a^{car} \right)^{\beta_{car}} + \gamma_{car} \left((x_a^{HGV} + F_a^{bus}) / C_a^{car} \right)^{\beta_{car}} \right) \right] \tag{6}$$

and $t_a^{car,0}$ is the car's free flow travel time in link a, $x_a^{car} = \sum_i \left(x_a^{i,car} + x_a^{i,taxi} \right)$ is total flow of private cars and taxies with different VOT. v_i is VOT of class i. x_a^{HGV} is the freight vehicle flows in link a, F_a^{bus} is the bus flow, C_a^{car} is the capacity, $toll_a$ is the toll of link a, $fuel$ is the fuel cost of one kilometer for cars and $length_a$ is the length of link a. It is worthwhile to remark that the link travel time function can reflect the level of service (LOS) of each mode in different congestion conditions. When the road is not congested, the LOSs' for different modes are considerably different. For example, cars will have higher speed than buses when the road is not congested. Similarly, the link travel time of freight vehicles is defined as

$$t_a^{HGV}(\mathbf{x_a}) = t_a^{HGV,0} \left[1 + \alpha_{HGV} \left(\left((x_a^{HGV} + F_a^{bus}) / C_a^{HGV} \right)^{\beta_{HGV}} + \gamma_{HGV} \left(x_a^{car} / C_a^{HGV} \right)^{\beta_{HGV}} \right) \right] \tag{7}$$

The necessary condition for $\nabla_a^{car,HGV}$ (Eqs.8) to be positive definite is that $0 < \gamma_{car} \cdot \gamma_{HGV} < 1$. The parameters in Eqs. (6) and (7), i.e., α_{HGV}, β_{HGV}, γ_{HGV}, α_{car}, β_{car}, γ_{car}, are calibrated and have a good fit of mixed traffic. Details are given in Zhang's PhD dissertation (2008).

$$\nabla_a^{car,HGV} = \begin{bmatrix} \dfrac{\partial t_{car}}{\partial x_{car}} & \dfrac{\partial t_{car}}{\partial x_{HGV}} \\ \dfrac{\partial t_{HGV}}{\partial x_{car}} & \dfrac{\partial t_{HGV}}{\partial x_{HGV}} \end{bmatrix} \tag{8}$$

The uniqueness of the model solution $x_a^{i,m}$ can't be guaranteed because we cannot expect the travel disutility vector appearing in the variational inequality (4) to be strictly monotone even though all the link travel cost functions are strictly monotone. So in this model, we attempt to test the multi-model asymmetric traffic assignment and multi-class traffic assignment simultaneously in large scale network. The uniqueness characteristic of solution (x_a^m and $x_a^{i,m}$) is demonstrated in large scale networks. Kuhn-Tucker conditions for this problem lead to fore-mentioned travel behavior assumption. In order to simplify the model, we change formula (4a) as determinate route choice, i.e. $\theta_1 \to \infty$.

$$\sum_{r,s,k,i,m} C_{rs,k}^{i,m}(\mathbf{f}^*)\left(f_{rs,k}^{i,m} - f_{rs,k}^{i,m*}\right) + \sum_{r,s,i,m}\left[q_{rs}^{i,m*}/\theta_2 \ln q_{rs}^{i,m*}/q_{rs}^{i*} + q_{rs}^{i,m*}V_{rs}^{i,m}\right]\left(q_{rs}^{i,m} - q_{rs}^{i,m*}\right) \geq 0 \tag{9}$$

2.3.Algorithms and convergence criterion

We use the generalized partial linearization (GPL) and simplified diagonal method to solve variational inequality problem (4).

Step0: Initialize the multi-modal multi-class travel cost as zero for each OD pair. Each link has zero flow. Set n=0;

Step1: Calculate the minimal cost $C_{rs}^{i,m}(n)$ and the modal split $e_{rs}^{i,m}(n)$. Do all or nothing assignment for multi-modal multi-class trips and update travel cost;

Step2: Do all or nothing assignment for multi-modal multi-class trips and obtain the subsidiary link flow solution $y_a^{i,m}(n)$. Set iteration number n=n+1;

Step3: Find the best combined search direction $\lambda(n)$ for $\min F\left[q_{rs}^{i,m}(n+1), x_a^{i,m}(n+1)\right]$

$$F\left[q_{rs}^{i,m}(n+1), x_a^{i,m}(n+1)\right] = \sum_{m,a}\alpha_m \int_0^{x_a^m(n+1)} t_a^m(x_a^1(n),\ldots,x_a^{m-1}(n), w, x_a^{m+1}(n),\ldots,x_a^{|M|}(n))dw \tag{10}$$

$$+\sum_{i,m,a} x_a^{i,m}(n+1)p_a^m/v_i + \frac{1}{\theta_2}\sum_{i,m,r,s} q_{rs}^{i,m}(n+1)\ln\frac{q_{rs}^{i,m}(n+1)}{q_{rs}^i} + \sum_{i,m,r,s} q_{rs}^{i,m}(n+1)V_{rs}^{i,m}$$

Step4: Convergence test. If not convergent, update the link flows and go to Step 1, otherwise terminate.

In Step 3, in finding the search direction $\lambda(n)$, the diagonal method is used. So the other mode's flows of objective function are fixed by last iteration. It is easy to use bi-section linear search method to find the optimal search direction $\lambda(n)$

$$\begin{aligned} \frac{d}{d\lambda}F\left[q_{rs}^{i,m}(n+1), x_a^{i,m}(n+1)\right] &= \sum_m \alpha_m \times \sum_{i,a}\left[y_a^{i,m}(n) - x_a^{i,m}(n)\right] + \sum_{i,m,a}\left[y_a^{i,m}(n) - x_a^{i,m}(n)\right] \times p_a^m/v_i \\ &+ \frac{1}{\theta_2}\sum_{i,m,r,s}\left\{\left[e_{rs}^{i,m}(n) - q_{rs}^{i,m}(n)\right] \times \ln\frac{q_{rs}^{i,m}(n) + \lambda(n)\left[e_{rs}^{i,m}(n) - q_{rs}^{i,m}(n)\right]}{q_{rs}^i} + \left[e_{rs}^{i,m}(n) - q_{rs}^{i,m}(n)\right]\right\} \\ &+ \sum_{i,m,r,s}\left[e_{rs}^{i,m}(n) - q_{rs}^{i,m}(n)\right]V_{rs}^{i,m} = 0 \end{aligned} \tag{11}$$

It has been generally understood that the weights yielded by the line search step of the above algorithms may be replaced by predetermined weights, based on the properties of the Method of Successive Averages (MSA). This method may become useful when no objective function $F[\mathbf{q}, \mathbf{x}]$ is available. The weights $\lambda(n)$ generally

applied with MSA are 1/n. Computational experiences revealed that using Constant Weights (CW), instead of MSA, may yield a substantially improved result (Sheffi, 1985). The values of 1/n in MSA are replaced by Constant Weights $\bar{\lambda}$.

In Step 4, the general convergence criterion we test in large scale network is

$$RGap = \frac{\sqrt{\sum_{i,m,a}(x_a^{i,m(n+1)} - x_a^{i,m(n)})^2}}{\sum_{i,m,a} x_a^{i,m(n)}} + \frac{\sum_{r,s}\sum_{i,m} q_{rs}^{i,m(n+1)} \mid q_{rs}^{i,m(n+1)} - q_{rs}^{i,m(n)} \mid}{\sum_{r,s}\sum_{i,m} q_{rs}^{i,m(n)}} \tag{12}$$

However, this convergence criterion is not so suitable for MSA algorithms and it is better to calculate the recent three iteration's value (Sheffi, 1985). This will require a considerable memory in practice. We give MSA Revised criterion (Noriega and Florian, 2007) as following

$$RGap = \frac{\sum_{a}\sum_{i,m} x_a^{i,m(n+1)} \times C_a^{i,m}(x_a^m) - \sum_{r,s}\sum_{i,m} MRC_{r,s}^{i,m(n+1)} \times q_{rs}^{i,m(n+1)}}{\sum_{r,s}\sum_{i,m} MRC_{r,s}^{i,m(n+1)} \times q_{rs}^{i,m(n+1)}} + \frac{\sum_{r,s}\sum_{i,m} q_{rs}^{i,m(n+1)} \mid q_{rs}^{i,m(n+1)} - q_{rs}^{i,m(n)} \mid}{\sum_{r,s}\sum_{i,m} q_{rs}^{i,m(n)}} \tag{13}$$

where $MRC_{r,s}^{i,m}$ is the minimal general cost of OD pair (r, s) for class i using mode m.

2.4. Convergence performance in case study

We realize the model's algorithm with VC++ coding and use a personal computer with Intel Pentium(R)D 2.8GHz CPU, 1GB memory to test it in a large scale network in Huizhou, southern China. There are 269 Traffic Analysis Zones, 13,006 road links and 65 bus lines related to the road network, 4,122 road nodes, 102 rail links and 49 rail stations, 2,600 centroid connectors and transfer links. There are 735,774 total motorization trips and 65,650 freight vehicle trips in a typical peak hour. According to the stated preference survey, the VOT distribution was estimated by mixed logit model. We divide the personal trips into five classes by Formula 1. In Huizhou's study, we considered multi-modal system foregoing. Some algorithm tips of multi-modal shortest path are available in Zhang's PhD dissertation (2008).

The relative gap decreased stably both by GPL and MSA methods as shown in Fig. 1. Generally, MSA Revised relative gap is larger than the value using Formula 10. It takes about one hour to research 0.01. Although CW methods work well in Boyce's separable multi-class combined mode (Boyce and Bar-Gera, 2003), in our case, it has no stable solution because there is no convergence after a long calculation. Fig. 2 shows that relative gap decreased at first, but moved up and down for a long time. It could not be decreased to 0.15. So in an asymmetry traffic assignment, CW may not work well. Note: we received the same result by testing this method in another large scale network of Shenzhen, with 491 Traffic Analysis Zones and about 13,000 links.

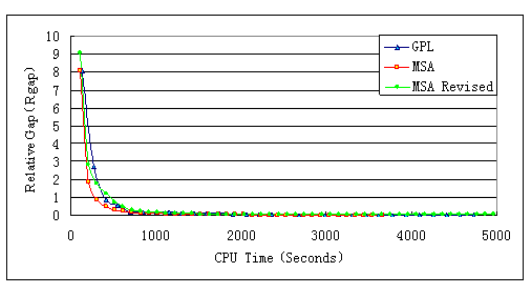

Figure 1. Convergence performance of GPL and MSA methods

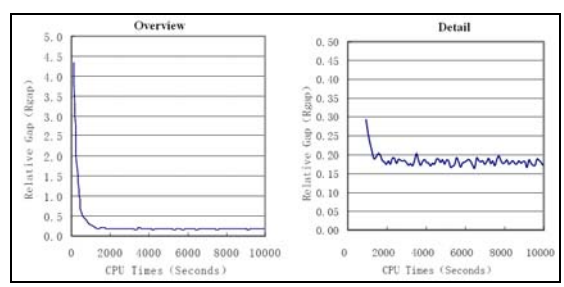

Figure 2. Convergence performance of CW method

3 TDM measures evaluation

We test 16 pure and combined TDM measures such as cordon based congestion charge, bridge's charge, parking charge, Park and Ride, fuel pricing, public transportation fares decrease, bus exclusive lanes construction, transfer time decreased and truck regulation. We set 17 scenarios, No.1 means no TDM measures (basic scenario) and No.2 to No.17 mean 16 pure and combined TDM measures. The detail of each TDM measure is listed in Tab. 1. The spatial position of Park and Ride, Cordon based Charge, Bridge Tolling, and Parking Charge are given in Fig. 3. The bus exclusive lanes are given in Fig. 4. There are abundant results such as different traveler classes having different travel behaviors under the TDM measures, car users changed their routes or use other transportation mode, and so on. For the limitation of the paper's length, we focus on following four themes.

Table 1. TDM measures test in Huizhou City

Measures	Measure Descriptions
1	Base scenario without TDM measure
2	Uniform bus fare 2 Yuan (mile based fare in basic scenario)
3	Increase 40% bus frequency in main corridor based on Measure 2
4	Free parking of P+R
5	Uniform Rail fare 3 Yuan
6	Combined Measure 2 and 5
7	Increase fuel fare
8	Bridge tolling: 10Yuan for cars and 15 Yuan for freight vehicles
9	Cordon based charge
10	Combined Measure 8 and 9
11	Combined Measure 10 and 12
12	Parking charge
13	Combined Measure 4, 6 and 10
14	Decrease the transfer time between bus and rail
15	Bus exclusive lanes setting
16	Combined Measure 4, 10 and 15
17	Measure 6 and some bridges do not allow freight vehicles pass

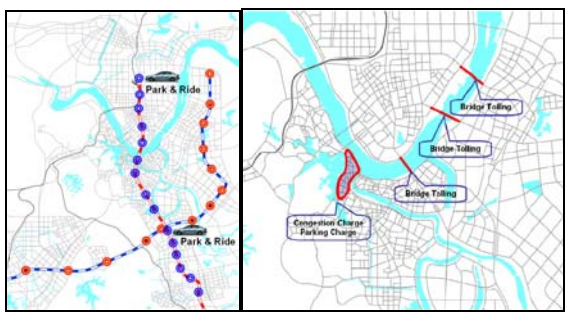

Figure 3. P+R, congestion charge, parking charge and bridge tolling position

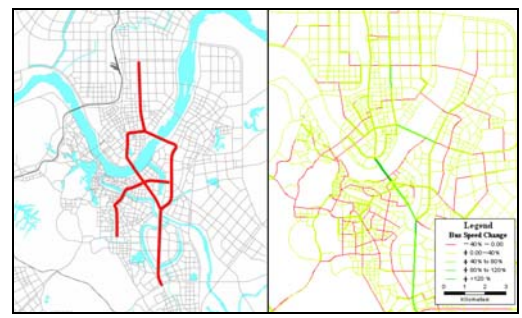

Figure 4. Bus exclusive lanes speed change before and after the TDM Measure

(1) Sensitivity of public transportation fares and the relationship between rail and taxi. When the bus fare decreased, more people will use the bus. Interestingly, the car's mode share does not obviously decrease. That means the mode share of public

transportation doesn't obviously increase. When bus users increased, the bus will become more congested. The result shows that bus and rail combined mode share greatly decreased when we use measure No.2 (see in Fig. 5). In many models, combined transfer modes are not considered. So these models may tell policy decision makers that the decreased bus fare will have a good effect on public transportation priority strategy. This is somewhat misleading. In fact, the new equilibrium leads to the more costly combined mode because of public transportation congestion. Now by using measure No.3 (meanwhile increase the frequency of buses in the main corridor), the bus congestion is alleviated and the increasing bus flow leads to private car congestion. Although the bus and rail combined mode share still decreased, policy makers will be gratified that the car mode share is decreased. When the rail fare decreased, there is a considerable decrease of private car and taxi users. This is mainly because the in-vehicle congestion of mass transit rail is not as obvious as bus. In many big Chinese cities, rail planning and construction are following the fashion. Taxi operators worry about the market of taxi users after the rail construction. In Huizhou's study, however, the combined mode share of taxi and private car transfer to rail is increased. Although the pure taxi users are decreased, taxi operators still can do their business well. The reason for this is there are only three rail lines in Huizhou and have no network scale effect. If rail fare deceased in a city with an accessible rail network, the result may be reversed. Nevertheless, rail fare decrease will reduce the private car usage if the rail is not so congested. From the model's test, we concluded that combined measures such as decreasing the fares of bus and rail simultaneously and increasing bus frequency, will lead to modal share shift more effectively (see in Fig. 5).

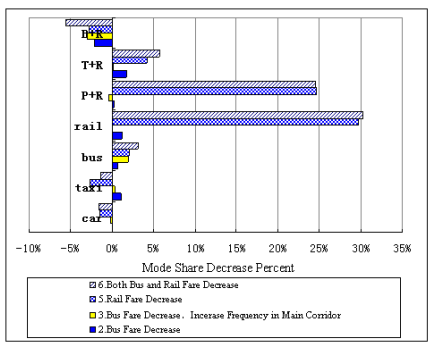

Figure 5. Modal share under the TDM measures of public transportation fare decrease

(2) The effect of bus exclusive lane. In many big Chinese cities, public transportation priority policies are very important and the bus exclusive lane setting is one of most popular measures. Using TDM measure No.15, the 28km bus exclusive lane's average flow density increased 540trips/km·h (see in Fig. 6). It seems that the public transportation priority policy works well by this measure. In fact, the total car users decreased only 126 trips. This is a lesson to decision makers who plan the bus exclusive lane blindly. When we set special lanes for buses, private cars will change their routes in order to minimize their travel time. In our multi-modal variational inequality model, the bus speed is affected by the flow of other vehicles such as private cars. This is very realistic and leads to more road congestion

in the bus lines with no exclusive lanes (see in Fig. 4). The decreasing of total buses' level of service in non-exclusive lanes leads to disutility of bus users. So it is important to plan a certain scale of bus exclusive lane networks and the private cars will have no way to change their routes. Until then, the new equilibrium will lead car users to use other modes.

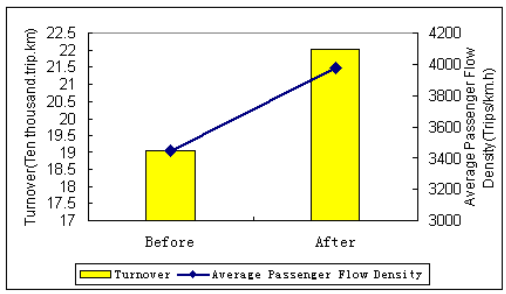

Figure 6. Passenger flow in bus exclusive lanes before and after the TDM Measure

(3) Comparing the effects of cordon-based congestion charge and parking charge. In order to compare the effects of cordon-based congestion charge and parking charge, we set them in the same area which contains four Traffic Analysis Zones (see Fig. 3). In the charging zone, the parking charge works more effectively than cordon-based congestion charge but has the reverse result in the whole city. Cordon-based congestion charge mainly affects through traffic and arrival traffic from non-charging areas to charging areas. Parking charge mainly influences the entire charging area's arrival traffic. The effect of route and modal change of private car users depends on the range of charging areas and the spatial distribution of travel demand. In the case study, congestion charge takes more effect on big volume through traffic and has restrained the car users more effectively than parking charge in the entire city, but it has reverse results in the parking charge area (see Fig. 7). Policy makers may choose combined TDM measures to control the target traffic.

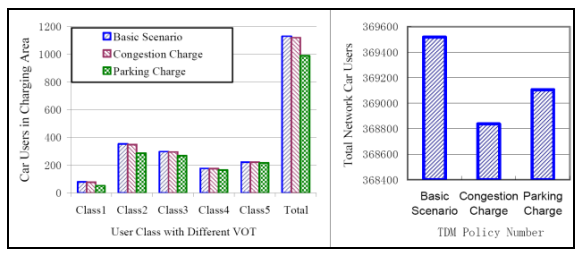

Figure 7. Comparing the effect of congestion charge and parking charge

(4) Park and Ride demand analysis. In our model, P+R demand is analyzed in multi-modal network. We also considered the P+R station choice behavior. If more than two P+R stations are available, the travelers will choose the station that minimizes their total general cost. Many factors like parking fare, rail fare, transfer time and the congestion of center area, affect the traveler to choose this mode. Our model is competent for considering these factors. In our model test, the parking fare is very sensitive. TDM measure No.4 is free parking charge. The total demand of P+R is twice the basic scenario. If we decrease the rail fare simultaneously in TDM

measure No.13, the demand increased more obviously. Using push and pull--combined policies will be more effective. Policy makers should consider the parking price, parking station land use pricing and the benefit of park operator comprehensively.

4 Conclusions

This paper uses a multi-class multi-modal network equilibrium model with combined modal split and route choice model to test various combined TDM measures in Huizhou City. Although further validation needs to be done for the model, this paper gives policy decision makers some valuable conclusions.

(1) Although bus fare decreases encourage people to use pure bus mode, passengers taking the combined mode with rail may be decreased because of the bus in-vehicle congestion. Combined measures such as decreasing the fare of bus and rail simultaneously and increasing bus frequency, will lead to modal share shift more effectively. Rail fare decrease will result in less use of pure taxi and private cars. But the combined mode between taxi and private car to rail may increase if the rail network has no scale effect. (2) Bus exclusive lanes will increase the passenger flow density on them. Meanwhile, cars will change their route to save time, thus decreasing the service of common buses. Consequently, the total modal share of bus can't obviously increase. So it is important to plan a certain scale of bus exclusive lane networks. (3) Cordon-based congestion charge mainly affects the through traffic and arrival traffic from non-charging areas to charging areas. Parking charge mainly influences the whole charging area's arrival traffic. The effect of route and modal change of private car users depends on the range of charging areas and the spatial distribution of travel demand. (4) Whether P+R mode works well depends on many factors like parking fare, rail fare, transfer time and the congestion of center areas. Using push and pull--combined policies will be more effective.

Nonlinear Analysis of Prestressed Steel Box Beams

Yanmin Jia

College of Civil Engineering, Northeast Forestry University, Harbin, No.26, Hexing Road, Xiangfang District, Harbin, Postcode:150040, China; Tel: 86- 0451-82191377; Email: yanminjia2008@126.com

ABSTRACT

Post-tensioning using high-strength cables or tendons can be effectively used to increase the load carrying capacity of steel structure. In this paper, a nonlinear analytical model is formulated for the elastic behavior of a simply supported steel box beam with curved prestressing tendons. The governing differential equation prestress and serve load are derived using the self-equilibrium principle and the principle of minimum potential energy, respectively. The effects of design parameters such as prestressing force, and tendon area on working load and deflection of the steel box beam are studied.

Key words: Prestressed Steel Box Beam; prestressing tendon; self-equilibrium principle

1. Fundamental Equation

The prestressed steel beam shown in fig. 1(Jia Yanmin et al. 2003)，the prestressing was anchored only at the ends with seven uniformly spaced intermediate connections deviators. The saddles are placed at specific locations along the steel beam to create different profiles of the tendons.

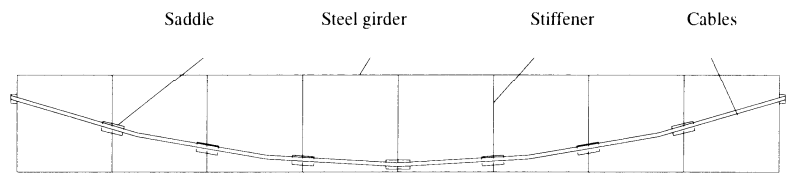

Fig. l Construction of prestressed steel beam

Tendons were provided for the prestressing, during the post-tensioning and under the loading process, the tendons remain in curve, and they could have displacement compatible with the steel beam at the saddle connection points in vertical direction, and there is a relative movement between the tendons and the steel beam along the tendons length.

As prestressed steel beam carries not only external loads, but also longitudinal compression force from prestressing tendons, it is reasonable to analyze them as bean-columns(Ni Yuanzheng et al. 1998). However, as the force in the tendons changes with the deflection of the beam and the external loads, it makes the

prestressed steel beams different from normal beam-columns; it is necessary to analyze the prestressed steel beam specifically.

There are two phases for prestressed steel box beam in the whole procedure (Vincenzo Nunziata. 1999). The first phase is the application of the prestressing force to them, and second one is the application of the external load. We try to perform nonlinear analysis for these two stages. The governing differential equations were derived and solved.

The fundamental assumptions of this analysis method are:

1. Plane surface is maintained;
2. Deformation of the steel box beam due to shear force is negligible;
3. Tendon's strain is considered uniformly distributed throughout the entire tendons.

2. Governing differential equation

2.1 prestressing

After applying tension to the tendons with jacks and tightening them, the steel beam must have upward deflection. The self-equilibrium system would be formed between steel beam and tendons, shown in Figure 2.

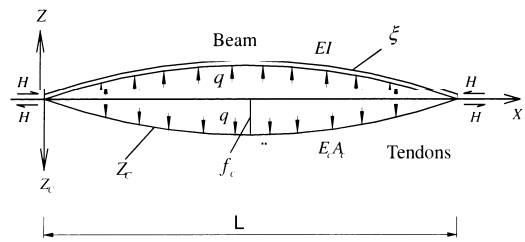

Fig.2 The self-equilibrium state of prestressed steel beam

Based on principal equilibrium, we can get self equilibrium equation of prestressed steel beam on prestressing phase:

$$EI\frac{d^4\xi}{dx^4}+H\frac{d^2\xi}{dx^2}+H\frac{d^2z_C}{dx^2}=0 \qquad (1)$$

Where: E is modulus of elasticity of steel beam; I- moment of inertia of steel beam section; H is the initial horizontal tendons force of tendons，ξ is the upward curve of steel beam was produced by prestressing force H; z_c is the curve of tendons (profile in the steel beam), its distance of mid-span is f_c ; q is equivalent uniform load that was unloading portion of self weight of steel beam.

2.2 loading

In the loading phase, assuming external uniform load is *Q*, $Q = q+p$, the tendons is in contact with the saddle at the tendons bend, but there is assumed to be no friction between the tendons and saddle (Bilal M. Ayyub et al. 1990), the deflection due to shear force of tendons and steel beam is considered negligible, and the tendons strain is considered uniformly distributed throughout the entire beam (Pisanil M A et al. 1996). Tendons were provided for the prestressing, As a result the tendons remain in curve during the loading process, so that they could have displacement compatibly with the steel beam at these connection points in vertical direction during the loading process.

Based on self -equilibrium phase, under acting uniformly external loading *p*, curve of displacement of beam and tendons w was produced shows in fig.3

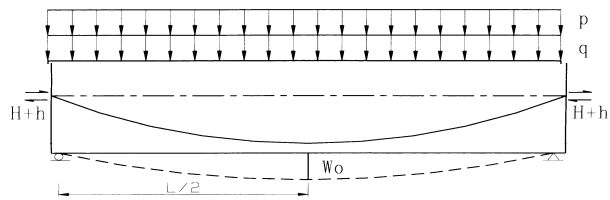

Fig.3 Calculation diagram of the prestressed steel girder under applied loading

In this case, *H* is the initial tendon force, *h* is tendons force increment. W_o is displacement of mid-span of steel beam by applying external load.

2 .3Governing differential equation

The prestressed steel beam was analyzed with the principle of minimum total potential energy. Since shear strain value of beam is small，the value of shear strain energy is negligible. Considering the strain energy of tendons and flexural strain energy of steel beam and loading potential energy, the total potential energy equation of the prestressed steel beam can be written

$$\pi = V_1 + V_2 + V \qquad (2)$$

Where: V_1 is strain energy of tendons; V_2 is flexural strain energy of steel beam; *V* is loading potential energy.

Based on the principle of minimum potential energy, this energy is at a stationary position when an infinitesimal variation from such position involves no change in energy. By differentiating π with respectively to $\delta \Pi = 0$ and considering arbitrariness of δw and $\delta w'$, we can get follow equation. The governing differential equation for prestressed steel beam on loading phase is derived

$$EIw^{IV} - (H + \frac{h}{2})w'' = p + \frac{h}{2}z_C'' \qquad (3)$$

3. Comparison of Predictions and Measurements

In order to investigate the fundamental mechanical behavior of prestressed steel beam, 1/10 -scale, 4m long specimen were constructed using the Q235 steel plates. One is normal steel box, The other is the steel box beam with curved prestressed tendon. The tendons are the low-relaxation, 15.2 mm diam，seven-wire stranded tendons with an ultimate stress of 1,860 MPa. Both specimens have the same box cross section, shown in fig. 4. The specimens for both were subjected to a similar quasi-static test.

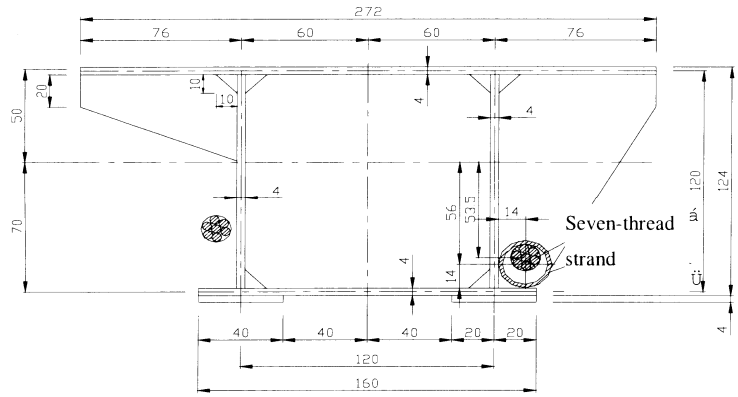

fig. 4. Diagram of the steel girder model

The normal specimen was tested with distributing load that were applied distributing load along the centerline of the beam and point load at the mid-span. The distributing load value is 2.5knlm and the point load value is 10kN. After applying pre-stressing force H=82.5kN，the pre-stressed specimen was tested using the same load with the normal specimen.

The comparisons of the calculated values and the test results of deflection that was produced by prestressing force are shown in Table 1.

Table 1 the bottom plate strains on mid-span and 1/4 span（μ ε）

Item	Distributing load（2.5kN/m）						Point load（10kN）					
	L/2			*L/4*			*L/2*			*L/4*		
	Measure	Calculation	Error	Measure	Calculation	Error	Measure	Calculation	Error	Measure	Calculation	Error
Steel beam	219.3	232.4	5.79%	168.0	174.3	3.70%	440.2	445.5	1.17%	213.7	222.75	4.23%
Prestressted steel beam	194.8	205.7	5.03%	147.8	152.3	3.05%	392.8	397.5	1.2%	185.7	193.31	4.1%
Improvement %	12.58	13.58		13.67	14.45		12.06	12.07		15.07	15.22	

Under the same test load，bottom plate strains on mid-span and 1/4 span of the prestressed steel beam is small than normal steel beam. The prestressing force can improve condition of mechanics on steel beam, reduce tension stress on bottom plate, and increase capacity of resistant fatigue.

4. Conclusions

The theory analysis and experiment expression as follow：

I. It can improve mechanics behavior of steel beam to apply prestressing force on steel beam.

2. The increasing stiffness for steel beam is directly proportional to the prestressing force H，and is inversely proportional to the square of the span length for the beam.

ABSTRACT

This paper introduces the OD matrix adjustment, especially the development and application for PFE. In the second part, the logical structure and core module algorithms are deeply analyzed and discussed. Finally, a data fusion model that combines sensor data and FCD is designed according to the fact in Shenzhen. With the core of PFE, the model is applied in Shenzhen Urban Transport Simulation System.

1 BACKGROUND

1.1 History of OD matrix adjustment

The OD matrix adjustment, which by using observed link volumes to estimate and adjust OD matrices, can be implemented for online urban traffic management and offline transportation planning applications. In 1980, Van Zuylen and Luis Willumsen pioneered a famous algorithm to deal with the OD matrix adjustment. After that, many scholars, such as Bell, M.G.H, Spiess, H., Chen Y., Yang H., Codina E. and Barcelo J., continuously improved the static OD matrix adjustment. However, most researchers estimated average OD movements by referencing to observed link volumes over a relatively long modeling period. Thus, the fluctuated nature of link flows and OD movements over the analysis period is not taken into consideration.

During the 1990s, the dynamic traffic assignment (DTA) and dynamic OD matrix adjustment gained increasing attention because they were gradually proving to be more useful tools for ITS, which asks for a dynamic approach of assigning the flows for detailed time slices within the modeling period. On the basis of static and dynamic OD matrix adjustment or path flow estimation, some assignment softwares were available for real-time analyses and simulation. Professor Bell from University of Newcastle upon Tyne initiated the development of a bi-level mathematical programming formulation for adjusting OD trip matrices that dynamically reproduced the observed traffic volumes[2]. Led by Professor Bell, the simulation team successfully developed a tool named PFE (Path Flow Estimator). The PFE has been subsequently integrated into the MONET (by Siemens) and VISUM-ONLINE (by PTV AG) as the key component for the matrix estimation mechanism. Both the MONET and VISUM-ONLINE are suitable for the analysis of real time traffic conditions for traffic information system (TIS).

1.2 Development of PFE

Through applying the PFE (Path Flow Estimator), the assignment syntheses and revised traffic volumes and travel times on the network. This information can be adopted for on-line and off-line applications in ITS. Given data from traffic detectors and other forms of sensors, path flows, and travel times are inferred on the basis of a LOGIT path choice model. The LOGIT model and the link cost functions allow the delays incurred by congestion to be taken into account. The most significant paths in the network are generated by an approximate steepest descent column generation method. A time-dependent PFE is formulated to better represent the transitory overloads situations that characterize congested conditions.

As a powerful tool, the PFE is widely used to support traffic studies (including traffic assessments, traffic impact studies, mode and route choice studies, etc.) as well as the real-time traffic condition monitoring and short-term traffic forecasts in the ITS applications. It was directly and indirectly taken into practice in Berlin, Hamburg, London, York, Athens, Turin, Lyon, Toulouse and Stockholm.

2. ALGORITHM OF PFE

2.1 Logical structure of PFE

The PFE uses two types of input data: static and dynamic. The output consists of path flows, path travel times, unmeasured link flows, link travel times, and OD flows. The input and output are shown in Figure 1:

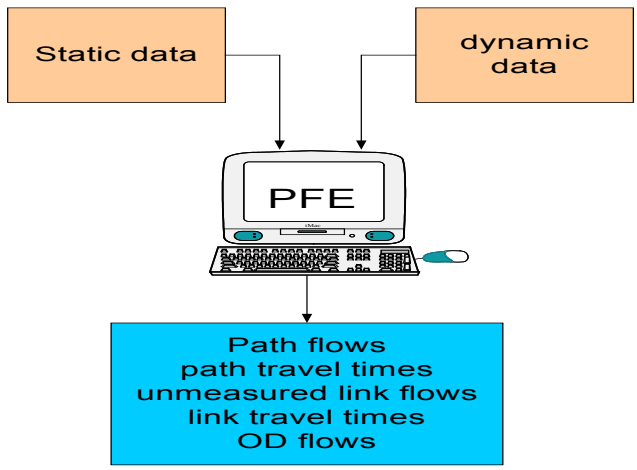

Figure 1: Input and Output of PFE

For ITS operations, there are two approaches used in online application of PFE: event-driven and time-driven. For activity we mean an action or a set of actions that have to be accomplished to perform certain operations within the system. The messages showed in the diagram can be any kind of signals useful to exchange information between two systems. The following figures show the two suggested approaches.

The event-driven solution requires the presence of a program manager in charge of scheduling the various activities. The following actions may take place in the system:

- The program manager sends a message to PFE notifying that the dynamic data for the current time slice are ready.

- PFE activates a filter program that reads the data necessary from the whole database, processes those data and writes the new dynamic files in PFE format into its file system. When finished, it sends an acknowledgement to PFE.
- PFE then operates and produces the results to be written into its file system. When terminated, it sends a message to the manager that results are ready for dispatch for further analyses.

The event-driven approach has several advantages. It is fully centralized so the program manager can change the scheduling of activities according to different scenarios. It is faster because the manager activates the necessary modules as soon as possible and, also, can alter the length of time slices according to the traffic conditions. It is also more reliable because the program manager, being familiar with the various modules, may encounter a faulty situation and take rapid actions accordingly. If any difficulty is found for any reason, the operator would only need to alert the program manager operating the relevant modules.

The time-driven solution is relatively simpler. In this case, PFE activate the filter at fixed time intervals and when the pre-processing phase is finished it elaborates the data. This approach is easier to

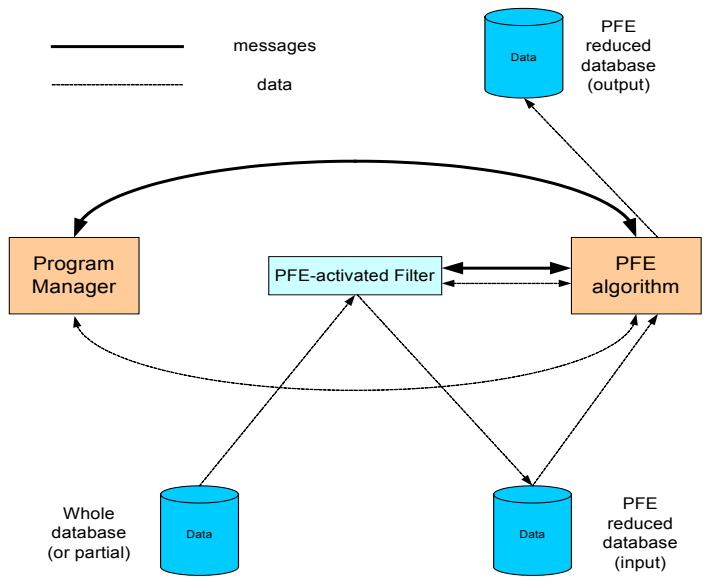

Figure 2: Event-driven PFE structure

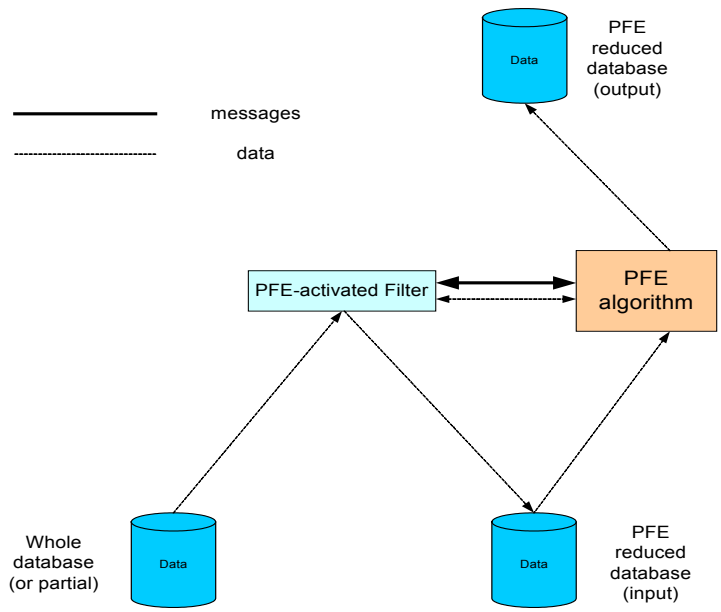

Figure 3: time-driven PFE structure

implement and more robust. The only requirement is to maintain “alive” status of the PFE program. Also it might be the only possible solution when the system is split over different computers.

2.2 Core Algorithm of PFE

Bell （2005）suggests two approaches for estimating the split fractions. In the first approach, which might be suitable for single intersections or small networks, it is assumed that the fastest vehicle between each O-D pair reaches its exit within one time interval and the slowest vehicle does not stay on the network for more than one interval. This is to say, all the vehicles enter and exit the networks in one interval. Each exit volume for an estimation interval h is then expressed as a convex combination of two terms. The first term represents the exit volume measured in the previous interval h-1. The second term represents the sum of all the OD flows departing during interval h that are headed towards the exit under consideration. Formally,

$$y_j(h) = (1-\alpha_j) y_j(h-1) + \alpha_j \sum_i b_{ij} q_i(h)$$

where $y_j(h)$ is the volume measured at exit j during interval h, $q_i(h)$ the entering volume at origin I during interval h, b_{ij} the unknown proportion of $q_i(h)$ headed towards exit j and α_i a travel time ”dispersion” parameter also to be estimated.

The second approach allows for vehicles to stay on the network for a pre-fixed number of intervals m with the fastest vehicle still taking within one time interval to traverse the network. For m=3, each exit volume is specified as follows:

$$y_j(h) = \sum_i b_{ij0} q_i(h) + \sum_i b_{ij1} q_i(h-1) + \sum_i b_{ij2} q_i(h-2$$

where b_{ijk} is the unknown proportion of traffic from entrance i destined for exit j with a travel time, when truncated, of exactly k intervals.

In both approaches, constrained weighted least squares are used to obtain estimates of the split fractions and additional travel-time dispersion parameters. While Bell's models offer some relaxation of the simplifying assumptions regarding travel times that characterize earlier approaches, a key limitation is that both split fractions and travel time dispersion parameters are assumed to be constant over time. The model, therefore, does not estimate a time varying split fraction, instead, it attempts to “refine”its previous estimate of the split fractions during each interval.

3. APPLICATION FOR PFE

3.1 Structure of SUTSS

With the rapid progress of information technology development and the requirements of making the transport system more efficient and the travelers being better informed for their planning of their travel arrangement, ITS are widely used to meet the above requirements for urban areas, in particular the central area with unstable traffic conditions.

Due to the rapid growth in car ownership and economic activities, Shenzhen, like other world-class cities, faces the difficulties of severe traffic congestion and related environmental impacts. As recommended in the Shenzhen Integral Transport Planning, among the traffic relaxation measures proposed, an ITS assignment called Shenzhen Urban Traffic Simulation System has been proposed to tackle the traffic related problems. SUTSS is the first phase for the development of an intelligent transport information platform for planning and public information service purposes. The traffic simulation system is considered the heart of the intelligent transport information platform for Shenzhen. The SUTSS consists of five components: a network and a communication subsystem, a data collection subsystem, a core traffic simulation subsystem (including macro, meso, and micro levels) and a service subsystem to provide supporting traffic information for planning and policy-making purposes. As a huge system, the major challenge is to develop a transport information platform to meet the framework of integrating the four subsystems mentioned above.

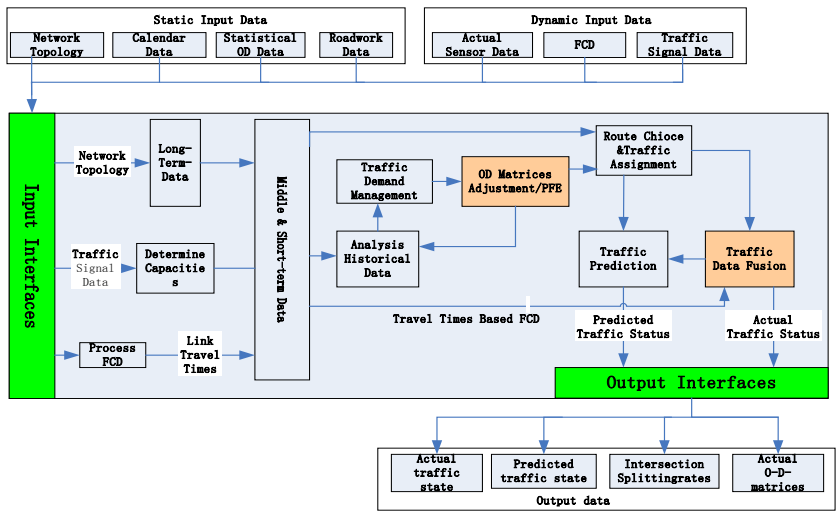

Figure 4: Data Flow Chart in SUTSS

3.2 Location optimization

The PFE algorithm estimates or adjusts an origin and destination matrix from traffic counts. The dynamic data that PFE needs is observed traffic volume at fixed locations and traffic control time slice setting. A Greedy-like algorithm [4] tries to maximize the information benefit (with respect to typical flow patterns) by adding

gradually further detectors. The goal of this procedure is to satisfy the following criteria:

(1) Observe as many paths as possible;
(2) Hit as much traffic as possible;
(3) Avoid unnecessary linear dependencies;
(4) Defined places with respect to variable message signs;
(5) Strategically important hot spots in terms of congestion;
(6) Highly occupied intersections;
(7) Traffic planning relevant spots;
(8) Local knowledge.

3.3 Visualization of PFE with FCD Enhanced

The task of PFE, with its ability of completing the traffic dataset for the observed links, is vital for the short-term forecast of traffic conditions. By making reference of the historical traffic data and the OD matrix, it could be suitable for event planning and operations. It is also worth noting that due to the synthetic nature of link speeds and travel time output from the assignment algorithm, the resultant time and speed are more dependable on the speed-flow relationship adopted for the model. With the availability of the floating car data (FCD), (Shenzen has a fleet of 6,000 taxis equipped with GPS), positioning data is constantly transmitted to their control centers. It is planned to complement the fixed detector, the FCD information will be used for the enhanced analyses of link traffic conditions (i.e. speed and travel time). An additional usage of the FCD is also planned for the recalibration/update of the speed flow relationship under different loading conditions; the corresponding traffic volume will come from the observations of the traffic detectors.

As Fig.4 shows, the fusion between FCD and PFE results expands the cover scope and improves the veracity of traffic information, so that more exact and entire visualization becomes possible. This is the advantage of fusion over each system.

Abstract

This paper researches the northeast economic zone, analyzes the impact factors of cargo, establishes the relationship between various factors and cargo by linear regression through the AHP, determines the weight of various factors, forms the systemic dynamics model on forecasting cargo volume in northeast economic zone, and proves the validity of the model through error analysis. In addition, the paper does a forecast for the cargo volume of the northeast economic zone 2011 to 2015, and its results can provide references for integrative transportation in northeast economic zone.

Key words : Systemic Dynamics Cargo Volume Forecast

It is necessary to lay down a scientific plan of regional integrative transportation with the development of regional economic integration. Therefore, forecasting the cargo volume can provide reliable evidences for this plan correctly.

This paper is based on the northeast economic zone covering Heilongjiang, Jilin, Liaoning province and some Inner Mongolia Autonomy, such as HuLunBeier City, Xingan league, Tongliao City, Chifeng City and the east XinLinGele league. The paper establishes some systematic dynamics models with some factors of cargo in northeast economic zone, so as to reflect the relationship between various factors and cargo systematically and dynamically, thus forecasting the cargo of northeast economic zone in an effective way. Generally speaking, it plays an important role for realizing and promoting transportation in efficiency and benefit, further more, making old northeast industry area prosper.

1. The relativity analysis of cargo volume and influential factors

1.1 The influential factors of cargo volume

Cargo volume is influenced by many factors, and the influential degrees are different, too. Among them the development of primary, secondary and tertiary productions have the most important influence on cargo volume. In addition, the

growth of consumer demand and fixed asset investments in society will continue to promote the cargo volume. Therefore, the study chooses a number of important socio-economic indicators for researching influential factors of cargo volume (FT). Such as, PIGDP (the value-added of the primary industry), SIGDP (the value-added of the secondary industry), TIGDP (the value-added of the tertiary industry), PL (population), PCDI (per capita disposable income), and FAT (the total social investment in fixed assets). Through such analysis, the development tendency of cargo can be reflected on influential factors overall.

1.2 The analysis of linear regression about cargo volume and influential factors

The research is based on northeast economic zone, adopting the statistical date from 1998 to 2006, and establishing the relevant mathematical model. Among, TCDI means total disposable income in the zone. The original cargo volume and influential factors are shown in the following table 1.

Units is 10000 tons, 100 million Yuan, 10000 people and Yuan respectively.

Table 1 . Table of cargo volume and factor s in Northeast Economic Zone.

Year	FT	PIGDP	SIGDP	TIGDP	PL	PCDI	TCDI	FAT
1998	185933.2	1554.86	4144.46	3142.85	11719.6	3377.94	3958.80	2381.82
1999	193712.1	1486.87	4458.92	3439.53	11773.4	3513.62	4136.71	2503.90
2000	195662.7	1454.52	5125.97	3933.84	11837.3	3655.57	4327.20	2845.01
2001	195573.5	1562.19	5382.75	4425.28	11865.5	3973.38	4714.61	3224.90
2002	198960.3	1691.28	5761.02	4927.86	11888.8	4443.95	5283.31	3687.25
2003	202255.8	1511.36	6548.66	5513.97	11906.7	5050.90	6013.96	4611.11
2004	217595.4	2212.54	7480.32	6318.46	11925.6	5588.31	6664.38	6187.88
2005	235134.0	2476.95	9361.05	7181.59	11953.7	6272.57	7498.07	8892.64
2006	257425.0	2700.07	11132.61	8193.46	11991.3	7081.58	8491.70	11768.30

From the above, it analyzes the relationship between cargo and those factors, there are the value-added of the primary industry, the value-added of the secondary industry, the value-added of the tertiary industry, total disposable income and the total social investment in fixed assets. From the analysis are the following formulas:

FT_1=122870.81+46.63PIGDP (R^2=0.918,SF=4.81E-5)

FT_2=144017.79+9.87SIGDP (R^2=0.978,SF=4.55E-7)

FT_3=141422.78+12.95TIGDP (R^2=0.914,SF=5.67E-5)

FT_4=129558.83+14.02TCDI (R^2=0.924,SF=3.62E-5)

FT_5=172587.14+7.14FAT (R^2=0.990,SF=3.08E-8)

From the testing results of parameter, the determinant parameters of regression models ‘R Square’ are all over 0.9. It shows that each influential factor has a close relationship with cargo volume. Every regression model ‘Significance F’ is lower

than 0.001, which shows that each regression formula is worthy of remark. And it illustrates that the models can reflect the relationship between influential factors and cargo volume accurately (Zhao 2008).

2. The definition of influential factor extent

On the basis of analyzing the deep relevance between cargo and influential factors, this research defines the degree of every influential factor by AHP and expert investigation.

2.1 The establish ment of the hierarchical structural levels

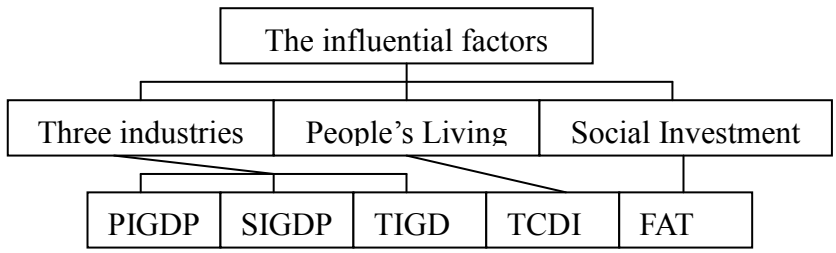

Figure 1. Figure of AHP structure

2.2 The Con formation of the estimate matrix

It applies expert investigation method to design question form, and define the correlation degree of adjacent hierarchical factors in the hierarchical structure according to the statistical survey result, so as to construct the estimate matrix of important degree on influential factors.

	PIGDP	SIGDP	TIGDP	TCDI	FAT
PIGDP	1	1/5	1/2	2	3
SIGDP	5	1	4	8	9
TIGDP	2	1/4	1	3	4
TCDI	1/2	1/8	1/3	1	2
FAT	1/3	1/9	1/4	1/2	1

Figure2. Figure of estimate m atrix

So it can get the maximal eigenvalue λ_{max} and characteristic vector v: $\lambda_{max} = 5.0746$.

$v = [0.1926 \quad 0.9223 \quad 0.3067 \quad 0.1132 \quad 0.0736]$

2.3 The c onsistent testing of estimate matrix

Consistent index $CI = \frac{\lambda_{max} - n}{n-1} = 0.01865$, and when n=5, RI=1.12 through looking over tables. thus, the stochastic consistency rate $CR = \frac{CI}{RI} = 0.0167 < 0.1$, illustrates that the estimate matrix passes the consistency testing. After incorporating the characteristic vector, it can get $w = [0.1197 \quad 0.5734 \quad 0.1907 \quad 0.0704 \quad 0.0458]$.

3. The establi shment of cargo volume forecast model.

3.1 The causality chart of cargo volume forecast system

It establishes the causality chart of cargo in northeast economic zone to reflect the relationship of cargo volume and every influential factor objectively through system analysis in the chart. The positive sign means that variable increases the source variable increase ,the variable increase vice verse variable, look at figure 3.

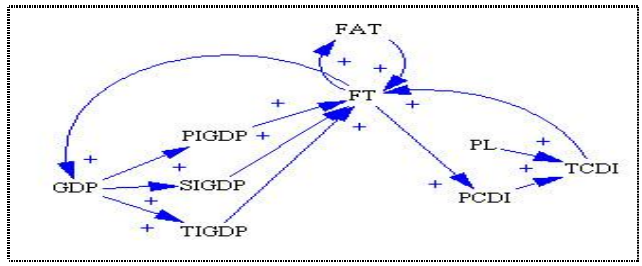

Figure3. Figure o f causal relationship in cargo forecast system

3.2 The establishment of systemic dynamic model

On the basis of studying the relationship between every influential factor and cargo volume, the systemic dynamic model is established. In this model , 'va' means the added value of a variable, 'rate' means the increase percent of a variable, and 'w' means the degree of a variable. In Figure 4, it is the systemic dynamic model of cargo volume in northeast economic zone (Wang 2004).

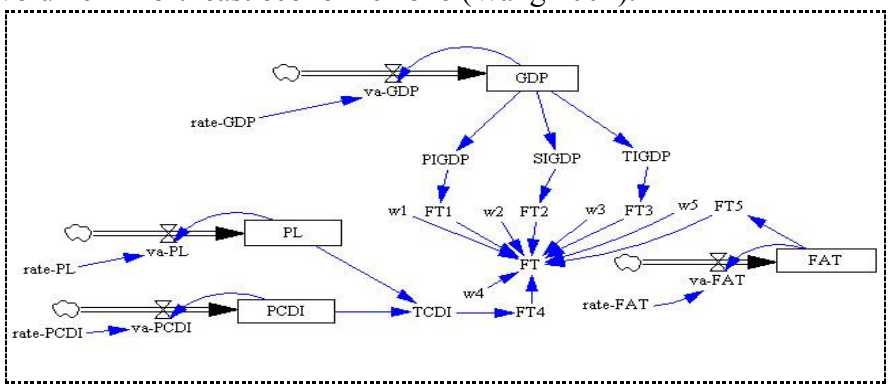

Figure4. Model figure of cargo forecast system

It describes the relationships among the factors by DYNAMO language. In the model, L is the level equation, R is the rate equation, and A is the assistant equation. In addition, the letter K means current, letter J means a moment ago , and letter L means future. DT means the time length between J and K or between K and L.

L GDP.K=INTEG(+"va-GDP.JK"); R "va-GDP.JK"=GDP.J*"rate-GDP.JK";
A FT1.K=122870.81+46.63PIGDP.K; A FT2.K=144017.79+9.87SIGDP.K
A FT3.K=141422.78+12.95TIGDP.K; L PL.K=INTEG(+"va-PL.JK")
R va-PL.JK=PL.J*"rate-PL.JK"; L PCDI.K=INTEG("va-PCDI.JK")
R "va-PCDI.JK"=PCDI.J*"rate-PCDI.JK"; A TCDI.K=PCDI.K*PL.K/10000
A FT4.K=129558.83+14.02TCDI.K; L FAT.K=INTEG(+"va-FAT.JK")
R "va-FAT.JK"=FAT.J*"rate-FAT.JK"; A FT5.K=172587.14+7.14FAT.K
A FT.K=FT1.K*w1+FT2.K*w2+FT3.K*w3+FT4.K*w4+FT5.K*w5

4. The forecast of cargo volume in northeast economic zone.

4.1 Model test

(1) The a nalysis of fitting degree

On the basis of actual cargo volume data in northeast economic zone from 1998 to 2006, the paper does the fitting degree analysis for the systemic dynamic forecast model which have been established. In order to get the emulational results of cargo volume on the past nine years and figure out the relevant error between actual value and emulational value, VENSIM software is applied. See Table 2.

Table 2 . Error analysis of cargo forecast result .

Year	Cargo volume （ ten thousand ton ）		Opposite error （%）
	Actual value	Emulational value	
1998	185933.2	183440.0	-1.34
1999	193712.1	188492.0	-2.69
2000	195662.7	194159.0	-0.77
2001	195573.5	200518.0	2.53
2002	198960.3	207655.0	4.37
2003	202255.8	215668.0	6.63
2004	217595.4	224670.0	3.25
2005	235134.0	234786.0	-0.15
2006	257425.0	246158.0	-4.38

The opposite error between forecast value and actual value can be seen in the above charts, it is less than 7%.The emulational result reflects the cargo development basically. So this model can be used to forecast cargo volume in future.

(2) Average value testing for data collectivity

Through analyzing, cargo volume data in the past years are normal distribution. First, it defines the original date of cargo volume $x_1 \sim N(\mu_1, \sigma^2)$ and emulational data $x_2 \sim N(\mu_2, \sigma^2)$, furthermore, x_1 and x_2 are reciprocal independent, and $n_1 = n_2 = 9$. $\overline{x_1}$ and $\overline{x_2}$ are the average values of data ,and s_1^2 and s_2^2 are the variances of data. Under the level of $\partial = 0.05$, the otherness of average values are as

follows.

Supposed $H_0: \mu_1 = \mu_2$ and $H_1: \mu_1 \neq \mu_2$, do the 't' testing for the two swath data.

$\overline{X_1} = 212039.87$, $S_1^2 = 538010395.86$, $\overline{X_2} = 214013.25$, $S_2^2 = 407024453.36$. Coalescence variance is $S_W = 472517424.61$, and inspection value is $|t| = 0.18156 < t_{0.025}(16) = 2.1199$. So, it can't refuse H_0. Under the level of $\partial = 0.05$, there is no distinct otherness between the average values of original date and emulational data.

(3) Variance testing for collectivity dat a

.Under the level of $\partial = 0.05$, the otherness of variance values are as follows.

Supposed $H_0: \sigma_1^2 = \sigma_2^2$, $H_1: \sigma_1^2 \neq \sigma_2^2$,do the 'F' testing .The inspection value is F=1.188. $F_{0.975}(8,8) = 0.2257 < F = 1.188 < F_{0.025}(8,8) = 4.43$. So it can't refuse H_0. Under the level of $\partial = 0.05$, there is no distinct otherness .

It shows that there is no distinct otherness between the swatch data through the testing of the average and variance. The emulational data can stand for the development tendency of actual cargo volume. The model is in effect, so it can be used to forecast the cargo volume recently.

4.2 The forecast of cargo volume

It applies the systemic dynamic model and VENSIM software to account unborn result of cargo volume. It shows Table 3 as follows.

Table 3 .Forecast result s of cargo in future (Unit: 10000 tons)

Year	2011	2012	2013	2014	2015
Forecast value	328414	351649	377885	407532	441064

See from Table 3, the cargo volume in northeast economic zone will keep increasing during the twelfth plan. In the zone, it can reach over 3 billion tons in this 2010, and it will reach over 4.4 billion tons in 2015.

5. Conclusion

The paper studies the influential factors of cargo volume from systemic dynamics. It establishes the systemic dynamics model to forecast cargo volume in the future. Compared with those foregoing methods, systemic dynamics model considers more influential factors, and adopts quantitative calculation methods to analyze the cargo development tendency objectively. It also reflects the dynamic influence from impact factor development on cargo volume development, meanwhile, it validates the practicality and effectiveness by VENSIM software.

A Study on the Location Selection of Public Traffic Transfer Hub Based on Improved Particle Swarm Algorithm

Lin Lifan[1], Zhang Weihua[1], Hu Jinxin[1] and Sun Qian[1]

[1]School of Mechanical and Automotive Engineering, Hefei University of Technology, Hefei 230009, China; PH (86)-0551-2901338 EXT 2512; FAX (86)-0551-2903450; email:linlifan2008@163.com

ABSTRACT

Location selection of public traffic transfer hubs is the key of urban public traffic planning. In this paper, according to the characteristics and requirements of public traffic transfer hubs, optimum objects and corresponding constraints are presented and a mathematical model of location selection is established. Then, improved Particle Swarm Algorithm, which has a higher success ratio on searching the optimal solution than Particle Swarm Algorithm, is used to compute the proposed model. At last, the application of algorithm is analyzed and the result proves that this method can effectively solve the problem of public traffic transfer hub location selection.

INTRODUCTION

As the key nodes of urban traffic system, public traffic transfer hubs are an important contact aspect of many kinds of passenger traffic modes-switch which links out-city traffic to in-city traffic and public transport to private transport and so on. Usually, a number of public transport lines and a variety of transportation modes, such as buses, trams, metro, taxi, etc., converge on the public traffic transfer hub, which not only has the basic function of passenger conversion/massing, but also outfits many kinds of working organizations and the multi-purpose architectural complexes to serve passengers. Practice shows that the quality of urban public traffic transfer hubs has a great effect on the city public transport service levels and road traffic system.

At present, much research regarding public traffic transfer hubs only took the one-fold problem of location selection itself into account. They didn't pay more attention to the problem of the hub's influence on surrounding roads and the passenger flow. Based on the previous statement, this paper sets up a location selection model with which the public traffic transfer hub and the net of surrounding roads can be optimized at the same time and then uses the improved particle swarm algorithm for solving the model calculation.

MODEL FOUNDATION

When a new public traffic transfer hub is built, it will bring a mass of traffic flow which can lead to more traffic congestion on its surrounding roads. This is

called counteractive of hub to the traffic network (Liu 2003). This kind of counteractive will impel some departments of city governments to widen some old pavement sections or new pavement sections. It will bring changes of traffic networks. In that case, the cost of traffic network ameliorating and the change of passenger flow should be considered. The first objective is the minimum cost. Another is the maximal management capability of passenger flow. Thus, a double-objective location selection model can be established as follows.

$$\min Z = \sum_{i=1}^{M}\sum_{r=1}^{n} b_{ir}\theta_{ir} + \sum_{a=1}^{m} c_a(\varphi_a) \tag{1}$$

$$\max E_i = \sum q'_{rs}\delta^i_{rs} \tag{2}$$

$$s.t. \quad q'_{rs} = q_{rs} + \sum_{i=1}^{M}\theta_{ir}p_{ir} + \sum_{i=1}^{M}\sum_{j=1}^{M}\theta_{ir}\theta_{js}u_{ij} \tag{3}$$

$$\theta_{ir} = \begin{cases} 1, & \text{hub 'i' in section 'r'} \\ 0, & \text{otherwise} \end{cases} \tag{4}$$

$$\delta^i_{rs} = \begin{cases} 1, & \text{when the shortest path between 'r' and 's' pass through 'i'} \\ 0, & \text{other conditions} \end{cases} \tag{5}$$

$$M \subset K \quad n \tag{6}$$

$$\varphi_a \geq 0, \quad 1 \quad m \tag{7}$$

$$1 \leq i \quad M, \quad 1 \quad K \tag{8}$$

The first objective of the model is the minimum cost of the hub construction and the surrounding road expansion. The second objective of the model is the minimum distances between the hubs and the nodes where the passenger flow is large in the service area. It is the transfer gross that has a much closer relationship with the indicators of the hub, so the model's second goal is the greatest distribution intensity of the hub's passenger flow. In the formula, n expresses that the target region is divided into n traffic communities; M expresses that M transportation hubs are proposed to be built in the target region; b_{ir} is the cost of land and construction when hub is located in the district of r; $\theta_{ir} \in \{0,1\}$, $\forall i \quad r \quad R$. Matrix θ is the location solution of multi-hubs; φ_a is the expansion volume of road section a; $c_a(\varphi_a)$ is the expansion construction cost of road section a; E_i is the passenger flow distribution intensity indicator of the alternative hub; q_{rs} is the passenger flow

distribution matrix OD between n districts before the hub's construction ; q'_{rs} is the OD passenger flow volume between the point r and s in OD after the construction of the hubs; p_{ir} is the distribution volume of the passenger flow from the hub i to the district r ; u_{ij} is the distribution volume of the passenger flow from the hub i to the hub j .

In order to reduce the difficulty in arriving at a solution, this paper uses the multi-objective linearity weighted algorithm (Hua 2007) to turn the double-objective optimization problem into the single-objective optimization problem. The objective function changes to:

$$\min g = \alpha Z - \beta E_i \qquad (9)$$

Among the above expressions, α 、 β are the weighted coefficients.

And: $\alpha + \beta = 1, 0 \le \alpha \le 1, 0 \le \beta \le 1$

IMPROVED PARTICLE SWARM ALGORITHM

PSO algorithm is similar to other evolutionary algorithms; the potential solution of each optimization problem is a "particle" in the search space. Each particle has an adaptive value which is decided by the optimized function and a velocity which decides the direction and distance to fly. Particles follow the current optimal solution to search in solution space. PSO is initialized as a group of random particles (random solutions), then finds the optimal solution through the iteration (Yu, 2008). In each iteration, the particle updates itself by tracking the two "extremes". The first is the optimal solution found by the particle itself, and this becomes the individual extremum; the other extremum is the optimal solution currently found by the whole group, and this extremum is a global extremum. Each particle updates their locations according to the following formula:

$$v_{id}^{k+1} = \omega v_{id}^{k} + c_1 Rand_1 (pbest_{id}^{k} - x_{id}^{k}) + c_2 Rand_2 (gbest_{d}^{k} - x_{id}^{k}) \qquad (10)$$

$$x_{id}^{k+1} = x_{id}^{k} + v_{id}^{k+1} \qquad (11)$$

In the expression: k is the times of iteration. v_{id}^{k} is the d dimension speed of particle i which in kth iteration. x_{id}^{k} is the d dimension location of particle i which is in kth iteration.

$Rand_1$ 、 $Rand_2$ are random numbers between 0 and 1. ω is the inertia weight coefficient. $pbest_{id}^{k}$ means the best location which particle i reached. $gbest_{id}^{k}$ means the best location which particle i will reach in global area. c_1 、 c_2 are the speedup coefficient. Their extent is （0~4）(Wang, 2004). And the degree of self-inherit and inherit from excellent individual is decided by them.

By analyzing, it is known that the larger inertia weight is in favor of the overall exploration at the initial stage of algorithm, while the smaller is in favor of the local optimization in the late evolution. Local minimum jumped out by adjusting the size of ω. Studies in literatures (Shi 1998; Trelea, 2003; Naka 2003) have shown that the parameter ω has a decisive effect on the astringency of the algorithm. If ω linearly decreases with the iterative process of the algorithm, the global search and local search capabilities of the particles can be weighed, and the algorithm performance and high search efficiency can be significantly improved. In this paper, based on the strategy of Linearly Decreasing Weight (Linearly Decreasing Weight PSO, LDWPSO) proposed in paper (Shi, 1998), a particle swarm method with a dynamic change in the inertia factor is applied, namely:

$$\begin{cases} \omega = \omega_{\max} - (k / k_{\max})^2 & 1 \le k \le k_{\max} / 2 \\ \omega = \omega_{\min} + (1 - k / k_{\max})^2 & k_{\max} / 2 < k \le k_{\max} \end{cases} \quad (12)$$

Specific calculation steps are as follows:

*Step*1 : N groups even-distributed random variables $X_i^{(0)}(x_{i1}^{(0)}, x_{i2}^{(0)}, \cdots, x_{ij}^{(0)}, \cdots, x_{ip}^{(0)})$ which fit the constraint condition were created from the extent [0,1] of every optimized variable simply marked as $X_i^{(0)}$, $i = 1, 2, \cdots, n$, $j = 1, 2, \cdots, p$. In addition, the $gbest_d$ (the best location in global area), $V_i^{(0)}(v_{i1}^{(0)}, v_{i2}^{(0)}, \cdots, v_{ij}^{(0)}, \cdots, v_{ip}^{(0)})$ and $pbest_{id}$ were initialized.

*Step*2: Calculate the objective function numerical value. The corresponding function value $g(X_i^{(0)})$ was solved by the use of the starting value $X_i^{(0)}$ from *Step*1 into the objective function.

*Step*3: Comparing the objective function value of each particle with $pbest_{id}$ which it reached. If the objective function value is better than $pbest_{id}$, it should be kept as the current best location. Otherwise, it should be kept as the $pbest_{id}$.

*Step*4: Select the particle which has the least objective function value and compare it with $gbest_d$. If it is better than $gbest_d$, it should be kept as the global best location. Otherwise, it should be kept as the $gbest_d$.

*Step*5: Solve the speed and location of change particles with the expression （10)、(11)、(12)．

*Step*6: Evolutional iteration. The paper gets the new particle $X_i^{(1)}$ from *Step*5 and solves the objective function value, and then turns the algorithm into *Step*3 and begins the next best location operation. It repeats this process up to

the termination condition (To reach the largest number of iteration or the optimal position of particle swarm adapting to meet the minimum target).

SIMULATION APPLICATION

The planning of the public traffic transfer hubs in the Hefei High-tech Zone is used as an example. According to investigations on the status of the traffic flow and road network, the paper divides the community into 27 traffic sections (as shown in Figure 1). Now we need to choose the location for five bus centers. That is: $n = 26$, $M = 5$. With four phase methods of transport planning, the bus passenger flow OD distribution matrix of the traffic community is predicted. The construction cost of the site is ascertained according to the relative proportions of the city regional land prices and the proposed site scales. The cost of road expansion and reconstruction depends on the status of the road network and predicted traffic flow.

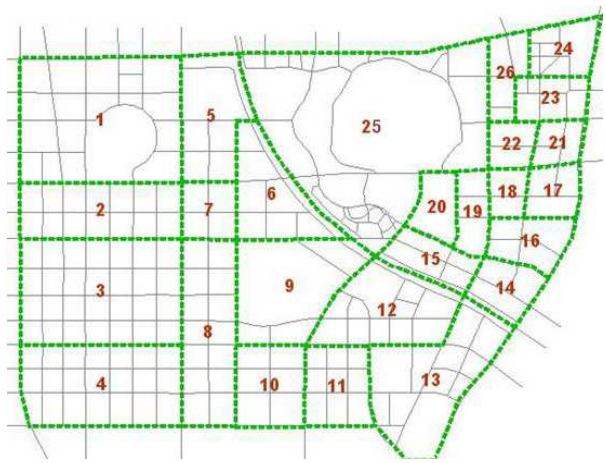

Figure 1. Cell division of the traffic map

The results of the improved particle swarm algorithm are compared with the basic PSO algorithm in order to verify the actual results. Related parameters are set as follows: particle number N=30, iteration number $k_{\max} = 250$, the inertia weight $\omega_{\min} = 0.4$, $\omega_{\max} = 0.9$, learning factor $c_1 = c_2 = 2.0$. With basic particle swarm optimization solved, the mean value is 375.82, the rate of the successful search for the optimal solution is 46%; while using improved particle swarm algorithm, the mean value is 369.05, the rate of the successful search for the optimal solution is 65%. By comparison, obviously it is not difficult to find out that improved particle swarm algorithm is much better at solving the problem than the basic particle swarm optimization.

Five transit hub locations identified by improved particle swarm algorithm are shown in Table 1, and the iterative process of the algorithm is shown in Figure 2.

In Figure 2, the turbulence line expresses the average target value of all the current particles, and the solid line expresses the iteration of the current optimal target.

Table1. The Results of the Location Parameter Table

	X coordinate	Y coordinate	Function value	Cell service
Hub for high-tech zones	51.3	14.6	303.7	4，8，9，10，11

CONCLUSION

In this paper, a theoretical model for public traffic transfer hub planning and location selection is presented to urban transport system. It considers the distribution intensity of passenger flow and the total cost of roads expanding and hub building. Then the paper uses the improved particle swarm algorithm to solve the model. The real example of public traffic transfer hub which is laid out in Hefei High-tech Zone proves the accuracy and usage of this model. It provides an effective method for the location selection of urban public traffic transfer hubs.

Abstract
Based on the thinking of balanced transport capacity and transport volume, this paper puts forward a regional bus dispatching method that suggests adjustments to transport capacity in multi-lines in order to achieve resource sharing and transport capacity sharing. The node and line's wait of public transportation network are analyzed in detail during regional bus dispatching processing in this article. The waiting factor is defined and the wait computational method is given in this paper. The capacity of the bus station is analyzed in detail. Based on this, this paper established the corresponding mathematical model taking the total wait time of the regional network as the main goal. The heuristic algorithm is used to carry on the solution to the model. This model effectively realizes that when the total wait time of simultaneous arrivals at transfer nodes is the greatest, the passenger in the network needs to transfers from one line to another line with the shortest standby period. This paper puts forward a regional public transportation timetable Optimization based on node and line's wait analysis.
Keywords: Traffic engineering; Bus regional dispatching; Heuristic algorithm; Synchronous transfer; Wait; Bus timetable

1. Introduction

Transit planning is a multi-objective problem where the user's and operator's interests conflict. The usual practice for the regulating authorities consists of imposing lines with given route configurations and frequencies so as to secure a certain level of coverage in time and space, while the operator then adjusts the line run departure times so as to match its employment resources in an economic manner. Consequently, transfer synchronization receives little concern. Transfer synchronization is a crucial element of service quality, and it is entirely dependent on departure time setting. The shortest flexible characteristics of traditional bus line timetables leads to vehicles remaining idle at off-peak periods and insufficient in peak periods. Based on the thinking of balanced transport capacity and transport volume, this paper recommends regional bus dispatching methods with adjustments made in transport capacity in multi-lines in order to achieve resource sharing and transport capacity sharing.

Valerie Guihaire and Jin-Kao Hao (2009) present a global review of the crucial strategic and tactical steps of transit planning: the design and scheduling of the network. They first exhibit the context and the goals of strategic and tactical transit planning. Following the objective of maximizing the number of direct travelers, Pape et al. (1992) present a heuristic method for the transit network design problems. The higher the frequency of bus stops on a route, the better the accessibility, but the

lower the travel speed. Murray (2003) studies two variations of this problem. The problem of simultaneous transit line configuration and passenger line assignment is dealt with by Guan et al. (2003). An aggregated meta-heuristic approach to the transit network design problem is considered by Zhao and Gan (2003), Zhao and Ubaka (2004) and Zhao and Zeng (2006) with the objective of minimizing the number of transfers and optimizing route directness while maximizing service coverage. Yu etal. (2005) developed an ant colony based optimization model for bus network design that aims at achieving minimum transfers and maximum passenger flow per unit length with route length and directness constraints.

Many specialists and scholars at home and abroad have extensively studied the regional bus dispatching problem. In 1992, Voss put forward network design formulations in schedule synchronization in order to reduce passenger wait time at transfer stations. In 1999, Magede Dessouky elaborated real-time control techniques of synchronous transfer; Ceder and Wilson , Shi Qin formulated maximum synchronicity of bus timetables in a given bus line network, thus enabling the passenger who in the network needs to transfer to another line to have the shortest standby period. Yang Xiaoguang etc. (2003) studied two bus lines' transfer problems. However, in these papers, the nodes and lines' wait time in the public transportation network are of equal rank. These papers didn't embody different significant degrees of various lines and nodes. For this reason, in this paper, we will present a definition of line and node's wait factor and assign the weight to line and node in model.

2. Definition of wait

2.1 Definition of node wait.

The objective of the synchronous transfer problem is to allow as many vehicles as possible to arrive at the same time at the transfer transit station. In order to obtain a quantification relationship, we establish the following assumption before creating the model: frequency of bus line is constant; suppose bus line operation is performing well and the running speed and cut-off interval is stead fastness; bus drivers don't overtake in all lines; running stop in bus line is determinate; the traffic flow and vehicle and operational condition of line is relatively stabilized; the need of passenger is not influenced by departure frequency and is also relatively stabilized.

Considering transfer stations in public bus networks, its wait coefficient is determined by passenger transfer volume at the station. α_n is the ratio of the passenger transfer volume at n node to the total passenger volume set down and picked up at n node .

$$\alpha_n = 2 \times Volume_n / TotalVolume_n \qquad (1)$$

Where, $Volume_n$ =the passenger transfer volume at n node; $TotalVolume_n$ = the total passenger volume set down and picked up at n node.

Because of different geographical positions of nodes, the transfer passenger volume is different. For example, nodes located as urban hinge, syntaxes multi-bus lines, are important nodes. Transfer passenger volume is great at those nodes and the wait time at the nodes is greater than others. We should give top priority to arrange

bus meetings at those nodes in order to promote the combined efficiency of passenger transfer and reduce the total bus waiting tone at the node.

2.2 Definition of bus line wait time.

We can allocate wait time in terms of departure intervals. For those buses where the departure interval is comparatively large the interval between pervious and latter bus is comparatively large. There is little probability to meet other buses; if passengers miss the previous bus, he or she must wait a long time to ride the latter bus. Short departure interval bus line has a high departure frequency which increases ride probability. The significance of synchronous arrival is greater for the long departure interval line than short departure interval. Define the line's wait time, which is the maximum value of least departure interval of all bus line, as unit 1. Let us introduce the notation:

$H_{\max k}$=Maximum departure interval of line k ; $H_{\min k}$=Minimum departure interval of line k ; β_k =the value of weight factor of lines; the value of weight factor of other lines is the ratio of least departure interval to the maximum departure interval.

$$\beta_k = H_{\min k} \Big/ H_{\max k} \tag{2}$$

3. Definition of station capacity.

Station capacity, C_n, is the maximum number of vehicles that can stop at the station at the same time. The perfect state of synchronous transfer is number of vehicles matched with station capacity.

$$C_n = \frac{L_n + d_s - 2d_e}{l + d_s} \tag{3}$$

$$C_n \le \frac{vt + d_s + l - l_d}{l + d_s} \tag{4}$$

Where, L_n =the length of stabling zone at node ; d_s = longitudinal safe distance between two stop vehicles ; l = length of vehicle; d_e= safe distance between bus and endpoint ; l_d= distance between back door and front door of bus; v = speed of travel; t = cut-off interval.

4. Creation of model

4.1 Constraints and assumptions

We define the following variables:

T =planning time quantum ; t =continuous time in the period $[0,T]$; M =total number of lines in a bus network ; N =the amounts of change nodes in bus network ; X_{ki} =outgoing time of ith bus services in kth line in T period ; F_k =the amount of departure of kth line in planning period ; R_n =the capacity of nth node ; T_{kn} = bus running time from starting point to nth node in line k, if bus of k line doesn't stop nth node, $T_{kn} = -1$;

D_{kiqjn}=binary variable, its value is 1 if i[th] vehicle in line k meet j vehicle in q line at n node, otherwise 0 ; D_{kitn}=binary variable, i[th] vehicle in k bus line arrives at n node at t moment , $D_{kitn}=1$ 。

4.2 Set up model

Based on node and line wait factor, regional bus dispatching optimization model aimed at maximum synchronous transfer rate is as follows:

$$f(z)=\max \sum_{n=1}^{N}\sum_{k=1}^{M-1}\sum_{i=1}^{F_k}\sum_{q=k+1}^{M}\sum_{j=1}^{F_q}\alpha_n D_{kiqjn} \tag{5}$$

$s.t$

$$X_{k1}\le H_{\max k} \quad , \quad 1\le k\le M \tag{6}$$

$$X_{kF_k}\le T \quad , \quad 1\le k\le M \tag{7}$$

$$H_{\min k}\le X_{k(i+1)}-X_{ki}\le H_{\max k} \quad , \quad 1\le k\le M, 1\le i\le F_k-1 \tag{8}$$

$$Y_{nt}=\sum_{n-1}^{N}\sum_{i=1}^{F_k} D_{kitn} \tag{9}$$

$$Y_{nt}\le C_n \tag{10}$$

In the above model, the meaning of objective function (5) is: the total wait is greatest in network, that is to say, buses of the larger wait bus line synchronous arrival has top priority at larger wait nodes. Constraint condition (6) will ensure that the interval from the starting time of T period to the first departure time is not more than the maximum departure interval. Constraint condition (7) will ensure that the departure time of the last vehicle comes within planning time. Constrain condition (8) indicates the restrictions of departure interval. Constraint condition (9) Y_{nt} denotes the number of vehicles at n node at t moment; Constrain condition (10) will ensure the arrival vehicle quantity is no more than station capacity.

5. Solution Approach

The algorithm flow chart in this paper is illustrated in Figure 1. Computational Experimentation gives **the** computational process in detail.

6. Computational Experimentation

In some regions, there are 3 unidirectional bus lines and 6 double action bus lines as illustrated in Figure 2. There are 3 transfer nodes 1 , 2 , 3 in 3 unidirectional bus lines. Every node capacity is 4. The travel time from the origin stop to change node is illustrated in Table 1 (if the line doesn't pass the node, the value is -1). Suppose the timetable is from 9:00~10:00. The value scope of the departure interval in double action 8 wait of 3 change nodes are specified respectively: $\alpha_1=0.2$, $\alpha_2=0.2$, $\alpha_3=0.6$.

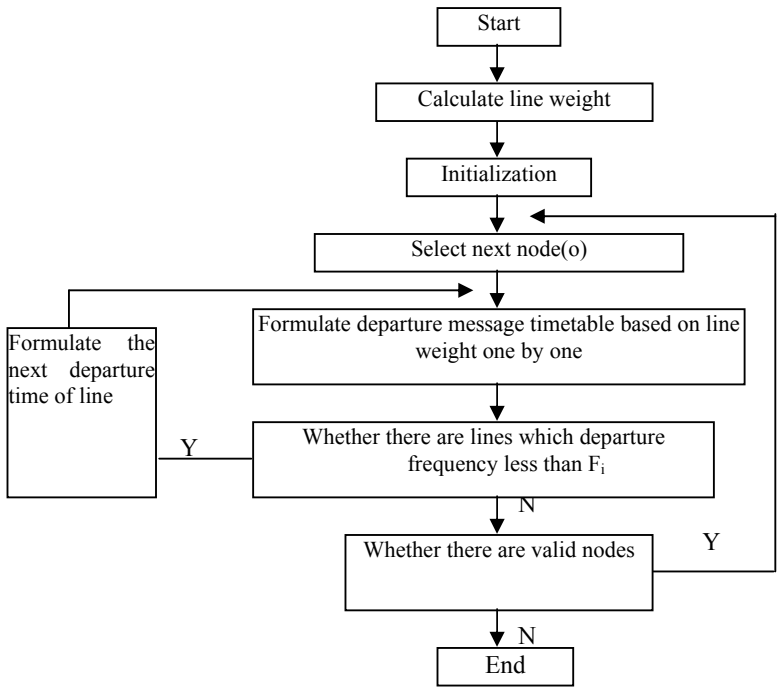

Figure.1 Flow process of basic solution

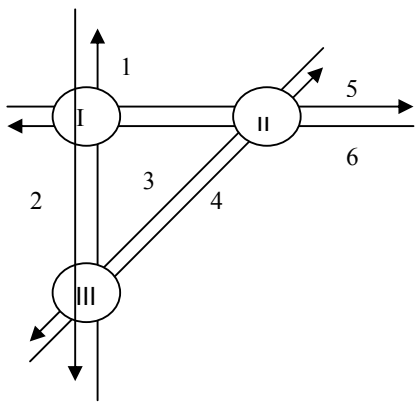

Fig.2 The basic network for example

Table.1 The traveling time of routes

Line	Node 1	Node 2	Node 3
1	16	-1	8
2	10	-1	16
3	-1	6	12
4	-1	8	22
5	7	15	-1
6	18	10	-1

Table.2 Structure of nodes

Node	Line number	μ_n	T_i/max	Corresponding line
1	4	4	18	6
2	4	4	15	5
3	4	4	22	4

Table.3 Data structure of bus

Line	$H_{\min i}$	$H_{\max i}$	Node	F_k
1	6	14	2	7
2	6	14	2	7
3	9	15	2	7
4	9	15	2	7
5	3	6	2	14
6	6	15	2	7

Step1: Calculate line wait. The wait of line 3 and line 4 are β_3, β_4 . $\beta_3 = \beta_4 = 0.231$. Calculate other line wait: $\beta_1 = \beta_2 = \beta_6 = 6/9 = 0.154$; $\beta_5 = 0.077$.

Step 2: Initialization. Nodes structure is illustrated in Table 2. Line data structure is illustrated in Table 3.All nodes are valid nodes.

Step 3: The wait of node 3 is largest, so node 3 is selected.

Step 4: $Y_{3t} = C_3 = 4$ .So the lines through 3 nodes are all selected. The wait factor of lines 3 and 4 are equal and largest. Based on the principle of the travel time from start stop to 3 node size down, the fourth node is selected. The earliest time is set for node 3. At this node, synchronous transfer is based on the condition: max (6 , 6 , 9 , 9) ≤d≤min(14 , 14 , 15 , 15), d = 9. At node 3, continuous meet time is formulated.

The travel time of line 4 from start stop to node 3 is largest, so buses start out as soon as possible in line 4. According to line 4 timetable, the departure timetable of 1, 2 , 3 is formulated. The timetable of node 3 is described in Table 4 and the arrival time of node 3 is illustrated in Table 5.

Table 4 Starting time of buses at node□

Line 1	9:00 9:14 9:23 9:32 9:41 9:50 9:59
Line 2	9:06 9:15 9:24 9:33 9:42 9:51 10:00
Line 3	9:02 9:11 9:20 9:29 9:38 9:47 9:56
Line 4	9:00 9:09 9:18 9:27 9:36 9:45 9:54

Table 5 Arrival time of buses at node③

Line 1	9:08 9:22 9:31 9:40 9:49 9:58 10:07
Line 2	9:22 9:31 9:40 9:49 9:58 10:07 10:16
Line 3	9:22 9:31 9:40 9:49 9:58 10:7 10:16
Line 4	9:22 9:31 9:40 9:49 9:58 10:7 10:16

From the tables we can see: line 2, line 3 and line 4 have three encounters every time at node 3. The first, second, third, fourth, fifth, sixth bus of line 2, 3, 4 encounters the second, third, fourth, fifth, sixth and seventh bus of line 1 at node 3. In given time slice, the number of encounters is 39, the number of encounter points is 7.

Step 5：The departure amount of line 2 is a little one. We may formulate the timetable for line 2 according to line 2 departure time in order to make the two lines have a synchronous transfer at node2 again.

The departure interval of line 2 is [6, 14] , so the other departure time for line 1 is 9:00。

Step 6：If other valid nodes exist, go to step 3. The wait factors of nodes 1 and 2 are equal. In addition, the number of vehicles arriving synchronously is equal to the line amount through nodes. However the wait factor of node 2 is larger so the node 2 is selected.

Step 7：As far as node 2 is concerned $Y_{2t} = C_2 = 4$. The departure timetable of line 3, 4 is determined. Calculate arrive time to determine line departure times. Departure time of line 6 is 6 times. Departure time of line 5 is 5 times.

Step 8：The departure time of line 6 is a little one. The departure time in line 5 is little 8. We can determine the departure time based on generating route departure times. Similarity, we can get other stops' timetables.

The result is as follows: the number of encounters is 15 in 1 set time at node 1; the number of encounter points is 14；the number of encounters is 37 in 1 set time at node 2；the number of encounter points is 7；the number of encounters is 39 in 1 set time at node 3；the number of encounter points is7；According to above departure times, we can get the total number of encounters in network as 91，the total number of encounter points is 28. The objective function value is 52.3511. The total wait time of the area is 52.3511. At last, result is obtained. The departure time of lines is in table 6.

Table.6 Starting time of routes

Line	Departure time						
1	9:00	9:14	9:23	9:32	9:41	9:50	9:59
2	9:06	9:15	9:24	9:33	9:42	9:51	10:00
3	9:02	9:11	9:20	9:29	9:38	9:47	9:56

5	9:02	9:05	9:11	9:14	9:20	9:23	9:29
6	9:00	9:07	9:16	9:25	9:34	9:43	9:52
Meeting time	9:22	9:31	9:40	9:49	9:58	10:07	

7. Conclusion

The node and line's wait of public transportation network are analyzed in detail in this article. The waiting factor is defined and the wait computational method is given in this paper. Based on this, the regional network with the greatest total wait time was taken as the study sample and the corresponding mathematical model was established. Using the heuristic algorithm to carry on the solution to the model, the following was obtained: This model can be effective in determining simultaneous arrivals in the network to reduce the public transportation's total wait time, thus enabling the passenger who needs to transfer lines to be able to do so in the shortest standby period possible. Further study on effect of departure frequency change on dispatch is needed. The regional bus dispatching prioritization model is established on the condition that the passenger flow is stable. Timely varied information on state of the road and emergency unpredictability inevitably change passenger flow quantity. We suppose the operational time of buses is constant. However, the operational time of buses is stochastic because of factors such as traffic signals, the state of road, pilot psychological factors and so on. It is necessary to probe bus dispatch optimization effected by random factor in uncertain environments.

ABSTRACT

Good transportation planning is the key to solving urban transportation problems. There are some technologies which need to be utilized in present transportation planning practices. How to get effective feedback from transportation planning to land use planning? How to quantitatively consider the impact of traffic on the future environment? How to forecast the future transportation demands correctly when the urban environment is developing rapidly? Under these considerations, we proposed a reverse regulatory transportation planning method. With this method, we can determine a range of land regulatory indexes for traffic zones after we have set the traffic state on future road network and have calculated the regulatory generation trips of transportation zones. In this paper, the basic idea and related technologies of reverse regulatory transportation planning method have been studied preliminarily.

Key words: transportation planning, traffic demand forecast, traffic environment, land use, TOD

1 Introduction

Traffic planning theory appears relatively late in China, and it's almost the copy of other countries'. Of which, the most often used set of theories is 'traditional traffic planning mode', which originated from western countries at a mature stage of the urbanization process. The core of the traditional mode is 'four-step traffic demand forecasting'. Traditional traffic planning is a process from demand to supply, the major aim of traffic demand forecasting is to supply the traffic demand of the planning year, to adjust (even supplement) the planning road network, and to propose a series of corresponding strategies. In other words, traditional traffic planning method goes from discovering problems to solving them. It ignores the idea that planning should control and adjust the demand reasonably. The objectivity has made it urgent for us to find a set of traffic planning theories, which can suit our own national conditions at present and for a long period in the future (for example, 30-50 years) when urbanization process goes from early stage of rapid development to a comparatively mature developmental stage. This paper is just the initial exploration of that.

The most important factors that affect urban traffic are land use and traffic development policies. Urban traffic and urban land use acts upon and influences each other: if urban traffic leads urban land use, the interaction between them will be positive; but if urban land use leads urban traffic, the relationship will become negative. The essence of the traditional traffic planning theory is exactly in

accordance with the latter. In our country, the urbanization is in the early stage of rapid development now, disorder development of urban land and rapid expansion of cities have resulted in uncertainty of space structure and of function layout, which limits the application of the traditional traffic planning theory. Thus, we should actively doubt the adaptability of traditional traffic planning theory in our present stage. This paper has put forward a new set of traffic planning theories based on the idea of 'traffic control urban planning'. Its core is 'inverse four-step' traffic planning mode. Its main aim is to identify land use characteristics, to develop intensity and construction sequence of traffic zones in planning years, to propose the matching traffic development policies, etc.

2 Aims and Significance of Study

'Inverse four-step' traffic control urban planning theory is a challenge and a inversion to traditional 'four-step' mode (John et al. 1999). It's totally a brand new exploration to present urban traffic planning theory with an ultimate goal of building a city development form that is harmonious, sustainable and human-oriented. If there's some new progress in this research, it will influence current urban traffic planning theory directly, together with establishing practical urban traffic planning. Some planning ideas and technique means can also be applied to guiding practice and to the establishment of practical urban traffic planning, thus, the research in this paper is very important to improve current planning theory, to solve problems of traffic jams, and to build a harmonious city of sustainable development.

Based on urban master planning, the aim of traditional urban traffic planning is to supply urban traffic demand to improve and optimize urban traffic conditions. Traditional 'four-step' traffic demand forecasting consists of trip generation, trip distribution, mode split and traffic assignment. With all of these, basic data collection and traffic investigation are the basis. However, there exists many problems in practical application of traditional 'four-step' traffic demand forecasting and planning technique (Edward, 1996).

First of all, urban scale is expanding rapidly; economic development zones and residential districts are dilating to suburban areas; urban population is also increasing substantially. Now, the urbanization process in our country has been in the rapid development stage, and 'city blasting' will be inevitable. Urban expansion has been experienced by developed countries is an evident characteristic of our current urban construction, and is supposed to be the necessity to develop social economy quickly. Urban expansion is in some extent inevitable, and finally increases the difficulty of controlling and forecasting urban land use in the future (Polzon 1996).

Second, at rapid urbanization stage, it's likely that each function of the city may be changed or adjusted, including configuration of urban land use and intensity of urban land exploitation. In addition, according with rapid development of urban infrastructure and with improvement of social economy, there will be much uncertainty in the modes that inhabitants attend urban activities. Therefore, at this stage of urban development, it's impossible to forecast future urban traffic demand truly with the traditional 'four-step' mode.

Third, urban branch roads have an important effect on traffic assignment, but the establishment of urban traffic planning often doesn't consider them, mainly for two reasons. On the one hand, urban master planning itself doesn't refer to urban

roads. On the other hand, there is no integrated urban control detailed planning to depend on. No consideration of urban branch roads results in the reduction in capacity of urban road network, hence, link flows gained from traffic assignment are always higher than their practical values.

3 Specific Steps of Inverse 'Four-step' Traffic Control Urban Planning

On the basis of analyzing and applying current traffic planning theory and traffic analysis software, this paper puts forward a new idea named 'traffic control urban planning'. The ultimate aim is to account for the severe conflicts between traffic demand and traffic supply resulting from disorder, urban expansion and high development intensity of urban land.

3.1 Basic Procedure

Through inversing traditional 'four-step' model based on some mature theory and developed traffic analysis software, we can obtain production and attraction flow firstly and the land use indexes of traffic zone secondly.

Basic procedure for traditional 'four-step' model is as (Miller 1998): trip generation--trip distribution--mode split--traffic assignment, finally, we get each link flow of the planning road network. But 'inverse four-step' model is completely opposite to that: first, assume the possible most link flows of planning road network, get OD distribution flows between each couple traffic zones based on OD inversion technique; then transform OD matrix to PA matrix; third, carry out traffic mode split on the basis of current trip characteristics and future economic conditions; at last, get residential trip generation and identify some land use control indexes of future traffic zones such as construction land area, parking sets, branch road density, plot ratio, construction density, etc (Sadek, et al. 2002). Planning technical line is as figure 1.

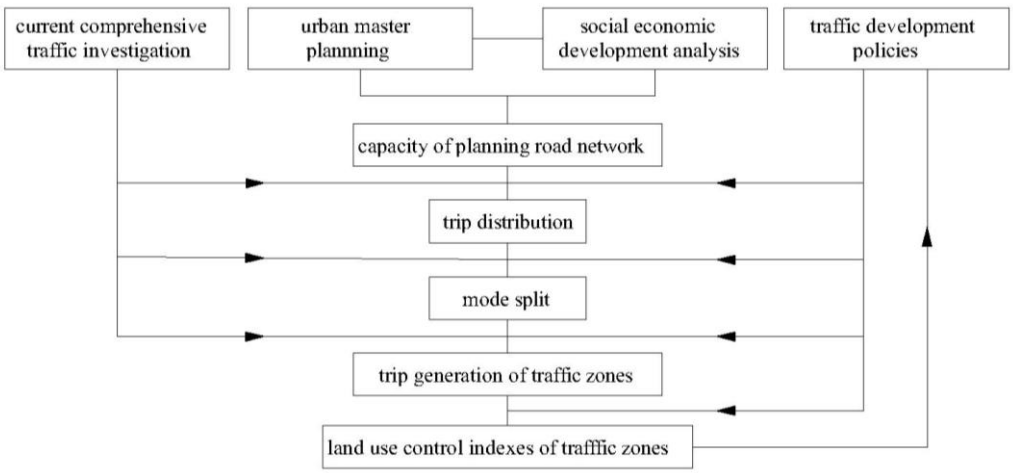

Fig. 1 **basic line of 'inverse four-step' traffic control urban planning**

3.2 Capacity of Planning Road Network

Capacity of urban planning road network is an important index to carry out and evaluate traffic planning. Provided capacity of road network, we could analyze the balance between traffic supply and traffic demand, identify urban development scale, establish planning road network, and propose sustainable traffic development strategies.

Capacity of road network depicts the capacity to contain urban traffic. Ideal capacity of road network refers to the most volume that only relates to road grade, road segment length, capacity and LOS (level of service) of adjacent intersections, and LOS of road segment. Of which, length of road segment should be longer than the biggest queuing length between the adjacent intersections. Capacity and LOS of intersections are identified on the grade and LOS of road segments. The capacity V of urban road network could be calculated by formula 1:

$$V = \sum_{i=1}^{n} C_i I_i N_i \alpha_i \beta_i \gamma_i \quad (\text{veh} \cdot \text{km/h}) \qquad (1)$$

Of which,

C_i --each lane's ideal capacity of grade i road (veh/h);

I_i --lane length of grade i road (km);

N_i --lane numbers of grade i road;

α_i --intersection's reduction coefficient of grade i road;

β_i --average saturation of grade i road;

γ_i --integrated reduction coefficient of grade i road;

i --grade of road.

Capacity of road network suggested by this paper is the ideal value under ideal conditions. As the form of road network and the road grade in future will not differ much from the planning alternative, the ideal capacity based on them is relatively exact.

3.3 Calculate OD Distribution Matrix of Traffic Zones

Given the capacity of urban planning road network, we could get the most trip demand of traffic zones through OD inversion technique (Gur, 1983), and finally get land use control indexes of each traffic zone through inversing current trip generation model. OD inversion technique is generated while the theory and model of traffic planning are relatively mature. At the same time, the application of electric computer, especially of simulation software to traffic planning makes OD inversion technique possible. All kinds of software have basically the same OD inversion principle and manipulation process, we don't introduce them one by one here.

3.4 Calculate controlling indexes of land use for traffic zones

Some controlling indexes presented in this paper such as plot ratio, construction density and branch road density are identified on a relative design code. In practical application, we should also take specific conditions such as urban scale, urban characteristics, land use layout, etc. into account. We should also calibrate certain factors through traffic investigation.

4 Testing in practice for the met hod

In Qianjiang in Hubei province, the urban traffic planning based on 'inverse four-step' traffic control urban planning theory and method has achieved agreement and applause of each expert attending the evaluation conference. At last, six exhibits of Qianjiang urban traffic planning are listed as figure 2 to figure 5, they're successively: capacity of urban planning road network, desire lines of traffic zones, trip production and trip distribution of traffic zones, and average control construction density of traffic zones.

ABSTRACT

This paper reviews our recent developments on applying a robust optimization approach to transportation network design problems where future travel demands are uncertain and traffic flows on the underlying network are in user equilibrium. We assume that the travel demands belong to an uncertainty set instead of having them follow some probability distributions and then design the network against the worst-case scenario realized in the set. The problems are formulated as mathematical programs with complementarity constraints, which are efficiently solvable by a cutting-plane scheme. Numerical examples are provided to demonstrate that the designs from the robust optimization approach perform more stably and guard better against worst-case scenarios than those from traditional deterministic approach.

INTRODUCTION

Network design problem (NDP) for transportation networks has been extensively studied in the literature. The problem is to determine a plan for modifying a road network (e.g., adding new roads and increasing the capacities of the existing ones) in order to minimize the total system travel cost or to optimize another performance measure subject to a given budget. In the literature, NDP has been formulated as a bi-level optimization problem or, equivalently, mathematical program with equilibrium constraints (MPEC), where users' responses in travel choices are captured by the lower-level user equilibrium (UE) problem or equilibrium constraints in form of a variational inequality. The formulation is thus nonlinear and non-convex, making it difficult to solve exactly. For an overview on NDP, see, e.g., Magnanti and Wong (1984) and Yang and Bell (1998).

NDP can be classified into two general categories depending on how additional capacities are represented, either as continuous or discrete variables. In the literature, many have considered continuous NDP or CNDP because the problem is more computationally tractable. However, an additional capacity is always stated in the unit of one lane in practice, thereby suggesting that discrete NDP or DNDP is more practical. On the other hand, the presence of the integer variables makes DNDP more difficult to solve because the gradient-based

approaches are not applicable. In the literature, algorithms for DNDP are primarily limited to, e.g., branch and bound (e.g., LeBlanc, 1975; Poorzahedy and Turnquist, 1982) and meta-heuristics such as genetic algorithms (e.g., Xiong and Schneider, 1992; Jeon et al., 2006). In addition, Gao et al. (2005) propose a decomposition technique and Zhang et al. (2009) present an active-set algorithm.

Previous studies on NDP typically assume that travel demands (or demand functions) are deterministic and known exactly. However, travel demands are intrinsically or epistemically uncertain. More specifically, the uncertainty could be attributed to contingent future developments in the socioeconomic system or prediction errors from travel demand modeling (e.g., Zhao and Kockelman, 2002) etc. A small number of recent studies account for such a demand uncertainty to obtain a network design that either 1) maximizes a reliability measure (e.g., Chootinan et al., 2005; Sumalee et al., 2006); or 2) maximizes system performance while satisfying a reliability-based chance constraint (e.g., Chen et al., 2007; Stathopoulos and Dimitriou, 2007); or 3) maximizes expected system performance or capacity (e.g., Waller and Zilliaskopoulos 2001; Sun and Turnquist, 2007); or 4) achieves a mean-variance tradeoff of the system performance (e.g., Chen et al., 2003; Yin et al., 2005). In general, those models can be viewed as a stochastic MPEC (e.g., Patriksson and Wynter, 1999), and they all require knowing the probability distribution associated with the travel demand for each origin-destination (O-D) pair, a type of information very difficult to obtain in practice.

In another stream of recent research, some (e.g., Yin and Lawphongpanich, 2007; Yin et al., 2008; Yin et al., 2009 and Lou et al., 2009) apply the notion of robust optimization (e.g., Ben-Tal and Nemirovski, 2002; Bertismas and Sim, 2003) to proactively consider demand uncertainty in network design. The approach differs from the above stochastic MPEC approach in the following aspects: 1) it is assumed that future travel demands belong to an uncertainty set instead of having them follow some probability distributions. Available information on future demand from transportation planning practice can be efficiently utilized to specify the uncertainty set; 2) the approach is flexible in representing the risk-taking behaviors of decision makers and controlling the conservatism of the resulting network design, and 3) the approach is amenable to an effective and efficient solution algorithm that has the potential for solving large network design problems. The purpose of this paper is to review those new developments because we believe that the robust optimization approach is general and can be applied to many other decision-making problems in transportation planning and management.

NETWORK DESIGN PROBLEM UNDER DEMAND UNCERTAINTY

To introduce our robust optimization approach to NDP under demand uncertainty, let N and A denote the sets of nodes and links in a transportation network. Instead of using probability distributions to model demand uncertainty,

we assume that future travel demands belong to an uncertainty set denoted as D As discussed in the next section, all available information on future travel demands should be used to specify D, but the key is to avoid being overly conservative with the belief that nature is neither an ally nor an enemy, but somewhere in between. At the same time, the construction of the uncertainty set should ensure that the resulting robust optimization model is computationally tractable.

For a given demand vector $d \in D$, $V(d)$ denotes the associated set of all feasible flow distributions and can be mathematically expressed as follows:

$$V(d) = \left\{ v \mid v = \sum_w x^w, \Delta x^w = E^w d_w, x^w \geq 0, \forall w \in W \right\},$$

where x^w is the vector of link flows associated with O-D pair w, v is the vector of total or aggregated link flows, and Δ is the node-link incidence matrix associated with the network. To specify the origins and destinations of link flows, E^w is a vector in $R^{|N|}$ with two nonzero components: one has a value of 1 in the component corresponding to the origin node of O-D pair w and the other has a value of -1 in the component for the destination. For each link $(i, j) \in A$, $t_{ij}(v_{ij}, y_{ij})$ denotes the travel cost (time) as a function of link flow v_{ij} and the expansion amount y_{ij} Below, $t(v, c)$ denotes a vector whose components consist of individual link travel costs, $t_{ij}(v_{ij}, y_{ij})$.

With an uncertainty set of future demands for the traffic network, the robust optimization approach is to design the network against the worst-case scenario realized in the set. More specifically, we attempt to find a capacity expansion plan that minimizes the maximum system travel time realized within the set. Without loss of generality, constructing new links can be treated as adding capacities to existing links with zero capacity. Using the above notation of robust optimization, a robust continuous network design model or RCND can be formulated as the following min-max program:

RCND

$$\min_{y} \max_{d,x,v,z,\pi} \sum_{ij \in A} t_{ij}(v_{ij}, y_{ij}) \cdot v_{ij}$$

s.t.
$$x_{ij}^w \cdot \left(t_{ij}(v_{ij}, y_{ij}) + \pi_i^w - \pi_j^w \right) = 0 \qquad \forall (i, j) \in A, w \in W \qquad (1)$$

$$t_{ij}(v_{ij}, y_{ij}) + \pi_i^w - \pi_j^w \geq 0 \qquad \forall (i, j) \in A, w \in W \qquad (2)$$

$$v \in V(d) \qquad (3)$$

$$d \in D \qquad (4)$$

$$\sum_{ij \in A} h_{ij}(y_{ij}) \leq B \qquad (5)$$

$$0 \leq y_{ij} \leq y_{ij}^{\max} \qquad \forall (i, j) \in A \qquad (6)$$

The objective of RCND is to minimize the maximum system travel cost realized from the uncertainty set of future demands. The decision variables of the outer problem (the minimization) compose a capacity expansion plan and those of the inner problem (the maximization) are the worst-case demand scenario and the associated UE flow distributions. Constraints (1)-(3) ensure that, for a given network design y and a demand vector d, the feasible flow distribution satisfies

UE conditions where variable π_i^w is the potential of node *i* for O-D pair *w*. Constraint (4) requires future demands to be realized from the uncertainty set and constraint (5) guarantees that the total cost of the expansion plan does not exceed *B*, the budget, where $h_{ij}(y_{ij})$ is the construction cost for link (i, j). Finally, constraint (6) ensures that the amount of capacity expansion for each link is nonnegative and less than its maximum. In the above, y_{ij} is a continuous scalar.

A robust discrete network design model, or RDND can be similarly formulated. Note that discrete capacity expansion (in the unit of one lane) can be always represented in binary digits. Let y_{ij}^k be a 0-1 variable in the k^{th} bit of the binary number corresponding to the capacity expansion of link $(i, j) \in A$. Let *K* be the number of bits (determined from the maximum possible number of lanes added), then the number of additional lanes is $\sum_{k=1}^{K} 2^{k-1} y_{ij}^k$, an integer between zero and $2^K - 1$. For example, if the number of additional lanes on link (i, j) is 3, *K*=2 and $y_{ij}^1 = y_{ij}^2 = 1$, leading to $\sum_{k=1}^{2} 2^{k-1} y_{ij}^k = 3$. y_{ij}^k can be treated as a continuous variable with two additional conditions $y_{ij}^k(1 - y_{ij}^k) = 0$ and $0 \le y_{ij}^k \le 1$. In the RDND formulation, y_{ij} represents a vector in R^K whose element is y_{ij}^k. RDND can be written as follows:

RDND

$$\min_{y} \max_{d,x,v,z,\pi} \sum_{ij \in A} t_{ij}(v_{ij}, y_{ij}) \cdot v_{ij}$$

s.t. (1)-(5)

$$y_{ij}^k(1 - y_{ij}^k) = 0 \qquad \forall (i, j) \in A, k \in \{1,2,..., K\} \qquad (7)$$

$$0 \le y_{ij}^k \le 1 \qquad \forall (i, j) \in A, k \in \{1,2,..., K\} \qquad (8)$$

With a simple transformation, it is easy to see that both CDND and RDND are MPEC or more precisely mathematical programs with complementarity constraints (MPCC), a class of optimization problems very difficult to solve for mainly two reasons. One is the fact that MPCC violates the Magasarian-Fromovitz constraint qualification and the other is the non-convexity of its feasible region (e.g., Scheel and Scholtes, 2000). Compounding to this difficulty is the fact that the problems have an infinite or astronomical number of constraints and decision variables.

UNCERTAINTY SET OF FUTURE DEMANDS

The above two robust models are worst-case oriented, but bounded by an uncertainty set. It is thus critical to specify an appropriate set to avoid being overly conservative and allow the flexibility in controlling the level of conservatism for designing the network expansion plans. Below we discuss three uncertainty sets that may be meaningful in confining uncertain travel demands. No underlying probability distributions of travel demands are assumed to be known, although such knowledge may be of use to obtain a reasonable uncertainty set.

Polyhedron. An example of a polyhedral uncertainty set is a box set (e.g., Soyster, 1973). Mathematically, $D = \{d \mid d_w^{\min} \le d_w \le d_w^{\max}, \forall w \in W\}$, where $d_w^{\min}$

and $d_w^{\max}$ represent the minimum and maximum travel demands for O-D pair *w*, respectively. The interval may be the confidence interval of an estimated demand obtained through a survey or by using an O-D estimation model. Although easy to specify, the box set may lead to a decision too conservative to be of interest. Additional information should be used to further confine the uncertainty. For example, $\sum_{w \in O_i} d_w \le Q_i^{\max}$, where O_i is the set of O-D pairs whose origin is node *i* and $Q_i^{\max}$ is the upper bound for the total number of trips generated from node *i*. The upper bound can be viewed as a variable to control the degree of uncertainty and may be determined via a trip generation model considering car ownership and population etc.

Ellipsoid. In its most familiar form, an ellipsoidal uncertainty set can be represented as $D = \{d \mid \sum_w \frac{(d_w - d_w^0)^2}{r_w^2} \le \theta^2\}$, where d_w^0 and r_w are the nominal demand and possible variation for O-D pair *w* and θ is a subjective value representing the decision maker's attitude toward risk. Given $d_w^{\min}$ and $d_w^{\max}$, one set of parameters for the above ellipsoid is $d_w^0 = \frac{1}{2}(d_w^{\min} + d_w^{\max})$ and $r_w = \frac{1}{2}(d_w^{\max} - d_w^{\min})$. When $\theta = 0$, *D* with the above parameters reduces to the singleton $\{d^0\}$, where d^0 is a vector of d_w^0. On the other hand, *D* becomes the largest volume ellipsoid inside and the smallest volume ellipsoid inscribing the box defined above when $\theta = 1$ and $\sqrt{m}$ respectively. In general, larger θ means the decision maker is more risk averse (Ben-Tal and Nemirovski, 2002).

Discrete. The set is similar in principle to Bertismas and Sim (2003). It is assumed that future demand of each O-D pair can be one of several values whose probabilities of occurrence, however, are unknown. These possible demand values are often identified with the alternative forecasts of socioeconomic and land-use developments by metropolitan planning organizations. To mathematically describe this set, let $d_w^s, s = 1,2,...,S_w$ denote the demand for O-D pair *w* under scenario *s*, where d_w^1 represents the nominal demand and z_w^s is a binary variable that indicates whether scenario *s* is realized for O-D pair *w*. Then, $\sum_{s=1}^{S_w} z_w^s = 1$ ensures that only one demand scenario will be realized for each O-D pair. In addition, we assume that there is an "uncertainty budget" Γ that allows demands for at most Γ O-D pairs to deviate from their nominal values simultaneously, i.e., $\sum_w \sum_{s=2}^{S_w} z_w^s \le \Gamma$. In words, Γ is a parameter for controlling the degree of conservatism and describing decision makers' attitudes toward risk. Then, the demand uncertainty set can be described as follows: $D = \left\{ d \middle| d_w = \sum_{s=1}^{S_w} z_w^s d_w^s,\ \sum_{s=1}^{S_w} z_w^s = 1,\ \sum_w \sum_{s=2}^{S_w} z_w^s \le \Gamma, z_w^s \in \{0,1\} \right\}$.

Combining the above uncertainty sets with two robust formulations yields different models, which can be solved by a cutting-plane algorithm presented in the next section. The choice of the uncertainty set should depend on the level of available information, i.e., planners' knowledge about future travel demands.

More importantly, it should ensure that the resulting robust counterpart is computationally tractable. For example, the discrete set in combination with RDND leads to an optimization model that is effectively and efficiently solvable (Lou et al., 2009).

CUTTING-PLANE SOLUTION SCHEME

The section presents a cutting-plane scheme for solving both RCND and RDND. The scheme solve a sequence of relaxed RCND or RDND with respect to a subset $\widetilde{D} \subset D$ that contains a smaller number of demand vectors and then solve another problem to generate demand vectors "as needed" to enlarge $\widetilde{D}$ and make it approximate *D* better.

In the following, we present the algorithm using the RDND formulation as an example. The relaxed RDND problem or R-RDND can be written as follows:

R-RDND

$$\min_{x,y,v,\pi,\xi} \xi$$

$$\text{s.t.} \quad \sum_{ij\in A} t_{ij}(v_{ij}^d, y_{ij}) \cdot v_{ij}^d \le \xi \qquad \forall d \in \widetilde{D} = \left\{d^1, \cdots d^n\right\}$$

$$x_{ij}^{w,d}\left(t_{ij}(v_{ij}^d, y_{ij}^k) + \pi_i^{w,d} - \pi_j^{w,d}\right) = 0 \qquad \forall (i,j) \in A, w \in W, d \in \widetilde{D}$$

$$t_{ij}(v_{ij}^d, y_{ij}) + \pi_i^{w,d} - \pi_j^{w,d} \ge 0 \qquad \forall (i,j) \in A, w \in W, d \in \widetilde{D}$$

$$v^d \in V(d) \qquad \forall d \in \widetilde{D} = \left\{d^1, \cdots d^n\right\}$$

(5), (7) and (8)

In the above, the superscript $(\bullet)^d$ denotes variables associated with a particular demand vector $d \in \widetilde{D}$. Let $(\hat{y}, \hat{\xi})$ be a global optimal to R-RDND. (To simplify our presentation, we ignore other components of the solution vector.) Note that $(\hat{y}, \hat{\xi})$ also solves the original RDND if, with the network design $\hat{y}$, the total system travel cost of the UE flow associated with every demand scenario in *D* is no greater than $\hat{\xi}$. Mathematically, this can be verified by solving the following worst-case demand problem or WCD:

WCD

$$\max_{d,x,v,z,\pi} \sum_{ij\in A} t_{ij}(v_{ij}, \hat{y}_{ij}) \cdot v_{ij}$$

$$\text{s.t.} \quad x_{ij}^w\left(t_{ij}(v_{ij}, \hat{y}_{ij}) + \pi_i^w - \pi_j^w\right) = 0 \qquad \forall (i,j) \in A, w \in W$$

$$t_{ij}(v_{ij}, \hat{y}_{ij}) + \pi_i^w - \pi_j^w \ge 0 \qquad \forall (i,j) \in A, w \in W$$

(3)-(4)

If the optimal objective value of WCD is no greater than $\hat{\xi}$, then $\hat{y}$ is optimal to RDND. Otherwise, an improved solution may be obtained by solving R-RDND with an expanded demand set $\widetilde{D} \cup \left\{\hat{d}\right\}$, where $\hat{d}$ solves the above WCD.

Both R-RDND and WCD are MPCC and require specialized solution algorithms to solve them, such as the manifold suboptimization algorithm by Lawphongpanich and Yin (2008) and the active-set algorithm by Zhang et al. (2009). Below we outline the cutting-plane solution procedure:

Step 0: Select a demand vector $d^1 \in D$. Set $n = 1$ and $\widetilde{D} = \{d^1\}$.

Step 1: Solve R-RDND with a subset $\widetilde{D}$. Let $(\hat{y}^n, \hat{\xi}^n)$ denote the resulting optimal solution.

Step 2: Solve WCD with capacity expansion plan $\hat{y}^n$. Let d_n denote the resulting optimal solution and $\hat{v}^n$ its corresponding UE flow.

Step 3: If $t(\hat{v}^n, \hat{y}^n)^T \hat{v}^n \le \hat{\xi}^n$, stop and $\hat{y}^n$ is an optimal capacity expansion vector. Otherwise, set $\widetilde{D} = \widetilde{D} \cup \{d_n\}$, $n = n + 1$ and go to Step 1.

The convergence proof of the above procedure can be found in Yin and Lawphongpanich (2007) and Lou et al. (2009).

NUMERICAL EXAMPLES

This section reports results from solving RDND with a discrete uncertainty set for two networks from the literature, Sioux Falls (e.g., LeBlanc et al., 1975) and Hull (e.g., Florian et al., 1987). The former consists of 76 links, 24 nodes and 528 O-D pairs while the latter comprises 741 links, 524 nodes and 142 O-D pairs. In the numerical examples, there are three possible demand scenarios for each O-D pair: nominal, low and high. The nominal demand is the original demand. The low and high scenarios are the nominal demand multiplied by uniform random numbers between [0.5, 1] and [1, 1.5], respectively. In both networks, all links are candidates for expanding capacity up to three additional lanes. Other details of the numerical examples can be found in Lou et al. (2009). The results reported as follows are from our GAMS implementation on a Dell Optiplex 755 computer with 3.16 GHz Intel Core2Duo CPU and 3.25GB of RAM.

Table 1 summarizes the computational efficiency for both Sioux Falls and Hull. In these examples, the cost budget *B* is 25 for Sioux Falls and 60 for Hull while the uncertainty budget Γ is 10 and 5 respectively. The computational CPU time is 392.05 and 474.11 seconds respectively, in which solving R-RDND consumes the majority of the resource. The elapsed time reported in the table includes the time for input and output. For Sioux Falls, it takes 7 iterations of the cutting-plane procedure while for Hull, it only takes 3 outer iterations, but requiring a bit more CPU time to solve two larger size sub-problems.

Table 1 Computation Efficiency

	Number of Iterations	Elapsed Time (mm:ss)	CPU Time (sec)	WCD (sec)	R-RDND (sec)
Sioux Falls	7	12:55	392.05	23.88	368.17
Hull	3	8:57	474.11	99.18	374.93

Figure 1 displays the amount of CPU time required to solve the RDND problem for Sioux Falls with the uncertainty budget Γ varying from 0 to 50. In general, it takes more outer iterations to solve the problem when the uncertainty budget is larger. But in all numerical experiments we conducted for Sioux Falls, the CPU time is less than 15 minutes. For Hull, it is less than 8 minutes with the uncertainty budget Γ up to 10. The experiments demonstrate that the algorithm is quite efficient and has the potential for solving larger

network design problems.

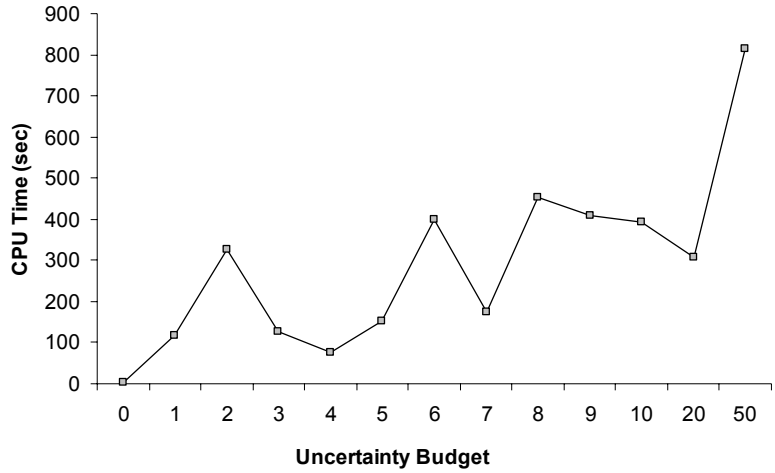

Figure 1 CPU time versus uncertainty budget

Table 2 reports the resulting robust and nominal expansion plans of the two examples illustrated in Table 1. The latter is obtained by solving RDND with $\Gamma=0$, i.e., a deterministic discrete network design problem with the nominal demand. It can be seen that although approximately 50%-60% of the investments in both plans are the same, the other differs in either the selection of link segment for expansion or the magnitude of capacity expansion.

Table 2 Comparison of Robust and Nominal Plans

Sioux Falls			Hull		
Link	Robust Plan	Nominal Plan	Link	Robust Plan	Nominal Plan
(6,8)	3	3	(1,207)	0	1
(8,6)	3	3	(5,406)	3	3
(10,16)	3	3	(8,215)	0	1
(11,14)	3	3	(10,241)	1	1
(13,24)	2	3	(11,272)	3	3
(14,11)	3	3	(270, 271)	0	1
(15,10)	0	1	(272,279,)	3	3
(16,10)	3	3	(280,281)	1	0
(22,23)	1	0	(282,283)	3	3
(23,22)	3	0	(406,412)	3	3
(24,13)	1	3	(412,410)	3	1
Total Cost	25	25	Total Cost	60	60

To compare the robust and nominal plans, we conducted three sets of Monte Carlo simulations. It is assumed that each of the low, nominal and high demand scenarios for each OD pair has a probability of 1/3, 1/3 and 1/3 to occur (discrete uniform distribution) in the first, 1/6, 1/6 and 2/3 ("pessimistically" asymmetric distribution) in the second and 2/3, 1/6 and 1/6 ("optimistically" asymmetric distribution) in the third simulation. In each simulation, 500 travel demand vectors were generated and for each of them, two UE distributions, one with robust plan and the other with nominal plan were obtained. The average, maximum and standard deviation of the total travel costs associated with the UE

distributions are computed and reported in Table 3. It can be seen that the robust plan for Sioux Falls reduces average, maximum and standard deviation of system travel costs by 2.5%, 3.0% and 6.3% respectively in the first, 3.2%, 3.8% and 6.7% in the second, and 2.1%, 1.8% and 2.3% in the third simulation. The reductions for Hull are 3.2%, 6.9% and 22.4% in the first, 4.3%, 6.5% and 16.9% in the second and 2.4%, 5.2% and 24.9% in the third simulation. The *t* and *F* tests show that the reductions are all statistically significant. The simulations confirm that the robust plans may lead to less volatile performances.

Table 3 Performances of Robust and Nominal Plans in Simulation

Simulation	Measures	Sioux Falls		Hull	
		Robust Plan	Nominal Plan	Robust Plan	Nominal Plan
Demands with Discrete Uniform Distribution	Average Travel Cost	7010.37	7183.42	40975.41	42290.13
	Maximum Travel Cost	7750.12	7985.76	55342.57	59175.90
	Std of Travel Costs	238.88	253.98	4112.58	5033.45
Demands with Pessimistically Asymmetric Distribution	Average Travel Cost	9880.67	10197.84	53870.98	56183.15
	Maximum Travel Cost	10899.70	11311.07	65196.74	69413.66
	Std of Travel Costs	332.23	354.55	5072.04	5929.25
Demands with Optimistically Asymmetric Distribution	Average Travel Cost	4987.23	5093.17	31518.91	32266.28
	Maximum Travel Cost	5467.39	5567.47	42384.06	44602.33
	Std of Travel Costs	155.78	159.40	2787.25	3481.39

Figure 2 and 3 compare the nominal (or the plan with $\Gamma = 0$) and robust plans with the uncertainty budget Γ varying from 0 to 50 for Sioux Falls and from 0 to 10 for Hull respectively under the discrete uniform distribution of future demands. There are three curves in both figures for relative percent difference in the mean, maximum and standard deviations of system travel costs (the performance resulting from the nominal plan minus the one from the robust plan divided by the latter). In general, as the uncertainty budget Γ increases, standard deviation associated with the robust plan becomes smaller, i.e., the total travel cost associated with the robust plan is less volatile. When the budget Γ is large enough, e.g., $\Gamma \geq 5$, the reduction in the maximum and average travel cost is pretty stable, approximately 2% and 2% respectively for Sioux Fall and 3% and 6% respectively for Hull. Note that when the budget Γ is very small, e.g., $\Gamma = 1$ or 2, the robust and nominal plans are either the same (for Hull), or have similar performance (For Sioux Falls, the reduction in average and maximum travel time is negative when $\Gamma = 1$ as shown in Figure 3, which, however, is statistically insignificant).

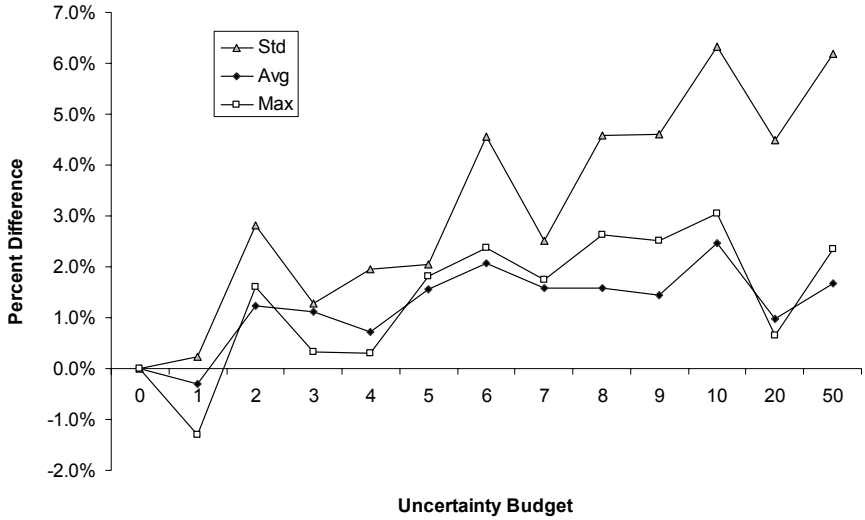

Figure 2 Comparison of the nominal and robust plans for Sioux Falls

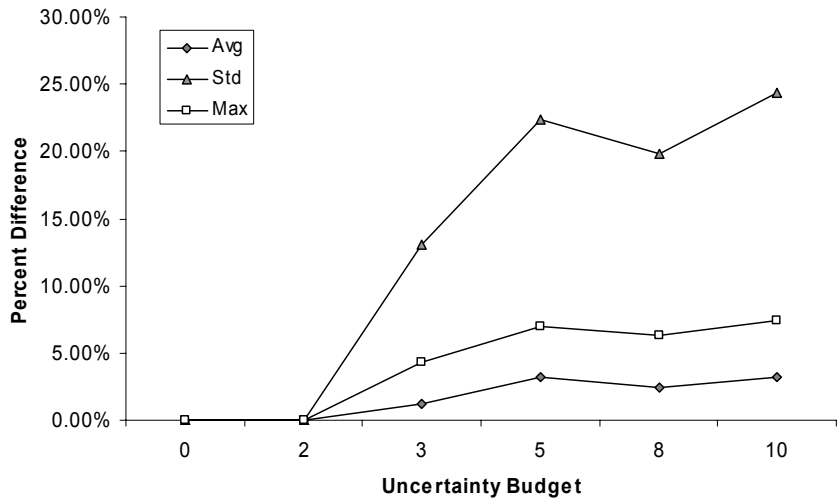

Figure 3 Comparison of the nominal and robust plans for Hull

CONCLUDING REMARKS

In this paper, we review a robust optimization approach for network design problem under demand uncertainty. Although the travel demand for each O-D pair is uncertain, this approach assumes that the vector of O-D travel demands realized for the network must belong to an uncertainty set. The network is then designed against the worst-case scenario realized in the set and the problems are then formulated as MPCC, which can be solved by the proposed iterative cutting-plane scheme. Numerical results from the Sioux Falls and Hull networks empirically demonstrate that the algorithm is effective in practice and has the potential to solve realistic network design problems. Moreover, the results from these two networks indicate that capacity expansion plans from our robust formulations are less volatile and perform better against worst-case demand

scenarios. Because many problems in transportation planning and management (e.g., congestion pricing and evacuation planning) share similar structure as network design, the proposed robust optimization framework can be applied to aid those decision-makings.

ABSTRACT

Since traffic impact study (TIS) of projects has been carried out in Beijing for more than ten years, a series of noticeable results have been achieved. However, there are still some unsolved problems in TIS. For example, there is a lack of quantitative analysis of traffic organization and public transportation. The objective of this paper is to attempt to develop standards of traffic impact study to assist the government in developing an appropriate evaluation criterion for assessing transportation related projects. A total of four evaluation indicators have been selected. The four evaluation indicators include: variation of v/c ratio, complexity of conflict, index of transit capacity and satisfactory degree of the public to projects. These indicators have been defined and modeled in quantitative format and the results can be applied in the evaluation process.

Key Words: Traffic Impact; Evaluation and Analysis; Quantitative Analysis

1. INTRODUCTION

Many traffic impact studies (TIS) of projects have been conducted since 1995 in Beijing. They have played a positive role in coordinating the relationship between city development and traffic infrastructure, relieving the conflicts between traffic supply and demand, and improving the traffic performance of highways (Pei et al. 2004). However, based on the experience in Beijing and other provinces, unified standards are not applied in TIS. The study on some important factors such as traffic organization, v/c ratio of intersections and public transit, has been limited in qualitative analysis. There is a lack of research of quantitative analysis on standard of traffic impact studies resulting in an inaccuracy of the conclusions in assessments.

On the basis of analysis of related influential factors in traffic impact studies and comprehensive investigations in Beijing, a total of four evaluation indicators have been proposed in this paper. The four evaluation indicators include: variation of v/c ratio, complexity of conflict, index of transit capacity and the degree of public satisfaction with projects. In order to identify the importance and acceptable degrees of each indicator in traffic impact studies, appropriate evaluation methods and

standards have been decided by modeling and quantifying these indicators. As a result, the conclusion of research can be beneficially applied in the evaluation process.

2.V/C RATIO AND SERVICE LEVEL OF SIGNALIZED INTERSECTION

Volume to capacity ratio (or v/c ratio) of section has always been used to evaluate the effect of traffic caused by projects (BJUT et al. 2008). As we all know, the change of v/c of intersections has played an important role in affecting the operation of the road network. Therefore, the variation of v/c ratio is used to reflect the traffic impact the projects bring to the neighborhood areas.

2.1 DEFINITION AND CALCULATION

Variation of v/c ratio in fact reflects the intensity of change of traffic volume produced by projects on intersections located near the affected areas. Its mathematical expression is as follows:

$$P = \frac{L_f - L_p}{M_{LOSi}} \qquad (1)$$

Where: P—variation of v/c ratio;

M_{LOSi}—allowable maximum range of variation of v/c ratio under given level of service i,

L_f—v/c ratio of intersection after implementation of projects;

L_p—v/c ratio of intersection at present.

2.2 EVALUATION STANDARD

The acceptable change of v/c ratio and LOS of network in different areas is not the same, so there are differences in allowable v/c ratio among different intersections. Therefore, the relative agencies can decide whether the projects are accepted or rejected, unlike traditional ways of evaluating traffic projects in which average approach is applied. In this study, the so-called “one-item denies all” approach is proposed. This approach attempts to demonstrate that if one and only one item (for example v/c ratio) is not acceptable for evaluation, this whole project will be rejected. As is known, there are three types of conclusions when conducting traffic impact studies for any transportation-related project. They are: accepting, needing improvement, and rejecting.

Table 1 Variation of v/c Ratio When Level of Service Changes

When LOS A→B	Accepting	Needing Improvement	Rejecting
Variation of v/c Ratio	≤0.4	0.4-0.9	＞0.9
Average speed（km/h）	≥50	45-50	＜45
When LOS B→C	Accepting	Needing Improvement	Rejecting
Variation of v/c ratio	≤0.5	0.5-0.9	＞0.9
Average speed（km/h）	≥40	35-40	＜35
When LOS C→D	Accepting	Needing Improvement	Rejecting
Variation of v/c ratio	≤0.5	0.5-0.9	＞0.9
Average speed（km/h）	≤30	25-30	＜25
When LOS D→E	Accepting	Needing Improvement	Rejecting
Variation of v/c ratio	≤0.6	0.6-0.9	＞0.9
Average speed（km/h）	≤20	15-20	＜15

As for variable P, it is determined that when the LOS has skipped more than two grades (such as A→C,B→D) the project is to be rejected. If the LOS has skipped less than two grades（such as A→B, B→C）then the above Table 1 can be used as evaluation criteria in terms of traffic intensity.

3. TRAFFIC ORGANIZATION

A lot of references have been involved in the traffic organization. Based on analysis of the distribution of traffic flow, location of access, as well as various conflicts, the traffic organization has been evaluated in the previous studies (Wang et al. 2007). However, these analyses were qualitative and more indicators about traffic organization were involved in evaluation making it difficult to evaluate appropriately. Hence, quantitative indicators have been brought forward to simplify the evaluation process on traffic organization.

3.1 DESCRIPTION OF INDICATOR

Traffic organization plays an important role in traffic impact evaluation on projects. Reasonable traffic organization can make existing road networks work well, eliminate traffic congestion and potential dangers, and keep trips safe and convenient. In order to improve the evaluation process in terms of traffic organization, a parameter called “complexity of conflict” is proposed in this study as a quantitative indicator of the evaluation on traffic organization.

3.2 DEFINITION AND CALCULATION

Complexity of conflict represents intensity and the degree of conflicts among any traffic movements as a result of the projects. This indicator is used to evaluate levels of traffic organization on the basis of number of conflicts within an affected area. Its mathematical equation can be expressed as follows:

$$C = K(1+\lambda_1\delta_1)(1+\lambda_2\delta_2)\sum\sqrt{\frac{N_1+N_2}{2}}C_i \quad (2)$$

Where: C—complexity of conflict;

K—distance punishment factor, which reflects the impact of distance from access of project to the nearest intersection and its values are shown in Table 2;

C_i—the degree of conflict intensity (n=1,2,…9), the value is in Figure 1;

$_1$—vehicle-bicycle conflict factor. The value is 0.5 for residential areas, commercial areas, and public buildings, while the value is 0.2 for others.

$_1$—0-1 variables. The value is 0 when there is no vehicle-bicycle conflict or 1 otherwise;

$_2$—emergency traffic impact index, of which the value is 0.2;

$_2$—0-1 variables. The value is 0 when evacuation corridor is set and 1 otherwise;

N_1—the number of lanes of conflicting flow 1;

N_2—the number of lanes of conflicting flow 2.

3.3 INTRODUCTION AND CALCULATION OF PARAMETERS

(1) Distance punishment factor K

This factor is used to reflect how distance from access connected with projects to the nearest intersection impacts traffic organization. The further the distance, the greater the impact, and vice versa (BMICPD et al. 2004). The value of the punishment factor is different regarding different ranges of distance and is shown in Table 2.

Table 2 Punishment Factor

Distance from intersection(m)	≥150	50-150	≤50
K	1	1.25	1.5

(2) Conflict intensity C_i

This factor is vital in evaluating traffic organization and reflects different kinds of traffic conflict generated directly by various traffic organizations. The greater the value of C_i, the heavier the traffic conflict is. The value of C_i is shown in Figure 1.

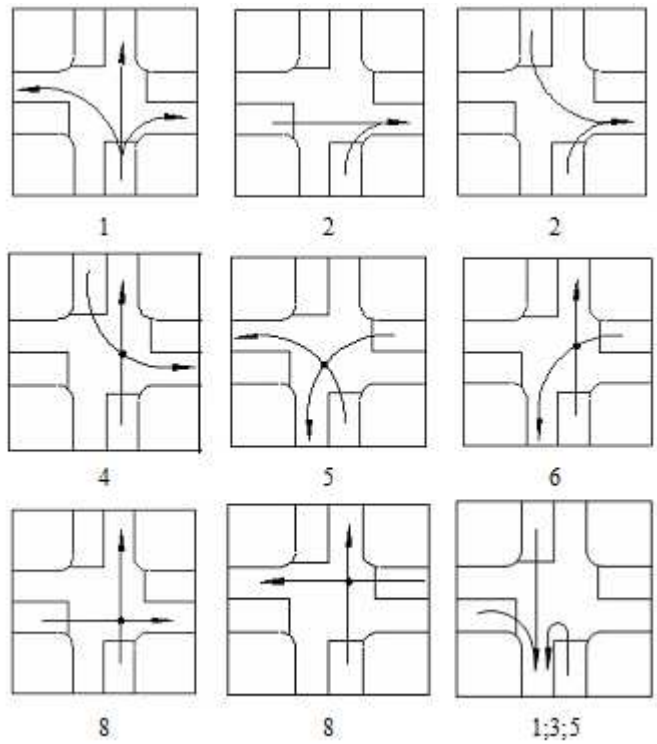

Figure 1 Complexity of Conflict in Different Cases

In figure 1, the last picture shows that when the number of lanes is 1, the conflict value is 5; when the number of lanes is 2, the conflict value is 3; when the number of lanes is 3, the conflict value is 1.

3.4 EVALUTION STANDARD

Based on the analysis of various traffic conflicts and the investigation of intersections, the evaluation criterion has been made in order to reduce conflicts and sustain safety. Finally, the evaluation conclusion for traffic organization is shown in Table 3.

Table 3 Complexity of Conflict

Indicator	Accepting	Needing Improvement	Rejecting
Complexity of Conflict	≤90	90~120	>120

4. PUBLIC TRANSIT

It's important to evaluate the impact of traffic caused by projects on public transit systems. Because of the many indicators involved in evaluation, it's difficult to obtain comprehensive data and the credibility of evaluation results seems rather low at present. In order to improve practicality of indicators, index of transit capacity has been selected to be an appropriate indicator in evaluation on public transit.

4.1 DESCRIPTION OF INDICATOR

The focus of the evaluation of impact on public transit systems is whether the demand for public transit trips generated by projects can be met. On one hand, the proportion of supply the nearest transit station to access offers to demand which is generated by projects should be considered. On the other hand, the service which is provided by public transit systems must also be considered. As the accessibility of transit stations is reduced, the probability of priority selection of station will be lower. This public transit indicator is provided on the basis of both considerations.

4.2 DEFINITION AND CALCULATION

Index of transit capacity is an indicator to demonstrate the ability of public transit to provide service to meet the travel demands generated by projects. The indicator allows the remaining capacity of public transit to measure the bus capacity and LOS. Accessibility adjustment is used to reflect the convenience of public transit, and there have been changes in capacity demand of public transit as accessibility is reduced. Its mathematical expression is as follows:

$$K_i = A \cdot Q_i = f(S_i) \cdot Q_i \tag{3}$$

Where: K_i—index of transit capacity in station i;

A—accessibility adjustment factor, is decided by the accessibility adjustment function $f(S_i)$. The value of it is shown in Table 4;

Q_i—The proportion of the remaining capacity to demand of public transit in station i ;

4.3 INTRODUCTION AND CALCULATION OF PARAMETERS

(1)Accessibility

The accessibility is obtained by function $f(S_i) = 0.15 \cdot \tanh(\frac{500 - S_i}{159.155}) + 0.85$, and the values are as shown in Table 4.

Table 4 Adjustment Factor of Accessibility

Accessibility (km)	0-200	200-300	300-400	400-500	500-600	600-700	700-800	800-1000
Adjustment Factor	0.998	0.988	0.960	0.896	0.804	0.740	0.712	0.702

(2) The proportion of the remaining capacity to demand of public transit

The remaining capacity can be gained by investigation of stations near the access of projects and public transit demand can be gained by trip prediction. The value is 1 when the capacity meets the demand and less than 1 otherwise.

4.4 EVALUATION STANDARD

Considering operation of public transit and actual need of evaluation, the results are divided into three conclusions according to the threshold as shown in Table 5.

Some of the thresholds should be adjusted in consistence with special cases in reality. The indicator is proposed to simplify the process of actual operation, considering the merits and demerits of other indicators comprehensively.

Table 5 The Value of Capacity Index of Transit

Indicator	Accepting	Needing Improvement	Rejecting
Capacity Index	≥1.2	1.2~1.0	<1.0

5 ENVIRONMENT INDICATOR

The indicator reflecting traffic impact on the environment is completely new in traffic impact studies. With more attention from government and public on living and working environments, the indicator reflects integrated effects of the surrounding environment and it definitely plays a more important role in the evaluation of planning projects. This indicator discussed in the paper is not the same as the environmental indicators which reflect the water pollution or air pollution. The indicator here is mainly put forward to describe the public's perception and feeling in regard to the external environment, as well as landscape created by projects. Therefore, the degree of public satisfaction with projects is brought forward to reflect traffic impact of related projects on the environment.

5.1 DESCRIPTION OF INDICATOR

According to the research of living environmental assessment, the criterion of livable city (You et al. 2008) is also available for environmental evaluation of traffic impact evaluation. Three factors, including safety, health and perception, are selected to assess environmental evaluation comprehensively in consistence with the demand of "livable city". Hence, the degree of public satisfaction with projects is proposed to integrate three factors above. This is a new indicator which reflects environmental effects caused by projects. It should be noted here that this indicator is different from those traditional environmental indicators.

5.2 DEFINITION AND CALCULATION

The degree of public satisfaction with projects is the degree of public satisfaction with environmental changes from safety, health and perception (or feeling). It reflects the influence on living and working environments when the projects are implemented.

$$E = \sum_{i=1}^{3} \alpha_i A_i \qquad (4)$$

Where: E —degree of public satisfaction with projects;

$_i$—the weight of factor i ;

A_1—safety satisfaction factor;

A_2—health satisfaction factor;

A_3—perception satisfaction factor,

5.3 DATA INVESTIGATION

The key of the environmental assessment is to gain the degree of public satisfaction with safety, health and perception of the projects. Therefore, the values of three factors are obtained through questionnaires. From the investigation results, the evaluation index of the degree of public satisfaction with projects can be obtained. In practical application, investigators need to collect as many samples as possible in order to increase the credibility of data.

5.4 EVALUATION STANDARD

Finally, the conclusions are divided into three results as shown in Table 6. In light of this fact, this indicator has occupied a smaller weight in traffic impact evaluation. It can be used as the reference indicator to assist with temporary decision making.

Table 6 Degree of Public Satisfaction with Projects

Indicator	Accepting	Needing Improvement	Rejecting
Satisfactory Degree	≥ 4	2-4	＜2

6 EVALUATION AND APPLICATION

On the basis of analysis of the indicators above, “Dual-degree evaluation method” is proposed to apply in the evaluation work. It means that variation of v/c ratio and complexity of conflict are used to be the criteria, and capacity index of transit and degree of public satisfaction with projects are used as reference indicators in evaluation. Specific operation is as follows: Variation of v/c ratio and complexity of conflict are kept as the previous and key indicators in evaluation. If both of them are accepted, the project will be permitted. If either of them is accepted, the project is to be improved. If neither of them is accepted, the project will be rejected. If both of them need to be improved, capacity index of transit and degree of public satisfaction with projects can be used as reference indicators to assist related agencies to work out an appropriate result for related projects.

7 CONCLUSION

On the basis of analysis of traffic demand and network structure, the flow distributions and travel mode distributions of traffic generated by related projects are obtained. Using the advanced experience of foreign countries (Guide for the Preparation of TIS 2002), a total of four indicators and corresponding evaluation methods are proposed to be applied in practice. These indicators are presented for practicality and reasonableness in the process of assessment, considering the merits and demerits of various indicators comprehensively. Variation of v/c ratio is proposed for the first time, which reflects the intensity of traffic flow on intersection. Complexity of conflict is proposed to do the quantitative analysis on conflicts of intersections, based on analyzing the factors and types of various conflicts affecting

the traffic organization. The environmental indicator of degree of public satisfaction with projects is also proposed as a reference indicator in traffic impact studies for the first time, as well. The theory proposed in the paper is the exploratory development, which requires a lot of data and cases to test and verify. It's necessary to do more investigations and collect much more available data to substantiate the validity of the evaluation standards set for these indicators. As a result, reliability and availability of the indicators and related parameters also need to be improved in evaluation.

Abstract: The method to determine the parking index of buildings is always based on the geographical position division and the building classification standard, which reflects the external parking demand characteristics of the building, but only considers the perspective of the geographical position and building and gets lop-sided. Therefore, the size of parking is difficult to determine for future needs with the change of the developing environment. This paper will revise the parking index model based on the ontological idea and function division of parking space with regard to its internal characteristic, in combination with the analysis of the parking location attribution, and increase the adaptability of the parking. At last, the paper will demonstrate that the new method used to determine the parking index is more comprehensive and objective when compared to the general method.

Keywords: parking index, the parking function, ontological idea, locational factor

0. Introduction

The parking problem is closely connected with the city plan, the city land-use and the structure of traffic infrastructures, which is important to ensure traffic safety, traffic free-flowing and the clean production environment (Wang Jing-xia, 1999). At the present time, the method used to determine the parking index is to adopt the investigation and statistical measure based on the geographical position partition and the construction classification standard, to a certain degree which reflects the external parking demand characteristic of the building, but has a potential hypothesis that the developing environment, which in fact always is in the process of dynamic changes, is consistent and stable. Therefore, the number of parking spaces resulting from the parking standard index is difficult to meet with the development of society and economy. In reality, we should make the parking size under the special environment condition in combination with the regional planning strategy. This paper should analyze the function of parking space in building and revise the parking standard index based on the ontological idea in combination with the consideration of location factors.

1. Analysis of the impact factors on parking demand

There are many impact factors on parking demand which include population scale, number of working position, vehicle volume and classification, parking management policy and so on from the view of the whole city planning. Also involved are the travel purpose, the parking price, parking utilization rate and turnover ratio, the form and intensity of land development, road capacity constraints and so on judging from the parking analysis of some building projects. However, it is

found that the main factors considered are from the external environment of the parking behavior. In fact, it is the internal slow variable that makes the decision for the parking demand.

Property of ontology is one kind of inside attribution of system, and the periphery environment can only be to be an object. If the system needs to increase its inner steady, the analysis must set off from the systematic property of ontology. (Guan Chu-du, 2000). However, current research almost unfolded surrounding the subjective and objective equilibrium theory. The property of subjective and objective equilibrium is a characteristic that the interaction of the systematic inner factors and the outside environmental factors make the subject and the object gain equal satisfaction. When creating a parking facilities plan, the traffic location factors surrounding the equilibrium of the parking demand and the traffic environment are always considered. The defects of the method lie in no discussion of the dominated effect exerted on the traffic demand by the inner factors of building. Once the outside environment changes, the parking facilities can't adapt to the changing needs. The only effective way is to improve the parking systematic stability using ontology theory if we want to make the parking facilities capable of withstanding the configuration of wide field environmental changes. For example, travel purpose and turnover rate of the parking space are the inherent characteristics of parking behavior. A different travel purpose often determines the parking time which is the key factor that decides the parking index of the building. It is more adaptive to determine the parking size based on these two factors. Therefore, in the study of parking index, we should focus on the internal slow variables while also considering the external environment.

2. Analysis of the parking function response for the parking demand

Different travel purposes will create different parking demands, and the parking demand diversity corresponding to the various parking spaces is the parking space function. In fact, even with a different building function in the same central business district, the function of parking spaces often is not consistent, mainly because the building function often determines different parking demand characteristics.

The different parking space function actually corresponds to different parking demand nature. According to the parking time, parking space function can be divided into long-time parking, medial-time parking and short-time parking, or be divided into internal and external service functions according to the service group. Generally speaking, commuter trips such as working and going to school have stable parking demand, and need long parking time and fixed parking place. The flexible travels for the purpose of business, catering and entertainment require a shorter parking time and involve careful parking space selection. Investigation of the parking characteristics of Gaoyang hotel and Yuehai hotel in Hongkou district of Shanghai (see fig.1 and fig.2) found that each period before late peak has a stable saturation, after late peak the parking saturation falls rapidly at the Gaoyang hotel. This status reflects the Gaoyang hotel parking place has a good operating factor in working hours but a low usage at night. Because the parking place services itself, there is a low parking saturation on holidays. On the contrary, at the Yuehai hotel, the parking saturation has the same change in the working days and holidays. In addition, the average parking time and peak parking time distribution also differs greatly in the

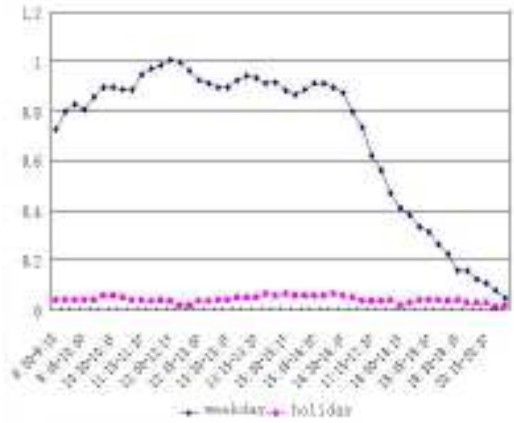

Fig.1 Parking saturation change status in Gaoyang hotel

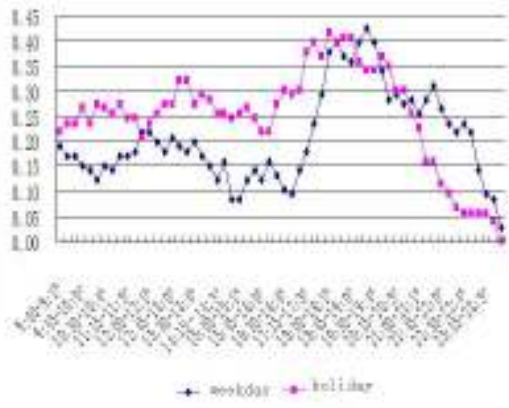

Fig.2 Parking saturation change status in Yuehai hotel

two parking places (see table 1). The survey found that the Gaoyang parking mainly services staff and foreign business personnel, and because travelers use the month card to pay for the parking fee and lightly consider the parking cost, the average parking time is longer. Yuehai hotel parking opens to the public, so parking demand is stable in the working days and holidays. Apparently, the different functions of parking space create the different usage. Therefore, if an analyis of the parking behavior with different demand characteristics from the parking space function division is performed, a better understanding of the response characteristics of different building parking demands will be achieved, thereby increasing the adaptability and stability in parking.

Table 1. Parking supply and demand status for Gaoyang hotel and Yuehai hotel

place	time	Number of the parking	Peak saturation	Average saturation	Turnover rate	Average parking time(minute)
Gaoyang hotel	Working day	136	1.01	0.70	2.32	239
	Holiday	136	0.07	0.04	0.26	235
Yuehai hotel	Working day	106	0.43	0.20	1.91	138
	Holiday	106	0.2	0.25	2.08	177

3. The influence of location condition on the parking demand

Location differences need to be considered because parking supply and demand relation is not only a project planning problem, but also a traffic resource allocation problem. Location becomes the compound concept of the trinity of position, transportation, and economics. We can think of it as the specific performance for the organic combination of natural geographic location and economic geographic location and traffic geographic location in space (Lu Hua-pu, 2006). Location factors and their different combinations form different location conditions also impacting the parking demand diversity.

From the analysis of the geographical location, parking demand diversity mainly

results from the difference of travel structure. The regional planning of urban areas creates different land use patterns which directly affect traffic structure. For example, central land use status requires public transport with a high capacity and the ability to require free traffic pattern conversely.

Traffic location can be considered from two aspects. One is traffic accessibility, which reflects the degree of convenience, the factor inducing motor vehicles into the parking places. Second is the bus service level, which reflects the ability of traffic sustainable development, the factor inhibiting parking behavior. Traffic accessibility and traffic area land-use clustering is proportional to the location potential, the ratio of the location potential between the ideal location and the study location. These reflect the advantage of the study location which also can be regarded as the effect value of traffic location on the travel.

The influence of the economic factor of location on the parking demand is mainly concentrated in the traveler. In a different area, the economic activity intensity diversity can also influence the parking demand: higher intensity, more travel times, more vehicles, more total parking demand. (Xiao Fei, 2009). On the other hand, whether the parking supply meets the parking demand also has influences on the development of regional economy.

4. Parking demand calculation based on the parking space function division

For parking demand at home and abroad, the calculation method has many major categories. One can be summarized as the parking demand and land-use analysis model with the parking production as the core, the other is the attracting travel model with the relationship between parking and vehicle travel as the core and the last is the multivariate regression analysis model based on the related analysis (Wu Tao, Yan Kefei, 2002). These methods are based basically on the subject and object equilibrium concept. This study will revise the parking index standard based on the analysis of parking space function division and location conditions to better reflect the building internal parking demands.

- The influence of the parking space function division on the parking index

First, the parking properties of the building should be identified as simple or public. Next, the parking space function needs be divided by referring the adjacent building with the same function, and determining the parking modifier based on the parking main function classification. Then, analyze the parking status quo and the policy guidance surrounding the parking, such as by parking sharing strategy to improve the overall efficiency of the parking. The parking space function correction coefficient is as follows:

$$\phi = \lambda \cdot \sum u_i d_i \qquad (1)$$

In equation: ϕ - parking space function correction coefficient; u_i - the modifier corresponding to different functions of parking space; d_i - share rate corresponding to different functions of parking space; λ - the modifier of the parking space sharing.

- The influence of the geographic location on the parking index

Both at home and abroad the location diversity in the static traffic aspects are mainly reflected in land use without consideration for the district function division. The regional diversity, historical background and structural diversity in different cities is different, so from the view of geographical factors, the determination of the

building parking index cannot be made according to the ring highway. Therefore, according to Wang Man (2009), this study would divide the city regions as urban center, urban edge, suburban area and suburban area edge to indentify the correction coefficient y_1 as table 2.

Table 2. Geographic location correction coefficient

Area / Correction coefficient	urban center	urban edge	suburban area	suburban area edge
y_1	1.0	1.0	1.1	1.2

- The influence of the economic location on the parking index

For the parking demand with the same nature, the land-use diversity would result in the demand difference. In CBD area, for example, there are three typical land-use patterns: the integration type, the hub type and the belt type center business district, others are mostly a combination of these three patterns. The different land use resulted in the different economic prosperity degree, which is reflected in the parking demand as parking demand characteristics. This study chooses the parking turnover as the representation of economic location in association with the comprehensive traffic survey data of Shanghai city (Wang Man, 2009). Therefore, the economic location correction coefficient can be represented:

$$y_2 = F_r \Big/ F_s \qquad (2)$$

In equation: F_r - the building parking turnover rate; F_s - the average turnover rate in city.

- The influence of the traffic location on the parking index

As indicated above, the influence of traffic location on the parking index is mainly embodied in two aspects: one is the traffic location potential and the other is the bus service level.

The influence of different traffic location potentials on parking demand is represented as the effect of location potential to travel which determines the concrete influence value. The traffic location potential means the ability to produce and attract travel, and is proportional to traffic accessibility and the traffic area land-use cluster (Wang Xiu-lin, et al. 2004). After calculating the inside accessibility and land-use cluster, we can get the traffic location correction coefficient as follow (Wang Man, et al. 2009):

$$y_3 = \left(\frac{K_r L_r}{K_s L_s}\right)^{\chi} \left(\frac{S_r}{S_s}\right)^{\delta} \qquad (3)$$

In equation： K_s - the standard average road grade; K_r - the reality average road grade; L_r - the reality road service lever ; L_s - the average road service lever; S_r - the reality cluster factor; S_s - the average cluster factor; χ - the elastic coefficient resulting from the contribution of traffic accessibility factors to the location potential growth; δ - the elastic coefficient of comprehensive cluster factors to the location potential growth.

The influence of public transportation on the parking lies in its ability to substitute cars. According to a survey, when the bus service level is high, 10 percent of people are willing to transfer from car to bus, with a higher service level, the proportion reaches 26%. With reference to the Hong Kong experience, it is suggested that the building of office, commercial and residential properties can decrease the parking supply 5% ~ 20% in a 500m range around the metro. It can greatly reduce the number of parking places in the central office building, while at the same time increasing the parking places of the rail transit site. The bus service level correction coefficient can be represented as follow:

$$y_4 = 1 - n_1 / n \qquad (4)$$

In equation: n_1 - the travel volume shifting from cars ; n - the total travel volume.

Through the analysis of the influence of the internal location factors on parking demand, we can obtain the method to identify the building parking demand under the consideration of the location conditions. The correction model can be expressed as:

$$P = \phi \cdot y_1 \cdot y_2 \cdot y_3 \cdot y_4 \cdot P_0 \qquad (5)$$

In equation: P - the building parking demand modifier; P_0 - the building parking demand by the standard parking index.

5. Case study

A building project with commercial and office integration located in Huaihai middle road in Luwan district of Shanghai, has technical parameters for the developing project as listed in the following table (see Table 3.)(Wu Bing, Li Lin-bo, Wang Man et al. 2009). According to the Shanghai Building Engineering Traffic Design and Parking (field) Set Standards, the building needs 385 parking places.

Table 3 . Basic technical parameter for the developing project

Total building area (m^2)	Hotel building area (m^2)	Office building area (m^2)	Hotel rooms (room)	Hotel apartments (room)	Villa guest rooms (room)
85,129	44,820	25,180	419	34	15

The analysis of the building attributes found that the parking place only opens to the internal personnel including stable office workers and flexible business flow into the building. But in fact, because of the uncertainty of business flow, in a certain level, it also owns the opening attributes of public parking.

The parking lot of the New Century building near the project, has the same function and attributes, so we thought that the new building would have the same parking demand properties as the New Century building. Through the investigation of the parking lot of the New Century building, we can get the parking number and parking time of different time periods (see fig.3 and fig.4).

After analyzing the peak time and parking time of the parking lot in the New Century building, the study defines 0~1.5 hours as short-time parking, 1.5~3 hours as middle-time parking and 3 hours as long-time parking. The investigation found that

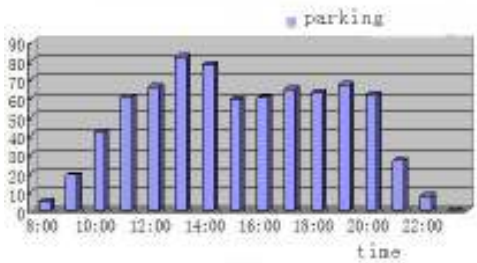

Fig.3 Parking time –vary figure in New century

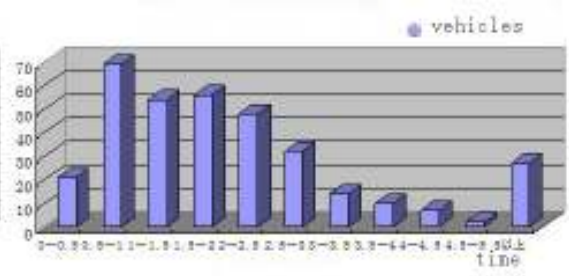

Fig.4 Parking time-distribution figure in New century

the average time is 52 minutes for the short-time parking, 135 minutes for the middle-time parking and 288 minutes for the long-time parking.

According to the Shanghai third traffic comprehensive survey data, the average parking time is 193 minutes in CBD and the corresponding parking space function is long-time parking, so we can get that $u_1 = 52/193 = 0.27$, $u_2 = 135/193 = 0.70$, $u_3 = 288/193 = 1.49$. According to the parking properties investigation in the area where the project is located, the share rate of different parking space function can take $d_1 = 15\%$,$d_2 = 50\%$,$d_3 = 35\%$,and get $\phi = 0.82$. At the same time, the parking peak in various parking lots is different in different time periods, so we can consider appropriate parking is shared and take λ for 0.9. Geographical location correction coefficient y_1 = 1. In the investigation case, the actual parking average turnover rate was 1.64, however the average turnover rate in the CBD was 2.35, so $y_2 = 0.763$. After the survey of the road grade level around the project and prediction, we can get K_r =1.778 , L_r =3.437 , L_s =3.520 , $K_s = 1.713$. This location has the fashion landmark, and through the analysis of the travel attraction to the eight business area, we can take s_r / s_s =1.1, and get $y_3 = 1.022$. The survey of the bus service level in this area found that 10 percent of travelers with motor vehicles were willing to shift to bus, therefore, y_4 can take 0.9. Now we can get the parking demand modifier as follows:

$$P = \phi y_1 y_2 y_3 y_4 P_0 = 0.82 \times 1.0 \times 0.763 \times 1.022 \times 0.9 \times 385 = 223$$

Comparing the modifier with the standard value, we found the parking volume in demand is decreased 162. In fact, the modifier is better to meet with the building parking demand with reference to the parking operation status quo in near buildings.

6. Conclusion

This study, aiming at the problems existing in the parking index standards, thought that the parking index based on the object and subject equilibrium theory cannot reasonably reflect the building's parking demand. To make the building parking scale meet the wide changes of the developing environment, we should adopt the concept of ontology to modify the parking standard index model based on the building parking space function division in combination with location condition. The

case study illustrates that the parking index based on the parking space function division and location conditions analysis can better reflect the building parking inherent demand, actively meet the wide changes of the developing environment, and provide a new train of thought to the development of the parking theory.

ABSTRACT

Traffic impedance is an important parameter in the urban traffic network's study. It directly affects traffic flow path selection and flow assignment. Traffic impedance can be described by a traffic impedance function in the traffic flow assignment, so the accuracy of establishing a traffic impedance function immediately affects the study's performance on the traffic network equilibrium. In this paper, a traffic impedance function is established, which is based on a narrow-sense traffic impedance and grey system theory. In order to effectively determine this, the section between Lujia Village and Lijia Village in Xi'an is analyzed and the traffic impedance function of this section is fitted. Through a comparison with the survey data, it is shown that the analogue result is accurate. Because this section is located in the urban arterial street, the fitted traffic impedance function has a valuable reference to similar situations, especially the urban arterial street in Xi'an.

INTRODUCTION

Traffic impedance is an important parameter in the urban traffic network's study. It directly affects traffic flow path selection and flow assignment. Traffic impedance can be described by a traffic impedance function in the traffic flow assignment. The traffic impedance function refers to the relationship between travel time and traffic loading of road section and delay and loading of road intersection. (Shao Chun-fu 2006) Generalized traffic impedance includes many factors, such as travel time, traffic cost, traffic delay, comfort degree, security and convenience. After performing extensive studies and analysis, it can be concluded that travel time is a critical factor and that a narrower definition of traffic impedance is necessary. Traffic impedance refers to the required time when vehicles pass through the path. the traffic impedance function is the mathematical expression which quantifies traffic impedance.

In the urban traffic network equilibrium, traffic impedance function describes the relationship between traffic flow and travel time, and the relationship is usually

proportional. As the first step in the urban traffic network study, the accuracy of establishing a traffic impedance function immediately affects the study's performance on the traffic network equilibrium. At present, the most common section impedance function is function BPR in the traffic network equilibrium study. However, it is not suitable to use the BPR impedance function directly in an urban mixed traffic environment in China. On one hand, because the function is attained from an investigation of a statistical database of American suburban highways, it is only suitable for long-distance road networks. On the other hand, considering the special situation of urban mixed traffic networks in China, the section impedance function as well as the correlation parameters should be demarcated (Si Bing-feng and Zhong Ming 2008).

In view of the above, a traffic impedance function is established, which is based on a narrow-sense traffic impedance and grey system theory.

GREY SYSTEM AND GM(1, 1) MODEL

Grey system theory and modeling idea. Grey system prediction theory is a relatively new prediction theory developed in the early 1980s. It takes an uncertain system, which is "partial information known, partial information unknown", "small sample" and "poor information", as a research object. Then, through producing and developing the right "part" of the known information, the valuable information is extracted, thereby the correct description and effective monitor to the system operating behavior and evolved rule is realized (Liu Si-feng and Dang Yao-guo 2004).

Grey system searches variation regularity through mining and sorting original data, which is a method of using data to search for data on reality law. Based on least square method, GM(1, 1) model can fit the sequence pairs to be curved to the utmost extent, and achieve a corresponding function equation. Usually, even when a small amount of new data is given, the model can also simulate function precisely.

GM(1,1) model. GM(1,1) modeling and solution process are as follows (Liu Si-feng and Dang Yao-guo 2004):

Sequence operator treatment. Assuming the primitive sequence is:

$$X^{(0)} = (x^{(0)}(1), x^{(0)}(2), \cdots, x^{(0)}(n))$$

with: $x^{(0)}(k) \geq 0, \quad k = 1, 2, \cdots, n$

$X^{(0)}$'s 1-AGO sequence $X^{(1)}$:

$$X^{(1)} = (x^{(1)}(1), x^{(1)}(2), \cdots, x^{(1)}(n))$$

with: $x^{(1)}(k) = \sum_{i=1}^{k} x^{(0)}(i), \quad k = 1, 2, \cdots n$

Average of adjacent value in $X^{(1)}$ consist of sequence $Z^{(1)}$:

$$Z^{(1)} = (z^{(1)}(2), z^{(1)}(3), \cdots, z^{(1)}(n))$$

with: $z^{(1)}(k) = 0.5(x^{(1)}(k) + x^{(1)}(k-1)), \quad k = 2,3,\cdots n$

Model building and parameter solution. The basic form of building GM (1, 1) model is:

$$x^{(0)}(k) + az^{(1)}(k) = b$$

Then the least square estimation parameters column of GM(1,1) basic model is:

$$\hat{a} = [a,b]^T = (B^T B)^{-1} Y$$

with: $Y = \begin{bmatrix} x^{(0)}(2) \\ x^{(0)}(3) \\ \cdots \\ x^{(0)}(n) \end{bmatrix}, \quad B = \begin{bmatrix} -z^{(1)}(2) & 1 \\ -z^{(1)}(3) & 1 \\ \cdots & \cdots \\ -z^{(1)}(n) & 1 \end{bmatrix}$

By substitution of above parameters into the original model, GM (1,1) function is obtained:

$$\hat{x}^{(1)}(k+1) = \left(x^{(0)}(1) - b/a\right)e^{-ak} + b/a, \quad k = 1,2,\cdots,n$$

Then, by using the value which is obtained above with continuous subtraction reduction, the estimated value is attained:

$$\hat{x}^{(0)}(k+1) = \hat{x}^{(1)}(k+1) - \hat{x}^{(1)}(k); \quad k = 1,2,\cdots,n$$

GM(1, 1) model accuracy test. Substitute the value of sequence K into the GM(1,1) equation, the simulated value of original sequence is attained as well as the simulated error sequence ε:

$$\varepsilon(k) = x^{(0)}(k) - \hat{x}^{(0)}(k), \quad k = 2,3,\cdots,n$$

Its average relative error is:

$$\bar{\Delta} = \frac{1}{n-1}\sum_{k=2}^{n}\frac{|\varepsilon(k)|}{x^{(0)}(k)}, \quad k = 2,3,\cdots,n \tag{1}$$

Accuracy test level is shown in Table 1 (Liu Si-feng and Dang Yao-guo 2004).

Table 1. Accuracy test level.

precision rank	first order	second order	third order	fourth order
the critical value of relative error	0.01	0.05	0.10	0.20

Steps of fitting the road section impedance function with GM(1,1) model:

1) Take the investigated vehicle speed as original data sequence.

$$X^{(0)} = (x^{(0)}(1), x^{(0)}(2), x^{(0)}(3), \cdots, x^{(0)}(n))$$

2) Carry on operator processing to original data sequence.

Carry on 1-AGO operator processing to $X^{(0)}$ and obtain $X^{(1)}$, then $Z^{(1)}$ is attained with average of adjacent value in $X^{(1)}$.

3) Build GM(1,1) model, solve it and carry on subtraction reduction, then the time response function is shown as：

$$\hat{x}^{(0)}(k+1) = (1-e^{a})\left(x^{(0)}(1) - b/a\right)e^{-ak}; \quad k = 1, 2, \cdots, n$$

4) Check accuracy of the model according to the fitting value which is obtained from above.

5) When the distance is constant, according to the relationship between time and speed, the section impedance function which takes time as impedance is obtained.

EXAMPLE ANALYSIS

Background information. Based on the theory above, the traffic flow and vehicle speed in the section between Lujia Village and Lijia Village in Xi'an are analyzed, and the traffic impedance function of the section is obtained. In practice, the function is always estimated with five to eight data. Too many data will bring larger fitting errors and lower accuracy (Xie Chen-li and Xia Hong 2007). In view of the above, the author extracts eight data from even peak time and peak time respectively. The data obtained from field survey is shown in Table 2 and Table 3.

Table 2. Even peak time survey data.

the average minute traffic volume (pcu/min)	16	17	18	19	20	21	22	23
the average vehicle speed(m/s)	13.33	12.77	12.37	11.65	11.11	10.34	9.92	9.38

Table3. Peak time survey data.

the average minute traffic volume (pcu/min)	22	23	24	25	26	27	28	29
the average vehicle speed(m/s)	9.68	9.16	8.57	7.69	6.70	5.85	5.45	5.06

Establish traffic volume-vehicle speed function.

***Original data processing*.**

$$\text{Define:}\begin{cases} q_1 = k + 15 \\ q_2 = k + 21 \end{cases}$$

with: q_1——the average minute traffic volume in the even peak time;

q_2——the average minute traffic volume in the peak time;

k——sequencing time, $k \geq 1$;

***Establish traffic volume-vehicle speed function*.**

Based on the method stated in this paper, the fitting results are obtained as follows:

The traffic volume-vehicle speed function in the even peak time:

$$\hat{x}(q_1) = 13.60135527 \exp(-0.052752 \times (q_1 - 15)) \quad (2)$$

The traffic volume-vehicle speed function in the peak time:

$$\hat{x}(q_2) = 10.3459925 \exp(-0.10611 \times (q_2 - 21)) \quad (3)$$

Precision inspection. Simulate and restore the average vehicle's speed through using function (2) and (3), the results are shown in Table 4 and Table 5.

Table 4. Vehicle speed simulation value of even peak time.

the average minute traffic volume (pcu/min)	17	18	19	20	21	22	23
the average vehicle speed(m/s)	12.9025	12.2395	11.6106	11.0140	10.4480	9.9111	9.4019

Table 5. Vehicle speed simulation value of peak time.

the average minute traffic volume (pcu/min)	23	24	25	26	27	28	29
the average vehicle speed(m/s)	9.3044	8.3677	7.5253	6.7677	6.0863	5.4736	4.9225

According to function (1): $\overline{\Delta}_1 = 0.0067$; $\overline{\Delta}_2 = 0.0204$;

Compared with Table 1, the accuracy is the first order in the even peak time and the second order in the peak time. It is shown that the fitting is precise. The

comparison between prediction values and actual values is shown in Figure 1 and Figure 2.

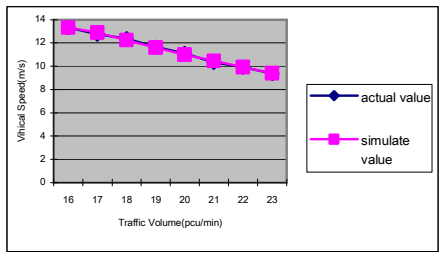

Figure 1. Chart of even peak time and actual value simulate comparison.

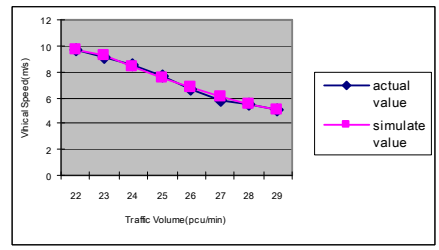

Figure 2. Chart of peak time simulate and actual value comparison.

Build road section impedance function. Assuming the road section length is *l* and time is taken as impedance, the section impedance function is:

$$t(q) = \frac{l}{\hat{x}(q)}$$

with：q = the average minute traffic volume (pcu/min)

$\hat{x}(q)$ = the section vehicle speed when the minute traffic volume is q (m/s)

t(q) = the time pass through section *l* when the minute traffic volume is q (s)

Then, the road section impedance function in the even peak time is:

$$t(q_1) = \frac{l}{\hat{x}(q_1)} = \frac{l}{13.60135527\exp(-0.052752\times(q_1-15))}$$

The road section impedance function in the peak time is:

$$t(q_2) = \frac{l}{\hat{x}(q_2)} = \frac{l}{\hat{x}(q_2) = 10.3459925\exp(-0.10611\times(q_2-21))}$$

CONCLUSION

The accuracy of road section impedance function is playing an important role on urban traffic network balanced research; it immediately affects validity of the research. Based on grey system theory, the author analyzed the section between Lujia Village and Lijia Village in Xi'an for example and fitted the traffic impedance function to this section. Through a comparison of the survey data, it is shown that the analogue result is accurate. Because this section is located in the urban arterial street, the fitted traffic impedance function has a valuable reference to the similar situation, especially the urban arterial street in Xi'an. During building model, several uncertain

factors were not considered, such as the drivers' psychological delay, weather conditions and curb parking. Thus, further research seems necessary.

ABSTRACT

This research aims at gaining a better understanding about how the travelers' attitude to public transport and psychological demands in travel affect the public transport use. Attitude and psychological demand questions are designed in the questionnaire and the survey data is obtained from the Huaibei in Anhui province. Besides descriptive statistics and cross-tabulation used in this study, the travelers' attitude and psychological demands are measured and a discrete mode choice model is built to analyze the related determinants of public transport use. The results suggest that although individual/household socio-demographics are still important, a clear relation is found among travelers' attitude, psychological demands and public transport use. Based on the results, advice is given for government and transportation planners to improve the competition of public transport.

1 INTRODUCTION

In order to design sustainable transportation systems, transportation planners must increase their understanding of the preference of individuals to choose their travel mode. And facilitating public transport use is considered one of the most effective policy options to moderate traffic congestion and environmental problems (Sinha, 2003). Thus, it is meaningful to study travelers' decision-making mechanics to gain some guidance for encouraging people to use public transport.

People's attitudes and psychological demands are generally acknowledged as important factors in travel mode choice, but little is known about this relationship in China. The researcher abroad is concerned about ways to encourage public transport use based on the analysis of habit, motivation and psychological demands of travelers (Satoshi, 2002; Benjamin, 2008). However, the present literature in China mainly focuses on the effect of individual/household socio-demographics (Liu, B.E. 2005; Shan X, 2007). With the survey data in Huaibei, Anhui province and a discrete choice model, this study provides some results about the attitudes and psychological demands influencing the public transport use in China.

2 DATA

The data source comes from the travel diary data of Huaibei in November,

2008. Random sampling and face-to-face interviews were applied in the survey. Apart from information on socio-demographic characteristics, 3150 respondents were asked some questions related with public transport to reflect their attitudes to public transport. They were asked to point out what is most important in travel with cited answers to explore the psychological demands of the respondents.

If the respondent used public transport in the survey day, we considered him to be a public transport user, regardless of whether he used another travel mode or not. Of the 3150 respondents, 708 were public transport users which accounts for 22.47 percent. The other 2442 respondents traveled by car, bicycle, motorcycle or on foot. Until 2008, Huaibei hadn't constructed mass rapid transit systems, therefore busing is the public transport referred to in this study.

3 ATTITUDE AND PUBLIC TRANSPORT USE

Four questions were asked in the survey to reflect the respondents' attitudes to transport mode as follows in Table 1:

Table1. The Questions Related the Attitudes towards the Transport Mode

Questions	Answers
1.Do you think public transport can moderate traffic congestion	1.Yes 2.No
2.Do you think wide use of cars is the primary cause of congestion	1.Yes 2.No
3.Do you think the use of public transport is convenient on travel	1.Yes 2.No
4.Would you adopt public transport as your travel mode if the public transport service is promoted in the future	1.Yes 3.No 2.Not sure

The effects of the attitude on travel mode choice are shown in Table 2. Crosstabs are used to decide whether the according variable's effect is significant.

Table2. Crosstab Analysis between Attitude and the Mode Choice

Attitudes question		Mode choice		Total	Pearson χ^2	Sig.
		Bus	Not bus			
Question 1	Answer Yes	23.1%	76.9%	100%	5.964	0.010
	Answer No	17.7%	82.3%	100%		
Question 2	Answer Yes	23.1%	76.9%	100%	0.562	0.367
	Answer No	21.8%	78.2%	100%		
Question 3	Answer Yes	25.5%	74.5%	100%	26.952	0.000
	Answer No	17.6%	82.4%	100%		
Question 4	Answer Yes	26.2%	73.8%	100%	84.135	0.000
	Answer Not sure	9.0%	91.0%	100%		
	Answer No	10.2%	89.8%	100%		

It is shown that the different feedback to question 1, 3 and 4 are significant at the level of $\alpha = 0.05$, according to the Pearson Chi-Square test. However, the different feedback to question 2 is not significant.

Table 2 shows that respondents who accept the point of view that the public transport can moderate traffic congestion are more likely to choose the bus system in their travel. Respondents who believe the use of public transport is convenient on their travel are also more likely to use the bus system. As seen from the results of

question 4, the bus users are prone to sequentially use public transport if the public transport service is promoted in the future. However, the individuals who don't use public transport in the survey present lack of confidence of public transport as compared to the actual bus users. Of the 708 bus user respondents, 1.8 percent chose not sure, and 8.3 percent chose won't use public transport. Conversely, 21.3 percent of respondents who don't use the bus in the survey stated they wouldn't use public transport in the future. The insignificance of the relation between feedback to question 2 and mode choice reflects that the attitude towards car usage is not an important factor in public transport use.

4 PSYCHOLOGICAL DEMAND AND PUBLIC TRANSPORT USE

In the survey, the respondent is requested to point out what is most important in his travel trips. He may choose two of the six options we provided, as follows: 1) quick arrival; 2) safe arrival; 3) comfortable travel; 4) travel convenience; 5) economical for travel; 6) expressing myself. The answer of every respondent reflects the psychological demands of him on his travel (see Table 3).

Table3. Crosstab Analysis between Psychological Demand and the Mode Choice

psychological demands		Mode choice		Total	Pearson χ^2	Sig.
		Bus user	Not bus			
quick arrival	choose	25.5%	74.5%	100%	9.846	0.002
	Not choose	20.6%	79.4%	100%		
safe arrival	choose	21.2%	78.8%	100%	12.465	0.000
	Not choose	28.0%	72.0%	100%		
comfortable travel	choose	8.4%	91.6%	100%	13.652	0.000
	Not choose	24.5%	75.5%	100%		
travel convenience	choose	21.3%	78.7%	100%	0.541	0.462
	Not choose	22.7%	77.3%	100%		
economical travel	choose	25.0%	75.0%	100%	7.626	0.006
	Not choose	20.8%	79.2%	100%		
self expression	choose	3.4%	96.6%	100%	4.022	0.045
	Not choose	22.2%	77.8%	100%		

As seen from Table 3, five kinds of psychological demands, including quick arrival, safe arrival, comfortable travel, economical travel and self expression, are significant at the level of $\alpha = 0.05$. The respondent requiring "quicker arrival" and "economical travel" is prone to use public transport, the difference between the decision to use or not use public transport is around 4 percent. While the respondents who chose "safe arrival", "comfortable travel" and "selfexpression" tend to not use public transport. Those who chose "comfortable travel" or "self expression" have more than a 16 percent possibility of not using public transport. The need for "travel convenience" is not a significant effective factor.

5. BINARY LOGISTIC REGRESSION MODEL

Model Structure. Since the outcome or response variable is binary when an individual chooses whether or not to use public transport, the binary regression

model is used to analyze the choice behavior. It was defined as y=0 (not use), or y=1 (use). In this research, there are several explanatory variables or predictors including socio-demographics, attitude to transport mode and psychological demand, which are denoted as x_1, …, x_n. Then the binary logistic regression is stated in terms of the probability that y=1 given x_1, …, x_n, as shown in the following expression:

$$p = \Pr(y = 1 \mid x) = (1 + \exp[-(\alpha + \sum_{k=1}^{n} \beta_k x_k)])^{-1} \quad (1)$$

Where p is the probability when y=1, α is the intercept parameter; β_k is the slope parameter of x_k. The odds of using public transport can be expressed as:

$$p/(1-p) = \exp(\alpha + \sum_{k=1}^{n} \beta_k x_k) \quad (2)$$

Explanatory variables. In our previous study (Wan X., 2008), the socio-demographics of respondents are significant influencing factors for mode choice, so they are selected as variables in the model. We employ a continuous latent variable to reflect the travelers' attitude towards public transport in the model. Based on the results in Table 2, the calculated method of latent variable is the score of question 1 plus questions 3 and 4. For questions 1 and 3, the respondent answering "yes" can get one score; for question 4, a "yes" choice can get two scores, and "not sure" deserves one score. For any question, if the answer is "no", the score is zero. The scope of the latent variable is form 0 to 4. The higher score the respondent attained, the more he advocates public transport. The six psychological demand options, except "travel convenience" are adopted as discrete variables in the model. The selected explanations along with their definitions are summarized in Table 4.

Table4. Explanatory Variables Used in the Model

	Variable	Description
Individual/household socio-demographics	Female	1, 0 otherwise
	Have driving license	1, 0 otherwise
	Have public bus commute ticket	1, 0 otherwise
	Higher education	1, 0 otherwise
	Age<30	1, 0 otherwise
	Aage>50	1, 0 otherwise
	One or more children under school age	1, 0 otherwise
	Household income >¥50,000	1, 0 otherwise
	One or more bicycles in household	1, 0 otherwise
	One or more motorcycles in household	1, 0 otherwise
	One or more private cars in household	1, 0 otherwise
	Company vehicle available	1, 0 otherwise

Attitude	the degree of advocating public transport	continuous variable
Psychological demand	quick arrival	1, 0 otherwise
	safe arrival	1, 0 otherwise
	comfortable travel	1, 0 otherwise
	economical travel	1, 0 otherwise
	self expression	1, 0 otherwise

Model Calibration and Discussion. By correlation matrix analysis, we removed the collinear variables, and eliminated the insignificant variables. Table 5 shows the final estimation results of the public transport use choice model. The binary logistic model without attitude and psychological demand variables is estimated as reference.

Table 5. Estimation Results of MODEL and MODEL Ref

Independent variables	MODEL			MODEL Ref		
	Parameter	Wald	Sig.	Parameter	Wald	Sig.
Constant	0.278	29.731	0.000	0.298	32.503	0.000
Female	0.269	10.930	0.002	0.378	11.125	0.000
Have driving license	-0.955	16.254	0.000	-1.565	17.144	0.000
Have bus commute ticket	1.334	13.126	0.000	1.364	18.536	0.000
Higher education	-0.430	16.250	0.000	-0.459	14.957	0.000
Age>50	0.631	3.123	0.063	0.752	2.908	0.082
Household	-0.410	5.782	0.020	-0.530	7.048	0.011
>1 bicycle in household	-0.504	14.002	0.000	-0.614	12.238	0.000
>1 motorcycle in household	-0.919	12.751	0.000	-1.193	14.933	0.000
>1 private car in household	-0.922	8.962	0.009	-1.021	7.324	0.010
Company vehicle	-1.365	13.257	0.000	-1.652	14.129	0.000
Attitude	0.232	20.631	0.000	/	/	/
Quick arrival	0.622	4.446	0.030	/	/	/
Safe arrival	-0.416	10.965	0.002	/	/	/
Comfortable travel	-0.932.	12.635	0.000	/	/	/
Economical travel	0.396	6.951	0.010	/	/	/
Self expression	-1.526	4.784	0.029	/	/	/
Hit rate	83.6%			77.1%		
Nagelkerke R^2	0.456			0.386		

The hit rate of mode with attitude and psychological demand variables is 83.6%, while the hit rate of reference mode is 77.1%. Based on the estimation result, some conclusions can be obtained.

Socio-demographics： Accordant with our previous study, females, elders, and those in possession of a bus commute ticket have a greater probability of using public transport; those with a higher income, higher education and with occupancy of

vehicles had a reduced possibility of bus use.

Attitude: The higher the score of attitude variable the traveler attained, the greater the possibility of him using public transport. It suggests that if somebody has the perception that public transport is friendly to the environment and has confidence in the quality of public transport services in the future, he is more likely to choose public transport instead of another mode. This suggests a need for the government and transportation planners to create a positive image of the public transport system in the future.

Psychological demand: Among six psychological demand options, quick arrival and economical travel have a significant positive effect on public transport use, which means travelers with stronger psychological demand for them will have a stronger tendency to choose the bus system. However, safe arrival, comfortable travel and self expression have significant negative effects on public transport use. Consequently, it could reflect the service quality of bus system in people's eyes. The bus system can provide quicker service for its mobility compared with on foot or bicycle usage, and provides lower cost service compared with using a car or taxi. In contrast, the bus system has disadvantages in regard to safety, comfort and status needs.

The difference of hit rate and Nagelkerke R^2 between two models demonstrates the effect of attitude and psychological demand on public transport use which indicates that these factors shouldn't be ignored in China.

6. CONCLUSION AND ADVICE

By descriptive statistics and logistic regression methods, this paper developed an empirical framework to examine the effect of the travelers' attitudes and psychological demands on travel mode choice. With the data of Huaibei travel dairy survey, the travelers' attitudes and psychological demands are successfully measured and proved to be effective for increasing the accuracy of the public transport use predicting model. For the mode including the attitude and psychological demand variables, the understanding of travel mode decision-making mechanics is improved.

Some useful advice can be drawn for government and transportation planners. Creating a positive image of public transport systems and widely propagandizing the public transport as an environmentally friendly transport mode could increase the possibility of travelers choosing public transport. Quick arrival and economical travel have been accepted as high grade characteristics for public transport, but the lack of ensured safety, comfort and self-expression on travel decrease the competition of public transport. These give some direction for improving the service of public transport in the future.

ABSTRACT

Urban traffic is closely connected to urban planning and different urban forms have different traffic patterns. This paper studies the coupled relations among urban forms, rail traffic patterns, public transportation patterns, bicycle traffic patterns and pedestrian traffic patterns, and it may also serve as good reference to solving city traffic congestion.

1. URBAN FORM AND RAIL TRAFFIC

With the constant expansion of cities, various urban patterns have come into being, such as conglomeration, star patterns and ribbon patterns, etc. (Li Haifeng, 2006)

(1)URBAN FORM AND RAIL TRAFFIC

In the urban form of conglomeration, rail traffic lines fall into two types: diameter lines and ring lines, with the former linking satellite towns to the city, while the latter serving as the means by which the traffic in urban center is leaded and the passenger flows among satellite towns are conducted (Li Haifeng, 2006).

In a star-shaped city, rail traffic lines radiate from the city center. Conventional public transport serves as feeders for rail transit and connects peripheral passengers to the trunk line. The framework of a star-shaped city is the axial rail transit, with the urban periphery being interlaced with green space, forests, farmland, etc, and thus an eco-city development pattern is formed. Though experts point out that this is the ideal urban form, urban system planning of major Chinese cities has shifted from centralization to decentralization, such as ribbon patterns and twin cities, etc., in favor of the development of rail transit.

Rail traffic is environment-friendly.

Cluster city is ideal for leading urban concentric circle development, forming clusters of various functions and land nature on the outskirts of a city, separated by green belts, which is the practice of the well-known Finnish planner Saarinen's theory on organic decentralization planning. Each cluster is a functional aggregation and daily life and work can be carried out in the cluster. Highway or rail transit links different clusters (Bian Jingwei, 2006). In Nantong, Qinhuangdao and other Chinese cities it is proposed that clusters be connected by light rail's diameter lines.

(2)RAIL TRANSIT DEVELOPMENT PATTERN

1) Within the scope of city

Subway systems should be prioritized in urban centers, with light rail taken into consideration where passenger flow is small. In urban centers, with large populations, large traffic volume, and significantly concentrated passenger flow during rush hour, subways may be the only by means of rapid evacuation without crowding and congestion. On routes with small traffic flow it is more economical to build light rail, whose cost is only 1/5 to 1/3 of that of subway. The light rail layout of Changchun is arranged from the center to the outskirts of the city. In the United States, Boston's three green branch lines and Philadelphia's five light rails near City Hall are also good examples.

The use of trolleys should be properly developed. According to incomplete statistics, the return of the trolley is advocated in 350 cities around the globe. Rail and trolley bus use are flourishing in Germany, France, Belgium, Holland and other western European countries. Trolley is also considered an important vehicle in Eastern Europe, and Russia where there are 60,000 trolleys. In the United States, trolleys eliminated in the 1960s and 1970s, are desterilized. In some large and medium-sized Chinese cities a new air-condition trolley is being developed, such as Guangzhou, Beijing, Dalian, Shanghai and Hangzhou and so on.

2) Suburbs

Light rail and suburban railway should be developed in suburbs. Light rail and suburban railway are used to connect satellite towns to urban centers. The capacity of light rail is between those of subway and public trolley, which could be rated as medium capacity system. It is suitable for suburbs, sub-center, urban areas (small and medium-sized cities) and places where subways are not economical.

3) Metropolitan circle

Suburban railway should be developed in metropolitan circle. Suburban railway is used to manage high capacity passenger traffic between urban and suburbs, suburbs and suburbs, satellite towns, ribbon cities and metropolis circle. There should be feeders between suburban railway and city rail transit net, readily available to passengers.

Medium capacity monorail or rail traffic system could be applied to commuter lines linking suburbs of big cities, new towns, and residential areas to urban centers.

According to the analysis above, metropolitan circle's development model is MRT+LRT, suburban railway +MRT or guide rail. Trolley, LRT, MRT and MRT+LRT could be included in the city's development model. (Note: MRT-subway, LRT-light rail).

2. URBAN FORM AND REGULAR PUBLIC TRAFFIC PATTERN

The major urban form in China is conglomeration city, which may evolve into multi-center city, cluster city and ribbon city. Conventional public transportation serves as the main urban traffic mode, and express buses serve in the city's outskirts for commuters. Currently, China's national revenue is increasing and a family with an annual income of mere 50,000 Yuan can afford a car, which results in a steady

growth in the number of private cars, which occupy urban road system and pose a challenge to public transport. The typical urban expansion model has resulted from car increase, which consequently leads to sprawling urban area, and negatively impacts urban development. Public transport mode should be the main urban development pattern (Sui Dong et al., 2007).

Take Beijing for example. Beijing's affordable housing is gradually expanding to the outskirts of the city, with residents utilizing public transport to get around. Beijing planned several express bus lines, abbreviated as BRT, i.e. Bus Rapid Transit, which has the exclusive right of way, incorporating the rapidity of subway, light rail and the flexibility of buses. The typical BRT system is Curitiba BRT system in Brazil, which is composed of fast lines, interval lines and branch lines (Wei Yaping, 2003). Different kinds of lines represent different passenger flow and are distinguished by different colors. Different kinds of public traffic lines have different road way conditions. Beijing's BRT extends from city center to periphery, through which public traffic service is provided; traffic cost and the utilization of private cars are reduced for the owners of affordable housing who moved outside of city. On the contrary, Beijing's Tiantongyuan and Huilongguan have been developed on a large scale, but the traffic facilities have not kept pace and many residents have to opt for motor vehicle traffic.

There are five development patterns for BRT: as a transition of subway or light rail; becoming the main body of overall public traffic; as an extension of subway or light rail; a combination of subway and light rail; and stand alone BRT system.

3. URBAN FORM AND BICYCLE TRAFFIC PATTERN

(1) URBAN FORM AND BICYCLE TRAFFIC

The evolution of urban form can be divided into three stages, initial stage, intermediate stage and advanced stage. In initial stage, the city is rendered as concentric circles with a single center, with pedestrian and bicycle as the main traffic pattern. In intermediate stage of urban development, urban form turns into conglomeration and bicycles dominate in city traffic pattern, with public traffic taking a certain proportion. In advanced stage, urban form evolves to star shape, cluster and other urban form, where public traffic is the main body of city traffic patterns, and bicycle and car are complementary to it.

Most cities in China are in the form of concentric circles with a single center, for which, compared with ribbon and star shape cities, it is difficult to open up high speed and large capacity public traffic corridors. Within an area of 113 square kilometers occupied by concentric circles(R=6km), public traffic and bicycle traffic

are in rivalry, where bicycle traffic form enjoys an advantage (Chu Jinlong, 2007). Currently, urban form in China is evolving from conglomeration into star shape and multi-clusters. Traffic form is changing from bicycle-based traffic form to public traffic-based traffic form. With the expansion of city and the rapid growth of private cars, the rate of city residents utilizing motorized traffic increases year by year. As an example, the rate of residents in the urban district of Nanjing utilizing motorized traffic form was 32.71% in 2008, while the rate of those utilizing public traffic (including subway) is 21.56%. The residents' satisfaction rate is 42.4%. The rate of those residents utilizing bicycle traffic is nearly 50%. These, on one hand, indicate that city constructions are compact and commuting distance is short. On the other hand, these (statistics?) mean that public traffic development is stagnant. In Shenyang, residents 90% probability traffic time interval is [7,77] in 2005. 90% probability pedestrian traffic time interval is [5,50], 90% probability bicycle traffic time interval is [8,67]. 90% probability public traffic time interval is [18,107]. The average traffic time of residents by bicycle is 29 minutes in Shenyang. The upper limit of bicycle traffic time is up to 67 minutes, which exceeds rational traffic time interval of bicycle travel. These show that bicycle traffic patterns cannot meet the development of Shenyang City. Residents should choose other traffic patterns to reduce bicycle traffic (Li Haifeng et al., 2007).

(2) DEVELOPMENT PATTERN OF BICYCLE TRAFFIC

City land use in China is mixed, which makes pedestrian and bicycle traffic feasible. Mixed use of land function can reduce traffic distance, increase traffic efficiency, and reduce fuel consumption of vehicle, which will help to build a human-oriented traffic environment.

According to city land function layout, city railways, traffic main lines and natural barriers, the city can be divided into several bicycle traffic districts using ring lines and radial lines to form urban bicycle networks. According to bicycle traffic's time-space, bicycle traffic and pedestrian traffic should be advocated within the region. Efficient public traffic corridors should be built between regions.

In order to adapt to urban development, China should build a new traffic pattern which is different from Europe and the United States' Park and Ride system (Chen Jun, 2007), and which coordinates urban bicycle traffic with public traffic. Public traffic is the main body of this new urban traffic pattern with bicycle traffic as an

auxiliary, forming a perfect bicycle-public traffic transfer system. Land use functions are mixed in China's cluster cities. Business, leisure, entertainment, shopping, working and living are linked by bicycle traffic, which develops bicycle's advantage within short range and achieves seamless connection among bicycle, public traffic and rail traffic.

4. URBAN FORM AND PEDESTRIAN TRAFFIC PATTERN

(1) URBAN FORM AND PEDESTRIAN TRAFFIC

Pedestrian traffic, designed by J. H. Crawford, resembles six clover leaves. The population of the city is about 1,000,000 scattering in 100 communities, among which there are 18 smaller ones called practical areas away from the city center. These non-residential areas are reserved for different land uses.

There are three high-capacity subway lines in the city, each of which begins from a leaf, then runs through the city center and reaches the opposite leaf.

Satellite towns can be built on the basis of this six-leave-clover city form, with each taking the shape of a rough circle and holding one million residents. Fast light rail serves as the connection among them.

(2) THE DEVELOPMENT PATTERN OF CHINA'S PEDESTRIAN TRAFFIC

Some parts of cities can be rebuilt as walking areas in China. Public traffic acts as feeder around the periphery of walking areas. The Hunan road in Nanjing is the first commercial pedestrian street in China. On weekend nights, vehicle traffic is banned in the pedestrian sections with open space reserved for shopping and entertainment.. According to the situation in China, light rail, rail, and trolley can all be used as modes of transportation instead of high-capacity railways. Light rail is only applicable in cities with a population smaller than 500,000.

The method can be extended to other cities' commercial pedestrian street and old districts. The ancient Chinese road network layout is square, such as those left in Suzhou, Xi'an and other cities. These old districts maintain a moderate population, and can be divided into several small districts. Exclusive public traffic main lines and trolley can be used to transport passengers. Pedestrian traffic patterns within these districts can protect historical and cultural remains and give more open space to residents.

Study on Road Network Reserved Capacity on Different Levels of Service and Stochastic Conditions

Liu Zhengwei[1] and Cheng Lin[1]

[1]School of transportation, Southeast University, Nanjing 210096, China; PH 86-25-83795469; email: zw_liu0806@yahoo.com.cn

Abstract

The paper investigates the road network capacity under uncertainty. By showing the characteristics of route choice and considering the link travel time reliability on a certain level of service, we set a bi-level programming model and the road network capacity can be gained. Firstly we consider the single link of a route under uncertainty, and then extend it to the whole road network capacity on a certain service level. Using the model we can escape from calculating a huge amount of data which is used in the Monte-Carlo method. An example is calculated, and then the result shows the efficiency of the model.

Key words: road network capacity; bi-level programming; sensitivity analysis; user equilibrium

1. Introduction

In reality, the road network's normal functions are frequently affected by many factors, including natural factors (e.g., earthquake; flood; volcanic eruption; mud-rock flow; etc) and man-made factors (e.g., road maintenance; ramp closure; parking in the road; traffic accidents; terrorist activities; etc), which cause the uncertainty of the road network. Therefore, it is necessary to introduce the stochasticity into the design and evaluation of road networks. Traffic elements' capability and spatial layout determine the capability of road network. The capability of urban road network results from a single section's transportation capability extending to the whole network that means how many volumes the urban road network can accommodate on a certain service level (Cheng *et al*. 2004). The capability of urban road network reflects its ability to deal with transportation demand.

2. Problem analysis and road network capacity model

2.1 Notation

A road network is defined as a system, which can be represented mathematically as a graph G(N, A) with a set of nodes N and sections A. To make more sense of following sections, the notation shows as below:

$\boldsymbol{W}$ set of OD(origin-destination)

$\boldsymbol{R_{(i,j)}}$ set of routes from node i to j

$\boldsymbol{x_a}$ traffic volume of section a

$\boldsymbol{t_{a0}}$ free-flow travel time of section a

$\boldsymbol{T_a}$ actual travel time of section a

$\boldsymbol{T_{(i,j)r}}$ travel time of route r

$\boldsymbol{\delta_{ar}}$ 0-1 variable. If section a is a composition of route r, δ_{ar} equal to 1; otherwise, δ_{ar} equal to 0

$\boldsymbol{q_{(i,j)}}$ existing traffic volume from node i to j

$\boldsymbol{C_a}$ actual capacity of section a

$\overline{C_a}$ design capacity of section a

$f_{(i,j)r}$ traffic volume of route r
c_a broadly-defined traffic cost of section a
$c_{(i,j)r}$ broadly-defined travel cost of route r
$\pi_{(i,j)}$ minimum of broadly-defined travel cost from node i to j
μ multiplier of origin-destination matrix

2.2 Problem analysis

With the proportion of OD-matrix's construction unchanged, the capability of the network usually refers to the maximum volume it can accommodate on a certain service level. Customarily it could be represented by using reserved capacity, because once the OD-matrix's construction has been fixed, the capability of network can be depicted by the largest multiplier corresponding to the OD-matrix. Network elements' capability recession, the stochastic of road travel time, and the users' behavior in choosing routes are the important factors which affect road network capability (Cheng *et al*. 2005). The reliability of transportation network capability refers to the probability that it can accommodate the maximum volumes on certain service levels (Chen *et al.* 1999). A reliability study needs large amounts of historic data as well as many hypothesizes as it is a complex program.. Nevertheless if we change this question to the maximum volume that a road network can accommodate on certain service levels, the question transfers to the solution of the network capability's distribution. We can solve this question through using chance-constrained model (Charnes et al. 1963).

The following assumptions are proposed to be convenient to solve the problem:
(1) The network is in a state of equilibrium based on the traveler's experiences of the state of the network and his clear realization of the value of the broadly-defined travel cost. The network in a state of equilibrium can be depicted as: all the selected routes' travel cost is equal to the same value and no more than that of the routes not selected. Depict mathematically:

$$c_{(i,j)r} = \begin{cases} = \pi_{(i,j)}, & \text{if} \quad f_{(i,j)r} > 0; \\ \geq \pi_{(i,j)}, & \text{if} \quad f_{(i,j)r} = 0; \end{cases} \qquad \forall (i,j) \in W, \ \forall r \in R_{(i,j)} \tag{1}$$

(2) The intersections are in the ideal state (absolutely reliable).
(3) The variety of sections' traffic flows are independent.

2.2.1 Travel time and broadly-defined cost of section

The actual capacity of section C_a is a random variable. Simply, we assume that C_a satisfies uniform distribution: $[\theta_a \overline{C_a}, \overline{C_a}]$ $(0 \leq \theta_a < 1)$.

Based on the BRP function, T_a is a random variable subjected to the section's volume x_a and actual capacity C_a.

$$T_a(x_a, C_a) = t_{a0}\left[1 + \alpha\left(x_a / C_a\right)^{\beta}\right] \tag{2}$$

Where, α and β are the parameters of BRP function. So the expectation e_a and the variance σ_a^2 of the travel time of a section can be depicted as follows:

$$e_a = E\left(T_a\right) = t_{a0} + \alpha t_{a0} x_a^{\beta} E\left[\left(1/C_a\right)^{\beta}\right] = t_{a0} + \alpha t_{a0} x_a^{\beta} \frac{1 - \theta_a^{1-\beta}}{\overline{C_a}^{\beta}\left(1-\theta_a\right)\left(1-\beta\right)} \tag{3}$$

$$\sigma_a^2 = D(T_a) = \alpha^2 t_{a0}^2 x_a^{2\beta} D\left[(1/C_a)^\beta\right] = \alpha^2 t_{a0}^2 \frac{x_a^{2\beta}}{\overline{C_a}^{2\beta}} \left\{ \frac{1-\theta_a^{1-2\beta}}{(1-\theta_a)(1-2\beta)} - \left[\frac{1-\theta_a^{1-\beta}}{(1-\theta_a)(1-\beta)} \right]^2 \right\} \quad (4)$$

From Eq (3) and Eq (4), we know that x_a is in synchronous growth with e_a and σ_a^2. The broadly-defined travel cost of section a is defined as follows:

$$c_a = e_a, \quad \forall a \in A \quad (5)$$

2.2.2 Travel time and broadly-defined cost of route

Considering that intersections are in the ideal state, travel time of a route are only made up of travel times of the sections.

$$c_{(i,j)r} = T_{(i,j)r} = \sum_{a \in A} T_a \delta_{ar}, \quad \forall a \in A \quad (6)$$

From the CLT, this distribution satisfies the normal distribution as follows:

$$T_{(i,j)r} \sim N\left[E\left(T_{(i,j)r}\right), \sigma_{w(i,j)}^2 \right] \quad (7)$$

$$E\left(T_{(i,j)r}\right) = \sum_{a \in A} E(T_a)\delta_{ar} = \sum_{a \in A} \left[t_{a0} + \alpha t_{a0} x_a^\beta \frac{1-\theta_a^{1-\beta}}{\overline{C_a}^\beta (1-\theta_a)(1-\beta)} \right] \delta_{ar} \quad (8)$$

$$\sigma_{(i,j)r} = \sqrt{\sum_{a \in A} D(T_a)\delta_{ar}} = \sqrt{\sum_{a \in A} \alpha^2 t_{a0}^2 \frac{x_a^{2\beta}}{\overline{C_a}^{2\beta}} \left\{ \frac{1-\theta_a^{1-2\beta}}{(1-\theta_a)(1-2\beta)} - \left[\frac{1-\theta_a^{1-\beta}}{(1-\theta_a)(1-\beta)} \right]^2 \right\} \delta_{ar}} \quad (9)$$

Basically the mean and standard deviation of travel time of the route impact the user's decision and represent the important information of the network's travel time reliability.

2.2.3 Analysis of the user's selecting behaviors

Travel time of routes continues to change, and the road network is in equilibrium as probability. All conditions are shown as follows:

(1) The expectation of travel time $E(T_{(i,j)r})$ of the selected route r equals to $\pi_{(i,j)}$ (the minimum of all the travel time of the routes from node i to j). Eq (1) shows that mathematically.

(2) The reliability of travel time of the selected route satisfies the following requirement:

$$P\left(T_{(i,j)r} - \pi_{(i,j)} \le \varepsilon \pi_{(i,j)}\right) \ge \lambda_{(i,j)r} \quad \forall (i,j) \in W, \forall r \in R_{(i,j)} \quad (10)$$
$$0 < \varepsilon, \lambda_{(i,j)r} \le 1$$

Where ε is the parameter representing how much travel time can be longer than the expected minimum; $\lambda_{(i,j)r}$ represents the user's requirement of the reliability of the travel time.

With satisfying the Eq. (1), we transform the Eq. (10):

$$\begin{aligned} P\left(T_{(i,j)r} - \pi_{(i,j)} \le \varepsilon \pi_{(i,j)}\right) \ge \lambda_{(i,j)r} &<=> P\left(T_{(i,j)r} - E\left(T_{(i,j)r}\right) \le \varepsilon E\left(T_{(i,j)r}\right)\right) \ge \lambda_{(i,j)r} \\ &<=> P\left(\frac{T_{(i,j)r} - E\left(T_{(i,j)r}\right)}{\sigma_{(i,j)r}} \le \frac{\varepsilon E\left(T_{(i,j)r}\right)}{\sigma_{(i,j)r}} \right) \ge \lambda_{(i,j)r} \end{aligned} \quad (11)$$

It's easy to know that $\frac{T_{(i,j)r} - E\left(T_{(i,j)r}\right)}{\sigma_{(i,j)r}} \sim N(0,1)$, so the equation can be transformed to:

$$\frac{\varepsilon E\left(T_{wr}\right)}{\sigma_{wr}} \geq \phi^{-1}\left(\lambda_{wr}\right) \tag{12}$$

Plugging Eq (8) and Eq (9) to Eq (12), we can get:

$$\frac{\varepsilon \sum_{a \in A}\left[t_{a0} + \alpha t_{a0} x_a^{\beta} \frac{1-\theta_a^{1-\beta}}{\overline{C_a}^{\beta}(1-\theta_a)(1-\beta)}\right]\delta_{ar}}{\sqrt{\sum_{a \in A} \alpha^2 t_{a0}^2 \frac{x_a^{2\beta}}{\overline{C_a}^{2\beta}}\left\{\frac{1-\theta_a^{1-2\beta}}{(1-\theta_a)(1-2\beta)} - \left[\frac{1-\theta_a^{1-\beta}}{(1-\theta_a)(1-\beta)}\right]^2\right\}\delta_{ar}}} \geq \phi^{-1}\left(\lambda_{(i,j)r}\right) \tag{13}$$

2.2.4 The model of road network capacity based on uncertainty of the capacity of section

It's necessary to make the road network satisfy a certain service level when we indentify the capacity of it; and the service level can be respectively represented by different sections. To the respective users the degree of traffic jam must be an approximately acceptable level. We use the reliability of travel time of sections to represent the acceptable service level which is firstly proposed by Lo *et al* (Lo *et al*. 2000).

$$P\left(T_a \geq \varphi_a t_{a0}\right) \leq \gamma_a \tag{14}$$

Where φ_a represents crowding coefficient of section a and $\varphi_a \geq 1$; γ_a represents how much the probability of the travel time of section a exceeds the acceptable travel time, which reflects people's acceptable degree of section traffic crowding and $0 \leq \gamma_a \leq 1$. Different sections have different γ_a because people may obtain different acceptable crowding degrees. Using Eq. (2) we can transform Eq. (14) to:

$$P\left(C_a \leq \frac{x_a}{\left(\frac{\varphi_a - 1}{\alpha}\right)^{1/\beta}}\right) \leq \gamma_a <=> x_a \leq \left(\frac{\varphi_a - 1}{\alpha}\right)^{1/\beta} F_{C_a}^{-1}\left(\gamma_a\right) = \left(\frac{\varphi_a - 1}{\alpha}\right)^{1/\beta} \overline{C_a}\left[\theta_a + \gamma_a\left(1-\theta_a\right)\right] \tag{15}$$

Where $F_{Ca}^{-1}(.)$ is the inverse function of C_a distribution function.

Considering the reliability of travel time of section and the reliability of travel time of route we set up the bi-level programming model which meets the user equilibrium principle as below:

$$\text{(U)} \quad \begin{aligned} &\max \quad \mu \\ &s.t. \quad x_a\left(\mu q\right) \leq \left(\frac{\varphi_a - 1}{\alpha}\right)^{1/\beta} \overline{C_a}\left[\theta_a + \gamma_a\left(1-\theta_a\right)\right] \end{aligned} \tag{16}$$

Where $x_a(\mu q)$ meets user equilibrium assignment as below:

$$
\begin{aligned}
&\min \quad Z(x) = \sum_{a \in A} \int_0^{x_a} c_a(w)dw \\
&s.t. \quad \sum_{r \in R_{(i,j)}} f_{(i,j)r} = \mu q_{(i,j)}, \quad \forall (i,j) \in W \\
(L) \quad & f_{(i,j)r} \geq 0, \quad \forall (i,j) \in W, \forall r \in R_{(i,j)} \qquad (17) \\
& f_{(i,j)r}\left(\frac{\varepsilon E\left(T_{(i,j)r}\right)}{\sigma_{(i,j)r}} - \phi^{-1}\left(\lambda_{(i,j)r}\right)\right) \geq 0, \quad \forall (i,j) \in W, \forall r \in R_{(i,j)} \\
& x_a = \sum_{(i,j) \in W} \sum_{r \in R_{(i,j)}} f_{(i,j)r} \delta_{ar}, \quad \forall a \in A
\end{aligned}
$$

3. Solution algorithm

There are many methods to solve the bi-level programming problem, but in summary, there are four main categories (i.e. pole searching method, kuhn-tucker method, descent method and direct method) (Gao *et al*. 2000). This paper uses the descent method, pointing out how to get the lower variables' information about derivatives or differences of the upper variables. Because the upper problem has only one decision variable μ, we can regard it as a variable of the lower road network equilibrium problem. First, we choose a μ little enough, then continue changing it until an upper problem's restriction condition is violated by an equilibrium volume of section. The concrete algorithm is a sensitivity analysis method which can solve this problem efficiently. The special procedures are introduced as follows:

(1) Choose a much less multiplier of origin-destination matrix $\mu^{(n)}$, whose order is zero (n=0).

(2) With the defined $\mu^{(n)}$, we solve the lower road equilibrium problem and get the equilibrium volume of sections $x^{(n)}$.

(3) Using a sensitivity analysis method of road equilibrium problem we can get the descents of the section's volume about the multiplier of origin-destination matrix $\mu^{(n)}$.

(4) With the information of descents we can get a local linear approximation equation of the reliability restrictive Eq. (16), so we transform the upper problem to a linear planning problem. With solving the linear planning problem we can get a new multiplier of origin-destination matrix $\mu^{(n+1)}$.

(5) If $\forall a \in A, |\mu^{(n+1)} - \mu^{(n)}| \leq \varepsilon$, where ε is the predestinated error, stop the programming; or order $n = n+1$ and go back to procedure (2).

4. Illustrative example

As an example of the proposed model, a simple road network is considered (Fig. 1). In the road network there are nine nodes, eighteen sections and two pairs of OD {(1,9),(2,9)}. The two origin-destinations have two respective volumes: $q_{1,9}$= 600pcu/h, $q_{2,9}$= 400 pcu/h. The parameters in BRP function are α=0.15, β=4. We assume that C_a satisfies uniform distribution: $[\theta_a \overline{C_a}, \overline{C_a}]$ ($0 \leq \theta_a < 1$). Simply, we make the parameters

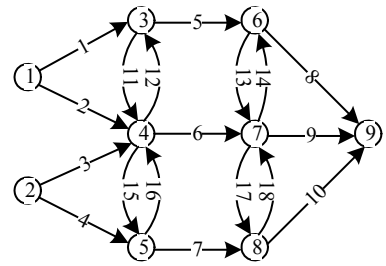

Fig.1 Road network for the illustrative example

of all the sections Θ_a=0.5, φ_a=1.2, ε=0.2. The information of capacities and free-flow travel time of the sections are presented in table 1.

Table 1 Design capacities and free-flow travel time of sections

No. of section	1	2	3	4	5	6	7	8	9
Free-flow travel time	15	15	15	15	10	10	10	15	15
Design capacity	1000	1000	1000	1000	1000	1000	1000	1000	1000
No. of section	10	11	12	13	14	15	16	17	18
Free-flow travel time	15	10	10	10	10	10	10	10	10
Design capacity	1000	1000	1000	1000	1000	1000	1000	1000	1000

On the same network condition we calculate it and find out the corresponding μ_{max} with setting up different $\lambda_{(i,j)r}$ and different γ_a (assume $\lambda_{(i,j)r}$ and γ_a of all the sections are same). The result is presented in table 2. The Fig. 2 illustrates it more clearly.

Table 2 Result

γ_a	μ_{max}	
	λ_1=0.9	λ_2=0.95
0.1	1.7	1.7
0.2	1.9	1.9
0.3	2.0	2.0
0.4	2.2	2.2
0.5	2.4	2.3
0.6	2.5	2.4
0.7	2.6	2.4

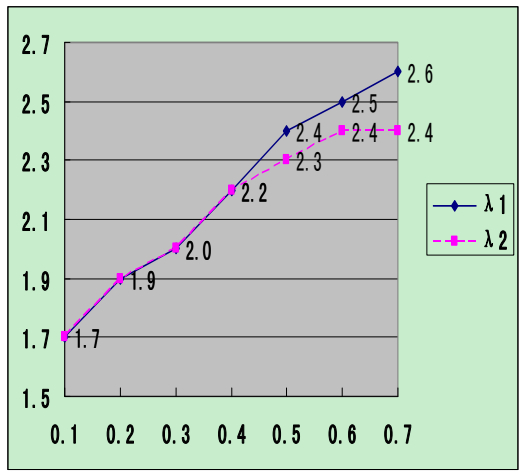

Fig. 2 The results comparison about λ_1 and λ_2

With Table 2 and Fig 2 it comes to the conclusion that the maximal multiplier of origin-destination matrix gets smaller along with $\lambda_{(i,j)r}$ getting bigger and γ_a getting smaller (i.e. the service level is improved), which means the capacity of the network decreases. The result illustrates that this model can efficiently give the information of the capacity of the road network on stochastic condition and a certain service level.

5. Conclusion

A bi-level programming model is set up to show the capacity of road network on different levels of service and stochastic conditions. This model introduces a method to solve the problem without a large amount of data which must be used in the Monte-Carlo method. The performance of the traffic flow in the model is deterministic user equilibrium, so it is used to long term capacity research. It also lays the foundation of further dynamic capacity research.

ABSTRACT

In order to update the basic transport database and obtain an in-depth understanding of the travel demands and patterns in Beijing, a series of transport and traffic surveys have been undertaken by the government. The household interview survey (HIS) is the most important undertaking with sample size over 80,000 households. Because of complexity and limitation in various stages of the surveys, errors and under-reporting are inevitable. Therefore, results of sample data and sample expansion can not reflect the real travel characteristics. This paper introduces the data expansion and validation process of Beijing household interview survey data. Errors and under-reporting were eliminated by a series of processes, such as sample expansion, matrix estimation, independent data checking and comprehensive validation.

Keywords: *Household interview survey, Sample Expansion, Matrix Estimation, Comprehensive Validation*

INTRODUCTION

In 2005 and 2006, a series of transport and traffic surveys were undertaken by Beijing municipal government and the Household Interview Survey (HIS) is the most important undertaking with sample size over 80,000 households. However, it was expected that the sample size on some of the minority modes, trip purposes, and person types would still be low, therefore supplementary surveys on some specific modes and trips purpose were carried out together with a complete screenline traffic count. The sample size of each survey is as followed:

- Household Interview Survey: 81760 households (sample rate is 1.5%)
- Taxi Survey: 6529 taxis (sample rate is 9.8%)
- Metro Survey: All station boarding and alighting counts, and 62,097 questionnaires
- Special Generator Interview Survey:8500 travellers in 7 sites

- Floating population travel survey (Including hotel guest): 10,517 samples in 7 sites and 36 hotels.
- Screenline Traffic Count: 400 links on 9 screenlines

Each of these surveys was independently carried out, and thus they provide an opportunity for cross checking results among the different surveys as well as providing a basis for data consolidation.

GENERAL APPROACH

The Base Year 2005/06 travel database building process has taken into consideration of the types of travel and traffic data available while maximizing the advantages of HIS and other supplementary survey data sources in the data consolidation process.

In general the overall database building process is basically divided into the following four stages:

- Stage 1 – Carry out sample expansion for the different surveys including HIS, Taxi, Metro, Special Generators, and Floating population;
- Stage 2 – Build O/D matrices by modes for time periods of some of the surveys for matrix estimation purpose;
- Stage 3 – Consolidate and finalise O/D matrices by modes from various data sources; and
- Stage 4 – Update the HIS and other appropriate database based on the final O/D matrices by modes and time period

This paper mainly describes the HIS sample expansion and O/D matrix estimation process.

SAMPLE EXPANSION

Household interview survey collected information on household and personal profiles and most importantly the trip characteristics of each household member on the sample day. Sample expansion of household interview survey data was primarily undertaken by the following three criteria:

- Car Available (CA) and Non-Car Available (NCA) Household to ensure the number of cars and the distribution of CA households are correctly expanded and hence their travel characteristics are adequately accounted for in particular mode choice; and
- Permanent residents and Temporary Residents to ensure the population is correctly expanded and their travel behaviors are adequately accounted for in trip rate and mode choice; and
- Age Distribution to ensure the population by age groups is correctly expanded and thus the different travel behaviors of different age profiles are properly accounted for, such as students, workers and retired persons.

A stepwise expansion approach was undertaken. In brief, the car available households were first expanded to the number of cars by zone. This was then followed by expanding non-car available households based on the residual

households after discounting the car available households. Then population of car available households and non-car available households were expanded with the same factor as their households. After that, the expanded permanent residents and temporary residents were validated to their total control number separately. These expansion factors were applied to the HIS database and then age adjustment factors for each groups were calculated by the controlled and expanded age distribution. The last step was to apply the expansion factors to the trips data.

After HIS sample expansion, household, person and trip profile information were obtained, such as number of households by vehicle availability types, household size, proportions of workers and students, trip rate, mode choice, and trip purpose. The data was cross-examined among districts and zones to ensure that they are within reasonable range. The key output is a series of O/D matrices by modes and time periods.

O/D MATRIX ESTIMATION

O/D matrix estimation is a cross checking process based on the sample expansion results. The most important data for O/D matrix estimation is the prior O/D matrices and screenline traffic counts. Prior O/D matrices were consolidated from sample expansion results of HIS and the other supplementary surveys. Screenline traffic counts were compiled for O/D matrix estimation as these represent a separate and independent source of data from the HIS data. The types of screenline data were basically vehicle flows by mode and period (BTRC, 2007).

As metro is a separate system, the sample metro trips were expanded and validated at the same time, based on its boarding and alighting at each station by lines.

Definitions of modes and time periods in O/D matrix estimation process are shown in Table 1.

Table 1. Modes and time periods in O/D matrix estimation

Mode	Car, Motorcycle, Bus, Taxi, Coach, Bicycle
Time period	0:00-7:00, 7:00-9:00, 9:00-17:00, 17:00-19:00, 19:00-24:00

In this paper, the main feature of O/D matrix estimation process is the hierarchical approach. O/D trips between large areas were validated first. Then O/D trips in local area were validated. The study area was split into 21 sectors by screenlines (Figure 1).

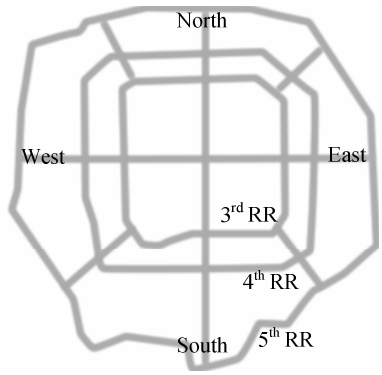

Figure 1. Screenlines and sectors

Different screenlines combinations were chosen to control the O/D movement between sectors. Four methods were considered and tested on different hierarchical approaches and path building methods (Table 2).

Table 2. Methods for O/D matrix estimation

Method	Screenline sequence for hierarchical estimation	Path Building
1	North/south→East/west→5th RR→4th RR→ 3rd RR→Radial	All or Nothing
2	(North/south+East/west)→ (5th RR +4th RR +3rd RR + Radial)	All or Nothing
3	(North/south+East/west+5th RR +4th RR +3rd RR + Radial)	All or Nothing
4	(North/south+East/west)→ (5th RR +4th RR +3rd RR + Radial)	Muti-path

Screenlines formed 20 sectors inside 5th ring road and 1 sector outside. O/D pairs between sectors were validated as they across the screenlines, while, intra-sector O/D movements were not validated during the matrix estimation process. Thus intra-sector O/D trips need to do additional validation. The intra-sector validation factor was calculated by the estimated and prior inter-sector trips. See Equation (1):

$$f_i^{Intra} = \frac{O_i^{est} + D_i^{est} - 2I_i^{est}}{O_i^{prior} + D_i^{prior} - 2I_i^{prior}} \quad i \in (1, 21) \tag{1}$$

Where:

f_i^{Intra} : intra-sector validation factor;

O_i^{est}, D_i^{est}, I_i^{est} : estimated trip ends and intra-sector trips of sector i;

O_i^{prior}, D_i^{prior}, I_i^{prior} : prior trip ends and intra-sector trips of sector i.

The O/D matrix estimation processes by modes by time periods were implemented using modeling software Cube ME. The input data includes prior O/D matrices, screenline traffic counts, highway network, and bus network. Each set of

data are given 'levels of confidence' or 'reliability' which conditions the influence of varying sources of data in the estimation. The estimation process is based on the Maximum Likelihood technique, coupled with an optimization procedure (CITILABS, 2004).

DATA CONSOLIDATION

After O/D matrix estimation, it is also necessary to use other independent sources of data for checking. Bus ridership, metro ridership, taxi ridership, car mileage, bus transfer per trip, and average trip distance were used for independent source of data checking. Differences were identified between the estimated results and the independent indicators. Then O/D matrix estimation approaches were chosen and improved.

The above O/D matrix estimation processes were done by trip modes and time periods. After completion of independent data checking, it is also necessary to check the integrated results of mode and time. The final overall daily person trips were consolidated from various data sources by summing across all mechanized modes (including bicycle) after O/D matrix estimation. The total person trip rates, modal split percentages, and trip length distribution were then referenced against historical patterns to ascertain whether they are consistent with socio-economic growth trends in terms of population and car fleet size as well as the expanding transport networks (BTRC, 2007).

The overall validation approaches were eventually selected in Table 3.

Table 3. Overall validation approaches

Mode	Approaches	
Car	O/D Estimation(Method 4) Independent data checking	Data Consolidation
Motorcycle	O/D Estimation(Method 4)	
Bus	O/D Estimation(Method 4) Independent data checking	
Metro	Sample expansion Independent data checking	
Taxi	O/D Estimation (Method 3) Independent data checking	
Coach	Sample expansion	
Bicycle	O/D Estimation(Method 3)	

DATABASE UPDATING

The final stage is to update the relevant database by time periods and modes based on the validated trip matrices. The purpose of this stage is to ascertain the resulting proportions of trips by trip purposes are in the right order, which has not been specifically dealt with in the expansion and validation process. If there appeared to be any unexpected results due to different levels of under-reporting by time

periods, some adjustments would be required based on previous results and references to other cities.

VALIDATION RESULTS

Comparing the validation results with sample data, we estimated that the overall under-reporting rate is 23%. According to other cities in China, the overall under-reporting rate is usually around 30% (GZTPRI, 2006; HKTD, 2003).

Key indicators before and after the validation process inside 6th ring road of Beijing were compared and shown in Table 4-5.

Table 4. Daily trips and trip rate

	Sample	Sample expansion	Validation Results
Trip Rate	2.16	2.16	2.64
Total trips (10000 trips)	30	2393	2920

Table 5. Daily mode share

Mode	Sample	Sample expansion	Validation Results
Car	28.2%	25.9%	29.8%
Taxi	2.4%	4.4%	7.6%
PT	27.7%	29.4%	29.8%
Coach	3.4%	3.1%	2.5%
Bicycle	38.3%	37.2%	30.3%
Total	100%	100%	100%

CONCLUSIONS

After a series of data fusion and validation process, such as sample expansion, O/D matrix estimation, independent data checking and integrated validation, under-reporting in HIS data had been eliminated. The consolidated data can reflect the current travel demands and patterns in Beijing; moreover the data played an important role in development of Beijing 2nd level transport model and supported some strategic transport planning or decision-making projects.

Abstract

Decision-making regarding logistics and supply chain need to be based on freight transportation modeling, but most of transportation models only consider passenger travel demand. An integrated land use transport model is introduced here which addresses both freight and passenger demand modeling. The framework is called PECAS, which stands for Production, Exchange, Commodity Allocation System. PECAS consists of the following three modules: Activity Allocation (AA), Space Development (SD) and Transport Supply (TS) and is linked to an aspatial regional economic model. The focus of this paper is to illustrate the capability of its AA module in modeling logistics and supply chains, for which the major economic sectors are considered and the flows of all commodities, including goods, service, space, land and labor, are simultaneously determined from production zones to exchange zones to consumption zones. This paper gives a brief introduction to the framework and presents detailed methodologies used in determining the locations of activities and exchanges between them.

INTRODUCTION

PECAS stands for Production, Exchange and Consumption Allocation System. It is a recently-developed, generalized approach for simulating spatial economic systems. It is designed to provide a simulation of the land use component of land use transport interactive modeling systems.

PECAS is a spatial economic simulation system with a focus on transportation and land development planning. The PECAS framework draws from previous modeling experiences, especially MEPLAN (Echenique *et al.* 1990) and TRANUS (De la Barra *et al.* 1984), and provides significant improvements in theoretical basis and behavior representation (Hunt and Abraham 2005).

The PECAS modeling framework consists of the following three modules: activity allocation (AA), space development (SD), and transport supply (TS), and it is linked with an aspatial economic model. The AA module represents how activities locate within the space provided by developers and how these activities interact with each other at a given point in time. The SD module simulates the actions of developers in the provision of space (land and floorspace) where activities can locate, including the new development, demolition and re-development that occurs from one point in time to the next. The TS module uses its networks to establish congested network times and costs and associated interchange (dis)utilities that PECAS uses in its consideration of the interactions between land use zones. The aspatial economic module forecasts future economy status, which provides the area-wide scale of activities considered in the model. PECAS uses an aggregate, equilibrium spatial I/O modeling approach for allocating activities into different zones, but has a micro-simulation based space development sub-model.

The focus of this paper is to introduce the capability of PECAS AA module in determining supply/exchange chain at a given year. The AA module uses an aggregate, equilibrium structure with separate flows of exchanges (including goods, services, labour and space) going from production to consumption based on variable technical coefficients and market clearing with exchange prices. Flows of exchanges from production to exchange zones and from exchange zones to consumption are allocated using nested logit models according to exchange prices and transport disutilities. These flows are converted to transport demands that are loaded to networks in order to determine congested travel disutilities. Exchange prices determined for space inform the calculation of changes in space thereby simulating developer actions. The system is run for each year being simulated, with the travel disutilities and changes in space for one year influencing the flows of exchanges in the next year.

PECAS STRUCTURE

The "land use" part of PECAS has two component modules. One is the space development (SD) module, which represents the actions of developers in the provision of space (land and floorspace) where activities can locate, including the new development, demolition and re-development that occurs from one point in time to the next. The other is the activity allocation (AA) module, which represents how activities locate within the space provided by developers and how these activities interact with each other at a given point in time.

Treatment of Space

The area covered by PECAS is organized into a set of land use zones. Activities locate in these zones and interact between each other. Ideally these zones are the same as the transport zones used in the transport model being run with PECAS, or at least are aggregations of whole numbers of adjacent transport zones. The connectivity among the land use zones is then based on the representation provided by the TS module, where the multimodal transportation model uses its networks to establish congested network times and costs and associated interchange (dis)utilities that PECAS uses in its consideration of the interactions between land

use zones.

Treatment of Time

PECAS works through time in a series of discrete, fixed steps from one point in time to the next, with the AA module running first at each point in time and then the SD module considering the period from each point in time to the next. The steps can be of any fixed duration, but 1 year time steps are recommended since they allow an appropriately quick response of land developers in the SD module to the prices established in the AA module.

Figure 1 illustrates the interactions among the modules and with other models (aspatial economic model and transport model) when the above two modules are run as part of an integrated land use transport modeling system. Each year, the model-wide aggregate economic model runs to forecast future scale of each economic sector (such as agriculture, retail, heavy industry, and services). Then the AA module runs to allocate these economic activities into land use zones and determine the exchange flows between them. The flows are then loaded on the transport network and the TS module is used to calculate the congested travel times and disutilities. The TS module is normally run for each year (after the AA module completes its run for that year) or, if travel conditions are relatively stable, the transport model can be run less often to save computation time. The changes of economy determine the size of economic sectors (or activities) considered in the model and subsequent space demand. Each year, the AA module passes the price of each type of space to the SD module and the SD module simulates developers' actions based on the price signals received. As it can be seen in Figure 1, between any two successive years, changes in model-wide economy, activity location, and transport supply and disutility will be passed to the next year to influence how the whole economy is evolving. Such a process will continue until the end of the planning window.

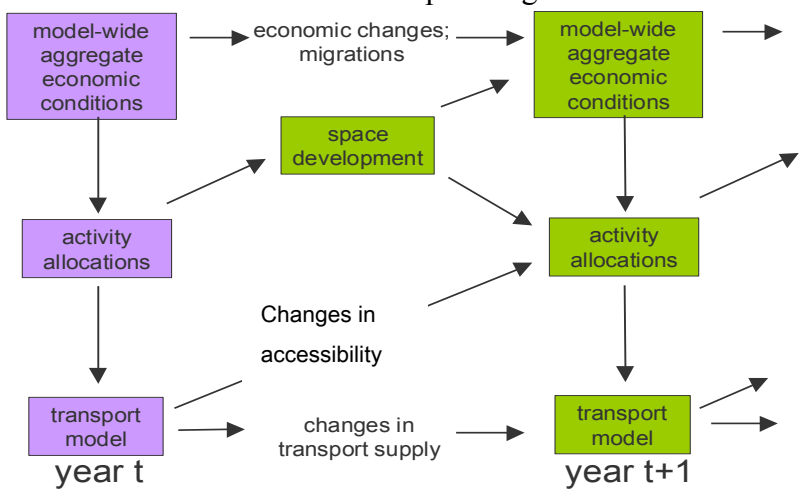

Figure 1 Interactions among modules simulating temporal dynamics

MODELING LOGISTICS AND SUPPLY CHAIN WITH ACTIVITY

on spatially-disaggregated forms of extended make and use input-output (I/O) tables, with variable technical coefficients and with households included – making the tables 'social accounting tables' rather than just input-output tables. Categories of activity

produce 'commodities' as indicated in the make table and consume these 'commodities' as indicated in the use table, where the 'commodities' include goods and services, labour and space (land and/or floorspace). The movement of these commodities from where they are produced (in zones) to where they are consumed (in zones) is the economic basis for travel and transport in the land use model. The travel conditions – distances, costs, times and associated (dis)utilities by mode – for the movement of these commodities determine how the transportation system influences the attractiveness of zones as locations for different activities.

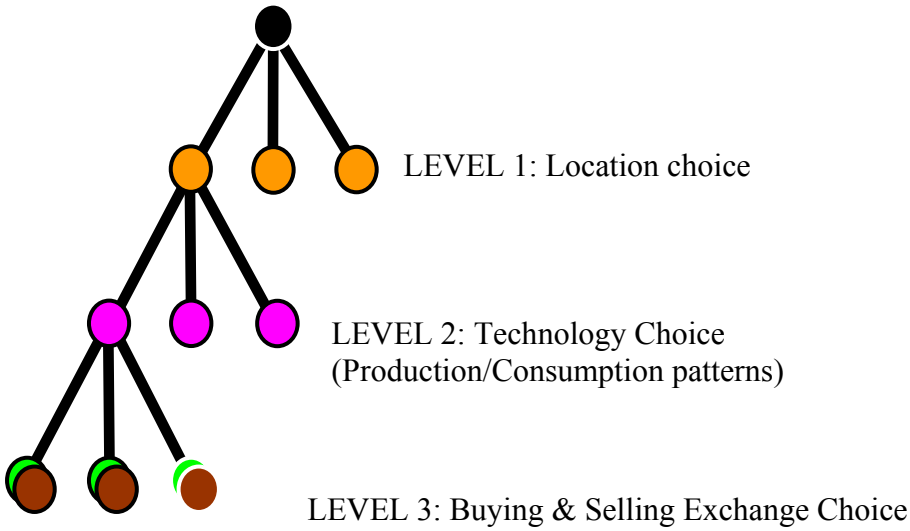

Figure 2 PECAS three-level logit choice model

The model-wide total quantity of production activity for each activity category is input to the AA module, which uses a three-level nested logit model to determine the exchange flows (or supply chains) of commodities considered, as shown in Figure 2. For each zone there are two 'lowest-level' logit allocation models (Level 3 in Figure 2) for each category of commodity considered in the model. The first is an allocation of the quantities purchased among various 'exchange locations' where they are sold to other activities. The second is an allocation of the quantities sold among the various exchange locations where they are bought by other activities. The utility of each alternative in these models is influenced by the price at the exchange location, and the characteristics of transporting the commodity to or from the exchange location. The composite utility values from these two 'lowest-level' logit models are called the 'buying utility' and the 'selling utility' for the commodity in the zone. They are used as the transportation-related inputs into the 'next-higher-level' logit allocation process for allocating the production and consumption of commodities by activities (Level 2 in Figure 2). It is the choice of which production technology to use, which in turn determines its commodity consumption pattern. The make and use technical coefficients indicating the rates at which activities produce and consume commodities are elastic, representing opportunities for substitution. From there, via the resulting utilities of production and consumption, they feed into the location utilities used at the 'highest-level' to allocate categories of industries and households to the land use zones (Level 1 in Figure 2).

The spatial allocation system with both buying and selling allocations gives

rise to exchanges from production to consumption locations in zones. The commodity flows or supply chains are being modeled as a process of moving goods or services from production to consumption zones through exchange zones. The exchange locations are location-specific markets for commodities, where sellers sell commodities to buyers. Prices are established at exchange locations so that the quantity bought equals the quantity sold – thus the spatial allocation procedure used in PECAS assumes a short-run market equilibrium in commodities.

The exchange zones simulate markets where the aggregate supply for each commodity (the sum of the selling allocations together with the quantity of imports, both of which are elastic with respect to exchange price), meets the aggregate demand for the commodity (the sum of the buying allocations together with the quantity of exports). The module solves for the equilibrium solution, adjusting the exchange prices in the exchange locations until all the markets clear, that is, where the total aggregate supply is equal to the total aggregate demand.

The AA module provides consistent activity allocations by activity category by zone, commodity flow quantities from production zone to consumption zone via exchange zone, imports and exports by exchange zone and exchange prices by commodity by exchange zone. It also provides the basis for assessing the changes in model-wide consumer surplus by production activity. In particular, the model-wide location composite utility for a given activity category is determined as follows:

$$CLU_a = (1/\lambda_a) \cdot \ln (\Sigma_{z \in Z} \exp (\lambda_a \cdot LU_{a,z})) \quad [1]$$

Where:

CLU_a = model-wide location composite utility for a unit of activity a.

λ_a = utility function dispersion parameter for allocation of activity a.

Changes in CLU_a for a given activity category can be used to calculate measures of the changes in consumer/producer surplus for different activity categories arising with the policy actions input to the model. These measures can help assess quality of life and business attractiveness for different household and industrial categories as represented.

CONCLUSIONS

This paper briefly introduces the PECAS framework with a focus on its AA module. The AA module is an aggregate I/O model, which allocates a forecasted future economy into zones based on a set of utility functions considering buying, selling, production/consumption, labor, space/land, and transport costs. This spatial I/O model (the AA module) produces, among other things, a landscape of prices by commodity, flow matrices by commodity and the locations of activities.

The theoretical base for the PECAS framework is described in detail in Hunt and Abraham (2005). Open software implementing the AA module has been developed in Java with many individuals and agencies' contributions.

PECAS or its components are being used in a number of practical modeling applications. A statewide model of Ohio is being developed using the full PECAS structure (PB Ohio *et al*, 1999). The Generation 2 modeling work in Oregon is using many of the elements of the PECAS activity allocation module as part of a larger system where various micro-simulation treatments are applied with the results of the activity allocation acting as inputs (Hunt, 2001). The full PECAS structure has been

used as the basis for a model specification for the Los Angeles Region, Baltimore, Montgomery and California State in the United States, City of Mumbai in India and the Province of Alberta, Canada (Zhong et al. 2007). A land use model for the Sacramento Region that is just starting to be developed is based in part on the PECAS activity allocation module (DKS et al. 2001). The intention is to use the full PECAS structure in the development of urban-level land use transport interaction models of both Edmonton and Calgary in Canada.

ABSTRACT

Mixed traffic of bicycles and motor vehicles is a major characteristic of urban transportation in China, and has led to traffic accidents, serious congestion and capacity reduction on urban signalized intersections. Determining bicycle capacity on signalized intersections is not only the basis for intersection design and planning, but also for signal configuration and operation management. Motor vehicles are a major influence on bicycles crossing through an intersection. Based on an analysis of the fluid diffusion characteristics at signalized intersections, the paper established a fluid diffusion model on bicycle capacity. Comparative analysis of large data sets shows that the model provides good results.

Keywords: Bicycle, Capacity, Signalized intersection, Fluid diffusion

INTRODUCTION

Current research on bicycle flow characteristics in the world focus on adaptive signal timing for bicycles (Ananth P et al., 2007), bicyclist and motorist gap acceptance behavior in mixed-traffic (Taylor and H. Mahmassani, 1998), traffic signal clearance interval requirements for bicycle-automobile mixed traffic (Taylor, 1993), capacity (HCM2000, 2000), bicycle traffic arrival characteristics (Qu et al., 2004) and bicycle traffic geometry and timing design (Forester J., 1994; Sun et al., 2004).

When crossing an intersection, bicycle flow does not depend solely on independent decisions make by individual riders, but has fluid diffusion characteristics. When the bicycle flow in traffic is sparse, the fluid fluctuation is not obvious. When the bicycle flow comes up to a certain level, riders generally make decisions concerning their own speed and direction according to the available space, and fluctuations become very obvious.

From the perspective of an overall macro-observation, bicycle flow travels at the crossing, just like fluid, as long as where there is no "resistance". It "flows" forward, matching the "space occupy theory", which is the bicycle's fluid diffusion characteristic.

The bicycle's behavior at a signalized intersection show that bicycle flow stops at the parking line, gathering and forming in a queue during the red light; and when the green light is activated, the bicycle flow gathers speed to pass the stop line, the bicycle density lessens along with the continuing green-light time,.

In actual observation, we can find that right-turn vehicles, pedestrians and the expansion of the bicycle all have a great impact on bicycle intersection capacity.

THE BICYCLE FLUID DIFFUSION MODEL

Generally, when a bicycle is crossing through a signal, there are three states: waiting during a red-light; dissemination at the intersection during a green light; and changing into free flow gradually after crossing the intersection.

Its fluid diffusion model is described as shown in Figure 1 (Xiong and Qiu, 2005).

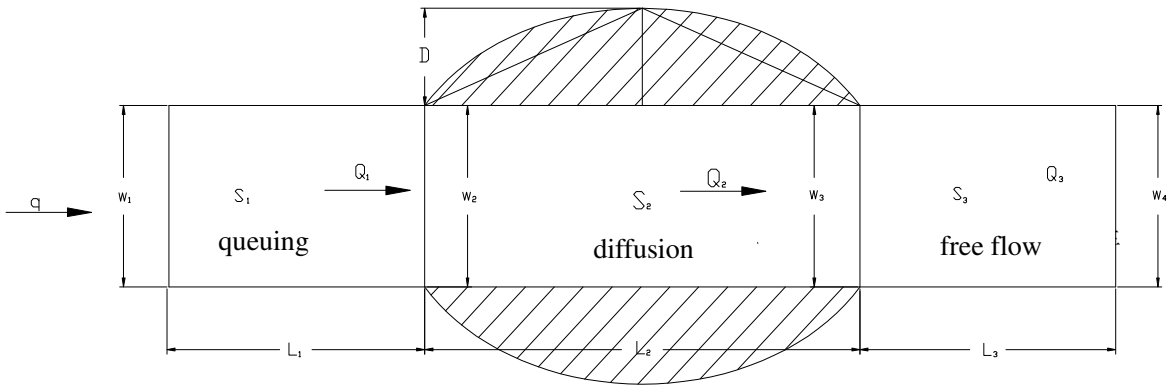

Fig.1 fluid diffusion model

Some definitions of concepts are given as follows: N is bicycle capacity in a signal cycle; q is bicycle average arrival rate of upper stream; G_e is signal green time; T is an average crossing time of bicycle; ρ_1 is queuing density; C is length of signal cycle; L_1 is length of the bicycle in a queue; L_2 is intersection width; L_3 is the length of the segment changing from bicycle diffusion flow to free flow; D is the maximum vector length of the bicycle's diffusion and distention at intersection; W_1 is the width of bicycle lane at the end of queuing length; W_2 is the width of bicycle lane at the parking line; W_3 is the width of the bicycle lane at the exit; W_4 is the borderline width of the bicycle lane while the bicycle flow changing from the aggregation flow to the freedom flow totally; S_1 is the area which is surrounded by the bicycles at the parking line; S_2 is the description of the bicycle running and diffusion at intersection. S_3 can contain aggregated compressing bicycle flow similar to S_1. After passing through S_3, the bicycles start to run in a state of free flow.

In a signal cycle, the single-lane flow rate N is as follow:

$$N = \int_T^{Ge} W_2 q dt + \int_T^{G_e} [\frac{(\rho_1 S_1 + W_1 qT)(W_3 + D)}{S_2} - W_2 q] e^{(-\frac{V(W_3+D)}{S_2} t)} dt \quad (1)$$

That is

$$N = W_2 q(G_e - T) + [\rho_1 S_1 + W_1 qT - \frac{W_2 qS_2}{V(W_3 + D)}][e^{\frac{V(W_3+D)}{S_2}G_e} - e^{\frac{V(W_3+D)}{S_2}T}] \quad (2)$$

Owing to

$$S_1 = W_1 * L_1 \quad (3)$$

$$S_2 = (W_2 + D) * L_2 \quad (4)$$

Taking into account the overwhelming majority intersection, W_1=W_2=W_3=W, the formula (2) can be simplified as:

$$N = q\{G_e - T + \rho_1(C - G_e)[e^{-1} - e^{-\frac{G_e}{T}}]\} \quad (5)$$

In a signal cycle, bicycle flow rate N raises along with the effective green time Ge. The less the T is, namely the speed passing through the intersection is greater, the greater the flow rate N is. This matches the real situation.

TRAFFIC SURVEY

This paper selects 4 signalized intersections in Harbin city to conduct the field survey. The intersections are as follows: intersection of XianFeng Road-XuanHuan Street (Intersection 1); intersection of HePing Road-XuanHuan Street (Intersection 2); intersection of HePing Road-ZhongShan Road (Intersection 3); intersection of HongQi Street -HuaiHe Road (Intersection 4). Survey results are shown in table 1 and figure 2.

Table 1 Signal timing at signalized intersection /s

Intersection1	Straight east-west	Left east-west	Straight north-South	Left north-South
	55	30	45	60
Intersection2	Straight + Left west	Straight + Left east	Straight north-South	Left north-South
	35	35	75	40
Intersection3	Straight east-west	Left east-west	Straight north-South	Left north-South
	45	30	45	20
Intersection4	Straight+ Left east-west		Left north-South	Straight north-South
	30		20	40

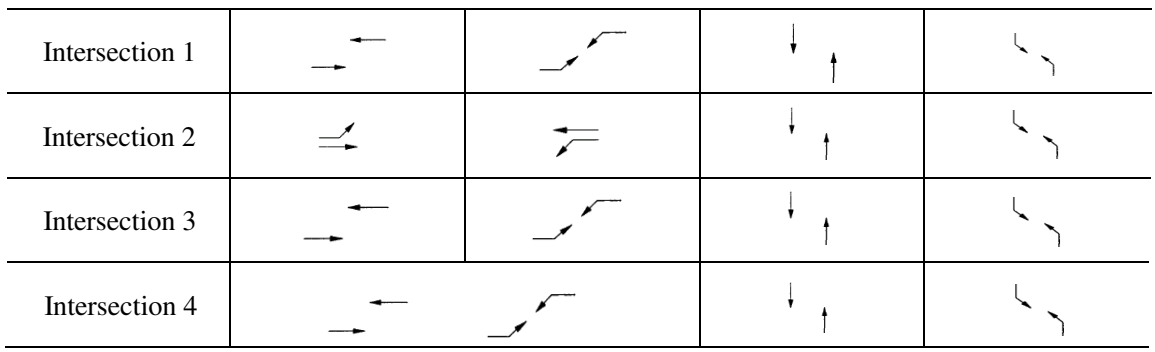

Figure 2 Phase distribution at signalized intersection

BICYCLE CAPACITY ANALYSIS AT SIGNALIZED INTERSECTION

Due to the function (5), bicycle capacity at Signalized intersection is as:

$$Cap = 3600 \cdot q\{\frac{G_e - T}{C} + \rho_1(1 - \frac{G_e}{C})[e^{-1} - e^{-\frac{G_e}{T}}]\} \quad (6)$$

The minimum safety headway time is 1.8s according to the experiments, so the maximum average arrival rate is 0.56 veh/s; generally, the density of bicycle in line in actual observation can reach 0.60veh/m^2, which is in basic accord with the investigation in document. In the four intersections investigated, the average running rate is 13.57km/h.

The width of signalized intersections is generally from 35m to 70m. The signal cycle gets its value in a certain range, getting the capacity as shown in table 2.

Table 2 A Part of Statistical Results of Evaluated Bicycle Capacity **veh· h^{-1}**

Signal time /s / Width (m)	*C*=120 *Ge*=40	*C*=130 *Ge*=50	*C*=140 *Ge*=45	*C*=140 *Ge*=50	*C*=150 *Ge*=50
35	207	333	197	278	231
40	193	314	183	262	216
45	181	297	172	247	204
50	170	282	162	234	193
55	160	268	154	222	183
60	150	255	146	211	174
65	140	242	138	201	166
70	130	229	131	191	158

Figure 3 shows that the relationship between the signalized intersection width and capacity. From the diagram, we find that there is a significantly linear relationship between the bicycle crossing width and capacity; while the crossing width increases, capacity decreases linearly.

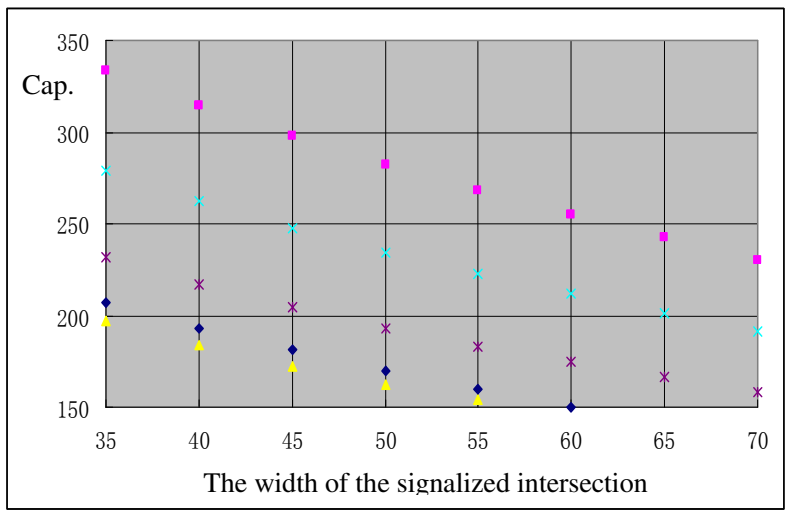

Figure3 Relationship between the width of a signalized intersection and capacity

BICYCLE FLUID DIFFUSION EFFECTS

A. Right turning and straight going vehicles in the same direction

The phenomenon of bicycle fluid diffusion in a signal control intersection has a great impact on straight and right turning vehicles, particularly right turning vehicles. Similarly, straight and right turning vehicles also produce a greater impact on the normal flow of bicycle traffic. This mutual influence constraints the performance of each, causing slow down for both bicycles and vehicles through the intersection.

B. Left turning vehicles in the opposite direction

For two-phase signal control intersections, when a green light starts, there is conflict between bicycle flow and left turning vehicles during the bicycle flow diffusion time. In this case, bicycles have a larger impact on the capacity of left turning vehicles.

BICYCLE FLUID DIFFUSION CORRECTION MODEL AND THE ACTUAL CAPACITY CALCULATION

Taking into account the actual operational modes according to analysis of 4.1 and 4.2, the maximum throughput *Cap'*/veh•h•lane can be calculated by reduced coefficient method:

$$Cap' = 3600 \cdot q \cdot f_{Rpb} \cdot f_{Lpb} \left\{ \frac{G_e - T}{C} + \rho_1 (1 - \frac{G_e}{C})[e^{-1} - e^{-\frac{G_e}{T}}] \right\} \tag{7}$$

$$f_{Rpb} = 1.0 - (1 - A_{Pbt})(1 - P_{RTA}) \tag{8}$$

$$f_{Lpb} = 1.0 - (1 - A_{Pbt})(1 - P_{LTA}) \tag{9}$$

Where f_{Rpb} is the impact factor of right turning vehicles in the same direction on the bicycle capacity; f_{Lpb} is the impact factor of left turning vehicles in the opposite direction of the bike capacity; $\mathrm{P_{RTA}}$ is adjustment factor of right turning phase for the protection, $0 < P_{\mathrm{RTA}} < 1$; P_{LTA} is adjustment factor of left turning phase for the protection, $0 < P_{\mathrm{LTA}} < 1$; A_{pbt} is adjustment factor of right and left turning vehicles when a bicycle is permitted to pass, $0 < A_{\mathrm{pbt}} < 1$.

Table 3 Different signal timing considering effects of vehicles **veh· h^{-1}**

Signal timing /s / Width (m)	*C*=120 *G*$_e$=40	*C*=130 *G*$_e$=50	*C*=140 *G*$_e$=45	*C*=140 *G*$_e$=50	*C*=150 *G*$_e$=50
35	307	328	315	325	323
40	293	319	305	316	314
45	277	308	292	306	304
50	260	296	279	294	293
55	243	283	264	282	281
60	224	269	248	268	267
65	206	254	232	254	253
70	188	328	315	325	323

Finally calculation results are based on a modified model that is the actual bicycle capacity in a signal control intersection, as shown in table 3. According to the value amended for some parameters for bicycles in the United States Capacity Manual, and combined with the actual situation in our country, the relevant parameter values are as follows: f_{Rpb}=0.87, f_{Lpb}=0.76.

CONCLUSIONS

Based on the fluid diffusion characteristics of bicycle and related theories, this paper establishes the fluid diffusion model of bicycle capacity at signalized intersections, demarcates the parameters, and analyzes the relationship between bicycle capacity with the signal cycle, green lights, and the bicycle arrival rate and so on. These factors impact development of theory and instruction for improving the signal timing and intersection channelization.

Mixed transportation is the main characteristic of most cities in China. How to determine the capacity of bicycles at intersection, to understand of the capacity characteristics of bicycles, the cooperative control of vehicles,, and to achieve the balance of development of non-motor vehicles and motor vehicles, is forever evolving. The actual survey indicates that effective time is wasted in waiting for right turn vehicles. It is meaningful for researchers to analyze the influence of the gap of turn right motor vehicles on the behavior of bicycle flow in depth, and how to coordinate control of motor vehicles to increase bicycle capacity at intersections.

ABSTRACT

Urban expressway plays an important role in the movement of goods, people, and services, and is essential for urban development and economic growth. Thus it is critical to plan it right in the first place, and to simulate the functions and evaluate the effectiveness of its planning scheme before implementation. We have developed an integrated macro and micro simulation method to evaluate the effectiveness of the planned expressway system. This paper summarizes the main contents of analysis and evaluation method in a case study. We found that the integrated macro and micro simulation method is very efficient and effective in analyzing and assessing the effectiveness of the planned expressway framework, and identifying the deficiency of the plan, which is unachievable by either macro and micro simulation alone. The method could be useful for other expressway planning, analysis and simulation.

1. INTRODUCTION

Urban expressway is the backbone of the urban transportation system, plays an important role in reducing traffic congestion, equilibrating road network traffic flow, separating fast traffic from slow traffic, and long-distance trips from short-distance ones *(Yang, et al., 2004)*. However, the investment for expressways is often large, which thus raises a higher demand for expressway planning. Any carelessness or deficiency of expressway schemes may lead to the congestion of local traffic in expressway systems, and even large-scale congestion in a transportation system. Thus it is critical to plan it right in the first place, simulate and evaluate the effectiveness of its planning scheme before implementation, which helps to identify the deficiency of the expressway plan and realize the planning objectives of expressway systems.

2. MAIN CONTENTS OF SIMULATION ANALYSIS AND EVALUATION

2.1 Overall layout of expressway systems

Based on the function requirements of urban expressway, analyze and assess:

1) Internal: Is the expressway trend consistent with the desire line of middle-long distance vehicle trips of internal city? Whether the expressway trend is compatible with urban spatial structure?

2) External: Does the layout of expressway systems help to evacuate external transportation and shield transit traffic quickly? Does the layout facilitate the smooth transition between internal and external transportation *(Miao, 1997)*?

2.2 Location of interchanges

The main content of analysis and evaluation regarding interchanges include their function orientation, configuration type selection, ramp combination and correlative noninterference setting. In addition, the effectiveness of the planned interchanges also needs to be simulated and evaluated to check whether they are beneficial to more orderly traffic *(Liu, 2000)*.

2.3 Setting of ramps

The analysis emphasis regarding ramp setting is the rational of their quantities and spaces, which is based on the fact that too many ramps and too small spaces will lead to traffic flows diverging, merging and weaving frequently, while too few ramps cannot provide enough flow for expressway mainlines *(Gao, 2006)*. In addition, the distances between on/off ramps and adjacent ground intersections as well as vehicle queues on ramps also need to be analyzed and assessed.

2.4 Traffic analysis of adjacent road networks

Does the capacity of on/off ramps match that of adjacent ground intersections? Is the structure of adjacent road networks reasonable? Are road functions of different types specific enough and meet the criteria? Are there frequent collisions between vehicles, non-motorized vehicles, and pedestrians, etc?

3. SIMULATION ANANLYSIS AND EVALUATION METHODS

Considering the complexity of analysis and evaluation of expressway planning schemes, this paper develops an integrated macro and micro simulation method. Two widely used traffic software TransCAD and VISSIM are applied. Figure1 shows the processes of the method.

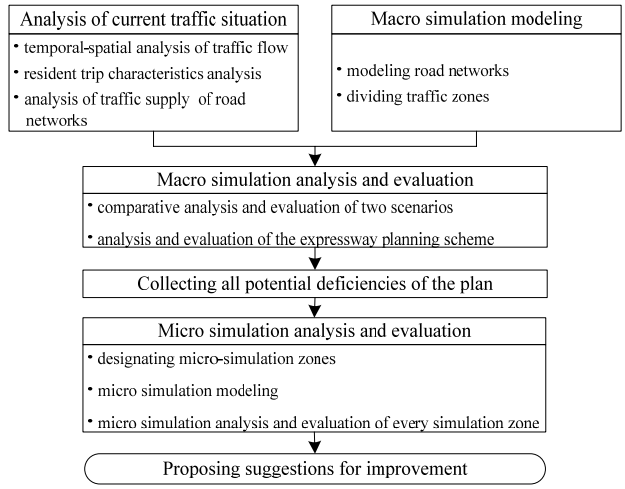

Figure1. Flow chart of analysis and evaluation of expressway planning schemes

3.1 Analysis of current traffic situation

Based on abundant basic data and urban comprehensive plans, conduct detailed analysis of current traffic situation through analyzing the temporal and spatial characteristics of traffic flow, trip characteristics, and the capacity and layout of the current road network in the study area.

3.2 Macro simulation modeling

The following two steps need to be taken to model road networks from a macroscopic perspective:

1) Modeling road networks: first specify required modeling parameters for every type of road (freeways, expressways, main trunk roads, secondary trunk roads and branches), then use TransCAD to establish macro-simulation models of road networks.

2) Dividing traffic zones: employ the common traffic zone division method to divide traffic zones or use the zones divided during transportation survey.

3.3 Macro simulation analysis and evaluation

In this stage we use TransCAD to analyze and assess the effectiveness of the planned expressway framework at the macroscopic level.

1) Comparative analysis and evaluation of two scenarios (without expressway system and with the planned expressway system): First, load the estimated OD distribution volumes of vehicles to the current road network and the network with the planned expressway framework respectively in TransCAD and carry out traffic assignment. Next assess the integral effectiveness of the expressway system through calculating and comparing a series of evaluation indicators including total travel time (veh·h), vehicle miles traveled (veh·km), the average speed of road networks (km/h), and so on.

2) Analysis and evaluation of the expressway planning scheme: Based on the macro-simulation results of the road network with the planned expressway

framework, make detailed analysis and evaluation of the planning scheme from different aspects as mentioned in the second part. Then collect all potential deficiencies of the expressway plan and determine all plots with these deficiencies to make a good preparation for the following in-depth micro simulation.

3.4 Micro simulation analysis and evaluation

Take the following three steps to simulate and evaluate whether the potential problems identified above will occur and how serious they would be in VISSIM.

1) Designating micro-simulation zones: Taking the plots with potential problems as the center, expand outward a certain distance (depending on the purpose of simulation) to designate micro-simulation zones.

2) Micro simulation modeling: For every simulation zone, build the micro simulation network and set up traffic flow characteristic parameters and traffic rules, where both traffic flow and route choice come from the macro-simulation results.

3) Micro simulation analysis and evaluation: Test and run every micro simulation model to assess whether the potential problems will happen and how serious they will be from qualitative and quantitative perspectives respectively.

3.5 Proposing suggestions for improvement

Combining the local conditions, put forward corresponding suggestions for improvement based on potential problems and their seriousness identified through integrating macro and micro simulation analysis and evaluation.

4. CASE STUDIES

We take the expressway planning scheme of Zhengzhou (Longhai Road and Shakou Road-Jingguang Road) as a case, to illustrate how to analyze and assess the effectiveness of expressway planning schemes in practice. The planning scheme is shown in Figure 2.

4.1 Preparing for simulation analysis and evaluation

1) Analysis of current traffic situation in downtown Zhengzhou

According to the transportation survey of Zhengzhou in 2007, the spatial distribution of traffic is quite unbalanced. It is mostly concentrated in the core region. The average trip rate of residents is 2.68 times/day; bicycle, electric bicycle and walking are still the main modes of residential travel; the vehicle trip accounts for 21.4% in total *(China Academy of Urban Planning & Design, 2007)*.

2) Macro simulation modeling of road networks

Taking the road network containing Shakou Road-Jingguang Road, Longhai Road and adjacent roads within 1~2 km along the planned expressway as the study area, we built macro-simulation network models with TransCAD. The central city of Zhengzhou is divided into 33 traffic zones (as shown in Figure 3).

3) Traffic demand forecasting in the planning year

By 2010, the average trip rate of residents will be 2.70 times/day; the total resident trip volume per day will approximately be 1134 times; the peak hour flow of vehicles will be 100 thousand pcu/h. The spatial distribution of vehicle trips in the

planning year is estimated and shown in Figure 3.

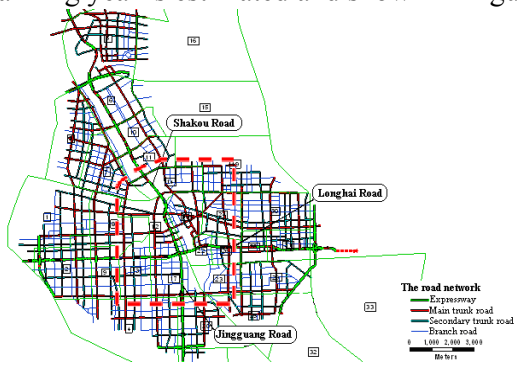

Figure 2. The expressway planning scheme of Zhengzhou

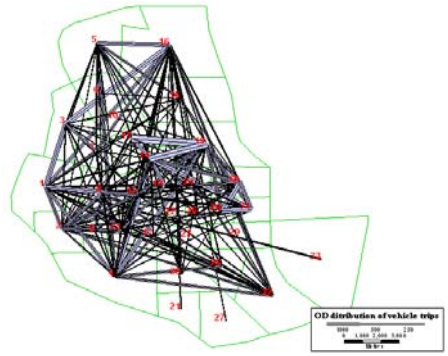

Figure 3. The OD distribution of vehicle trips in Zhengzhou in 2010

4.2 Macro simulation analysis and evaluation of the expressway system

Carry out macro simulation of two scenarios (without expressway system and with the planned expressway system) respectively in TransCAD and analyze the road network saturation in the core region (as shown in Figure 4 and Figure 5).

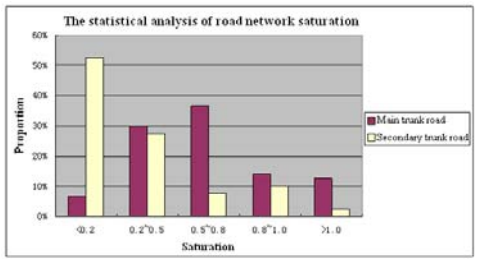

Figure 4. Analysis of saturation in the core region without expressway system

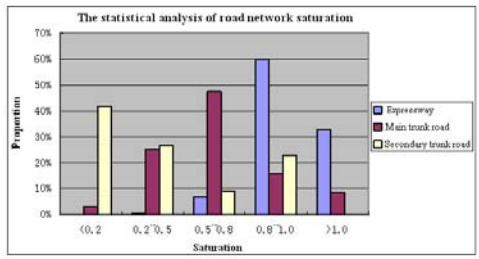

Figure 5. Analysis of saturation in the core region with the planned expressway

From Figure 4 and 5, we can see that a large amount of traffic transfers from adjacent ground roads to the planned expressway system, which results in a lot of traffic pressure to the expressway system, however, it decreases the traffic pressure of ground roads. At the core region, the saturation above 90% for expressway sections is higher than 0.8. The proportion of oversaturated sections of main and secondary trunk roads decreases from 13% and 3% to 8% and 0 respectively.

Furthermore, the comparison of the total travel time of two scenarios (Table 1) shows that the efficiency of the road network improves significantly. At the core region, the increase of vehicle miles traveled and the reduction of the total travel time implies that the vehicle speed improves in spite of increased traffic volume. This is also suggested by the average speed of the core region.

Table 1. The comparison of two scenarios

Scenarios \ Indicators	Total travel time of the road network (veh•h)	Total travel time in the core region (veh•h)	Vehicle miles traveled in the core region (veh•km)	Average speed in the core region (km/h)
Without expressway system	23584	4935	182488	29.3
With the planned expressway system	20709	4577	213685	41.5

4.3 Micro simulation analysis and evaluation of critical sites

Based on the plots with potential problems identified in the macro simulation, the study area is designated into 14 micro-simulation zones. We then applied VISSIM to carry out micro-simulation analysis and evaluation one by one. It is found that there are some potential deficiencies in the planning scheme. Take the 14th simulation zone as an example. The simulation results indicate that there are two potential problems in this area: (1) traffic on the off-ramp located in the western of Longhai Road-Weilai Road interweaves seriously with the ground traffic, which leads to long queues of off-ramp traffic with danger of extending to the expressway mainline (Figure 6). (2) On Longhai Road, the capacity of the ground road between Front Street and Dongming Road cannot satisfy the actual traffic demand, which causes heavy congestion on the ground road network (Figure 7).

Figure 6. The congestion of the off-ramp between Longhai Road-Weilai Road

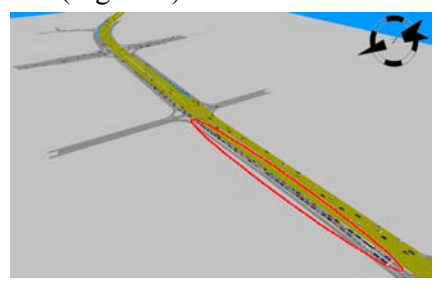

Figure 7. The congestion of the ground road between Front Street~Dongming Road

4.4 Corresponding suggestions for improvement of the planning scheme

Based on the simulation results, we can make specific suggestions for improvement. For the 14th simulation zone we suggest the following improvements: (1) According to the traffic turning characteristics of the off-ramp as well as the ground roads, adjust the intersection channeling scheme of the western approaches to meet the demand of traffic turning: increasing a left-turn lane and decreasing a straight lane. (2) Widen the ground road between Front Street and Dongming Road to add another lane to improve the capacity of the ground road.

5. CONCLUSIONS

The construction of urban expressways involves huge investments and has a profound influence on urban development and economic growth. Once implemented, it is very difficult to modify. Thus it is very crucial and necessary to evaluate the

effectiveness of its planning scheme before implementation. This paper summarized the main contents of simulation analysis and evaluation of expressway planning scheme and developed an integrated macro and micro simulation method, which was applied in an actual project of Zhengzhou. It was found that the integrated method is very efficient and effective in analyzing and assessing the effectiveness of the planned expressway framework, and identifying the deficiencies of the expressway plan, which is difficult to achieve only by macro or micro simulation. This method can shed a light on other similar expressway planning, analysis and evaluation.

ABSTRACT

The assessment of the amount of traffic impact on land development projects is the basis of traffic impact analysis for decision making. This also provides theoretic support for the collection of traffic impact fees. Because the traffic impact analysis involves many factors that are difficult to quantify, we propose a traffic impact evaluation model for land development projects based on the matter-element analysis theory. Seven evaluation criteria are chosen to reflect the impact on the road segments, intersections, parking facilities, public transportation, traffic safety, pedestrian traffic, as well as the atmospheric environment. We further conduct a quantitative evaluation of air pollution using simulation software-VISSIM. A case study was carried out in Shanghai using the matter-element model proposed in the paper, and the impact of land development projects on the surrounding traffic network were quantified. We found that the matter-element evaluation model for traffic impact analysis could provide more objective and reasonable results.

1 INTRODUCTION

Traffic Impact Analysis (TIA) is a means of evaluating the influence on the surrounding road network for urban large-scale land development projects. The evaluation of traffic impacts, which is an important composition in traffic impact analysis, has recently become a core research problem. Currently, some mature evaluation methods, such as the analytic hierarchy process (AHP), the fuzzy comprehensive evaluation and the gray system evaluation have been widely used in the traffic impact analysis for different land development projects. However, there are great differences on methods chosen among different cities due to local traffic conditions and the research depth in traffic impact analysis. Most of the methods can only qualitatively determine the traffic impacts on traffic network, which cannot reflect the grade of traffic impacts definitely. Moreover, the selection of evaluation criteria often neglects the impacts on atmospheric environment. Both of them result in subjective bias during the evaluation process.

Matter-element analysis theory, established by a Chinese scholar-Prof. Caiwen, is a new interdisciplinary subject between mathematics and experimental science *(Cai, 1994)*. With the combination of qualitative and quantitative factors, the matter-element analysis method can quantify traffic impacts through the correlation degree analysis. The correlation degree analysis extends the evaluation value range from the conventional [0, 1] to the real axis $(-\infty, +\infty)$, which can highly increase the evaluation accuracy and influence the factors integrity.

Therefore, this paper introduces the matter-element analysis method into the evaluation of traffic impacts. Combined with a reasonable selection of evaluating criteria, we establish a traffic impact evaluation model based on matter-element analysis and quantitatively get the grade of traffic impacts for land development projects. The details are discussed in the following sections.

2 SELECTION OF EVALUATION CRITERIA

2.1 Road segments analysis

Considering the complex characteristics of urban traffic environments, we take the average load of main road segments in the study area I_1 *(Xiong, 2004)* as the evaluating criterion and its mathematical formula is as below:

$$I_1 = \sum_{i=1}^{n}\left(\left(\frac{Q_{sbi}}{C_i}\Big/\sum_{i=1}^{n}\frac{Q_{sbi}}{C_i}\right)\cdot I_{si}\right) \tag{1}$$

Where I_{si} is the impact factor of land development projects on road segments i, $I_{si} = \Delta Q_i / C_i$, ΔQ_i is the peak hour increased traffic volumes of road segments i in the planning year (pcu/h); C_i is the traffic capacity of road segments i (pcu/h); Q_{sbi} is background peak hour traffic volumes of road segments i in the planning year (pcu/h); n is the number of main road segments in the study area.

2.2 Road intersections analysis

For the road intersections, we take average traffic load of main intersections I_2 *(Li and Xu, 2008)* as the evaluating criterion and its mathematical formula is as follows:

$$I_2 = \sum_{i=1}^{n}\left(\left(\frac{1}{k_i}\sum_{j=1}^{k_i}\frac{Q_{cbij}}{C_{ij}}\Big/\sum_{i=1}^{n}\left(\frac{1}{k_i}\sum_{j=1}^{k_i}\frac{Q_{cbij}}{C_{ij}}\right)\right)\cdot I_{ci}\right) \tag{2}$$

Where I_{ci} is the impact factor of road intersections i, $I_{ci} = \sum_{j=1}^{k_i}\left(\left(Q_{cbij}/C_{ij}\Big/\sum_{j=1}^{k_i}Q_{cbij}/C_{ij}\right)\cdot I_{cij}\right)$, I_{cij} is the impact factor of the j^{th} entrance lane in i^{th} road intersection, $I_{cij} = \left(C_{ij} - Q_{cij}\right)/C_{ij}$, Q_{cij} is the peak hour traffic volumes of j^{th} entrance lane in i^{th} road intersections in the planning year, (pcu/h); Q_{cbij} is the background peak hour traffic volumes of j^{th} entrance lane in i^{th} road intersections in the planning year, (pcu/h); C_{ij} is the traffic capacity of j^{th} entrance lane in i^{th} road intersection, (pcu/h); k_i is the number of entrance lane in road intersection i; n is the number of road intersections.

2.3 Parking facilities analysis

In terms of parking facilities impact analysis, we select the parking facility load in the rush hour I_3 *(Xiong, 2004)* as the evaluating criterion and its mathematical formula is: $I_3 = D_3 / C_3$ (3)

Where D_3 is the peak hour parking demand in the planning year, (pcu/h); C_3 is the parking space numbers of land development projects.

2.4 Public transport facilities analysis

For the public transport facilities impact analysis, we take public transport load in the rush hour I_4 *(Xiong, 2004)* as the evaluating criterion and the formula is illustrated as follows: $I_4 = D_4 / C_4$ (4)

Where D_4 is the peak hour increased public transport demand in the planning year, (pcu/h); C_4 is the average passenger capacity hourly in one bus line.

2.5 Traffic safety analysis

For the sake of describing the influence quantitatively, we take the connection form between road and passageway of land development projects I_5 *(Shang, 2006)* as the evaluating criterion. The concrete quantification standards are as follows: (1) if the passageway is connected with branches, its value is 1; (2) if the passageway is connected with urban secondary main road directly, its value is 2; (3) if the passageway is connected with urban main road directly, its value is 3; (4) if the passageway is connected with urban expressway, its value is 4.

2.6 Pedestrian traffic analysis

In order to quantify the impacts on the pedestrian traffic, we select traffic load of pedestrian crossing I_6 *(Huo, 2007)* as the evaluating criterion and its formula is as follows: $I_6 = D_6 / C_6$ (5)

Where D_6 is the peak hour pedestrian crossing demand in the planning year, (pcu/h); C_6 is the service capability provided by pedestrian traffic facilities in the planning year, (pcu/h).

2.7 Atmospheric environment analysis

Attempting to quantify the influence on the atmospheric environment, we take the average air pollution degree I_7 as the evaluating criterion. Referring to the research achievements of Zhang Yi in Hunan University *(Zhang, 2006)* on the environment impact assessment of urban traffic network, we obtain the criterion value using the microscopic simulation software-VISSIM. We chose the emissions of CO, HC and NO_x in each of the road segments as the research objects, and then the sub-criterion $I_{7i}\,(i = 1, 2, 3)$ of basic criterion I_7 which reflects the total emissions of these three kinds of air pollutants is expressed as:

$$I_{7i} = 86400T \cdot Q_i \cdot \sum_{i=1}^{m} (L_i \cdot n_i) \quad (6)$$

Where I_{7i} is the total emissions for air pollutants i produced by all vehicle categories (mg); Q_i is the emissions factor for air pollutants i in urban traffic

network(mg/m/s), which is obtained by VISSIM simulation; L_i is the single lane length of road segments i; n_i is the total number of lane in road segments i; m is the number of road segments in traffic network; T is the length of control cycle. Through the respective computation of I_{7i} before or after the projects implementation in the planning year, we finally obtain the value of criterion $I_7 = \left(\frac{1}{3}\sum_{i=1}^{3} I_{7iafter} - \frac{1}{3}\sum_{i=1}^{3} I_{7ibefore} \right) \Big/ \frac{1}{3}\sum_{i=1}^{3} I_{7iafter}$.

3 ESTABLISHMENT OF MATTER-ELEMENT ANALYSIS MODEL

3.1 Determination of matter to evaluate

We take the urban road network system which is influenced by land development projects as matter N; $C_1, C_2, ..., C_n$ denotes the characteristics of traffic impacts and the corresponding value range is expressed as $X_1, X_2, ..., X_n$; then the matter to evaluate R can be represented as follows *(Cai, 1994)*:

$$R = \begin{bmatrix} N & C_1 & X_1 \\ & C_2 & X_2 \\ & \vdots & \vdots \\ & C_n & X_n \end{bmatrix} \tag{7}$$

3.2 Determination of classic field matter-element matrix

The classic field matter-element matrix R_j can be expressed as follows *(Wang, et al., 2007, Cai, 1994)*:

$$R_j = \left[N_j, C_i, X_{ji} \right] = \begin{bmatrix} N_j & C_1 & X_{j1} \\ & C_2 & X_{j2} \\ & \vdots & \vdots \\ & C_n & X_{jn} \end{bmatrix} = \begin{bmatrix} N_j & C_1 & \left[a_{j1}, b_{j1} \right] \\ & C_2 & \left[a_{j2}, b_{j2} \right] \\ & \vdots & \vdots \\ & C_n & \left[a_{jn}, b_{jn} \right] \end{bmatrix} \tag{8}$$

Where N_j denotes the j^{th} grade of the matter to evaluate. We call the value range $X_{ji} = \left[a_{ji}, b_{ji} \right]$ of characteristic C_i in grade j as the classic field.

3.3 Determination of controlled field matter-element matrix

The controlled field matter-element matrix R_p can be expressed as follows *(Cai, 1994)*:

$$R_p = \left[P, C_i, X_p \right] = \begin{bmatrix} P & C_1 & X_{p1} \\ & C_2 & X_{p2} \\ & \vdots & \vdots \\ & C_n & X_{pn} \end{bmatrix} = \begin{bmatrix} P & C_1 & \left[a_{p1}, b_{p1} \right] \\ & C_2 & \left[a_{p2}, b_{p2} \right] \\ & \vdots & \vdots \\ & C_n & \left[a_{pn}, b_{pn} \right] \end{bmatrix} \tag{9}$$

Where $P = \left[N_1, N_2, ..., N_n \right]$ denotes the whole of matter grade; X_{pi} denotes the value range of N to characteristic C_i, namely controlled field. The upper and lower limits of value range $\left[a_{pi}, b_{pi} \right]$ for characteristic C_i are the maximum and the minimum value of corresponding criteria.

3.4 Calculate the weight of each criterion

We determine the weight $\omega_i \left(i = 1, 2, ..., n\right)$ of characteristic C_i, where $\sum_{i=1}^{n} \omega_i = 1$; and determine the weight $\omega_{ik} \left(k = 1, 2, ..., n_i\right)$ of the sub-criteria C_{ik} on the base of basic criteria C_i, where $\sum_{k=1}^{n_i} \omega_{ik} = 1$. The weight ω_i and the sub-criteria weight ω_{ik} can be obtained through the Analytic Hierarchy Process (AHP) *(Lv, et al., 2003)*.

3.5 Compute correlation function

Correlation function measures how the value of matter-element at any point of the real axis is correlated to its value at some other point. Let d be the mold of $\left[a_{ji}, b_{ji}\right]$: $d = \left|X_{ji}\right| = \left|b_{ji} - a_{ji}\right|$; then the distance from point to interval is: $\rho\left(x_i, X_{ji}\right) = \left|x_i - \left(a_{ji} + b_{ji}\right)/2\right| - \left(b_{ji} - a_{ji}\right)/2$; and the correlation function can be defined as *(Cai, 1994)*:

$$K_j\left(x_i\right) = \begin{cases} -\rho\left(x_i, X_{ji}\right)/d & x_i \in X_{ji} \\ \rho\left(x_i, X_{ji}\right)/\left(\rho\left(x_i, X_{Pi}\right) - \rho\left(x_i, X_{ji}\right)\right) & x_i \notin X_{ji} \end{cases} \tag{10}$$

3.6 Determination of subjection degree

First of all, we carry on the first-stage evaluation to each of the characteristics and calculate the correlation of characteristic C_i with grade j : $K_{ij}\left(N\right) = \sum_{k=1}^{n_i} \omega_{ik} K_j\left(x_{ik}\right)$; then, we carry on the second-stage evaluation and calculate the correlation of N to grade j : $K_j\left(N\right) = \sum_{i=1}^{n} \omega_i K_{ij}\left(N\right)$. If $K_{j_0}\left(N\right) = \max K_j\left(N\right)$, we can conclude that matter to evaluate N belongs to grade j_0.

4 CASE STUDIES

We took a certain land development project-Debit Building in Shanghai as an example; used the model described above to explain the application of matter-element analysis theory in the evaluation of traffic impact. The original data are drawn from the reference *(Peng, et al., 2005)*.

4.1 Determination of matter to evaluate

According to the calculation method of criteria in the second part, combined with the current conditions of surrounding road network, we can obtain a matrix for matter to evaluate R as follows:

$$R = \begin{bmatrix} \textit{Traffic Impacts of Debit Building} & I_1 & 0.41 \\ & I_2 & 0.37 \\ & I_3 & 1.05 \\ & I_4 & 0.45 \\ & I_5 & 2.33 \\ & I_6 & 0.54 \\ & I_7 & 0.67 \end{bmatrix}$$

4.2 Determination of classic field and controlled field matter-element matrix

According to the method mentioned in 3.2, we can list the value range with respect to each evaluation criteria and obtain the following classic field

matter-element matrix:

$$R_1=\begin{bmatrix} \mathrm{I} & I_1 & [0.3,0.5] \\ & I_2 & [0.25,0.4] \\ & I_3 & [1.2,1.5] \\ & I_4 & [1.5,2] \\ & I_5 & [3.4,4] \\ & I_6 & [1,1.3] \\ & I_7 & [0.8,1] \end{bmatrix} \quad R_2=\begin{bmatrix} \mathrm{II} & I_1 & [0.2,0.3] \\ & I_2 & [0.15,0.25] \\ & I_3 & [1,1.2] \\ & I_4 & [1,1.5] \\ & I_5 & [2.8,3.4] \\ & I_6 & [0.7,1] \\ & I_7 & [0.5,0.8] \end{bmatrix} \quad R_3=\begin{bmatrix} \mathrm{III} & I_1 & [0.1,0.2] \\ & I_2 & [0.1,0.15] \\ & I_3 & [0.8,1] \\ & I_4 & [0.5,1] \\ & I_5 & [2.2,2.8] \\ & I_6 & [0.4,0.7] \\ & I_7 & [0.3,0.5] \end{bmatrix}$$

$$R_4=\begin{bmatrix} \mathrm{IV} & I_1 & [0.05,0.1] \\ & I_2 & [0.05,0.1] \\ & I_3 & [0.6,0.8] \\ & I_4 & [0.25,0.5] \\ & I_5 & [1.6,2.2] \\ & I_6 & [0.2,0.4] \\ & I_7 & [0.2,0.3] \end{bmatrix} \quad R_5=\begin{bmatrix} \mathrm{V} & I_1 & [0,0.05] \\ & I_2 & [0,0.05] \\ & I_3 & [0,0.6] \\ & I_4 & [0,0.25] \\ & I_5 & [1,1.6] \\ & I_6 & [0,0.2] \\ & I_7 & [0,0.2] \end{bmatrix}.$$

Meanwhile, we can also easily determine a controlled field matter-element matrix. For example, for the average load of road intersections I_2, its value range of controlled field is [0, 1].

4.3 Calculate the weight of each criterion

We then calculate the weight of the following seven criteria $I_1, I_2, I_3, I_4, I_5, I_6, I_7$ using Analytic Hierarchy Process (AHP). The results are as shown in Table 1.

Table1. Weight of Each Criterion Using AHP

Indices	I_1	I_2	I_3	I_4	I_5	I_6	I_7	ω_i	Consistency Check
I_1	1	1	1	2	6	5	7	0.251	
I_2	1	1	1	2	6	5	7	0.251	$\lambda_{max}=7.081$
I_3	1	1	1	2	5	4	6	0.232	$CI=0.013$
I_4	1/2	1/2	1/2	1	3	3	5	0.136	$RI=1.320$
I_5	1/6	1/6	1/5	1/3	1	1/2	2	0.043	
I_6	1/5	1/5	1/4	1/3	2	1	2	0.057	$CR=0.010$
I_7	1/7	1/7	1/6	1/5	1/2	1/2	1	0.031	

4.4 Compute correlation function

Firstly, we obtain correlation of criteria I_i to grade j- $K_j(x_i)$ for land development projects based on the method mentioned in 3.5 and the results are shown in Table 2.

Table2. Correlation of Each Criterion to Grade j

Indices	$K_j(x_i)$				
	I	II	III	IV	V
I_1	−0.45	−1.1	−2.1	−1.55	−1.44
I_2	0.2	−0.8	−0.88	−0.9	−0.91
I_3	−0.75	0.25	−0.5	−0.83	−0.9
I_4	−0.95	−0.92	−0.5	0.2	−0.8
I_5	−0.89	−0.78	0.22	−0.5	−0.85
I_6	−0.77	−0.53	0.47	−0.5	−0.71
I_7	−0.5	0.43	−0.57	−0.74	−0.78

We then calculate the correlation of land development projects to each grade, the results are shown as follows: $K_1(N)=-0.808$, $K_2(N)=-0.527$, $K_3(N)=-0.913$, $K_4(N)=-0.853$, $K_5(N)=-1.009$; where $K_{j_0}(N)=\max K_j(N)$, therefore, $j_0=2$.

Consequently, according to analysis results and the classification of traffic impacts, we can conclude that the traffic impacts of Debit building belong to grade II, namely, the land development projects have a great influence on the surrounding road network. We need to make some adjustments to the scale of land development

project and adopt the corresponding improvement measures to enhance the level of service. Meanwhile, we also need to collect appropriate traffic impact fees of this land development project.

5 CONCLUSIONS AND RECOMMENDATIONS

The evaluation of traffic impacts is an extremely complex process, which involves many factors that are difficult to quantify. Based on previous research, this paper makes an attempt to quantify criteria and establish the traffic impact evaluation model based on the matter-element analysis theory. The application indicates that the matter-element analysis method can quantitatively evaluate the grade of traffic impacts on land development projects, which effectively avoids subjective bias in conventional evaluations. Even though the matter-element analysis method enhances reliability and accuracy to a great extent on the evaluation of traffic impact, there is a high demand on reasonable selection and quantification of evaluation criteria, especially difficult quantitative ones like traffic safety and pedestrian traffic. Thus, further research is needed on selecting criteria that can make a comprehensive influence of urban land development projects on the surrounding road network.

ABSTRACT

Currently, public transportation systems in our cities generally have many problems, such as frequent transfer times, a low rate of stops overlap, causing a lot of wait time for passengers to catch buses. Undoubtedly these factors influence the citizens' choice of public transportation. These problems result from various reasons, such as irrational network and stops, low density of public transportation networks, and network density distributing not matching with citizen trips distributing. In public transportation systems, network is the basic of the function, so, optimizing the network is essential to improve the levels of the service of public transportation systems, improve the public transportation flow, and to establish the most economic and efficient method of transportation. Network optimization needs the support of related theories and technologies. Though some domestic research organizations have completed many helpful works and proposed many kinds of theories and methods of public transportation network optimization, most of the theories are not applied. Additionally, optimal methods lack of the support of corresponding theories. This paper studies the main factors influencing citizens' trips by analyzing public transportation network optimization. The primary goal of this is to build an optimal network model with minimal transfer times, and minimizing stops as the secondary goal. This model comprehensively reflects the design principle of the public transportation network and the limitations of various objective conditions. Through the qualification of stops, lines and network, we can decrease the number of the workable networks, and eliminate unnecessary calculation in the optimizing phase.

Key words: *public transportation network，optimization，model*

INTRODUCTION

Public transportation provides for much of the city public passenger volume; determining the level of public transport service, and influencing the effective operation management. The original distributions of city buses lines are mainly developed with the development of the city, and are usually designed based on some experiential methods of line planning (Chen Hongren et al.2001).. Among that, many

rational and feasible lines and some irrational aspect brought in by the limitations of the traditional planning methods both exist (Chang Yulin et al.2001). Thus, adjusting and perfecting public transportation networks according to the demand of citizen trips and directions as well as the changes in city development, is a important project of public transportation system planning, construction, and management (Hu Jianming et al.2001). By now, many experts have completed many helpful works, and proposed many kinds of theories and models of public transportation network optimization, but most of the theories are not applied, while the optimal methods lack the support of corresponding theories.

INVESTIGATION AND ANALYSIS OF CITIZENS' NEEDS FOR PUBLIC TRANSPORT

The ultimate aim of the public transportation network is to meet the citizens' trip needs as much as possible. In order to establish a rational optimization model of line networks, it is important to investigate and study the citizens' psychology and conduct, so as to determine the optimization objectives and restricting conditions of the model.

Citizens' needs for public transport are their expectations for public transport services. Recently, Shijiazhuang conducted a questionnaire on citizens' needs for public transport. 400 questionnaires were issued and 367 were returned, with a return rate of 91.8%.The survey found that: 34.47% of citizens wanting less transfers, followed by 25.31% wanting shorter travel time, 18.59% wanting shortest distance of travel, 12.44% wanting lower trip costs, and 6.19% for "other". Thus, the three main factors that affect citizens' needs for public transport are as follows: "number of transfers", "trip distance" and "travel time". A questionnaire conducted in Nanjing in 1999 showed similar results (Yang Xinmiao et al. 2000).

The number of transfers refers to the number of buses that a passenger needs to change during a single trip. It is one of the objectives of urban bus system planning to minimize the number of transfers (Fernadez et al. 1993). With the improvement of people's living standards, this requirement is increasing. Results from the survey concerning citizens' needs for public transport show: the number of bus transfers has the greatest impact on people's choice. If too many transfers are needed, travelers will give up buses and resort to more convenient transportation. In addition, in an operating system where public transport fares are unified, the increase of transfers also means an increase of costs (ZhaoFang et al. 2003).

Travel time is another major factor that affects citizens' bus travel. When travel time takes too long, people may choose other ways to travel.

Trip distance is another factor that affect citizens' bus travel. Trip distance usually includes two parts: distances in and out of buses. Distance out of buses refers to the distance that passengers need to walk. It includes the distance from the starting point to the get-on station, the distance of transferring and the distance from the get-off station to the destination (Wu Qiujin et al.2004;Yang Xinmiao et al.2000).

Obviously, the distance out of buses has a greater effect on citizens' bus travel. If this distance is too long, citizens may abandon the bus and choose other ways.

ESTABLISHMENT OF NETWORK OPTIMIZATION MODEL

In all the factors that affect citizens' needs for public transport, "the least number of transfers" is the most important one. So we put it as the primary goal of optimization. "The shortest travel time" is the second most important factor. But because it is related to the level of road traffic congestion and the start intervals, it is difficult to measure accurately. However, as the actual distances between sites are different, the storage of data becomes complex. Thus, we chose "the least number of stops" as the second goal of optimization. This will meet the requirement of the shortest route, be more in line with passengers' actual travel psychology and greatly simplify the computing and data storage.

The optimization of public transport networks has many characteristics, such as too many influencing factors, complex process and the unfixed passenger-flow distribution. So before we establish the model, we should summarize and simplify the actual situation. This article, based on the analysis and the optimization of the actual process, assumes that citizens' needs for public transport are fixed, considers citizens' needs for public transport, with a goal of the least number of sites that passengers have to go through, and finally establish the optimization model of public transport networks.

$$\begin{cases} \min Z = \alpha_1 \dfrac{\sum_{j=1}^{n}\sum_{i=1}^{n} TN_{ij} \cdot OD_{ij}}{\sum_{j=1}^{n}\sum_{i=1}^{n} OD_{ij}} + \alpha_2 \dfrac{\sum_{j=1}^{n}\sum_{i=1}^{n} N_{ij} \cdot OD_{ij}}{\delta \sum_{j=1}^{n}\sum_{i=1}^{n} OD_{ij}} \\ \text{s.t.} \quad 5\text{km} \le L \le 15\text{km} \\ \quad q_x \le 1.40 \\ \quad Q_k^{\min} \le Q_k \le Q_k^{\max} \\ \quad b_n \le 1.5 \\ \quad \rho_{\min} \le \rho \le \rho_{\max} \\ \quad T \le T_{\max} \end{cases}$$

In the formula, α_1, α_2 ——weight coefficient， $\alpha_1 > \alpha_2$;

n——number of nodes in bus network;

TN_{ij}——possibly the least times of transfersr from Note i to Note j in bus network;

OD_{ij}——traffic flow from Note i to Note j;

N_{ij}——possibly the fewest sites from Note i to Note j;

δ ——the reduction of sites equivalent to the addition of one transfer;

L——the length of a single line in public transport network；

q_x——non-linear coefficient；

Q_k——flow of cross-section of Line k；

$Q_k^{\max}$——the largest flow of cross-section of line k；

$Q_k^{\min}$——the smallest flow of cross-section of line k；

b_n——uneven coefficient of flow of cross-section；

ρ——density of Public transportation network；

T——largest time-consuming of one-way travel among 95% of citizens。

THE ANALYSIS OF THE MODEL AND RESTRICTING CONDITIONS

The above model comprehensively reflects the design principles of public transport networks and the constraint of various objective conditions. It excludes unreasonable alignments at the beginning of the road network. The constraints of line length and non-linear coefficient greatly reduce lines between points. The constraint of section traffic assures the smooth of lines and rationality of the network. In the collection formed by lines, the model adds constraints of public transport network density and the restriction of citizens' travel time with the deflection of a few networks that cannot satisfy the constraints. In this way, through all the constrictions of notes, lines and nets, the model reduces the number of lines and eliminates unnecessary calculations in the optimization stage.

In the model, the first constricting condition is length constriction of a single line. The length of a single line is related to the size of the city and urban citizens' average travel distance. A long line will increase the system's operating costs, while a short line is unfavorable to operation scheduling and will increase the number of transfers. According to the requirements of "Standards of Traffic Planning and Design of Urban Roads" and the actual situation in metropolis, the maximum is 15 km and the minimum is 5 km when the requirement of public transportation operation is taken into account.

The second constraint is a non-linear coefficient. The non-linear coefficient is the smaller the better, so passengers will arrive at the destination as soon as possible. For an average city, 1.15 ~ 1.20 is appropriate. For a single bus line, it is ideal to have it be less than 1.4.

The third restricting condition is the passenger-capacity of a single line. The maximum flow of a line section can be calculated as follows,

$$Q_k^{\max} = 60 C_x l_k X_{cr} / h_k$$

In the formula, C_x——passenger-capacity of different kinds of cars, generally, 72 people per single-compartment bus, 129 people per dual-hinge bus, 120 people per double-decked bus, and 26

people per medium-sized bus；

l_k ——fully loaded rate of line k, 0.85 in peak hour and 0.60in non-peak times；

X_{cr} ——influence coefficient caused by lines repetition, X is the largest coefficient that is repeated with a certain line；

$$X_{cr} = f(X_c) = \begin{cases} 1.00 & X_c = 0 \text{ or } 1 \\ 0.85 & X_c = 2 \text{ or } 3 \\ 0.70 & X_c \geq 4 \end{cases}$$

h_k ——intervals of bus start in peak hour。

Given the requirements of public transport operation, the flow of a section should be no less than the minimum flow.

The fourth restricting condition is the uneven coefficient of the volume of passenger traffic of a cross-section.

$$b_n = \max Q_s / \bar{Q}$$

In the formula, Q_s ——the volume of passenger traffic of Section S；

$\bar{Q}$ ——average volume of a line。

The fifth restricting condition is the density of the public transportation network. In the process of network optimization, it's size can not increase indefinitely, thereby there is an upper limit of the density of the network. $\rho_{\max}$ is a function related to the size of the city and the volume of passenger traffic.

The sixth restricting condition is citizens' trip time. $T \leq T_{\max}$ .The ceiling of 95% of urban citizens' largest one-way travel time will impact the selection of urban transport. Therefore, it should be considered as one of the constraints of the network optimization model.

CONCLUSIONS

This article is based on the study of the citizens' needs for public transport, through which, we can find the major factors affecting citizens' public transport, and finally build a network optimization model with the goal of the least number of transfers and the least number of bus sites. This model provides a theoretical basis for optimizing public transportation networks.

ABSTRACT

This study deals with the problem of urban transport network capacity under a given level of service. After a thorough review of urban transport network capacity modeling and multiple objectivity programming, a multiple objectivity bi-level programming model is formulated, which considers that the network capacity analysis should link the level of service of a road network together. In an upper level program is a multiple objectivity model which includes: (i) the maximization of the network capacity; and (ii) the maximization of the level of service. And a logit-based stochastic traffic assignment model is adopted in the lower level model. Then the goal programming method is proposed. An example is given and numerical results show the algorithm is feasible for practical applications.

KEY WORDS

transport network capacity; level of service; multiple objectivity bi-level programming, O-D demand pattern

1. INTRODUCTION

Transport network capacity is very important to system planning and operation. But most previous researchers do not consider the level of service of network when computing the network capacity. Level of service, which significantly influences the network capacity, should capture the operating conditions of individual road segments or links in the network.

Transportation researchers and engineers have studied these issues during several decades. Buchanan proposed the concept of both network physical and even environmental capacity in their London case studies (Buchanan 1963; Smeed 1966). Iida proposed a heuristic method to determine the road network capacity based on a simple incremental assignment technique (Iida 1972). Yang formulated the problem for determining the maximum zonal trip generation as a bi-level programming problem (Yang and Bell 2000). And the multi-objective programming approach become popular in transport system research (Khorranshahgol and Steiner, 1988; Pearman et al. 1989; Gomes 1989; Won 1990; Azis 1990).

This study concerns the modeling of the transport network capacity under a

given level of service. A new definition of network capacity is proposed and a multiple objectivity bi-level programming formulation is formulated. Then an algorithm is proposed, and an illustrating example is analyzed. For the remainder, Section 2 formulates the multiple objectivity bi-level programming model. Section 3 is devoted to the algorithm and following with a numerical example in Section 4. Conclusions are offered in the last section.

2. FORMULATION

2.1 Definition of the transport network capacity

The transport network capacity is the maximum vehicle numbers that the network can support under given OD demand pattern and level of service.

2.2 Notations

A	link set
a	link index, $a \in A$
C_a	capacity of link a
x_a	flow on link a
RS	OD set
rs	OD pair index, $rs \in RS$
q_{rs}	OD demand between pair rs
f_{rs}	path flow on rs
k_{rs}	path between OD pair rs
$\delta_{a,k}^{rs}$	link-path incidence parameter; one if link a is on path k, zero otherwise
t_a	travel time on link a
G	network (N, A)
Q	multiplier for given OD demand pattern
$\beta(\cdot)$	the inverse cumulative distribution function for the standard Normal distribution
cl	the required degree of confidence
σ_a	the standard deviation of x_a/C_a

2.3 Level of service of network

The Highway Capacity Manual (TRB, 1980) states that for a single freeway section, a useful procedure in operational analysis should link the maximum service flow and the level of service of a road network together. The level of service should capture the operating conditions of individual road segments or links in the network. The higher x_a/C_a, the lower level of service of a road network, which make us define the level of service function of the network as follows:

$$\text{level of service function} = \left\{ \ln[\sum_a (\frac{x_a}{C_a}) + \beta(1-\text{cl})\sigma(\frac{x_a}{C_a}) \times n] \right\}^{-1} \qquad (1)$$

2.4 Multiple objectivity bi-level programming model

Here the multiple objectivity bi-level programming model is adopted. The lower-level problem is a SUE traffic assignment mode. The upper-level problem is the multiple objectivity programming model which includes: (i) the maximization of the network capacity; and (ii) the maximization of the level of service.

$$\max_{Q} \quad Q\sum q_{rs} \tag{2}$$

$$\max \quad \left\{ \ln[\sum_{a}(\frac{x_a}{C_a}) + \beta(1-cl)\sigma(\frac{x_a}{C_a}) \times n] \right\}^{-1} \tag{3}$$

$$st: \quad Q \geq 0 \tag{4}$$

$$\min \sum_{a}\int_{0}^{x_a} t_a(\omega)d(\omega) + \frac{1}{\alpha}\sum_{k} f_k^{rs}(\ln f_k^{rs} - 1) \tag{5}$$

$$s.t. \quad \sum_{k} f_k^{rs} = Qq_{rs} \quad \forall r,s \tag{6}$$

$$f_k^{rs} \geq 0 \quad \forall r,s \tag{7}$$

$$x_a = \sum_{r}\sum_{s}\sum_{k} f_k^{rs}\delta_{a,k}^{rs} \quad \forall a \tag{8}$$

3. SOLUTION ALGORITHM

Goal programming was developed by Charnes and Cooper in 1961 to resolve the multiple objectivity programming. The basic idea of goal programming is to make the objective function $f(x) = (f_1(x), f_2(x),..., f_m(x))^T$ near the target value $f^0 = (f_1^0, f_2^0,..., f_m^0)^T$,. This problem can be presented as the minimization of the deviation between $f(x)$ and f^0, which can be represented as

$$\min_{x \in X} d_p(f(x), f^0, \omega) \tag{9}$$

In our problem, we let $p = +\infty$, then the objective function is converted to

$$\min \quad t \tag{10}$$

$$s.t. \quad \omega_i(f_i(x) - f_i^0) \leq t, \ i = 1,2,..., m \tag{11}$$

$$x \in X, \ t \geq 0 \tag{12}$$

Following is the goal programming formulation.

$$\min \quad t \tag{13}$$

$$st: \omega_1(Q\sum q_{rs} - f_1^0) \le t \tag{14}$$

$$\omega_2(\left\{\ln[\sum_a(\frac{x_a}{C_a}) + \beta(1-cl)\sigma(\frac{x_a}{C_a})\times n]\right\}^{-1} - f_2^0) \le t \tag{15}$$

$$Q \ge 0 \tag{16}$$

$$\min \sum_a \int_0^{x_a} t_a(\omega)d(\omega) + \frac{1}{\alpha}\sum_k f_k^{rs}(\ln f_k^{rs} - 1) \tag{16}$$

$$\text{s.t.} \quad \sum_k f_k^{rs} = Qq_{rs} \quad \forall r,s \tag{18}$$

$$f_k^{rs} \ge 0 \qquad \forall r,s \tag{19}$$

$$x_a = \sum_r\sum_s\sum_k f_k^{rs}\delta_{a,k}^{rs} \quad \forall a \tag{20}$$

Using this model, we cannot compute the capacity of a network. If we want to obtain the optimal solution, the utility function of the road users should be given. Otherwise, we could only obtain the Pareto-optimal solution (Markowitz, 1959).

4. NUMERCIAL STUDYES

The test network is shown in Figure 1. Table 1 and Table 2 are the basic data.

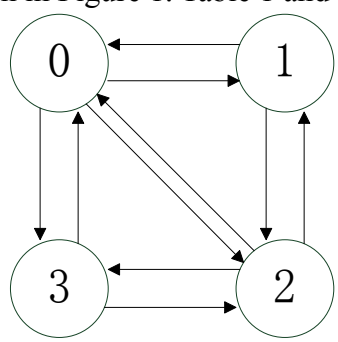

Figure 1.Test network for the proposed algorithm

Table 1.Basic OD matrix

OD zone	0	1	2	3	Production
0	6	5	6	7	24
1	4	5	7	3	19
2	3	6	4	3	16
3	4	5	7	2	18
Attraction	17	21	24	15	77

Table 2.Link character data of test network

Link	Start Node	End Node	AB Capacity	BA Capacity	AB free-flow	BA free-flow

					travel time	travel time
0	0	1	100	100	50	100
1	1	2	100	100	60	100
2	2	3	100	100	60	100
3	3	4	100	100	50	100

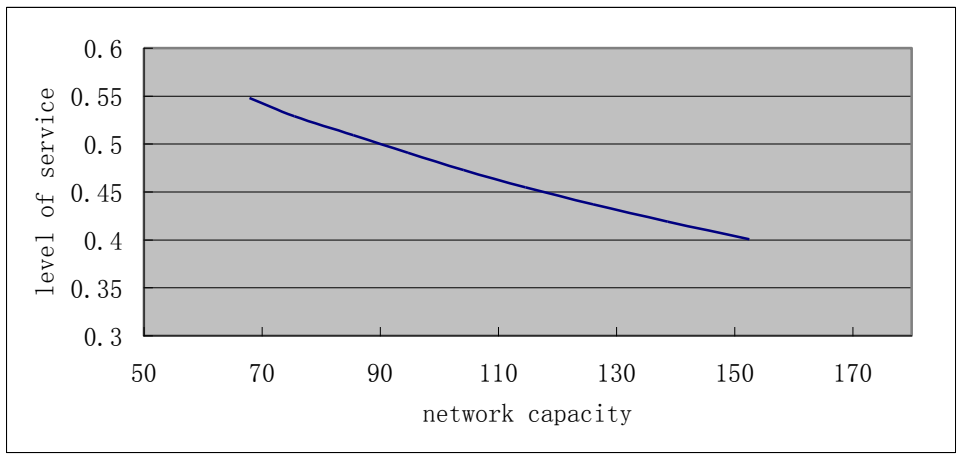

Figure 2 The relationship between capacity and level of service

According to numerical results, the relationship of the capacity and level of service is represented in Figure 2, which illustrates that the higher the network capacity, the lower level of service of a road network.

5 CONCLUSIONS

In this study, a multiple objectivity bi-level programming model is developed and an algorithm is proposed to analyze the transport network capacity considering the level of service. Numerical results show that the model and algorithm is effective. Moreover，this model can be extended to a case considering the elastic demand or

variable OD pattern.

THE BALANCE LINES OF INTERNATIONAL FREIGHT AND INCIDENTALS

Liu Xian[1]

ABSTRACT

In cargo transportation between Europe and Asia, 'balance lines' in international freight and incidentals is a concept describing rational choices for shipping by freight over land or by ocean. Many factors cause warping in these balance lines, especially the lack of a comprehensive intercontinental rail cargo agreement. The balance lines of international freight and incidentals are thus relevant to a new comprehensive Eurasia railway cargo transportation convention. Taking balance lines into consideration could benefit trade between many countries. Although a long-term objective, the balance lines of international freight and incidentals should be pursued by European, Asian, and North African countries.

INTRODUCTION

Traditionally, there have been two main modes of cargo transportation between China and Europe: ocean shipping and land carriage. The trade and investment between EU and China is one of the most successful examples in international economic cooperation in the world. As economic cooperation increases between China and Europe it is important to select a reasonable cargo transportation mode. One important aspect of the selection is the comparison of cargo transportation costs.

BALANCE LINES OF INTERNATIONAL FREIGHT AND INCIDENTALS

Most cargo exported from China to Europe is conveyed by ship. However, the transportation process can be can be broken into three sections: first, shipping from inland depot to the Chinese port of embarkation (by train or truck transportation and sometimes by riverboat); second, by ocean-going vessel from China to a European port; and third, from the European port to the good's final destination. It is, therefore, not difficult to realize that the farther the freight is from the Chinese port, the more expensive the inland freight and incidentals are, and so too is the situation on the European leg of the journey. One can therefore appreciate the merits of international railway transportation.

Relative to every European location where freight is transported (especially at the inland locations) there are *balance lines* of international freight and incidentals. These lines are dynamic, they vary as the changing of ocean freight, port load and unload fees, international oil prices, exchange rates, premium, railway freight, cargo variety, canal tolls, storage and trans-shipment charges, what kind container is used (if a container is used), etc. For different locations where freight travels, the balance lines are different. For example, in China, transportation lines go roughly north-south.

If the freight locations are east of the north-south line, general freight and incidentals of ocean shipping and its parts are less costly since the routes are closer to the ports. If however, the freight locales and incidentals are west of the line, then the cost of general freight and incidentals using international railway transportation is less expensive (since the distance is that much closer to European destinations). If the freight locales are located on the north-south line, then the cost of shipping by sea or by rail is equal. The situation is the same for freight coming for importation of freight from Europe to China.

SELECTION OF CARGO TRANSPORTATION COURSES

Warping Phenomenon. In the course of arranging the cargo transportation from inland China locales to inland European locales, apart from common freight and incidentals, many other factors can influence the selection of a suitable transportation mode. These factors giving rise to a *warping* phenomenon in the selection of cargo transportation courses. For example, cargo checking and pick up procedures may vary in complexity, understanding bills of lading, language difficulties, force majeure situations, applicable insurance clauses, differing laws and importation regulations between countries, problems over the liquidity of transportation bills, the energy and motivation of shippers, importers and exporters accustomed to different procedures, etc. Even west of the balance lines of international freight and incidentals (where rail cargo is cheaper than ocean shipping) a lot of cargo exported from China is shipped by sea. The phenomenon is similar in how the courses of cargo transportations are chosen from inland Europe to inland China.

Warping aggravated by lack of comprehensive intercontinental rail agreement. There has been no integrated railway transportation convention in Eurasia for a long time. The reality is that since the 1950s, two agreements concerning intercontinental rail traffic have existed side by side, the "Agreement of International Railway Through Transport" (1951) and the "Convention Concerning International Carriage of Goods by Rail" (1975). China, Mongolia, Vietnam, North Korea, and many countries of the Commonwealth of the Independent States, etc., are parties to the Agreement. Those participating in the Convention include many European, North African, and Middle Eastern countries. These transportation agreements are essential for managing rail traffic through the rail systems of their member countries.

A comprehensive agreement bridging the Convention and the Agreement is important for the development of international trade between the signatories of the Convention and the Agreement. Currently, rail shipping from countries signed to the Agreement but not to the Convention (and vice-versa) involves time delays and additional expense. Way bills of countries signed to the Agreement are not recognized as law under countries signed to the Convention.

For example, cargo shipped from China to Western Europe by railway must first be transported to a border station in Eastern Europe. Acting as a shipping agent, the head of an Eastern European border station fills out a new *relative* way bill indicating the final destination for the cargo. It is necessary for the heads of border stations to continuously manage these transportation procedures as shipping agents, filling in Convention standard way bills for rail cargo arriving from Asian countries

signed to the Agreement. To complicate matters, some Eastern European countries have already retired or wish to retire from the Agreement and want to join the Convention exclusively.

Other uncertain factors impact shipping between Agreement and Convention signatories: the natural gas dispute between Russia and Ukraine, changes in the means of payment for freight and incidentals and the currency used in transaction, use of English in Agreement way bills, changes in customs declaration procedures, unenforced penalties for overdue shipping, etc. Railway cargo transportation across Eurasia thus faces many uncertain factors producing warping. Due to these difficulties, the choice to "give up on land, and go to the ocean" becomes the common practice in selecting transportation modes.

A COMPREHENISVE NEW EURASIAN RAILWAY CARGO TRANSPORTATION CONVENTION

A solution. In order to rationalize the railway cargo transportation sequence across Eurasia, and to develop reasonable competition between intercontinental railway cargo transportation and ocean shipping, a new comprehensive railway cargo transportation convention is needed that takes into account the balance lines of international freight and incidentals. The scope of the new convention could cover all of Eurasia, and even North Africa and the United Kingdom.

To merge and improve the two existing agreements, it will be necessary to summarize the historical experiences of operating the Convention and the Agreement while respecting sovereignties and desires of all countries fully. Earlier attempts to bridge the gap between the Convention and the Agreement, like the October 2003 Memorandum of Understanding and Cooperation on passenger and cargo transport in Yekaterinburg, Russia (Wanjian 2003), included limited temporary and local measures that were insufficient in altering the railway traffic situation across Eurasia.

Decreasing warping phenomenon. The signing of a new comprehensive Eurasia railway cargo transportation convention means that an integrated legal system managing Eurasian railway cargo transportation will need to be established. Once all countries will have common rules to follow, general transportation costs will decrease. The current warping phenomenon will be corrected and the *watershed function* of the balance lines of international freight and incidentals will come begin to improve trade over the whole. Shipping choices between China and Europe will become increasingly rational. In short, with a new agreement, there will be a new railway cargo transportation situation in Eurasia.

After the new convention becomes effective, not only would rail cargo shipping costs across Eurasia decrease, but other benefits could also be obtained: shortened transportation time, reduced load and unload frequency, increased arrival estimates, a lessened influence of inclement weather, improved speed of cargo loss investigations, etc. The serious phenomenon of "giving up on land, and going to the ocean" would be corrected. The more reasonable international division of labor and resource utilization could be realized. Meanwhile, shipping difficulties experienced with ocean shipping such as force majeure, pirates, and other troubles could be avoided altogether. To bring this mutually beneficial state of affairs into being depends on a new convention becoming effective.

The fair competition between international railway through goods traffic and ocean shipping will stimulate ocean shipping to improve its service quality further. The balance between the two transportation modes should be a balance at a higher level of service.

BENEFITS OF RATIONALIZED SHIPPING

Increased trade between East Asia and Europe. A new comprehensive Eurasian railway cargo transportation convention will make overland shipping more convenient. Cargo formerly shipped over ocean shipping might be transported by international railway through goods traffic after the new convention becomes effective. Some trade from Japan, Korea, Mongolia, Vietnam, China (including Taiwan and Hong Kong) will take shortcuts to reach parts of Europe. With a rationalized shipping system incorporating balance lines, local troubles impacting transportation networks such as warfare or piracy can be bypassed.

Increased traffic between Russia, Asian, and European countries. Russian railway transit traffic is endowed by the expanse of Russian lands spanning Europe and Asia, the vastest expanse of land in the world. Russia could obtain considerable income from railway traffic between East Asia and Europe. Currently, the density of Russia's railway network is far smaller than that of Chinese railway network, however, the benefit of a new comprehensive convention and rational shipping considering the balance lines of international freight and incidentals would benefit investment in an improved Russian railway network.

Many countries in Europe and Asia, that do not have Russia's obvious geographic advantage, could also obtain profits from more rationalized shipping decisions that improve everyone's situation. Central Asian and European countries (such as Kazakhstan and Poland) would also profit from improved and increased railway traffic, although the profits are different in degree.

OTHER BALANCE LINES

In choosing suitable transportation for shipping in the north-east region of China, there is another balance line for freight and incidentals. General freight and incidentals are equal relative to a specific destination, no matter which direction, when shipping cargo to Japan and other countries and regions either south through Dalian port or east through the lower reach channel of Tumen River (China owning the navigating right of the channel). The balance line of freight and incidentals could be taken as a watershed function to decide which way cheaper transportation way. As eastern ports in Russia and ports in North Korea are leased for Chinese cargo, these new shipping opportunities influence the balance lines of freight and incidentals in northeastern China. Furthermore, as global climate change warms the Arctic Ocean, a new commercial northeast passage may be realized. The balance lines of freight and incidentals produced by this new shipping option will be seen distinctly.

CONCLUSION

Although the heavy infrastructure of intercontinental rail traffic already exists (tracks, stations, communication apparatuses, warehouses, etc.) and is developed ceaselessly, the intercontinental legal environment remains deficient. This may be

remedied with a comprehensive new agreement for intercontinental rail cargo traffic. Work towards this goal does not require as much labor and investment of material and land resources. Strengthening mutual trust and cooperation between Eurasian countries energetically, can achieve a significant reward for all.

Although the achievement of rationalized balance lines needs time to develop, it is a realistic objective that deserves the participation of Eurasian countries (as well as North African countries and the U.K.). Because of the common interests of so many countries, improvements in Eurasian railway cargo transportation may become a reality, and not even in the remote future.

ABSTRACT

An elevated urban expressway connects to its frontage roads by on/off ramps. Under the expressway, frontage roads, two pairs of on/off ramp terminal and cross streets construct the complex at-grade intersection. One typical complex intersection under the Inner Ring Expressway in Shanghai was selected in this study. The main reason for congestion at this intersection is that traffic movements with different origin-destination (OD) weave within the section from the ramp terminal to the stop-line on the departure legs. To eliminate the weaving operation, lane function was reassigned, and signal timing was redesigned to a five-phase scheme. Simulation tool VISSIM 4.1 was applied to evaluate performance of the new intersection. Simulation results indicated that significant reduction of vehicle delay and queue length in the new scheme.

INTRODUCTION

In Shanghai, the urban expressways are elevated roads lying over their frontage roads, connecting to a frontage road by on- and off-ramps. Therefore, frontage roads, ramp terminal and street road constitute the special intersection type (see Fig. 1). Compared with standard street intersections, this intersection is more complex, due to the movements leaving or heading for the ramps within the intersection area. Also, this intersection is different from the Single Point Urban Interchange with frontage road (SPUI/F, see Fig. 2) in America, from the location and mode of connecting to intersecting street roads.

One problem in this intersection is an insufficient separation distance from the off-ramp terminal to downstream signalized intersection. This contributes to traffic conflicts and excessive congestion along the approach legs. A second problem is insufficient distance from the on-ramp terminal to the signalized intersection. This causes traffic conflicts along the departure legs. This paper focuses on this type of junctions and introduces improvements by optimizing traffic management and signal timing programs.

Professional research about this complicated intersection is not very rich. Intensive and relevant research has been conducted on single point urban

interchanges (SPUI) for 35 years in America. Messer et al. (1997) reported that the SPUI/F typically uses one actuated controller and operates with four basic phases: (1) crossroad left movements, (2) crossroad through movements, (3) frontage roads left-turn movements, and (4) frontage roads through movements. Jim C. Lee et al.. (2002) also compared the merits and adaptation of three-phase and four-phase. They proposed the signal interval calculating method and applied their findings to ten interchanges in the Phoenix, Arizona metropolitan area.

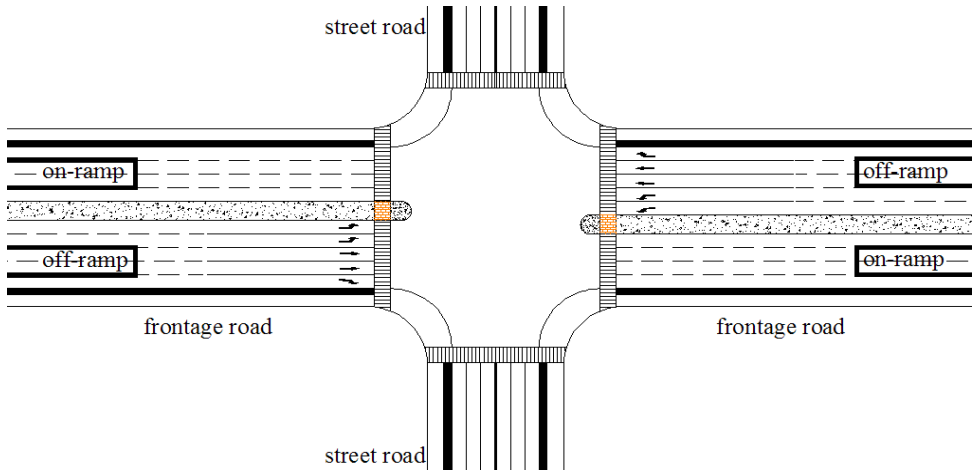

Fig. 1. Typical intersection connecting to expressway ramps.

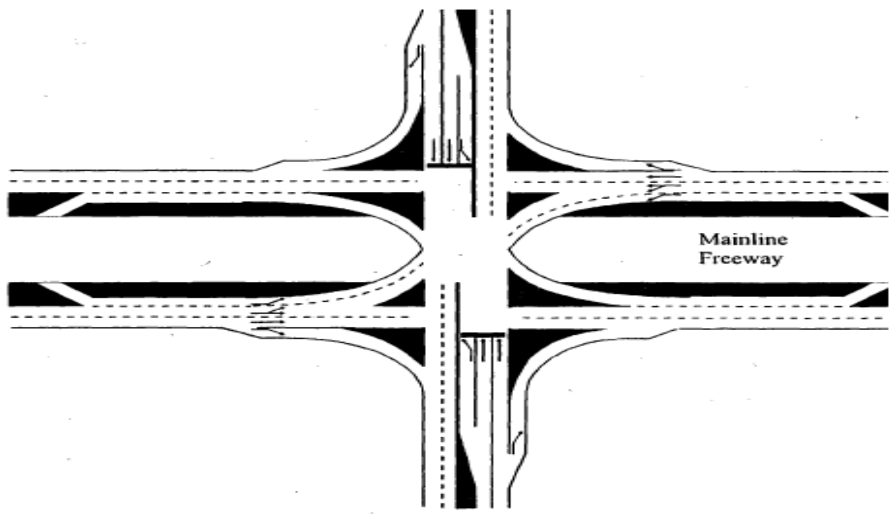

Fig. 2. Typical single point urban interchange with frontage road (From: Paul, Thomas [2]).

Recently, some researchers (Garber and Smith) found that SPUI is much easier to coordinate with an adjacent signalized intersection on the crossroad (relative to other diamond interchanges). Through coordination with other intersections, the systematic efficiency can be improved. Other research (Leisch et al., 1989) [4] studied the clearance interval and lost time at SPUI The SPUI's large size and lengthy travel paths require clearance intervals in excess of 8 to 9

seconds. They also observed that long clearance intervals create considerable lost time at the end of a phase, resulting in an SPUI capacity decrease. There are some American proposed guidelines for diamond interchange planning and design, The California Department of Transportation Division of Design (2001) proposed guidelines for single point interchange planning, design and operations. This guideline was applied in all states in America. Many researchers (Tian, 2004; Lindgren, 2004; Selinger; Messer, 1997; Engelbrecht, 2001) have applied a traffic simulator to evaluate the operational quality of diamond interchanges, including SPUI, SPUI/F, Tight Urban Diamond Interchange and standard diamond interchange.

Compared to SPUI, the type of more complex junction selected in this research is quite different from the diamonds with respect to geometric structure and traffic composition. So, this complex intersection requires special work.

The authors selected a typical Shanghai intersection as an example for research on the optimum traffic management and signal timing scheme. In the following sections, the existing condition of the intersection is introduced, improving alternatives are proposed, and simulation evaluation for the alternatives is conducted by VISSIM. Finally, a conclusion and recommendations are offered.

EXISTING CONDITIONS

The selected intersection is located in the Putuo District of Shanghai China. The frontage road of the Inner-Ring Expressway and Wuning arterial road are the intersecting roads. The existing intersection is a four-leg junction, with an intersecting angle of 70 degrees. The width of red-line of the expressway frontage road is fifty meters, The Wuning arterial is also fifty meters wide. On the northern and southern approach and departure legs, one pair of on/off ramp terminals connects to the elevated expressway. Distance from the ramp terminal to the junction stop-line is 60 to 105 meters.

Fig. 3. Existing geometric condition.

Function assignments for every approach are listed in Table 1. P.M. peak hour traffic volume in this junction was surveyed and listed in Table 1. The total volume is 9063 pcu/h, and the bus ratio is relatively high, especially on frontage roads. Signal timing is a three-phase scheme, and the circle length is 227 seconds. Left-turn movements on the northern/southern approaches are prohibited. They are accommodated by the U-turn and the adjacent intersection downstream.

Table 1 lists the theoretical value of saturation and delay at this intersection according to HCM2000. It shows that the degree of saturation on northern/southern approaches was only about 0.5. Delays on these two approaches were also small.. Field investigation indicated, however, that the junction was extremely saturated on every approach during peak hours. This significant inconsistency indicated that HCM2000 cannot analyze this junction correctly, because a large portion of delay was not generated on the approaches but on the departure legs. Therefore, our evaluation applied simulation tool VISSIM 4.1.

TABLE 1 Traffic volume during the Peak hour (P.M)

Approach	Direction	Number of lane	Volume (pcu)	Bus ratio	Saturation	Delay (s)
Northern	Left-turn	----	---	---

	Average	146.2	36.8	-74.8	256	418	40	102.5	-84.4	-75.5
Average of all		107.4	46.5	-56.7	117.8	249	39.8	122.3	-66.2	-50.9

Note: In the table heading, 'ave' denotes the average queue length of the movements, 'max' denotes the maximum queue length of the movements.

SIMULATION EVALUATING PRESENT PERFOMANCE

Results of the evaluation conducted by VISSIM 4.1 are listed in Table 2. Compared with table 1, the simulating results are clearly different from the theoretical results. From Table 2, the total average delay at this intersection was up to 107.4s, with the southern approach over 120s and western approach over 150s. Queue length was very long on every approach, especially on the western approach where the maximum length was longer than 410 meters. Very long

queues influenced the neighboring intersection and the expressway's mainline.

Through simulation and field investigation, we find the main reasons for congestion on this site include:

1) The distance from the ramp terminal to the intersection stop-line is too shor. The result is serious conflict between movements on the frontage road and the ramps and reduced passing efficiency.

2) Weaving operations on departure legs greatly degrade junction efficiency. For example, the northern departure leg, illustrated as Figure 4, has two weaving operations: (1) left turns from the western approach weave with right turns from the eastern approach and (2) movements with origins from the off-ramp and frontage road destination on the southern approach, weave with the origin frontage road and on-ramp destination.

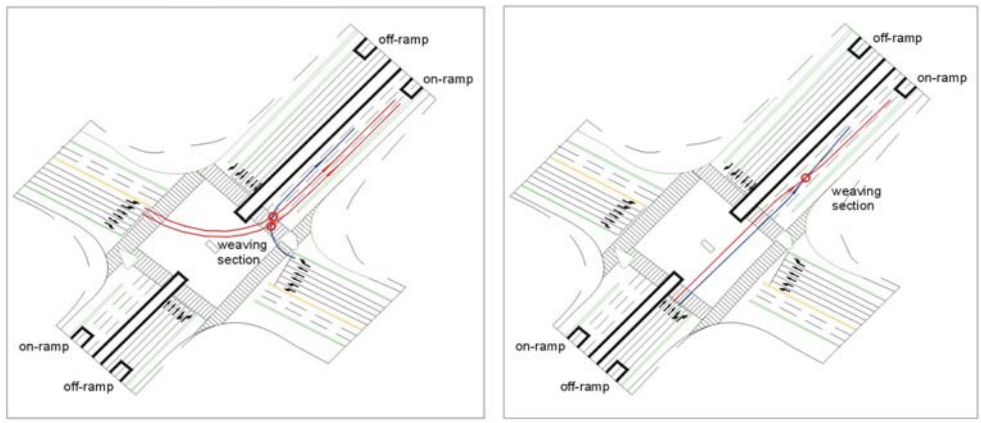

Fig. 4. Weaving operation on intersection departure legs.

3) The considerable volume of bicycle and pedestrian traffic, interweaved with right-turn vehicles, worsened operating conditions.

PROPOSED IMPROVEMENT SCHEME

Our findings above demonstrate that the main reasons for congestion at this junction are mainly from weaving operations on the approach and departure legs. Accordingly, we propose lane function assignment and signal timing measures to eliminate these weaving operations.

Lane function assignment

(1) On the northern approach: The bike lane was changed to a truck lane. There are six lanes on this approach. The lane next to the curb accommodates through movements of buses on the frontage road and vehicles from the off-ramp. The next two lanes are for right-turn movements from the off-ramp and frontage road. The next one is only for through frontage road movements heading for the on-ramp. The last two lanes are for through frontage road movements not entering onto the expressway through the on-ramp.

(2) On the southern approach: The bike lane is changed to a truck lane.

There are eight lanes. The lane next to the curb accommodates through bus only. The next three lanes are for right turns The next one is for through movements from the off ramp. The next is for through movements on the frontage road heading for the on ramp. Finally, the last two lanes are for through movements on the frontage road not entering the on-ramp.

Clear signs should be provided on the approaches to prevent drivers from selecting the wrong lane. The proposed sign layout is shown in Fig. 5.

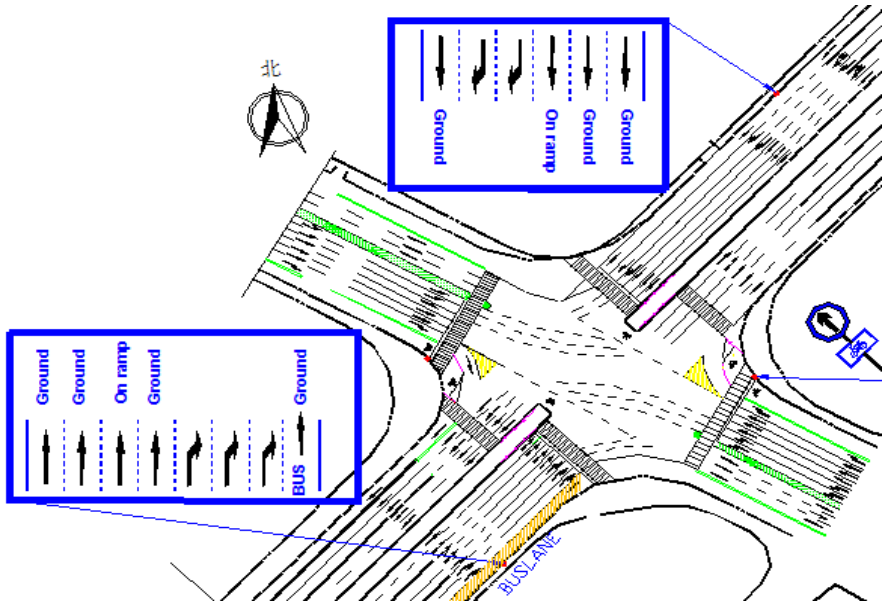

Fig. 5. Proposed traffic organization on northern approach.

Signal timing

A five-phase signal timing scheme was proposed, as shown in Table 3. Circle length is lessened to 150 seconds, in which:

Phase 1 is for a left turn on eastern/western approaches and right turn on the four approaches.

Phase 2 is for a left turn on a western approach, through movements on lane 4 of the southern approach and a right-turn of three approaches. Obviously, phase 2 is embedded between phase 1 and 3. Phase 2 has two advantages: (1) separating the through movements with different OD on the southern approach to eliminate the weaving operation and, (2) considering the imbalance of left-turn traffic volume between eastern and western approaches, shortening the green time of phase 1 and improving the efficiency of the whole intersection.

STUDY RESULTS

As pointed out above, the main bottleneck of this complex intersection is not the approach, but the departure legs. So the theoretic formula of Highway Capacity Manual 2000 was invalid for evaluation here. The proposed evaluation tool was simulation model VISSIM 4.1. Two simulation models were constructed for the present and the improving scenarios. Three performance measures —

delay and the average and maximum queue length — were selected for comparison. Simulation results are listed in Table 3.

TABLE 3 PROPOSED SIGNAL TIMING SCHEME

Phase	1	2	3	4	5
Vehicle movements					
Bicycle					
Pedestrian					
Green time (s)	40	28	34	20	15
Circle time (s)			150		

From Table 3, we can find that the proposed improvements result in significant efficiencies in delay and queue length:

On the northern approach, although the average queue length was slightly increased by 6.0 percent, the maximum length was reduced by 25.8 percent.

On the southern approach, delay of through movements was reduced by 57.7 percent. The maximum queue length was shortened to 117 meters not extending to the expressway mainline.

On the eastern approach, delay of left-turn and through movement was reduced by 36.3 to 38.3 percent.

On the western approach, delay was reduced by 61.5 to 84.1 percent and maximum queue length was shortened to 100 meters.

CONCLUSION

(1) The junction studied in this paper is more complex than the standard junction, due to the pairs of ramps on intersection legs.

(2) The main problem and traffic bottleneck in this intersection is located on the departure legs. Vehicles with different OD weave in the section from stop bar to on-ramp terminal and thus degrade the operating efficiency of the whole system.

(3) Appropriate lane function assignment was redesigned to eliminate the weaving operation.

(4) Signal timing was optimized as well. Movements with different OD were separated by special signal phase sequence. An embedded phase was applied.

(5) In this complex intersection, some traffic direction should be prohibited to simplify traffic composition. Here, the left-turn on northern/southern approaches was prohibited and replaced by through movement plus U-turn.

(6) Future work will be directed to signal coordination with the neighboring intersections.

ABSTRACT

Special events are an important part of our daily life. During the special events, the relative subway station will involve a large number of pedestrians converging in a short amount of time. So, whether pedestrian organization of subway station is prepared well enough should be evaluated in advance. The involvement of pedestrian simulation can compare and evaluate the scenarios and thus be able to improve the service quality of traffic facilities. In this paper, a process on how to make an organization scenario with the help of pedestrian simulation tools is given following a brief overview of the pedestrian model research. Then the legion 2006 studio was used to test the pedestrian traffic organization plans of a typical subway station involved during the Olympic Games. At last, some improvement measures were given based on the simulation results.

KEYWORD: special events, pedestrian simulation, Legion

BACKGROUND

Special events are more and more common in our daily life. Because of a convergence of pedestrians in a short period of time and limited area, the pedestrians involved in special events are mostly encouraged to use public transport. During the 2008 Beijing Olympic Games, more than 60% of the audience selected public transportion. Gymnasiums are near the subway station, such as WUKESONG gymnasium. Whether the capacity of the facilities in the subway station is enough for the demand, whether the train timetable is suitable for such amounts of pedestrians, whether the temporary facility is required and how to set them are questions which should be solved in advance. But, due to the lack of historic demand and the unique character of each special event, the organization work is very complicated.

Simulation tools can play an important role in such issues. They are able to provide some numerical indication of different scenarios. Also, they can provide intuitive answers for the questions mentioned above.

This paper provides a process on how to make a decision with the help of simulation model. Firstly, a brief state-of-the-art overview of pedestrian model is presented. Then the pedestrian characteristics of subway stations during a special

event are analyzed based on amounts of survey. At last, a typical subway station which has important relevance to the Olympic Games is modeled with legion studio and advice for the pedestrian organization are given based on the simulation results.

PEDESTRIAN MODELING TECHNIQUES

This section presents an overview of pedestrian simulation models with a focus on the micro-models which are used to depict the detail pedestrian behaviors.

Cellular Automata Model (Burstedde et al. 2001) is an idealized model of physical systems, whose time and space are discrete and physical parameters can only be got from a limited set of values. Probability model will be built to decide whether the pedestrian will turn to other cells or just stay where he/she is.

Agent-based Models use an agent as their basic unit. An agent is a software entity that is "situated" in an environment, where it can sense happenings and act accordingly. Agents act autonomously and can communicate with each other. This unit represents human behavior quite well, in particular, our decision-making skills.

In addition to the above pedestrian models, there are also many pedestrian models have been studied and used, such as “Social Force Model”, “Mental Stress Model”, “Magnetic Force Model”, “Queuing Network Model” and “Discrete Choice Framework Model”.

A lot of simulation tools were developed based on the models mentioned above. The Rail Safety and Station Board (RSSB) listed the main simulation software which can be used to evaluate pedestrian organization (2003). Table 1 shows the software and its supplier.

Table 1. Main Software and Suppliers.

Software	Suppliers in brackets
Building EXODUS	Fire Safety Engineering Group
EGRESS	AEA Technology plc
Legion	Legion International Ltd.
MYRIAD	Crowd Dynamics
STEPS	Mott MacDonald

Among them, Legion studio is very professional software specializing in modeling crowd behavior. The core of Legion is Agent-based Model. It treats each person as a "virtual person" who senses their environment and makes decisions about where to move accordingly. Legion can be used in a lot of fields relevant to pedestrian such as new station designs, pre-feasibility assessment, and station refurbishment projects. So, in this paper, the Legion studio 2006 is used to build the simulation model of subway station.

PROCESS OF PEDESTRIAN SIMUALTION

After the confirming of the simulation tools, the process of the models building should be set too. Figure 1 shows the process of how to make a decision with the help of Legion.

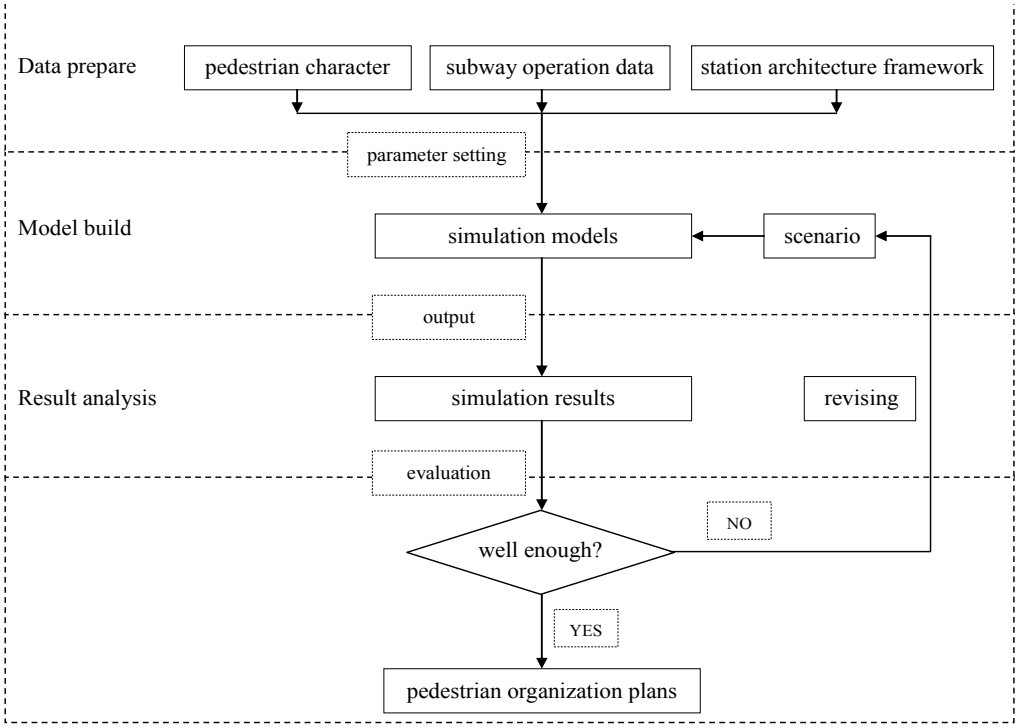

Figure 1. Main Survey Areas in Subway

Data Prepare

The data needs for simulation model can be divided into three types: pedestrian character data, subway operation data and the station architecture framework.

The pedestrian character data is the most complicated data and needs large amounts of input, such as the free speed and traffic flow relationship in pedestrian facilities, and the hobby of route-selecting. Lucky, these data can be obtained from historic data. The more survey and analyzing work done, the more accurate data one can get. Figure 2 shows the areas where the pedestrian character can be attained.

Entrance Passageway Stair AFC Concourse Platform

Figure 2.Main Survey Areas in Subway

Other data, such as pedestrian volume and the pedestrian constitute will be different from each other, because of the most special events are unique. But this

data can be obtained from the host of the special event.

Subway operation and station architecture framework data, such as the service time of ticket checking and the train timetable, can be obtained from the subway administers.

Models Build

Based on the preparing data and pedestrian organization scenario, the simulation model can be built appropriately.

Result Analysis

The simulation results should be analyzed to evaluate whether the pedestrian organization scenario is appropriate. The two main indications are density and evacuation time. Legion studio can output these indications freely. If the density is too high or the evacuation time is too long, the scenario should be revised and the simulation models should be built again.

TYPICAL STATION SIMULATUIION

Among 31 Olympic venues, the Workers Stadium (WS) is the most representative one. The WS is located in Workers Stadium North Road, Chaoyang District. It will host boxing, football games and other competitions. During the Olympic Games, subway lines 2 and 10 will take the main responsibility of evacuating the audience, especially subway line 2 which is closer to the Workers Stadium. Therefore, the DONGSISHITIAO station (DS station) of line 2 is chosen as an example of pedestrian simulation application.

Demand Forecast

The Workers Stadium can accommodate and audience of 65,700 people. According to Table 1, 40.7% of the audience will select subway and 18.3% of the audience will choose Line 2, so there are 12,034 people in all.

Table 2. Traffic Mode Split for Audience Evacuation

D / O	Line 2	Line 10	Bus	Special line	Other	Total
WS	18.3%	22.4%	8.30%	43%	8%	100%
Percent	40.70%	8.30%	43%	8%	100%	
Amount	12034	14709	5410	28291	5256	65700

Figure 3 shows the audience and daily volume of the DS station. Obviously, the sum of them is the total demand of the DS station during the evacuation time.

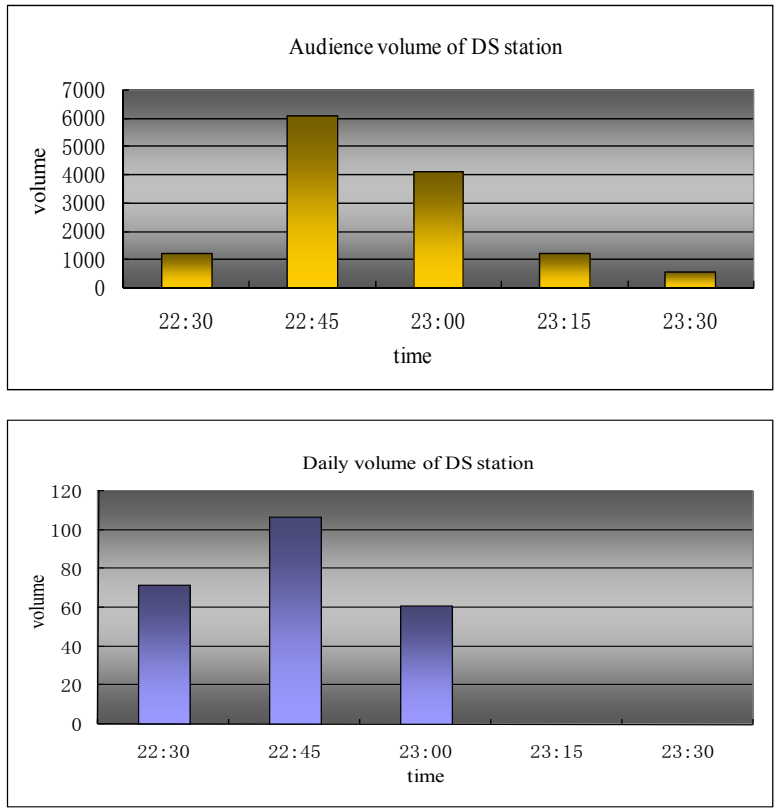

Figure 3. Audience and Daily Volume of the DS Station

Parameter Set

Table 3 shows the detail parameter setting during the model building.

Table 3. Detail Parameter Setting

Type	Detail	Parameter
Facility	Stair, escalator, exit, entrance, AFC	CAD
Constitute and volume	Commuter and audience	Figure 3
service	Ticket-checking	0 second for audience
Evaluation indications	Density and speed	LOS (HCM 2000)

Model Build

Figure 4 shows the layout of the DS station and the simulation model. As WS locates at the southeast of the DS station, most audience will choose Entrance C. So the initial scenario assumes that 80% of the audiences choose Entrance C and 20% of the audiences choose Entrance B.

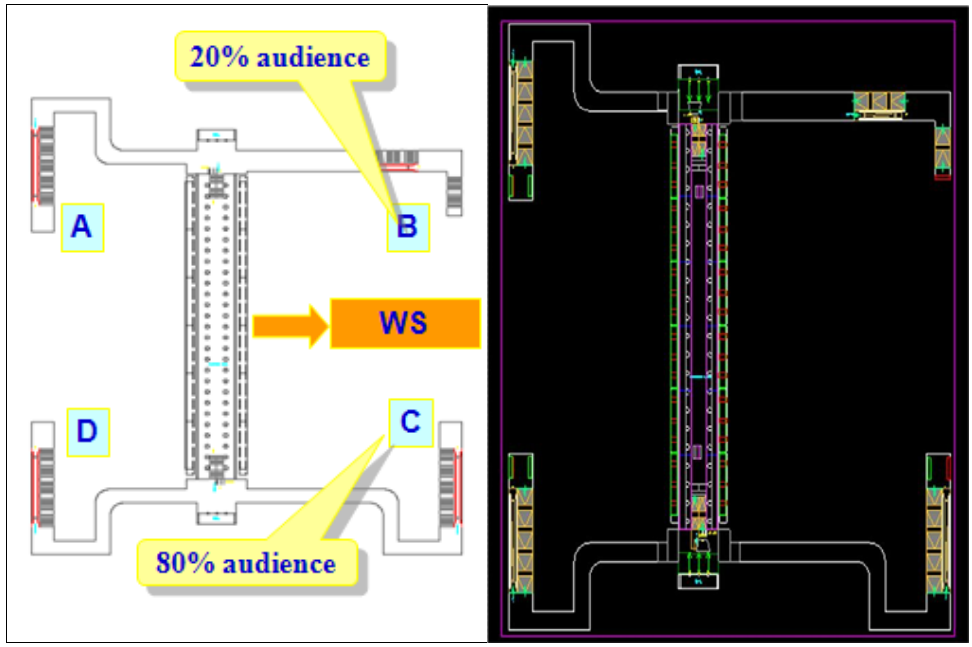

Figure 4. Layout of the DS Station and the Simulation Model

Result analysis

Figure 5 shows the average density of stair, passageway and platform. With the increase of volume in Entrance C, the density of the stair rises dramatically and is greater than 1 peds/m^2. The situation of passageway is much worse than the stair. The average density is above 2 peds/m^2. The LOS (level of service) of the passageway is E. The pedestrian will feel very uncomfortable here. The average density of the platform is below 0.4 peds/m^2 but it is partially because of the congestion of the stair. The pedestrian cannot reach the platform freely.

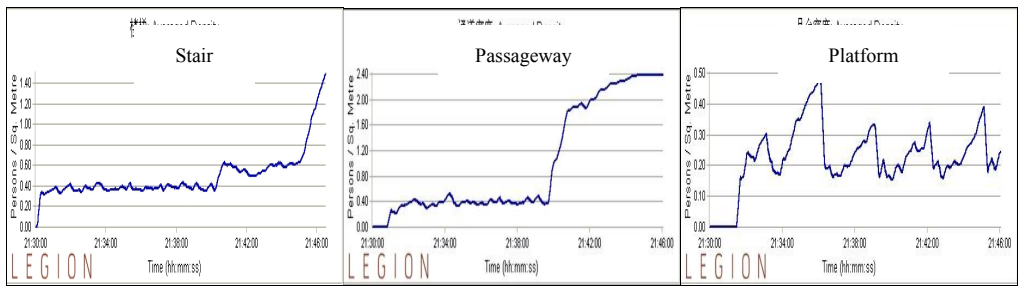

Figure 5. Average Density of Stair, Passageway and Platform

Based on the analysis of the simulation result, several problems of the initial scenario can be found:

- ✓ There are too many pedestrians at Entrance C during the peak time of the evacuation.
- ✓ There are only two ticket-checking channels between Entrance C and D.
- ✓ Commuter pedestrian has conflict with the audience and affect the efficiency of the evacuation.

Improve Measures

Most of the problems of the initial scenario can be solved with proper pedestrian organization. The following are the improvement measures:

- ✓ The stair between Entrance B and C are only used for descending pedestrians. Contrarily, the stair between Entrance A and D are only used for ascending pedestrian.
- ✓ Guiding the 40% of the audience to Entrance B to reduce the pressure of Entrance C.
- ✓ Setting waiting outside of the entrances to control the volume entering the station

Figure 6 shows the average density of the same places of the initial scenario. The improvement is very obvious. The average density of the stair raises is below 1 ped/m^2 which is LOS D. The change of passageway is the most obvious. The average density is lower than 0.5 peds/m^2. The LOS of the passageway is B. The pedestrian will not feel uncomfortable here. The average density of platform is still below 0.4 peds/ m^2. It is sure now that the timetable of the train is suitable.

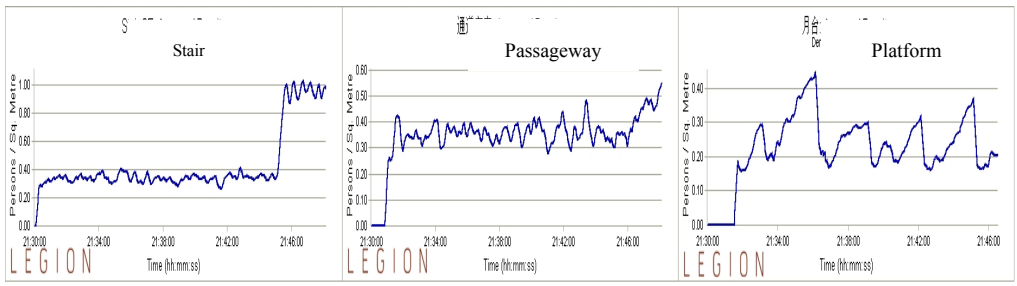

Figure 6. Average Density of Stair, Passageway and Platform

CONCLUSION

Special events are an important part of the society life. With involving a large number of pedestrians in a small area for a short period of time, most special events encourage the pedestrians to come by public transportion. The subway is the most suitable way. Therefore, the pedestrian organization for subway stations during special events is very important. Simulation can be used as an effective tool to support the decision making. But, however, the parameters should be set based on the characteristics of Chinese pedestrian. This paper built a simulation model of a typical subway station relevant with the Olympic Games. Based on the evaluation of the simulation results for the initial scenario, some improvement measures are provided. This process will be an example of pedestrian organization for subway stations during special events.

ABSTRACT

Since the fact that the non-signal roundabout allows less flow rate, and with the increasing of roundabout flow rates, a series of problems have occurred in respect to traffic jams, rising accident rates, growth of traffic delays, increasing of saturation degrees, etc. Arrangement of signal control help to enhance the capacity at roundabout and security, but there exist a big difference for applicable conditions and traffic efficiencies under different signal control methods. The main concern of this text, on the foundation of Left-turn with Two-stop Control Method at Roundabout with consideration of the number of different entrance paths and on the basis of signal control theory and optimal method, is on the four control methods related with "Control of In-turn Discharge Clockwise at Signal-entrance Path", "Control of In-turn Discharge Clockwise at Signal-entrance Path + Interlace of Minor Flow", "Association Roundabout Control at Multi--entrance Path" and "Associated Roundabout Control at Multi--entrance Path + Left-turn Inductive Control". It is on such a basis that the methods analyzing the effect rule on capacity come from the signal period of time and space strategy parameters and radius of island under different signal control methods by applying approaches of numerical calculation and experimental traffic engineering. The research achievement will perfect the theory system for signal control roundabout and provide technical support for the reconstruction of uncontrolled roundabouts as well as selection of signal control methods for roundabouts, meaning significant application value.

INTRODUCTION

Uncontrolled roundabouts have unique features of less conflict points, no stopover and easy means of management, helping to effectively reduce vehicle delays and accident rates under a lower capacity. With increasing demand for island traffics, a series of problems occur for uncontrolled roundabouts, resulting in traffic jams, increased accident rates, more vehicle delays, a greater saturation, etc. From these, researchers from home and abroad have done so much in trying to find relative ways to improve. According to researchers of China, the idea of Control Method for Left-turn with Two-stops for effective signal control at roundabout is put forward, improving capacity of roundabout to the greatest extent. The same as the controlling method of other intersections, the control mode, phase and phase sequence of roundabout signals is quite necessary to be

decided according to practical situation. Applicable conditions and traffic efficiency vary under different control methods. It is on the basis of Control Method for Left-turn with Two-stops at Roundabout that a systematic traffic control method and relevant method for optimized controlling parameters is established as well as that research on the adaptability of all types of controlling methods are made in connection with the internal character of roundabouts and the operating features of such method.

RESEARCH REVIEW

It is divided into two directions of unsignal-controlled roundabouts and controlled roundabouts in the related domestic research. For the research of unsignal-controlled roundabouts, it mainly involves the study of traffic characteristics and its applicable conditions, capacity, delay, safety and geometrical design, etc. in which, for most cases, the capacity and delay of roundabout entrances under different conditions of entrances and loops is calculated by using gap-acceptance model (Yang 2004, Brilon 1997, Flannery 1998, Flannery 2000). Foreign researchers tend to connect safety with a geometric design of roundabouts made under the guidance of safety requirements for vehicles and pedestrians (Flannery 2001, Baranowski 2005, Douglas 2005). In the countries of the States, Australia and Britain, numbers of national regulations have been issued concerning roundabout designs, which have laid a foundation for the study of space related optimal design of signal-controlled roundabouts and evaluation of traffic efficiency.

The study on signal-controlled roundabouts started at a later time and according to designing guidance for roundabouts in the States and Australia, it qualitatively regulates that signal control could be implemented for certain entrances if necessary, stressing that it should be used with great care and should not be used for the purpose of a long-term solution to traffic jam. Baranowski (Baranowski 2005) made a study on the signal control method for roundabout pedestrians, exploring condition and safety of arranging signals for roundabout pedestrians. Akçelik made a study on the limit control of capacity at entrance of roundabouts (Akçelik 2005). We study the relevant research in our country in 1998, which was initially raised by researchers from the engineering department of Tongji University (Xue 2003, Wang 2007). They established basic principle and approach for left-turn with two-stop control at roundabouts and gave it a good study in the way of traffic laws, signal timing methods, applicable conditions, optimization control methods and efficiency evaluations. Mr. Ao Guchang (Ao 2003) put forward signal control method for roundabouts under conditions without straight flow.

Researches from home and abroad focus on the field of non-signal controlled roundabouts, with less time in the study of signal-controlled roundabouts. It needs further research in capacity of signal-controlled

roundabouts, condition of geometric topology, demand for mixed traffic flows and adaptability of signals at roundabouts.

INTRODUCTION TO SIGNAL CONTROL METHOD AT ROUNDABOUT

Control of In-turn Discharge Clockwise at Signal-entrance Path. In this control method, each entrance lane discharge In-turn of clockwise, see Figure 1.

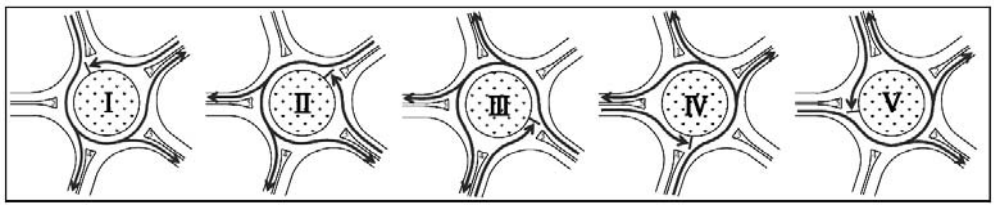

Figure 1. Phase sequence of control of in-turn discharge clockwise at signal-entrance path

This control method could be converted into a one-way closed intersection group (Figure 2). To take the five-fork intersection as an example, it could be regarded as an intersection group made of five intersections of A, B, C, D and E. To select datum point of coordination control, to set the Max delay as optimization target and to choose signal period, phase difference and queuing length as constraint condition, the optimization of other parameters will be carried out.

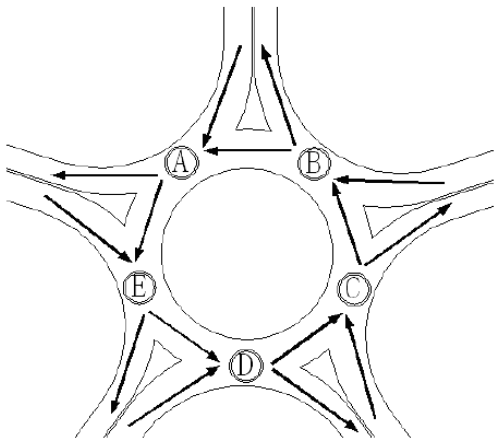

Figure 2. Schematic diagram for one-way closed intersection group of signal controlled intersections

Control of In-turn Discharge Clockwise at Signal-entrance Path + Interlace of Minor Flow. With consideration of order and efficiency of multi-fork roundabout, on the basis of Control of In-turn Discharge Clockwise at Signal-entrance Path, the interlace of secondary traffic flow is introduced (Figure 3), i.e. to treat a main flow and several secondary flows which have the least conflicts between each other as the same phase.

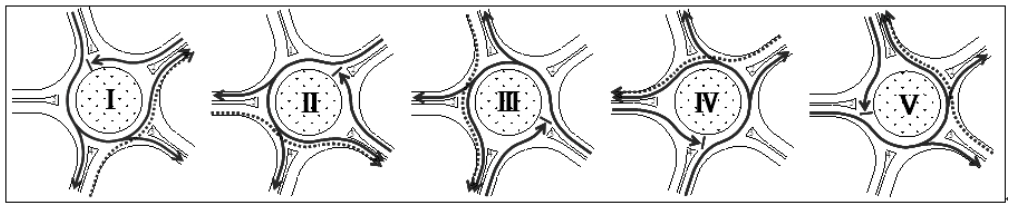

Figure 3. Schematic diagram for Control of In-turn Discharge Clockwise at Signal-entrance Path + the Interlace Phase of Minor Flow

Association Roundabout Control at Multi--entrance Path. Three phases are usually designed for three-fork roundabouts and twice is released within one period at each entrance (Figure 4). Two phases are usually designed for four-fork roundabouts (Figure 5). Twice is released within one period at each entrance of five-fork roundabouts, and release is made clockwise at entrance (Figure 6). Three phases are arranged at for six-fork roundabouts and release is made clockwise at entrance (Figure 7).

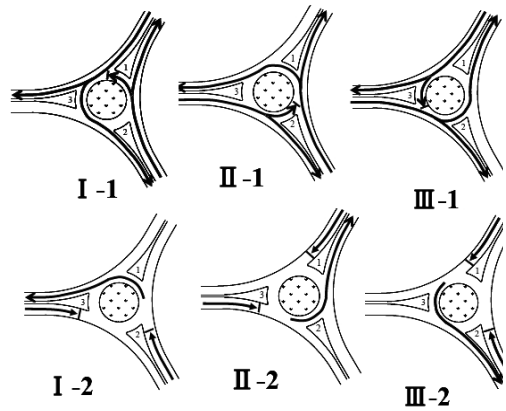

Figure 4. Schematic diagram for three-fork roundabout

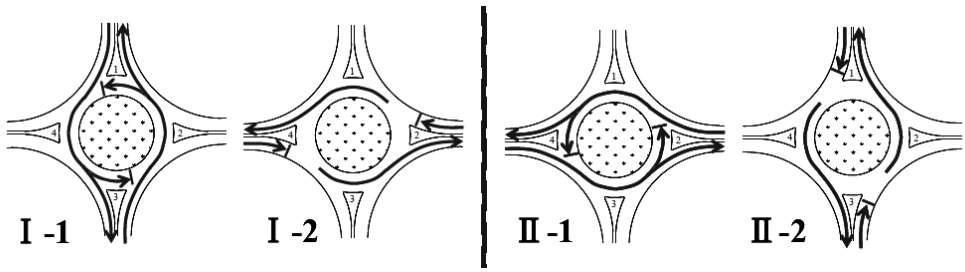

Figure 5. Schematic diagram for four-fork roundabout

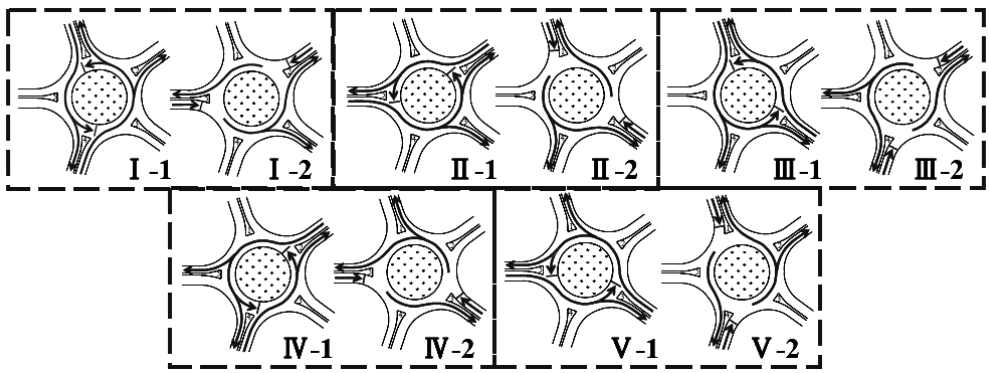

Figure 6. Schematic diagram for five-fork roundabout

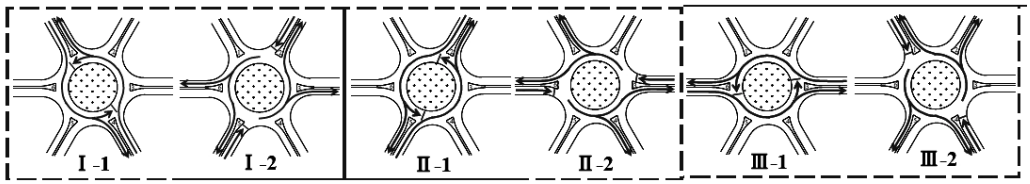

Figure 7. Schematic diagram for six-fork roundabout

Associated Roundabout Control at Multi-entrance Path includes, in two ways, the coordination of entrance signal and loop signal, and then the coordination with loop signal. The optimization model of timing parameters is established under the concept of equisaturation, but the space constraint of loop parking should be realized. When flow ratio between different entrance lanes in the same phase is unbalanced, or queuing vehicles inside the loop go beyond conflict point (or stop line) influencing the normal traffic, it is suggested to take coordination measures of delayed start-up, early disconnection or start-up and late disconnection for green signals of conflict flows.

Associated Roundabout Control at Multi--entrance Path + Left-turn Inductive Control. On the basis of control of association roundabout control at multi--entrance lane, for full utilization of left-turn green time, the arrangement of induction coil at partial positions of roundabout will help both to play function of left-turn capacity at intersection and to prevent occurrence of “deadlocking” to left-turn traffic flow on the loop. In the model of inductive flow, induction coil is arranged before the stop line of the left-turn lane at the entrance and during discharge of the left-turn phase at such entrance when the traffic volume passing the stop line of the entrance lane reach queuing capacity for the left-turn vehicle on the loop, the left-turn green light terminates. When the model of queuing induction is at the rear of the left-turn queuing space of loop, induction coil is arranged in advance at a proper distance, when the queuing position of the left-turn vehicle on the loop is approximately at the queuing capacity on the loop, the related left-turn green light at entrance terminates. (Figure 8, Figure 9)

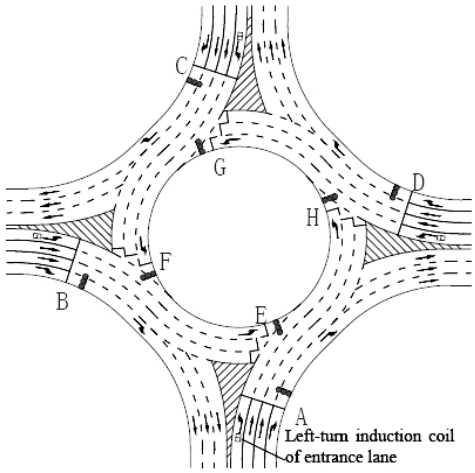

Figure 8. Flow induction control of entrance lane

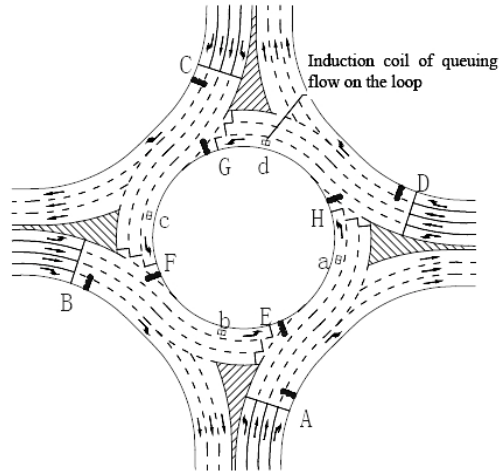

Figure 9. Control of queuing induction on the loop

CALCULATION METHOD FOR SIGNAL-CONTROLLED ROUNDABOUT CAPACITY

Capacity of straight traffic. In circumstances that the requirement for green intervals is met and after the straightforward vehicles go through the first stop line, no obstruction occurs on the loop helping to drive directly into exist lane through the roundabout. We can conclude that the capacity of the straightforward vehicles is the arithmetic product between saturation of straightforward lane and green ratio of signal phase, i.e.:

$$CAP_{iT}=3600\cdot n_{iT}\cdot S_{iT}\cdot \lambda_{iT}=3600\cdot n_{iT}\cdot S_{iT}\cdot (g_{eiT}/C) \quad (1)$$

In which, CAP_{iT} is the straightforward capacity (pcu/h) of No.i entrance, n_{iT} is the number of straightforward lanes at No.i entrance, S_{iT} is the saturation (pcu/s) of straightforward lanes at No.i entrance, λ_{iT} is the straightforward green ratio at No.i entrance, g_{eiT} is the effective straightforward green time (s) at No.i entrance, C is the signal period (s) at intersection.

Capacity of left-turn traffic. The left-turn capacity at signal-controlled roundabouts has a relationship with the way of signal control, at the same time, it is quite necessary to consider the constraint that loop capacity has on the left-turn vehicles for Associated Roundabout Control at Multi-entrance Path.

- Left-turn capacity at the first stop line.

The calculation method for left-turn capacity at the first stop line is similar to the straightforward case, which is equal to the arithmetic product between saturation of left-turn lanes and its green ratio of signal phase, i.e.:

$$CAP_{iL}^{a}=3600\cdot n_{iL}\cdot S_{iL}\cdot \lambda_{iL}=3600\cdot n_{iL}\cdot S_{iL}\cdot (g_{eiL}/C) \quad (2)$$

In which, CAP_{iL}^{a} is the left-turn capacity at the first stop line (pcu/h) of No.i entrance, n_{iL} is number of lanes for left-turn vehicles at No.i entrance, S_{iL} is the saturated flow (pcu/s) of left-turn lane at No.i entrance, λ_{iL} is the left-turn ratio

at No.*i* entrance and g_{eiL} is the effective left-turn green time (s) at No.*i* entrance. Others are the same as above.

- Consideration of restraints of loop capacity to left-turn vehicles.

In the case of symmetry timing, signal lights at the two relative entrances are the same. When the second stop line discharges, the first stop line will definitely cease to discharge. Hence, we can say that in this period, to certain entrances, the Max value of left-turn vehicles which are able to pass through the second stop line is the loop capacity corresponding to such entrance lane. In determining loop capacity, it is necessary to consider the number of lanes queuing on the loop and to guarantee that there will be no conflicts between left-turn tail position of this phase and left-turn head position of opposite phase when discharging.

To take crossing roundabouts as an example, the parking area is divided into two parts, in which the primary parking area is the partial loop way corresponding to the left-turn lane of entrance (Refer to Area 1 of Figure10) while the secondary parking area is the trapezoid space between the safety island of entrance lane and the central island (Refer to Area 2 of Figure10).

Capacity of left-turn vehicles on the loop corresponding to No.i entrance is as following:

$$CAP_{ihL}=\sum_{k=1}^{m}\left[\frac{\alpha_k \cdot R_k}{l_v}\right]+\sum_{k=m+1}^{n}\left[\frac{\beta_k \cdot R_k}{l_v}\right] \quad (3)$$

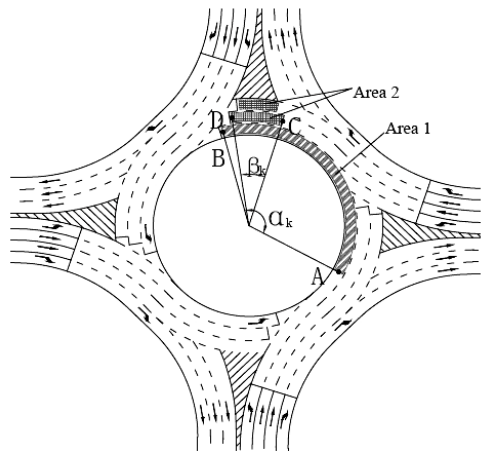

Figure 10. Schematic diagram of waiting area for left-turn vehicle on the loop.

In which, CAP_{ihL} is the capacity (pcu) of left-turn vehicle on the loop corresponding to No.*i* entrance, m is the number of loop way corresponding to left-turn lane of entrance, *n* is the total number of loop way (with exception of right-turn), α_k is the arc radian starting from the conflict point A corresponding to No.*k* loop way counting from inside to outside till the central point B of the second stop line, β_k is the arc radian starting from the conflict point C corresponding to No.*k* loop way counting from inside to outside till the central point D of the second stop line, R_k is radius corresponding to No.*k* loop way counting from inside to outside, l_v is the lane length (m) that a standard vehicle occupies while parking.

With consideration of left-turn capacities restricted by loop capacity:

$$CAP_{iL}{}^{b}=3600\cdot CAP_{ihL}/C \quad (4)$$

In which, $CAP_{iL}{}^{b}$ is the left-turn capacity at No.*i* entrance with consideration of loop capacity (pcu/h). Others are the same as above.

- Determination of left-turn capacity.

For the left-turn capacity of roundabouts under the control of association roundabout control at multi--entrance lane, it should be the lower value of left-turn capacity CAP_{iL}^{a} at the first stop line and left-turn capacity CAP_{iL}^{b} with consideration of capacity constraint on the loop, i.e.:

$$CAP_{iL}=min\{CAP_{iL}^{a}\ ,\ CAP_{iL}^{b}\} \qquad (5)$$

In which, CAP_{iL} is the left-turn capacity (pcu/h) at No.i entrance. Other items keep same as above.

INFLUENCE LAW ON CAPACITY BY TIME-SPACE PARAMETER

Besides the regular conditions of road way and traffics, main factors influencing capacity of signal-controlled roundabouts also include the number of roundabouts, radius of central island, signal period, interval of green time and so on (Wang 2007). The text puts emphasis on associability between radius of central island + signal period and capacity. Radius of central island influences the movement tracks of vehicles, left-turn capacity of the loop as well as on left-turn capacity of intersections. Signal period directly effects the capacity of a roundabout.

Capacity of associated roundabout control at Multi-entrance Path. For the purpose of indicating the influence on capacity by radius of central island and signal period under such control mode, it is necessary to assume that certain parameters are fixed values. Starting from the physical significance of parameters, it is assumed that when the roundabout is a cross orthogonal roundabout, number of entrance lanes, number of loop driveways and number of entrance lanes match. When saturation flow of through lane at entrance is 1650pcu/h and saturation flow of left-turn lane is 1550 pcu/h, they are symmetrically timed.

- Average capacity of straightforward signal lane at entrance CAP_T.

According to above calculation, the change law of average capacity of straightforward signal lane at entrance is as shown in Figure11 when changes with radius of central island and signal period. We get:

1. When radius of the central island R is given, the longer the signal period T is, the larger the CAP_T, similar to the ordinary signal-controlled intersections.

2. When signal period T is given, the larger the radius of the central island, the smaller the CAP_T.

3. When the radius of the central island is a groovy value, to choose the suitable signal period T and the Max value of CAP_T is 550~650 pcu/h.

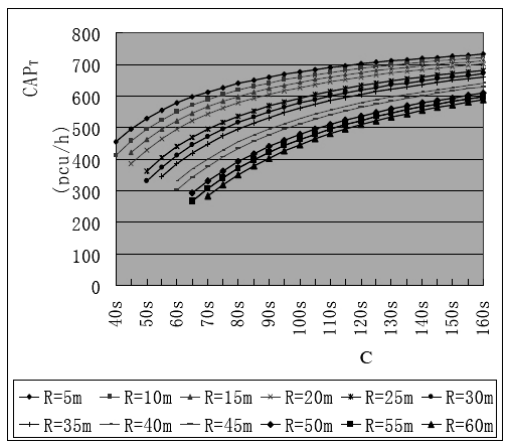

Figure 11. Capacity of straightforward signal lane

- Analysis on average capacity of left-turn signal lane at entrance CAP_L.

Considering capacity constraints of left-turn vehicles on the loop as well as the capacity at the first stop line, the change law of the capacity of the left-turn lane at entrance is as shown in Figure 12 when changes with radius of central island and signal period. We get:

1. When the radius of the central island, R, is given, CAP_L becomes larger in the first hand as the signal period, *T,* increases. When the capacity of left-turn vehicles at the first stop line within one period is larger than the capacity of left-turn vehicles on the loop, CAP_L becomes smaller with the increase of signal period, *T*.

2. When the capacity of left-turn vehicles at the first stop line within one period is smaller than the capacity of left-turn vehicles on the loop and signal period, *T,* is given, the smaller the radius, *R,* of central island is , the bigger the CAP_L is.

3. When the capacity of left-turn vehicles at the first stop line within one period is larger than the capacity of left-turn vehicles on the loop and the signal period, *T,* is given, the larger the radius, *R,* of the central island, the larger the CAP_L.

4. The smaller the radius, *R,* of the central island, the smaller the period length is when reaching the maximum value CAP_{Lmax} of capacity of the left-turn single lane.

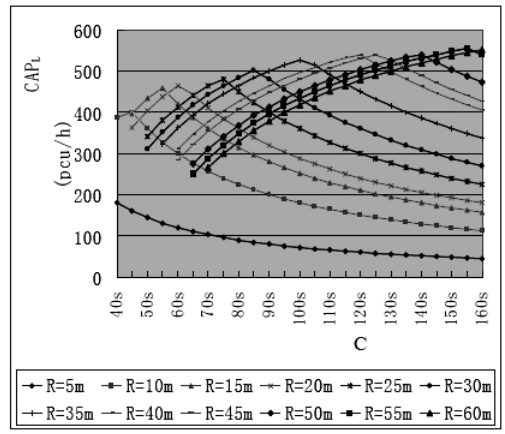

Figure 12. Capacity of left-turn single lane

5. For ordinary radius, *R,* of the central island and proper signal period, *T,* is chosen, the maximum value of CAP_L slightly increases when the radius becomes larger and the maximum value is around 450~550 pcu/h.

- Overall capacity of roundabout.

Change law of specific value of left-turn average capacity at intersections and straightforward single lanes develop when the radius of the central island and signal period change. From Figure 13, we get:

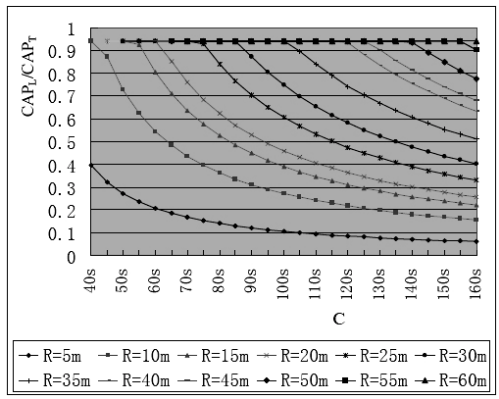

Figure 13. Specific value of capacity for left-turn and straightforward single lane

1. When the capacity of left-turn vehicles at the first stop line within one period is smaller than the capacity of left-turn vehicles on the loop, specific value of average capacity of left-turn and straightforward single lanes do not change with the period.

2. When the capacity of left-turn vehicles at the first stop line within one period is larger than the capacity of left-turn vehicles on the loop, the longer the signal period is at roundabout, the smaller the proportion of left-turn capacity is, which is more suitable to the traffic composition with higher proportion of straightforward traffics.

3. The larger the radius of the central island is, the more suitable is for traffic composition with higher proportion of left-turn traffics.

Change law of overall capacity at intersection (with exception of right turn) develops when the radius of the central island and signal period change. From Figure 14, we can find:

1. The main determinants for the maximum capacity which could be reached at signal-controlled roundabout are the number of entrance lanes and their relative loop number followed by the radius of the central island.

2. The larger the radius is, the more obvious it is for the increased signal period to enhance capacity.

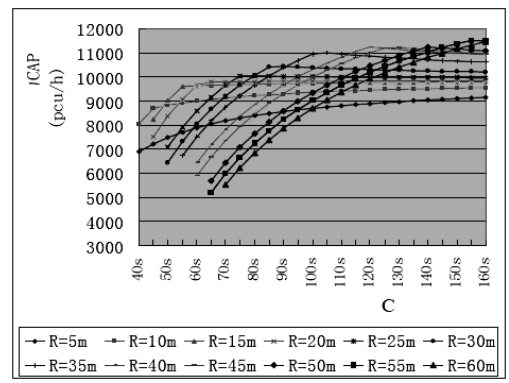

Figure 14. Overall capacity under condition of 3 left and 2 straight at each of entrance

3. The overall capacity is restricted by the left-turn capacity of loop way and when the radius is given, it will reach a higher point with the increase of period. Next, the increase of period influences less on the improvement of capacity, and even some of it will lead to a reduction of the overall capacity because of the larger proportion of the decreased left-turn capacity.

Capacity of control of in-turn discharge clockwise at single entrance lane. For roundabouts with in-turn discharge clockwise at a single entrance lane, when the radius of the central island reaches a certain value, the neighboring phases before and after will have a period of green overlapping time. Change law of overall capacity at intersection develops when radius of central island and signal period change. From Figure 15, we get:

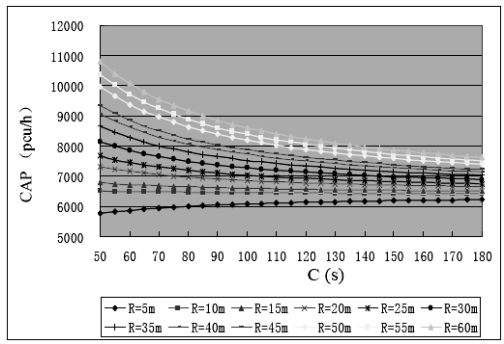

Figure 15. Capacity for discharge signal-controlled intersection at single entrance lane

1. For small-sized roundabouts (usually R<10m) with control of in-turn discharge clockwise at a single entrance lane, capacity slightly increases when the period becomes larger.

2. For small-sized roundabouts (usually R>10m) with control of in-turn discharge clockwise at a single entrance lane, because of existence of green overlapping, capacity decreases when the period becomes larger.

CONCLUSIONS

Arrangement of signal control at roundabouts will help greatly to improve capacity and safety, and applicable condition and traffic efficiency vary according to different ways of controlling. The research in this text intends to put forward four traffic control methods for motor vehicles at signal-controlled roundabouts, to establish models for straightforward and left-turn capacity of signal-controlled roundabouts as well as to analyze the law that signal period of time-space parameters and the radius of the central island influence the capacity of signal-controlled roundabouts under two ways of Control of Association Roundabout Control at Multi--entrance Path and Control of In-turn discharge clockwise at single entrance lane.

Studies have shown that the main determinants for the maximum capacity, which could be reached at signal-controlled roundabouts, are number of entrance lanes and its relative loop number followed by the radius of the central island. When the capacity of control of in-turn discharge clockwise at single entrance lane is adopted, capacity is smaller than that of control of association roundabout control at multi-entrance lane. In the case of a larger central island radius, it has superior adaptability for roundabout with a larger proportion of left-turn flow to that of associated roundabout control at multi-entrance lane. Meanwhile, because of constraints by left-turn waiting capacity on the loop, the capacity and period indicate a non-monotonic correlation, and capacity will be decreased if signal

period is greater than the best period. This research achievement will supply a theoretical foundation for the selection of a signal-controlled method.

ABSTRACT

This paper establishes the relation model of driving-into rate and spacing of service areas. Based on the survey of Beijing-Shenyang expressway in Hebei province and the traffic data of service areas, this paper gets the relationship between spacing and driving-into rate of service areas, verifies that the driving time obeys the normal distribution using the Empirical Distribution Function of Probability and Statistics, then, establishes the Recursive Model of driving-into rate whose random variable is the driving time. The driving time is the function of spacing, so the relationship between spacing and driving-into rate is expressed by the formula. This model clarifies and quantifies the relationship between the driving-into rate and spacing by giving concrete form and makes up for the defects of the present methods. At the end, the two examples prove the applicability and advantage of new model.

KEYWORDS: expressway, service area, driving-into rate, model

INTRODUCTION

The driving-into rate (DR) of service area is the rate that the number of vehicles (NV) entering into the expressway service area (vehicles / day) accounts for the main line traffic volume of the highway (vehicles / day), which is the prerequisite for planning and designing service area district and directly determines the scale and operation of the service area (ITP 2004). The driving-into rate is affected by people's physiology and psychology, vehicle performance, traffic conditions, the spacing of service area and so on (Shaolan Guan et al.1995). Especially, the service area spacing which has great impacts on the driving-into rate (MCPRC 2004) can not be ignored. Nowadays, the recommended fixed value in Chinese existing norms can not reflect changes of the above-mentioned factors which are not applicable in some areas.

In addition, the current research about the driving-into rate does not explain the real relationship between service area spacing and the driving-into rate (**Huarong** Qin et al. 2005). For example, (Jinzhang Ji et al. 2006), in "Empirical Research on Computing Model of the Service Area Scale" the calculation model of the driving-into rate is $T = KA/3V$. T is the driving-into rate, A is average spacing of service area, and V is the average speed of different types of vehicles.

This model, having a simple linear relationship, has some defects. Firstly, K, determined by experience value, will make the driving-into rate deviate from the actual value. Secondly, the spacing which is different from a dozen or so *km* to

hundred *km* in a large region in actual is an average value in the formula. Thirdly, it is the most important that the driving-into rate is fixed when the spacing is made certain, but this is inconsistent with the actual.

Based on the current studies, combining with the investigation of Beijing-Shenyang Expressway Service Areas, we study the probability distribution of traffic time, find out the nature relationship between the driving-into rate and service area spacing, and establish the new model to calculate the driving-into rate. This model that rationally explains the relationship between the driving-into rate and service area spacing fetches up the disadvantages of current methods.

MODEL BUILDING ON THE RELATIONSHIP BETWEEN DRIVING-INTO RATE AND SERVICE AREA SPACING

Driving-into rate study of service areas of Beijing-Shenyang expressway

This investigation on five service areas of the Beijing-Shenyang expressway as the survey spots was made on June 2, 2007, containing infrastructure, traffic flow, the service areas, user information and so on. The data divided by driving time (DT) are classified into three kinds: trucks (T), large and medium-sized passenger cars (L) and small passenger cars(S). Firstly, we adapt the two types of data-----passenger cars (PC) and trucks. See Table 1:

Table 1. The Relationship Between Driving-into Rate and Driving Time

DT	NV		DT	NV		DT	NV		DT	NV	
	T	PC		T	PC		T	PC		T	PC
00:15	0	2	02:45	11	23	05:15	4	1	07:45	1	1
00:30	1	3	03:00	11	18	05:30	2	1	08:00	1	0
00:45	2	6	03:15	15	7	05:45	2	2	08:15	1	0
01:00	2	5	03:30	13	5	06:00	2	2	08:30	0	0
01:15	3	8	03:45	13	3	06:15	1	1	08:45	0	0
01:30	3	16	04:00	12	3	06:30	2	1	09:00	1	0
01:45	4	29	04:15	6	2	06:45	1	0	09:15	0	0
02:00	5	34	04:30	4	1	07:00	1	0	09:30	0	0
02:15	6	31	04:45	5	2	07:15	0	1	09:45	1	0
02:30	8	26	05:00	3	1	07:30	1	0	10:00	0	0
Total										148	219

The investigation shows that driving time has affection on the vehicle number. For better analysis, we take the data from Table 1 into legend (see Figure 1).

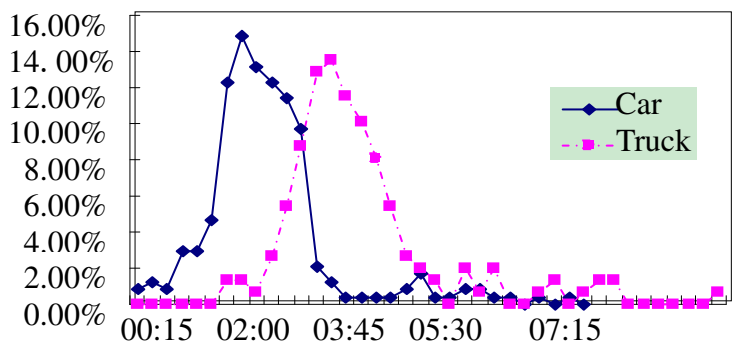

Figure 1. The Change of Vehicle Driving-into Rate Along the Driving Time

From the legend we know that there is the certain specific relationship between driving-into rate and driving time. The figure is similar to the graph of the normal distribution which has much good nature and is easy to conduct in-depth theoretical studies comparing with a common distribution. The following study will give actual form of the particular relationship.

Data Analysis

Analyzing the Figure 1, we suppose that the driving-into rate obeys the normal distribution $\xi - N(\mu,\sigma^2)$, hereinto, μ,σ are unknown parameters. χ^2 is satisfied with the Gaussian fitting test. The maximum likelihood estimator of $\hat{\mu}$ and $\hat{\sigma}$ represent μ and σ. According the Figure 1, the results are:

$$\hat{\mu} = \frac{1}{148}\sum_{i=1}^{148} x_i = \frac{31095}{148} = 210.1014,\quad \hat{\sigma} = \sqrt{\frac{1}{148}\sum_{i=1}^{148}(x_i - \bar{x})^2} = 94.10401.$$

Come to the conclusion that the χ^2 observation is $\chi^2 = 20.11141$. There are two unknowns that need to be estimated by the maximum likelihood estimates, so $l = 2$. When H_0 is true, χ^2 obeys $\chi^2(15-2-1)$. Since the significance level is $\alpha = 0.05$, the result is $\chi^2_{0.05}(13) = 22.362$. $\chi^2 = 20.11141 < 22.362$, so accept H_0; namely, the driving-into rate obeys the normal distribution means that driving time obeys the normal distribution under the condition that the significance level is $\alpha = 0.05$.

Similarly, for large and medium-sized passenger cars and small passenger cars, driving-into rate obeys the normal distribution under the condition that the significance level is $\alpha = 0.05$. After analyzing and calculating we gain:

The nonstop driving time of small passenger cars obeys $\xi - N(147.9918,\ 100.1667)$

The nonstop driving time of large and medium passenger cars obeys $\xi - N(148.9286,\ 69.5438)$

The nonstop driving time of trucks obeys $\xi - N(210.1014,\ 94.1014)$.

The above analysis shows that the driving time and driving-into rate basically obey the normal distribution. There is a fixed relationship between the driving time and driving-into rate that do not happen by chance. The reasons: firstly, the time of the vehicles can run before driving into the service area has great relationship with vehicle type and nature; secondly, physiological demand of drivers and passengers has some influence on the driving-into rate; thirdly, the road conditions also can affect the driving-into rate to some extent. Those reasons result in the fixed relationship between the driving time and driving-into rate. Building the calculating model for driving-into rate can provide a foundation for confirming the service area scale and spacing reasonably.

Model Derivation

Suppose: the traffic flow between origin r and destination s is T_{rs}, the distance from other service areas to origin r is L_i, there are n service areas between r and s. $(L_i / v - \mu)/\sigma = t_i$, μ is average value, v is vehicle driving speed, σ is variance, $\phi(t)$ is the function of Standard Normal Distribution.

Following:

The driving-into rate of the first service area is: $P_1 = \phi(t_1)$ (1)

The driving-into rate of the second service area is: $P_2 = (1-P_1)\phi(t_2) + P_1\phi(t_2 - t_1)$ (2)

Where: $P_1\phi(t_2 - t_1)$ is the probability that the vehicle drives into both the first and the second service area; $(1-P_1)\phi(t_2 - t_1)$ is the probability that the vehicle drives into the second but not into the first.

The driving-into rate of the third service area is:

$$P_3 = (1-P_1)(1-P_2)\phi(t_3) + (1-P_1)P_2\phi(t_3 - t_2) + (1-P_2)P_1\phi(t_3 - t_1) + P_1P_2\phi(t_3 - t_2) \quad (3)$$

Where: $(1-P_1)(1-P_2)\phi(t_3)$ is the probability that the vehicle draws into the third but not into the first and second; $(1-P_1)P_2\phi(t_3 - t_2)$, $(1-P_2)P_1\phi(t_3 - t_2)$ are the probability that the vehicle draws into both one or other in the middle and the third; $P_1 P_2 \phi(t_3 - t_2)$ is the probability that the vehicle drives into all service areas of the three.

To simplify the P_3:

$$P_3 = P_1(1-P_2)\phi(t_3 - t_1) + P_2\phi(t_3 - t_2) - P_1P_2\phi(t_3 - t_2) \quad (4)$$

Similarly, we can gain:

$$P_4 = P_1(1-P_2)(1-P_3)\phi(t_4 - t_1) + P_2(1-P_3)\phi(t_4 - t_2) + P_3(1-P_2)(1-P_1)\phi(t_4 - t_3) + (1-P_3)P_1P_2\phi(t_4) \quad (5)$$

$$P_5 = P_1(1-P_2)(1-P_3)(1-P_4)\phi(t_5 - t_1) + P_2(1-P_3)(1-P_4)\phi(t_5 - t_2) + P_3(1-P_4)(1-P_2)(1-P_1)\phi(t_5 - t_3) + P_4\phi(t_5 - t_4) + (1-P_1)(1-P_2)(1-P_3)(1-P_4)\phi(t_5) \quad (6)$$

Observing the structure of the formula P_i, we find the recursive formula, namely the driving-into rate of the N th service area is:

$$P_N = \sum_{i=1}^{N-1} P_i \prod_{j=i+1}^{N-1}(1-P_j)\phi(t_N - t_i) + \prod_{k=1}^{N-1}(1-P_k)\phi(t_N) \quad (7)$$

Analyzing the P_N: P_N has $N-i+1$ total factors, in the total factors of $\sum_{i=1}^{N-1} P_i \prod_{j=i+1}^{N-1}(1-P_j)\phi(t_N - t_i)$ the i th has $(N-i+1)$ multiple multiplication factors.

Between origin r and destination s the volume of a certain type of vehicles driving into various service areas is:

$$Q_N^{rs} = T_{rs} \cdot P_N^{rs} \quad (8)$$

Therefore, in highway design, as long as we predict the traffic distribution (OD Matrix) of the expressway service district, the total vehicle of each service area can be worked out by this formula, and then the driving-into rate of service area can be identified.

$$Q_N = \sum_r Q_N^{rs} = \sum_r T_{rs} \cdot P_N^{rs} \quad (9)$$

$$\alpha_N = \frac{Q_N}{A_N} = \frac{\sum_r T_{rs} \cdot P_N^{rs}}{A_N} \quad (10)$$

Where: Q_N is the volume of vehicles driving into the service area N; Q_N^{rs} is the volume of vehicles driving into the service area N between origin r and destination s; P_N^{rs} is the probability that vehicles drive into the service area N between origin r and destination s; α_N is the driving-into rate of the service area N; A_N is the main line traffic volume in the cross-section where the service area N locates.

MODEL ANALYSES

Model Application

Example 1: On the assumption that there are five service areas at a certain section of expressway, as shown: *R* is a city, *S* is another, 1, 2, 3, 4, 5 are separately on behalf of the five service areas. From R to 5, the distance between adjacent two points are 30 *km*, 80 *km*, 60 *km*, 50 *km*, and 40 *km*. There is a traffic flow from *R* to *S*; hereinto, there are 1000 small passenger cars, 500 large and middle passenger cars, and 800 trucks. Now calculate the volume of vehicle drawing into every service area. In reference to relevant information about the speed of a variety of cars, assume the average speeds of three kinds of vehicles are 110 *km/h*, 90 *km/h*, 70 *km/h*. The layout of the service area is shown in Figure 2:

Figure 2. Arrangement of Service Facilities between R and S

Analysis: Via the above-mentioned proof we know that the vehicle driving-into rate obeys the normal distribution. The mean and variances of the vehicles in three types are: Small passenger car: $\mu = 147.9918$, $\sigma = 100.1667$, Large and middle passenger car: $\mu = 148.9286$, $\sigma = 69.54389$, Truck: $\mu = 210.1014$, $\sigma = 94.1014$.

Using formulas (7) and (8), we gain the vehicle driving-into rate in each service area and the volume of vehicle driving into the certain service area shown in Table 2.

Table 2. The Driving-into Number and Driving-into Rate of Service Area

Type	Probability	P_1	P_2	P_3	P_4	P_5	P_T
S	DR	9.44%	18.60%	25.27%	28.82%	29.38%	111.80%
	NV	94	186	256	288	294	1118
L	DR	3.18%	13.67%	27.04%	33.13%	31.57%	108.62%
	NV	16	68	135	166	158	543
T	DR	2.50%	10.81%	22.84%	29.78%	30.07%	96.00%
	NV	20	87	183	238	241	768

As Table 3 shows: $P_1, \cdots, P_5$ is the driving-into rate of service areas, P_T is total probability that vehicle drives into the service areas. It also contains the number of different kinds of vehicles that drive into the service areas. Following is the same.

Example 2: Change the spacing of the service areas, as shown: the distance from *R* to 1 is 30 *km*, the distances between 1 and 2, 2 and 3, 4 and 5, 5 and *S* are all 30 *km*; the distance between 3 and 4 is 100 *km*. Now calculate the volume of vehicle driving into every service area. Others are the same as example 1. The

layout of the service area is shown in Figure 3:

Figure 3. Arrangement of Service Facilities Between R and S After Changing the Distance

Analysis: The calculation process is the same as the example 1 and shown in Table 3.

Table 3. The Driving-into Number and Driving-into Rate After Changing the Distance

Type	Probability	P_1	P_2	P_3	P_4	P_5	P_T
S	DR	9.44%	12.20%	15.04%	30.06%	27.93%	94.68%
	VM	94	122	150	301	279	947
L	DR	3.18%	5.78%	9.77%	34.68%	30.55%	83.97%
	VM	16	29	49	178	153	425
T	DR	2.50%	4.54%	7.85%	28.23%	17.95%	71.06%
	VM	20	36	63	226	224	569

Result Analysis

The two examples show the changes of the driving-into rate of service areas in the condition that the spacing and number of service areas are changing. Table 3 shows that the distances between 1 and 2, 2 and 3, 4 and 5, 5 and *S* are the same, but the driving-into rate of each service area is different and is increasing with the increase of the distance from the origin.

A specific relationship exists between driving-into rate and travel distance of the vehicle. As Table 2 shows, in a certain travel distance, the driving-into rate of vehicle increases with the increase of the travel distance. The present methods which have the consistent driving-into rate following the consistent spacing have disadvantage, and ignore the influence of accumulated traveling distance of vehicles.

The driving-into rate is becoming steady with the accretion of the spacing. As Table 2 and Table 3 show, the driving-into rate reaches a steady value when the vehicle arrives at the fourth service area.

CONCLUSIONS

The driving-into rate is a decisive factor of the service area design. This paper studies the driving-into rate on support of substantial survey data in detail. Firstly, data is collated by the form of charts by which this paper analyzes the relationship of driving time and driving-into rate and verifies that the driving time obeys the normal distribution. Secondly, it is the emphasis that this paper deduces the recurrence formula of driving-into rate whose random variable is the driving time. This model clarifies and quantifies the relationship of the driving-into rate and spacing by giving concrete form, and makes up for the defects of the present methods. It is a breakthrough that the driving-into rate of each service area can be calculated in practical applications as long as the origin-destination trip matrix is obtained.

ABSTRACT

The operational status of road networks in snowy conditions is quite different from that in general conditions, especially in the process of traffic assignment. Traffic assignment in snowy conditions of different snowfall degrees is studied in this paper, and the impedance function is modified by amending the three following parameters: time, speed and capacity.

In snowy conditions, speed is modified by considering the change of road surface friction coefficient. The minimum safe headway is taken into consideration in the modification of capacity, and the modification of time is obtained by simulation. Based on the new impedance function and equilibrium assignment model, the traffic in the road network are assigned in the snowy conditions of different snowfall degrees. An example was also cited to prove that the algorithm is feasible. By comparing the assignment results in the general conditions and snowy conditions of different snowfall degrees in the example, changes of characteristic indexes of road networks like average travel speed and traffic flow in all grade of roads are given. The changing trend of the indexes is also presented. At last, some suggestions are put forward on the value of reserve capacity to enhance the environmental adaptability of road networks in snowy conditions.

Key words snowy conditions, impedance function, traffic assignment, adaptability of road network

INTRODUCTION

In snowy conditions, traffic demand would not change obviously in a short time, but the operational status of road network changes. Since speed, time and capacity all change, the traffic volume assigned in the road network also changes. At present, the research abroad about urban roads in snowy conditions mainly concentrates on traffic signal timing and analysis of delay, such as the timing programs of SIGNAL85 and TRANSYT-7F(Bernardin et al., 1995) proposed by Bernardin and others. The domestic research mainly concentrates on the aspects of

traffic security management. There is currently little research on the dynamic characteristics of road networks in snowy conditions at home and abroad. In this paper, the process of the modification of speed, time, and capacity is given in snowy conditions of different snowfall degrees, and a new impedance function can be obtained based on the three modified parameters. It assigns traffic with the new impedance function, and then compares and analyzes the dynamic characteristics of road network by the traffic assignment results in general and the snowy conditions of the two snowfall degrees. A calculation example is showed in the second part. From the example, the theoretical results are tested and applied, and the changing range of road network indexes in snowy conditions can be obtained.

THEORETICAL ANALYSIS

In snowy conditions, the changes of operational characteristics of traffic flow and capacity of road sections are caused by the changes of road conditions. In the process of traffic assignment, the impedance of road sections affects people's route choice very much. Therefore, the three parameters of time, speed and capacity in snowy conditions are discussed and modified by establishing models. By combining the three modified parameters to set up the model, the new impedance function can be obtained.

The modification of speed in snowy conditions . The free-flow traveling time is achieved when the road section's saturation is very low and the vehicles run with free-flow speed. In this case, vehicles would not affect each other and run with the maximum speed. In this state, the running speed of vehicles could be considered to be mainly determined by the motive performance of vehicles and the road conditions.

When a car runs, adhesive conditions between the tires and ground surface must be satisfied, namely

$$p_t \le Z_\varphi \varphi \qquad (1)$$

Where Z_φ is the pressure between the driving wheel and the ground surface; φ is the adhesive coefficient between tires and ground surface.

From the formula, it can be known that the maximum value of traction force is $P_{t\max} = Z_\varphi \varphi$, at this time, vehicles get the maximum running speed, i.e. the free-flow speed. Under this state, there is:

$$Z_\varphi \varphi = Ggf + Ggi + C\rho AV^2 \qquad (2)$$

Where G is the car body weight; g is the acceleration of gravity; f the is rolling resistance; i is the road gradient; C is the car streamlined coefficient; ρ is the air density; A is the cars' windward area; V is the cars' running speed.

It can be known from vehicles structure:

$$Z_\varphi = Gg\left(d + h_g i\right)/L \qquad (3)$$

Where d is the distance from the car's center of gravity to driven shaft; h_g is the height of car center of gravity; L is the wheel base.

It can be known from formula (2) that the maximum speed that a vehicle can reach is determined by car weight and the adhesive coefficient between the tires and the ground surface. Under the snowy conditions, the adhesive coefficient

between the tires and the ground surface decreases, and the maximum traction force that a car can obtain decreases as well (Erwin R Boer1999; Daniel Isenberg, 2004). Meanwhile, the ratio of the free-flow speed in the two different conditions can be calculated from formula (2) and formula (3):

$$\frac{V_s}{V}=\left(\frac{\frac{d+h_g i}{L}\varphi_s - f_s - i}{\frac{d+h_g i}{L}\varphi - f - i}\right)^{1/2} \qquad (4)$$

Take the structural parameters of a certain type of HYUNDAI ELANTRA as an example. Its wheel base is 2.65m, the height of car's center of gravity is 0.4m and the distance from car's center of gravity to its moving shaft is 1.05m. In general conditions, the road adhesive coefficient $\varphi = 0.5$ and the rolling resistance $f = 0.02$. If no management measure is taken in snowy conditions of the two different snowfall degrees, the values of φ_s in different grades of roads are as the following table shows (Sandeep Datla and Satish Sharma 2007). Rolling resistance $f_s = 0.03$. In the design of urban roads, it is demanded to guarantee the minimum slope of road $i = 0.3\%$ in order to meet the requirements of water drainage. Substitute all the data into the formula (4), and then V_S / V is obtained in the two conditions (Lynette C. Goodwin and Mitretek Systems, Inc, 2002).

Table 1. The values of φ_s and V_S/V in snowy conditions

Road grade	φ_s		V_S/V (%)	
	Severe degree	Slight degree	Severe degree	Slight degree
Expressway	0.45	0.4	91.1	84.7
Main trunk road	0.4	0.35	84.7	77.7
Secondary trunk road	0.35	0.3	77.7	70.0
Branch road	0.3	0.2	70.0	51.4

The modification of capacity in snowy conditions . When traffic flow runs incessantly with the speed V and the vehicles keep the minimum longitudinal distance "safe headway" L, the number of passing vehicles reaches the maximum volume. Thus the ideal capacity is:

$$C = S/L = 1000V/L \text{ (pcu/h)} \qquad (5)$$

Where S is vehicle's driving distance per hour; L is safe space headway.

In the usual case, "safe space headway" includes the following four items:

he driving distance of vehicle in the driver's reaction time $L_1 = \frac{Vt}{3.6}$ (t=2.5s) ;,Vehicle's braking distance $L_2 = \frac{V^2}{254\varphi}$ (φ is the frictional factor between wheels and the ground surface), Vehicle's body length L_3 (generally take 5~10m), and Safe distance L_4 (generally take 3~5m).

Thereby, formula (5) can be rewritten as

$$C = \frac{1000V}{Vt/3.6 + V^2/254\varphi + L_3 + L_4} \quad (6)$$

It can be known from formula (6) that capacity can be regarded as a function between speed V and frictional coefficient φ. The higher the value of φ gets, the lower the value of braking distance L_2 will be. Thus, under the condition of the same speed, vehicles traveling with a higher value of φ can reduce the "safe space headway", so a higher value of capacity can be got. However, in the snowy conditions, the value of φ decreases significantly, which inevitably leads to the reduction of capacity.

When driving on the snowy roads, the driver had to keep a minimum distance from the car in front for the sake of safety. Therefore, study the relationship between headway L and speed V, select the frictional coefficient of the two kinds of ground surface and get the theoretical equation of the capacity in the two conditions:

$$C_s / C = \left(\frac{1000V_s}{V_s t/3.6 + V_s^2/254\varphi_s + L_3 + L_4} \right) / \left(\frac{1000V}{Vt/3.6 + V^2/254\varphi + L_3 + L_4} \right) \quad (7)$$

Judging from the above analysis, it can be seen that capacity reduces dramatically in snowy conditions and is greatly affected by the change of speed.

The modification of time in snowy conditions. Due to the change of capacity and the free-flow speed in snowy conditions, t_{0S} can't be expressed by L/V_S, it should accordingly be modified. Simulate the traffic operational characteristics in the typical road network in snowy conditions of the two different snowfall degrees by grey box theory. And then, according to the simulation results, deduce the linear functional relationship between the three modified parameters t_{0S}, L and V in different grades of roads. The mathematical models are as follows:

Table 2.The values of t_{0S} in snowy conditions

Grades of Road	$t_{0S} = f(L, V_S)$	
	Severe degree	Slight degree
Main trunk road	$t_{0S} = 1.084L/V_S$	$t_{0S} = 1.105L/V_S$
Secondary trunk road	$t_{0S} = 1.121L/V_S$	$t_{0S} = 1.162L/V_S$
Branch road	$t_{0S} = 1.176L/V_S$	$t_{0S} = 1.257L/V_S$

The impedance function in snowy conditions. Substitute the modified traveling time and speed as well as capacity into impedance function. Then, it is possible to obtain the impedance function in snowy conditions. Its expression is as follows:

$$t_s(q) = \eta t_{0S}\left[1 + \alpha(q/C_s)^{\beta}\right] \quad (8)$$

Where t_{0S} is the free-flow traveling time in snowy conditions; C_s is the capacity of road sections in snowy conditions; α, β are regression coefficients; η is the modified parameter of visibility in snowy condition.

The new impedance function in snowy conditions is simple and is easy to compute iteratively. What's more, the new impedance function can combine the computer technique Optional Input to establish the model. With the established model, traffic assignment in snowy condition would be realized.

ANALYSIS OF EXAMPLES

The sketch map of the road networks from the calculation example is shown in Figure 1; it is used to simulate the actual road network. The simulation of traffic demand is in the peak period. The road grade is divided into 3 parts: main trunk road, secondary trunk road, and branch road. The divisions of traffic zones and OD quantity are known. Based on the new impedance function after modification and stochastic user equilibrium, do traffic assignment in the road network of this calculation example in general and snowy conditions. Then the assignment results can be obtained in both conditions.

Compared with the traffic volume assigned in general conditions, it can be concluded that there are indeed changes when the traffic is assigned in snowy conditions. The related indexes of the assignment results are listed in Table 3 and 4.

It can be seen from Table 3 and Table 4, that when compared with general conditions, the trends of changes in both slight and severe snowfall conditions are the same, but the degree of changes in snowy conditions of severe snowfall is more strenuous. So, Table 3 is analyzed in that case. The value of $C \bullet L$ declines in snowy conditions. It means that the road service level decreases accordingly. Meanwhile, the average traveling speed in each grade of road slows down greatly, with 44.9% decline in main trunk roads, 49% decline in secondary trunk roads, and 57.6% decline in branch roads. The traffic volume in each grade of road doesn't follow the graded changing law, with 6.9% increase in main trunk roads, 1.2% increase in secondary trunk roads, but with 31.4% decrease in branch roads. The number of road sections reaching their saturation points appears to be in the increasing trend. The saturation degree in main and secondary trunk roads rises obviously, but it doesn't rise in branch roads. This is because the traffic volume in branch roads decreases as the branch road's capacity declines.

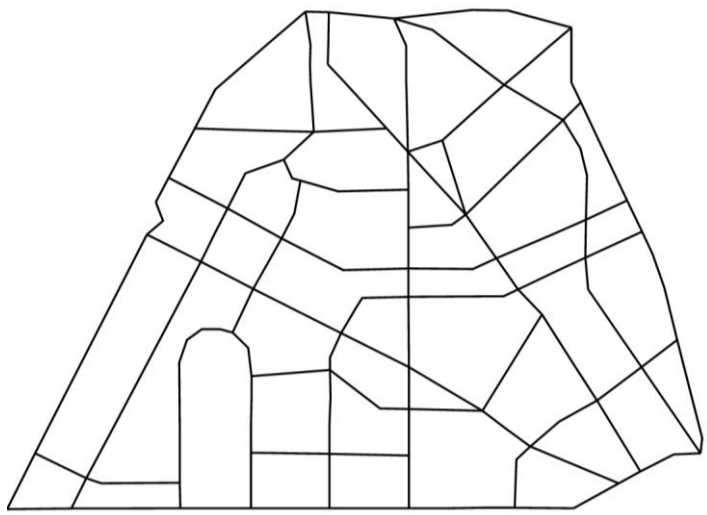

Figure1. The sketch map of the road network of the calculation example

Table 3. Indexes of assignment results in general conditions and slight

snowfall conditions

Road grade	C • L (puc • km/h)		The average traveling speed of road sections (km/h)		Traffic flow in each grade of roads (pcu/h)		The number of road sections reaching its saturation point	
	snowy	general	snowy	general	snowy	general	snowy	general
Main trunk road	41548	43936	12.1	16.7	311925	307995	44	38
Secondary trunk road	36982	39394	14.7	20.0	185374	184564	18	15
Branch road	9541	11165	10.5	17.2	33514	41014	7	7

Table 4. Indexes of assignment results in general conditions and severe snowfall conditions

Road grade	C • L (puc • km/h)		The average traveling speed of road sections (km/h)		Traffic flow in each grade of roads (pcu/h)		The number of road sections reaching its saturation point	
	snowy	general	snowy	general	snowy	general	snowy	general
Main trunk road	40502	43936	9.2	16.7	329368	307995	47	38
Secondary trunk road	34615	39394	10.2	20.0	186699	184564	21	15
Branch road	8351	11165	7.3	17.2	28135	41014	7	7

CONCLUSION

Judging from the theoretical analysis and the results of traffic assignment in the analysis of the calculation example in snowy conditions, it is concluded that the whole service level of the road network decreases. What's more, the average

traveling speed in each grade of roads also slows down, and it is in a way of decreasing by the order of branch roads, secondary trunk roads and main trunk roads. At the same time, the traffic flow also changes in each grade of road in the road network. It increases in both main and secondary trunk roads. The traffic flow has a great degree of increase in the main trunk roads but a sharp decrease in branch roads. In order to enhance the environmental adaptability of the road network, compared with the operational characteristics in general conditions, it is advised to reserve 10% capacity of the road network in main trunk roads and reserve 5% capacity in secondary trunk roads in snowy conditions. The values are obtained according to the analysis of the assignment results in the calculation examples. Thus doing, it can relieve the traffic pressure of the road network in special conditions, especially in snowy conditions, and it can also improve the environmental adaptability of the road network.

ABSTRACT

The Cowan M3 distribution and its parameters are discussed based on four years of data observed from three approaches to the Xueyuan roundabout in Dalian to explore the suitability of the Cowan M3 distribution model. Already widely used around the world for capacity and performance analysis of roundabouts, the Cowan M3 distribution is explored to see if it correctly models the Xueyuan roundabout. By means of the goodness-of-fit test, it is concluded that the Cowan M3 distribution could be applied to the Xueyuan roundabout to analyze the headway of the traffic flow there. The minimum headway is between 0.38 seconds and 0.88 seconds, according to the observed data. As a result of vehicles experiencing free driving and a flow sharing priority, this 0.38s lower headway is observed and a higher proportion of free driving vehicles results when using the method of moments. There is a linear relationship between the proportion of free vehicles and the traffic volume. The results of this study are helpful in that they allow us to analyze the capacity and performance of the Xueyuan roundabout in Dalian.

Key words: roundabout, headway, the headway distribution, Cowan M3 distribution

INTRODUCTION

Headway is used to analyze traffic characteristics, capacity and performance for the roundabout. While analyzing the traffic characteristics, the distribution of the headway and of the special headway, the critical gap, can show information about vehicle arrival, vehicle lane changing, and how the traffic is moving. Also, when using the accept-gap theory in the capacity analysis of the roundabout, the distribution of the headway plays an important role. When analyzing performance, the distribution of the headway can be used to discuss delay. It is important to study how the traffic flow moves since a traffic jam affects roundabouts during peak volume times. This can hopefully have a positive

impact on roundabout operation and design.

A simple distribution, such as the negative exponential, has some disadvantages when trying to model the sharp peak and the long tail of the sample headway distribution. Instead, a composite distribution, like Cowan M3, is widely used for capacity and performance analysis of a roundabout like the Xueyuan. In this case, Cowan M3 is widely studied around the world.

The Cowan M3 distribution is the third of four distribution models (Cowan 1975). Akcelik, Hagring, and Troutbeck etc. researched the parameters of the Cowan M3 for an uncontrolled intersection and for roundabouts, and found that the τ parameter varied between 0.5 and 2.5s (Akcelik 1994, Hagring 1998). They also researched the relationship between the proportion of free vehicles (α) and the traffic flow ratio (q or τq), and found that there existed a linear or exponential relationship (Akcelik 1994, Tanyel and Yayla 2003). Hagring discussed the distributions for a simultaneous two-lane model, a superposed two-lane mode, and for a one-lane mode (Hagring 1998). Hagring also tested three methods for the estimation of parameters in the Cowan M3 distribution in a roundabout (Hagring 2002). Tanyel and Yayla discussed the parameters of the Cowan M3 distribution for Turkey and obtained a higher α because of the driver behavior experienced (Tanyel and Yayla 2003). In China, the Cowan M3 distribution, without being tested, was used to discuss the capacity of the roundabout in a recent year.

COWAN M3 DISTRIBUTION AND ANALYSIS METHODS

According to the studies of Cowan (1975), the Cowan M3 headway distribution model can be used in traffic engineering studies:

$$\text{Cowan M3:} \quad F(t) = \begin{cases} 0, t < 0 \\ 1 - \alpha e^{-\lambda(t-\tau)}, t \geq 0 \end{cases} \tag{1}$$

Where: λ is the decay constant
τ is the minimum headway between bunched vehicles
α the proportion of free vehicles.

The Cowan M3 distribution model is widely used in the capacity analysis of intersections without traffic signals. In this study, the Cowan M3 distribution and its parameters are applied to analyze the headway of traffic flow in the Xueyuan roundabout.

In order to determine the parameters of the Cowan M3 distribution, three different methods can be used: the method of moments, the maximum likelihood method, and the least squares method. Hagring stated that these methods normally provide reliable results and that they are quite easy to implement (Hagring 2002). Luttinen stated that the method of moments is an effective parameter estimation method and that it gives good results for α and λ, but that it should not be used to estimate τ (Luttinen 1999). Luttinen and Akcelik both stated that to choose a constant value for τ may be appropriate and that different τ values should be

determined for different traffic conditions (Luttinen 1999 and Akcelik 1994).

In this study, the method of moments is used in determining the parameters α and λ of the Cowan M3 distribution based on the observed τ. The following formula was used:

$$E(H) = \alpha(\tau + \frac{1}{\lambda}) \tag{2}$$

$$Var(H) = \frac{1}{\lambda^2} + (\tau + \frac{1}{\lambda})^2(\alpha - \alpha^2) \tag{3}$$

FIELD DATA COLLECTION

Field and Time. Data was collected for four years from the Xueyuan roundabout in Dalian, China. This intersection is one terminal of the Zhongshan road, the beginning of a highly technical district, and the unavoidable road to Lushun from the south (see Figure 1). As the highly technical and the Lushun districts continue to develop, the traffic flows of the three approaches of the Xueyuan roundabout is increasing every year. Traffic jams occur during peak traffic times more and more.

Observations are made by using video cameras positioned at a high building near the roundabout intersection where the view is adequate for observation. At least one hour of recordings are produced during the morning rush hour in May each year and the data is extracted from the recordings at the office.

Data Collection. At each intersection circle and approach, there are two or three lanes. In the study, the two or three lanes are treated as one lane. The headway is defined as the difference in time between when two vehicles in succession pass a common observed point through the same section of the roundabout, and which can provide an accessible opportunity. The time difference between two vehicles that arrived at the same time or almost at the same time is ignored since there is no opportunity and no gap between the vehicles. There were more than 500 pieces of data in each subset of each observed place.

From the data collected from the recordings and site observation, drivers did not pay attention to priority, so the phenomenon of sharing priority was also observed at the roundabout. Shared priority is the condition where the priority of the major-stream vehicles is not necessarily absolute and the minor-stream drivers accept relatively small gaps in the major stream to merge, causing major-stream drivers to have the need to decelerate or completely stop.

Figure1. The Xueyuan roundabout and observed place.

THE COWAN M3 DISTRIBUTION FOR THE XUEYUAN ROUNDABOUT

It is obvious that parameters of the Cowan M3 distribution are different in different regions due to local driver behavior. In this study, the parameters of the Cowan M3 distribution were investigated based on the observations made.

Minimum headway (τ). The minimum headway value has an important role in the validation of the Cowan M3 distribution. Studies have shown that headway values under 1.0 seconds are observed mostly between vehicles in different lanes on roads which have more than one lane.

Headway values are observed for major and minor streams and τ values are obtained by the data. From the data, the τ value can be chosen between 0.38 seconds and 0.88 seconds. The minimum headway value which was lower than 0.5 seconds was observed and the results can be seen in Table 1.

The λ parameter. The λ parameter can be defined as ‘‘the intensity of proportion of free vehicles on the traffic flow’’. In other words, the λ parameter shows the effect of the arrival of vehicles (Tanyel and Yayla 2003). The values of λ are obtained by using the method of moments. The results can be seen in Table 1.

Proportion of free vehicles (α). The proportion of free vehicles (α) is an important parameter that affects the structure of the Cowan M3 distribution. Thus, this parameter is strongly related to the τ parameter. The important decision to make is how to determine the proportion of free vehicles. In this study, the values of α were obtained by using only the method of moments instead of choosing the proportion of free vehicles. The results can be seen in Table 1. The values of α increase because the drivers travel freely and they do not care about shared priority.

Table 1. Parameters values according to the method of moments and observation.

Observed place	q(vps)	τ(s)	α	λ
XueYuan (circle1,06)	0.1542	0.75	0.8378	0.1424
XueYuan(circle2,06)	0.2112	0.88	0.8546	0.2133
XueYuan(circle3,06)	0.4668	0.58	0.754	0.4395
XueYuan(circle3,07)	0.4346	0.38	0.9061	0.1964
XueYuan (circle1,08)	0.471	0.58	0.657	0.4973
XueYuan(circle2,08)	0.5466	0.54	0.7863	0.5574
XueYuan(circle3,08)	0.591	0.46	0.7918	0.5889
XueYuan (approach 1 05)	0.4644	0.42	0.8218	0.2612
XueYuan (approach 2 05)	0.3122	0.75	0.7259	0.3707
XueYuan(approach 3 05)	0.4811	0.42	0.6743	0.4453
XueYuan (approach 1 06)	0.5167	0.46	0.5681	0.2880
XueYuan (approach 2 06)	0.3955	0.46	0.8029	0.2792
XueYuan(approach 3 06)	0.6133	0.5	0.6349	0.4338
XueYuan(approach 3 07)	0.6054	0.42	0.6529	0.4146
XueYuan (approach 1 08)	0.6883	0.42	0.6542	0.3257
XueYuan (approach 2 08)	0.4277	0.46	0.8174	0.3163
XueYuan(approach 3 08)	0.7056	0.46	0.6909	0.3991

Relationship between the proportion of free vehicles and volume. According to the studies of Troutbeck, Akcelik, and others, there is a linear relationship or an exponential relationship between the proportion of free vehicles (α) and the traffic flow ratio (q or τq) (Akcelik 1994, Tanyel and Yayla 2003). The regression analysis was done between α and τq for all data groups. The graphic can be seen in Figure 2. There was linear relationship. The equation obtained is given below:

For all the data: $$\alpha = 1.004 - 1.1328\tau q \quad (4)$$

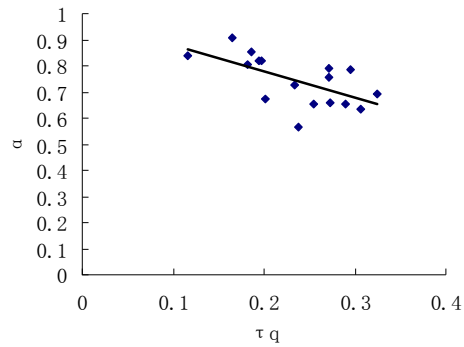

Figure 2. The relationship between α and τq.

Goodness-of-fit test. Once the parameters of the Cowan M3 distribution have been estimated, a goodness-of-fit test is needed to test whether the estimated distribution function is the distribution that has generated the sample.

*H*0: observed sample of headways from Cowan M3 (estimated distribution) (5)

Because the interest of this study is on the tail of the distribution, it is only necessary to test the null-hypothesis, Eq. (5) for $t > \tau$. In this study, χ^2 tests are used as well. The results show that all the subsets accept the null-hypothesis. Hence, the Cowan M3 distribution is fit for the headway distribution of the Xueyuan roundabout in Dalian. For example, the distribution of approach 1 in '06 was shown in Figure 3.

CONCLUSION

The Cowan M3 distribution model is found to be fit for the observed headways in the Xueyuan roundabout of Dalian. The result provides a basis to analyze the capacity and performance of the roundabout. The investigations on the parameters of the Cowan M3 distribution, the lower headway and the higher proportion of free vehicles, have shown that there is some difference between driver behavior in Dalian and driver behavior in other areas.

In order to achieve better results, a more detailed study on the parameters of the Cowan M3 distribution model, such as on the methods for parameter estimation, on the proportion of free vehicles, and on the relationship between the proportion and volume, should be conducted. The number of examples should be increased in order to gain a good result.

ABSTRACT

Median busways have caused many pedestrian crossing problems, especially when the bus station is placed beside an intersection. The Lishan Road station, which is set beside an intersection, is adopted as the case study for the analysis of pedestrian crossing characteristics. The pedestrian crossing characteristics found near the Lishan Road station are different from the characteristics seen at intersections without a busway in a number of ways. There is a larger pedestrian volume, the pedestrian arrival rate on the road sides obey the Negative Binomial Distribution, the passenger arrival rate in the middle of the road, influenced by the Bus Rapid Transit (BRT) operation, is impulsive and its cycle and peak value are not stable, the walking speed of pedestrians can be modeled by a normal distribution, and the walking speed on the crosswalk proximal to the BRT station is 7% higher than that of the distal. Since the setting up of BRT stations, the pedestrians' violation times has increased by 10-15%. The main reasons for this increase include the increase of pedestrian volume and the pedestrian desire to catch a bus causes the pedestrian to disregard any danger. The pedestrian crossing characteristics analysis in this paper can serve as a reference for signal-timing, policy making and the setting up of management facilities.

Key words: Median busway, pedestrian crossing, pedestrian crossing characteristics

FOREWORD

Research background. Median busway Bus Rapid Transit (BRT) systems should pay more attention to the issue of the street crossing of passengers, especially in the case of locating bus stations at intersections where passengers use crosswalks to cross the street. At intersections like these, traffic flow is intermixed with a large number of pedestrians and passengers. The trip purposes and routes of

pedestrians and passengers interweave and conflict because their behaviors have obvious differences. As bus passenger volume increases, the phenomenon of the interweaving and interference between pedestrians and passengers is becoming more acute, influencing an intersection's operation and also disturbing the implementation of the bus priority policy.

Currently, BRT systems are at their early stages in China, and there have been only a few studies on the issue of passengers crossing the street. Literatures (Gao Yangbing et al. 2005; Ma Wangjing 2007) have studied on the passengers street crossing facilities design and pedestrian phases combination design for median BRT station. However, these papers are only focused on a conceptive analysis and lack basic data. This study starts with the survey data, analyzes the pedestrian street-crossing characteristics, including walking speed, arrival regularity, and violation behavior, and provides data to aid in the design of passenger street-crossing facilities and signal optimization.

Study Object. The object of this study is the median BRT station which is located at the edge of an intersection and extended from the center of a crosswalk to form a "T" shaped region. This region is regarded as the research object. This study focuses on pedestrian street-crossing characteristics (as shown in Figure 1).

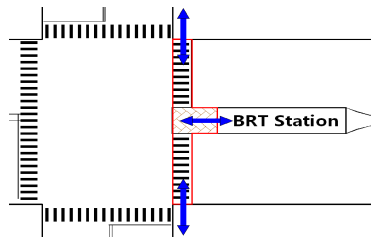

Figure1. Research object.

CROSSING PEDESTRIAN WALKING SPEED

The intersection of Lishan Road and Wenhuaxi Road is chosen as the study case. The equation for pedestrian street-crossing speed is as follows:

$$v_c = l_c / t_c$$

Where: v_c is the pedestrian street-crossing speed,
l_c is the length of the crosswalk, and
t_c is the time used to cross the street, excluding the delay in the street-crossing process.

Windows Movie Maker is used to collect t_c.

Pedestrian street-crossing speed. SPSS was used to analyze the pedestrian street-crossing speed and the statistical data is shown in Table 1. The street-crossing speed distribution histogram with a normal curve is shown in

Figure 2.

Table 1. Statistical Data of Pedestrian Walking Speed (Overall) (Unit: m/s).

Sample Size	Min. Value	Max. Value	Mean	Median	15th percentile	Standard Deviation	Variance
320	0.54	2.34	1.253	1.20	0.96	0.321	0.103

The fifteenth percentile is 0.96m/s, which is different from the 1.1m/s documented by HCM. The reasons for this include: (a) the main trip purpose is for purchasing because of a nearby Super Market and (b) the existence of the BRT station results in a severe interweaving of pedestrians and passengers, leading to a decrease in walking speed. By comparing the speed distribution histogram and the normal curve shown in Figure 2, we can see that the speed distribution is anisomerous. The peak value is found on the left. After transforming the survey data into a logarithmic model, and outputting the lognormal distribution Q-Q, we get Figure 3.

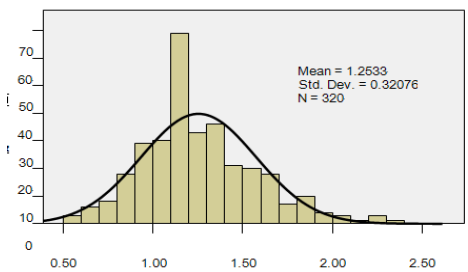

Figure2. Histogram of speed.

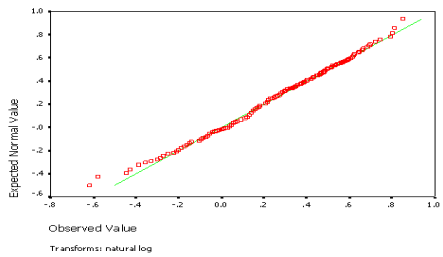

Figure3 . Normal Q-Q plot of speed.

According to Figure 3, the expected value and observed value anastomose very well. A goodness-of-fit test is performed on the converted speed using Kolmogorov-Smirnov. The outcome, shown in Table 2, shows the sample significance level to be greater than 0.05. As a result, it obeys a normal distribution and $\log X \sim N(1.253, 0.32)$.

Table 2. Kolmogorov-Smirnov test table for pedestrian speeds' logarithmic transformation.

Degree of freedom	Mean (m/s)	Standard deviation	Kolmogorov-Smirnov statistic value	Significance level
320	1.253	0.32	0.88	0.435

BRT stations' influence on walking speed. The BRT station on Lishan Road has an entrance on two sides. As a result, the passenger volume is different in each of the four crosswalks in that intersection. In order to study the BRT station's influence on pedestrian walking speed, the two crosswalks with the largest

difference in walking speed are chosen for a comparison: a) the northern crosswalk linking to the BRT station that has the largest passenger volume of the four crosswalks and b) the southern crosswalk farthest from the BRT station with a passenger volume small enough to assume that the pedestrian walking speed is not influenced by the passengers. The statistical results are shown in Table 3 below:

Table 3. Speed distributions of northern and southern crosswalk (Unit: m/s).

Location	Mean value	Standard deviation	Median	Min. Value	Max. Value	15th per-centile	Sample size
Northern crosswalk	1.22	0.31	1.16	0.54	2.34	0.93	179
Southern crosswalk	1.30	0.32	1.25	0.65	2.25	1.04	141

The average walking speed on the northern crosswalk is seven percent lower than that of the southern crosswalk. The fifteenth percentile speed on the southern crosswalk is 1.04m/s, which is almost the same as the speed stated in the HCM, 1.1m/s. Therefore, the BRT station has little influence on pedestrians using the southern crosswalk. However, the average pedestrian walking speed on the northern crosswalk is 1.22m/s and the fifteenth percentile speed is 0.93m/s, which is much lower than that of the southern crosswalk. Tables 5 and 6 show the speed distribution of the two crosswalks. The northern crosswalk walking speed is more discrete. There are two influencing factors leading to this phenomenon: a large pedestrian volume and the interweaving of and interference between pedestrians and passengers.

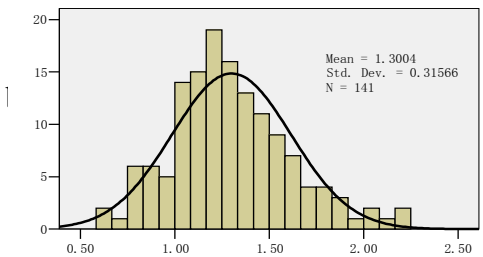

Figure 4. Histogram of speed. (Southern crosswalk)

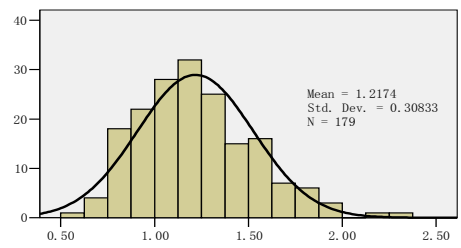

Figure 5. Histogram of speed. (Northern crosswalk)

Relationship between passenger volume and walking speed. According to the study above, the increase of passenger volume and interweaving of pedestrian flows are the two main factors influencing walking speed. However, different quantities of passenger volume have different levels of influence on walking speed. Consequently, this study chooses three time zones with different passenger volumes to analyze the influence level at different passenger volumes. The statistical results are shown in Table 4.

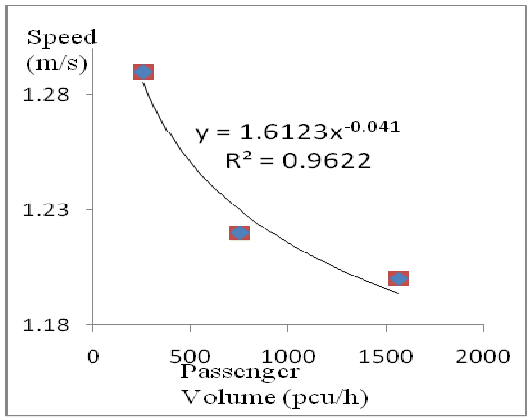

Figure 6. Relation between passenger volume and speed.

Table 4. Passenger Volumes' Influence on Walking Sp eed (Unit: m/s).

Time zone	Mean	Standard Deviation	Median	Min. Value	Max. Value	15th per-centile	Passenger Volume
1	1.29	0.29	1.22	0.68	2.34	0.94	256
2	1.22	0.33	1.20	0.67	2.21	0.92	750
3	1.20	0.35	1.15	0.54	1.94	0.92	1564

Passenger volume is closely related to walking speed. The walking speed decreases with the increase of passenger volume. The relationship between the two factors is not linear, but instead exponential. Due to the limited sample size, the speed for large passenger volumes could not be speculated.

Conclusion. Two conclusions are drawn from the above analysis: (a) the walking speed on the crosswalk which is linked to the BRT station is much lower than that of other crosswalks and (b) passenger volume is an important factor that influences the walking speed. Different sizes of passenger volume have different levels of influence on walking speed. The relationship between passenger volume and walking speed is exponential.

PASSENGER FLOW ARRIVAL REGULARITY

The arrival regularity is the basic rule of traffic movement, and provides support for the design of pedestrian traffic control systems. The arrival of pedestrians at a signalized intersection is random and is described by a discrete distribution of probability theory. The literature, specifically the work of Qu, Zhou, and Wang in 2004, has shown that the pedestrian arrival at intersections located near a business district obeys a negative binomial distribution. However, there have been few studies on the arrival regularity of BRT passengers alighting on a safety island.

General test. Select a non-holiday evening peak traffic time to collect data and use a sample interval of ten seconds. The survey data consists of two parts: (a) the number of pedestrians on the road-side (crossing street pedestrians and passengers included) and (b) the volume of passengers arriving at a safety island after getting off from a BRT, as shown in Figure 1. The statistical data is in Tables 5 and 6. After calculating the distribution model, apply it to the goodness-of-fit test. The goodness-of-fit test process is as follows:

(1) H0: Assume the arrival regularity obeys a negative binomial distribution.

(2) Set up the statistics: $x^2 = \sum \frac{(f_i - F_i)^2}{F_i}$;

(3) Test results: Look up the table, and then get the value of X^2_d. At the confidence level of 95%, accept the hypothesis H0 because the X^2 value of pedestrians on the roadside is less than X^2_d, and refuse the hypothesis H0 because the X^2 value of passenger flow on the median road is greater than X^2_d.

Table 5. Lishan Road & Wenhuaxi Road Intersection Arrival Rate Statistics.

Location	Avg.Volume (pcu/10s)	Variance	p		^{2}	^2_d	Sample Size
Road-side	4.367	7.748	0.56	5.64	10.52	16.9	360
Median-side	1.189	8.538	0.14	0.19	28.44	11.07	362

Therefore, the arrival regularity of pedestrians on the roadside obeys a negative binomial distribution, namely:

$$P(x) = C^{5.64-1}_{x+5.64-1} 0.56^{5.64} (1-0.56)^x, x = 0,1,2,\ldots 15$$

Where: x is the number of the arrival pedestrians.

The arrival regularity of passengers. From the last section, we can see that the arrival regularity of passengers on an average road is not in accordance with the negative binomial distribution, so this study selects other fitting methods.

The number and arrival law of passengers on an average road are jointly decided by the service frequency, rated capacity of BRT vehicles, and the number of passengers. Generally, the departing time interval of a successful BRT system abroad does not exceed one minute, assuming that the departing time interval is average and the arrival law of BRT passengers will show cyclically. However, the irregularity of vehicle arrival leads to uncertainties in passenger arrival because of the influence of intersection traffic lights and of the platform stopping time. Figure 8 shows the arrival rate of passengers at the observation periods and has a pulse and randomness in the cycle and peak. After analyzing the survey data, the sample data can be divided into two categories. The first category is one in which

no passengers arrive at the observed time, and the second is one in which passengers arrive at the observed time. Then, analyzing the second category, we get a pulse wave with a pulse width of four and a pulse amplitude of nine, based on the least square method (as shown in Figure 8).

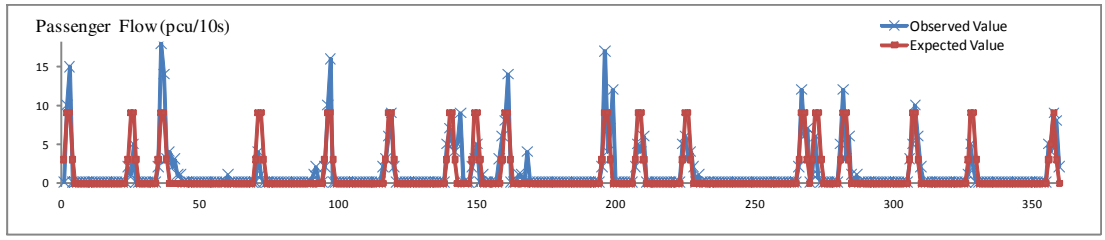

Figure 8. Passengers'arrival regularity.

Summary. First, the roadside pedestrian arrival conforms to the negative binomial distribution, but the median passenger arrival rule is obviously affected by the roadside passengers and does not conform to the negative binomial distribution. Second, the arrival of median passengers reflects a certain pulse character, but the pulsed-wave is not a perfect fit because of the high arrival of BRT vehicles with irregular coefficients.

VIOLATIONS

Generally speaking, the proportion of violations is about ten to fifteen percent higher after a BRT station is established. This data is shown in Table 6. The main reason for this increase in violations is that passengers become more concentrated, and the accumulation of passengers increases their sense of security. Subsequently, when the waiting time is more than what is acceptable to a pedestrian, that pedestrian will attempt to cross the crosswalk out of turn, and others will follow him or her. Passengers violate in order to catch BRT.

Table 6. Pedestrian Violations before and after BRT establishment.

Intersection	No BRT stations set (2007.11)	BRT stations set (2007.12)
Lishan- wenhuaxi	7.2%	19.9%
Lishan-jiefang	8.6%	12.5%
Lishan-heping	6.6%	10.9%

CONCLUSIONS AND OUTLOOK

When medium BRT stations are located at an intersection, the arrival regularity of pedestrians on roadsides conforms to a negative binomial distribution. Passenger arrival regularity is significantly different from the roadside design, and it is constrained by BRT vehicles and shows a certain degree of impulsiveness and randomness. The average pedestrian walking speed is 1.25

m/s and the fifteenth percentile walking speed is 0.96m/s, significantly different from the 1.1m/s stated in HCM. This is due to passenger interference. Considering the investigation time, the specific environment and that the sample size is limited, the data should not be used as a standard. However, it can serve as a reference for urban signal control at intersections in a mixed-traffic situation. From the above analysis, it can be concluded that the method proposed in this paper is feasible.

The Analysis of Transportation Demand Generation Mechanisms of the Urban Agglomerations in China

Dong Zhi[1],Wu Bing[2] and Li Linbo[3]

[1,2,3]Key Laboratory of the Education Ministry of Road and Traffic Engineering, Tongji University. Shanghai 201804, China; email: 65dongzhi@tongji.edu.cn

ABSTRACT

The emergence and development of urban agglomerations is an inevitable trend of the rapid urbanization. Exploring the mechanism of transportation demand generation is the basis of transportation planning of urban agglomerations. Combined with the reality of urban agglomeration, the factors which impact the transportation demand generation in urban agglomerations are classified into the origin factors, promoting factors and inhibitory factors. This paper studies the transportation demand generation mechanism on both passenger transportation and freight transportation. The research findings identify the characteristics of the transportation demand generation of urban agglomeration in China.

1. Introduction to the Development of Chinese Urban Agglomeration

Due to the rapid development of urbanization, urban agglomerations emerge in the worldwide area. French geographer Jane • Gottman proposed the concept of Megalopolis in the year 1957 and a large number of domestic and foreign scholars devote to conduct related research afterwards. The first relevant monograph in China is "Chinese Urban Agglomeration" written by Yao Shimou. According to this monograph, urban agglomeration can be defined as a relatively complete city "aggregates", which is in specific geographical area with a considerable number of cities with different features and relied on the natural environmental conditions. Urban agglomeration usually has one or two super-or mega-cities as the core of the regional economy and contains modern transportation modes, accessible integrated transport network, as well as the highly-developed information network. (Yao Shimou, 1992)

Chinese urbanization process is speeding up and a group of urban agglomerations, represented as the Yangtze River Delta Urban Agglomeration, the Pearl River Delta Urban Agglomeration and the Beijing-Tianjin-Hebei Urban Agglomeration have formed. Urban agglomeration in the southeastern region of China, where the urbanization level is relatively high, is now in the stage of rapid development, while the central and western urban agglomerations are is continually forming and evolving.

2. Concept of Transportation Demand

In the monograph "Transportation Economics" written by Chen Yilong, transportation demand is defined as a kind of need with necessary capacity to pay in a

certain period of time on the movement of goods and passenger in social-economic living under a certain price level (Yilong Chen, Shao Zhenyi, 1999) .Transportation demand of urban agglomeration should be the need which is in favor of the economic and social development of urban agglomeration and the necessary displacement of people and goods. It is closely linked with all aspects of urban agglomeration development.

3. Analysis on Influencing Factors and Characteristics of Transportation Demand Generation of Chinese Urban Agglomeration

3.1 Classification of Transportation Demand of Urban Agglomeration

Transportation demand generation mechanisms of urban agglomerations aim at exploring the factors influencing transportation demand generation and the interactive process. Transportation demand of urban agglomeration is mainly divided into the passenger demand and freight demand, which have large differences in origination due to their different targets. Freight transportation demand can be divided into origin demand and induced demand. The generation of origin demand is the result of the uneven geographical distribution of natural resources which required by the social-economic activities in the urban agglomeration or among the urban agglomerations. Induced demand comes from the clear specialization of city functions and the separation of production and consumption in space. Passenger demand of urban agglomeration can be divided into the productive demand and consumed demand according to different travel purposes. Productive demand is related with the activities such as production, exchange and distribution, for example, the travel induced by various orders, sales, technical exchanges, and financial and labor activities in the urban agglomeration. Consumed demand makes consumption as the travel purposes, such as visiting relatives and friends, and taking holiday.

3.2 Analysis of the Factors Influenced the Transportation Demand Generation of Chinese Urban Agglomeration

3.2.1 Origin Factor

Origin factors, the primary power to generate transportation demand, come from the human instinct to survive and the difference in regional resource. First of all, the displacement of people and goods are born required. The resources and production to maintain human survival are distributed in various geographical regions in the urban agglomeration. No region can provide all the necessary resources; only through the transportation activities can the resources be obtained. Transportation activity is one of the human production and living activities.

Secondly, the uneven distribution of natural resources is objective geographical situation in China. 87% of Chinese proved coal concentrates in the Northern region; iron ore is mainly distributed in Hubei, Liaoning and Sichuan Province. (Peng Tang,2006) This uneven distribution of natural resources generates transportation demands in the urban agglomeration and among the urban agglomerations especially.

3.2.2Promoting Factor

(1) Specialization of urban development

The position of every city in the social productive activities in urban agglomeration is different. They resume different functions, and the core cities and their surrounding cities and towns can complement with each other on the functions. Goods, services, capital, information and commuting will form a close two-way contact. Specialized division of labor in society enhances the contact intensity within the urban agglomeration. With the continuous expansion of production scale, the economic collaborations and co-operations among the cities are strengthened, and a variety of economic entities have become more closely linked. The chance and frequency of movement of people and goods are increased, so that transportation demand is continuous generated and changed.

(2) Urban aggregation and diffusion

Urban aggregation refers to the flowing of socio-economic elements from non-city area to the city area or from the small and medium-sized cities to the core cities in the urban agglomeration. Urban diffusion is reflected in the impact caused by the urban development will influence adjacent area and the regional economic area and stimulate the economic and transportation development of adjacent area. In particular, the economic core city promotes the development of the entire urban agglomeration by technology diffusion, exportation of capital, industry diffusion and exemplary role through transportation services.

(3) Urban population movement

According to statistics, the cause of internal migration flows in urban agglomeration varied and the migrant workers take the larger proportion, this is because sustained and rapid economic growth of urban agglomeration attracts enormous scale migration of population. The scope of migrating is related to the level of economic development. From the sample from the census data can be seen that migrating population of Beijing-Tianjin-Hebei agglomeration, which the economical level is higher, possesses 73% of the whole population, while the proportion is 9% in Chengdu Plain agglomeration and the population is mainly migrating among the cities and towns in the urban agglomeration.

Because of the unique Chinese cultural traditions, thus there is difference in working, rest time, the period of holiday, and social organization structure and management practices. For instance, on the eve of annual Chinese Spring Festival, a large number of outside workers would return to their hometown to celebrate the Chinese New Year, so that enormous transportation demand is caused in the urban agglomerations. Influenced by the internal layout and related socio-economic factors, inter-city commuter flow in the urban agglomeration is constantly arising and growing. Some workers choose the way of life like migratory birds, such as some people in the Yangtze River Delta urban agglomeration choose to live in Jiangsu or Zhejiang Province but work in Shanghai.

(4) The improvement of residents' income level and consumption level

Urban agglomeration is the place where economic power and population gather and the as a gathering place and the improvement of income level and consumption level are more obvious than in other regions. According to the survey in the first half of the year 2008, average income level of Changsha, Zhuzhou and Xiangtan urban agglomeration is 27.3% higher than that of the entire Hunan Province. The overall consumption of central Plain Urban agglomeration is 85% more than that of the Henan Province. Purchasing ability is depended on the national income level, with the improvement of purchasing ability, the demand of required productive materials is increased and new integrated transportation demand is generated as well. The adjustment to consumption structure results in the increased demand in visiting relatives, resting, travelling and etc...

(5) Perfecting of transportation system of urban agglomeration

Perfecting of the transportation network can improve the accessibility and so that new demand is generated. In the same premise, the area which has better geographic location and more convenient transportation service would process more opportunities on external transportation links, thus the possibility of produced transportation demand is relatively high. The relevant developed urban agglomeration in China, such as the Yangtze River Delta urban agglomeration and the Pearl River Delta urban agglomeration, have a natural geographical advantage, diverse and convenient transport facilities, good port conditions which could promote international trade, resulting in a wider scope transportation demand.

3.2.3 Inhibitory Factor

(1) The shortage of transportation infrastructure of urban agglomeration

Transportation infrastructure is the basis of the economic development of urban agglomeration and the important conditions for the transportation demand generation. The shortage of transportation infrastructure and the incompletion of transportation structure would lead to the high transportation cost and reduction in transportation timeliness, thereby people's economic activities are confined to a small geographical space, and then people's transportation demand is inhibited.

(2)Rise in transportation charge and reduction in service quality

Changes in transportation charge would impact on the integrated transportation of urban agglomeration, especially the passenger demands. When the charge increase, some traveler would give up travelling so that these demand can not produced. The influence of the quality of transportation services is also large; travelers are expected to obtain good services. Low quality transportation services would fail to meet their expectations and requirements and they may reduce the demand, and therefore for this part of transportation demand is inhibited.

(3) Partition in regional administrative management

Regional transportation administration involves the administrative center, economic center and transportation center, etc. .

The non-cooperative phenomenon like local governments making their own decisions, duplicated construction and price competition are usually. Because of the partition of national transportation management system, regional transportation planning is decided by different transportation department, which has significant limitations. Partition in administrative regions blocks the horizontal movement of productive factors. Influencing factors on transportation demand generation of the urban agglomerations in China can be concluded in Figure1 below.

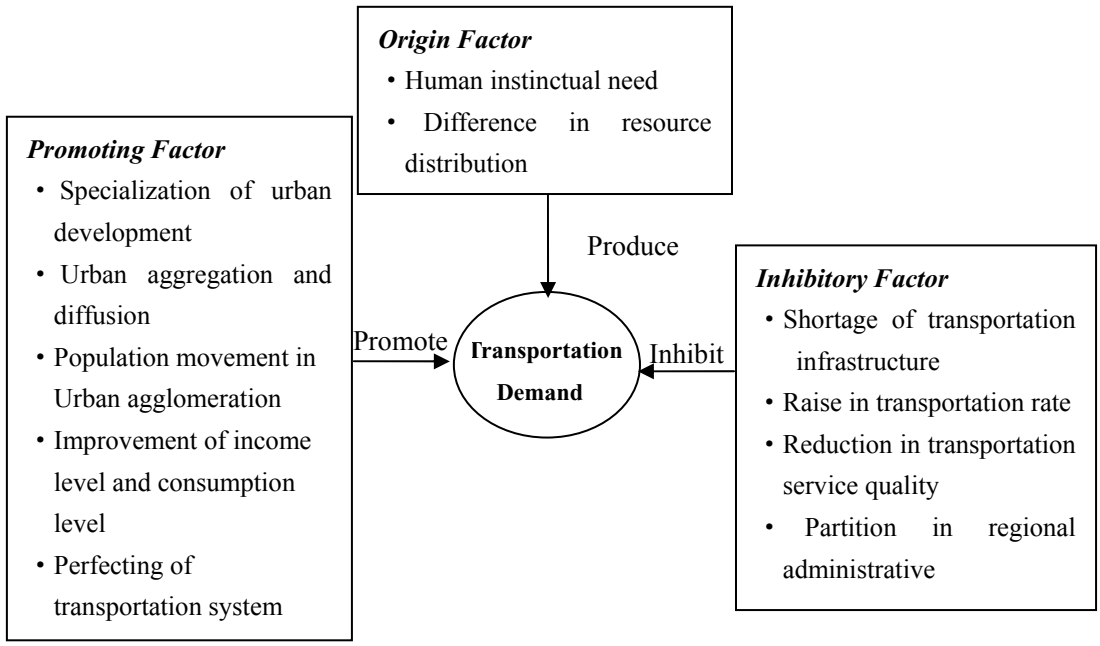

Figure1. Influencing Factors on Transportation Demand Generation of the Urban Agglomerations in China

3.3 Characteristics of transportation demand generation of urban agglomeration

The characteristics of urban agglomeration can be reflected in non-equilibrium in space and time, diversity and economic restrict.

3.3.1 Non-equilibrium in space and time

The transportation demands of urban agglomeration is uneven in space and time. From the perspective of space, uneven distribution of resources within urban agglomeration and urban specialized development introduce the regional difference in transportation demand generation. Take the Pearl River Delta urban agglomeration as an example, the distribution ratio of both freight transportation demands and passenger transportation demands of Guangzhou are head among all the cities, which are 35.66% and 27.65% respectively. The least distribution ratios of freight transportation demands and passenger transportation demands are appeared in Zhuhai(3.2%) and Huizhou(3.81%). From the perspective of time, cyclical individual movements, cyclical economic development and seasonal production and consumption lead to the transportation demand generation over time.

3.3.2 Economic constraints

When travelers have the expectation to move, the economic consideration and judge are inevitable. However, the considerations of different travelers are diverse, such as the length of time, the value of goods, the level of the transportation rate and etc. Competition of transportation markets in urban agglomeration and the adjustment to the transportation rate influences the freight demand. Therefore, under the economical restrict on transportation demands, the choice on transportation time and modes of different travelers is random, so that the transportation demand generation is fluctuated with the price.

3.3.3 Diversity of transportation demand generation

With continuously shortened inter-city distance time, there are different demands in the choice of travelling time, and modes according to different income levels, trip purposes and preferences. The requirements on the quality of transportation service are inevitable. These requirements are directly reflected in the choice made by travelers when they receive transportation services, and thus individual behavior has impact on the transportation demand generation.

4. Conclusion

Research on the transportation demand generation mechanism of urban agglomeration is the basis of transportation demand forecast of urban agglomeration. In this paper, transportation demand of Chinese urban agglomeration is investigated, and origin factor, promoting factor and inhibitory factor which influence the generation of transportation demand are proposed and discussed. The mechanism of transportation demand generation is further discussed and the characteristics of transportation demand generation is studied. It not only supplements the existing transportation demand theory, but also plays a vital role in configuring transportation modes, forming effective transportation capacity and improving integrated transport system of urban agglomeration.

ABSTRACT

En-route travel choice behavior is one of the primary travel behavior over residential daily trips. Providing traffic information will exert an impact on en-route travel choice behavior. Through comparative studies, the paper reveals that RP/SP joint survey and the disaggregate model are two suitable methods. On the basis of that, the paper develops a scheme for RP/SP joint survey and a Multinomial Logit (MNL) Model for modeling and analysis. The aim of the paper is to provide theoretical and practical support for the research of en-route travel choice behavior with traffic information in China.

KEYWORDS

En-route travel choice behavior; Traffic information; RP/SP joint survey; Disaggregate model

1. Background

The application of Intelligent Transportation Systems (ITS) has facilitated transportation system operations. As an important component of ITS, traffic information systems help travelers to enhance their travel reliability by providing effective traffic information. In recent years, traffic information service is developing in China and the travelers' behavior is changing accordingly. To research the characteristics and evolution mechanisms of the changes of travel behavior will help to make better use of traffic information service and enhance the efficiency of transportation systems.

The travel behavior of a trip could be considered as two parts, i.e., pre-trip

travel behavior and en-route travel behavior. En-route travel choice behavior is one of the primary travel behavior of residential daily trips. The en-route travel behavior of a single trip is mainly route choice. Considering a trip chain which links all trips in a day, the en-route travel behavior would be more complex than that of a single trip. The two most commonly accepted definitions of a trip chain are (Primerano et al. 2008): (1) a sequence of trip segments beginning at the "home" activity and continuing until the traveler returns "home" and, (2) a sequence of trip segments between a pair of anchor activities "home" and "work" or "school". Therefore the en-route travel behavior of a trip chain includes destination choice, travel mode choice, departure time choice, route choice, etc. Providing traffic information in a timely manner will make an impact on en-route travel choice behavior and bring changes to it. The data for the research is collected by specific surveys and the analysis is conducted based on appropriate models. Through comparative studies, the paper reveals that the RP/SP joint survey and the disaggregate model are two suitable methods. The paper further develops the survey scheme for a RP/SP joint survey and a Multinomial Logit (MNL) Model.

2. Research Progress in China

The research of traditional travel behavior has conducted for several decades. In recent years, the research on travel behavior with traffic information has been newly emerging. For example, Pei Yulong (2006) compared "the characteristics of trip and the regularity of information used before and after the information age, and concluded tendencies of trip development" (PEI et al.2006), Juan Zhicai (2008) discussed "the positive role and limitation of traffic information in order to provide correct cognition and reasonable thought of using traffic information for planning management department" (JUAN et al. 2008). At the same time, due to the limitation of data resources, analysis methods, etc., the overall progress of the research in China still appears to be macroscopic, with the general characteristics concluded as following:

(1) The survey data is insufficient as it's collected from household travel surveys but not specific surveys.

(2) The analysis methods needs to be updated from the current "four-stage" aggregate method to a disaggregate method so that the characteristics of individuals could be better revealed.

(3) The research findings stay at the descriptive level with less microscopic analysis.

Therefore, this study will focus to design a proper survey scheme for necessary data and apply appropriate models to analyze the data.

3. Application of RP/SP Joint Survey

3.1 RP Survey and SP Survey

The first stage of research on en-route travel behavior with traffic information is to conduct a survey for collecting necessary data. Generally, there're two kinds of surveys, the traditional Revealed Preference Survey, i.e., RP Survey and the emerging Stated Preference Survey, i.e., SP Survey.

In a RP survey, the data colleted is about the choices in real conditions of people's daily life. The parameter calibration of models based on such data is more reliable. On the contrary, a SP survey aims at revealing people's subjective preference in assumed conditions. Nowadays traffic information service is not widely used in China and the survey sample for a RP survey is not big enough for modeling. Therefore, a RP/SP joint survey is suggested in the research so as to combine the advantages of RP Survey and SP Survey and collect necessary data.

3.2 RP/SP Joint Survey

Compared to a RP survey or a SP survey, it's important to carry on the division and integration processes in a RP/SP joint survey. The division process is to divide the questionnaire into a RP part and a SP part. The integration process afterwards is to integrate different data from RP and SP survey so as to ensure its application in same models. The design of a RP/SP joint survey involves four steps: (1) determining variables, (2) classification of attributes, (3) determining attribute level and, (4) designing detailed survey scheme.

The main purpose of a RP survey part in a RP/SP joint survey is to collect personal attributes, including gender, age, occupation, income, travel mode, travel time, etc. These attributes are classified into different levels. In this study the age, occupation, income, travel mode are classified into five, six, six and seven levels respectively in the questionnaire.

The main purpose of a SP survey part is to collect data about characteristics of inhabitants' en-route travel behavior with traffic information. Assumed that inhabitants will receive sufficient en-route sufficient traffic information, the survey reveals their behavior including travel mode choice, departure time choice, route choice, etc.

To enhance the efficiency of SP surveys, it's recommended to optimize the questionnaire with mathematical method such as the Uniform Design Method (Guan 2004). At the same time the overall accuracy of collected data should be maintained. To better integrate RP and SP survey data, it's recommended to introduce scale parameter and anisotropic parameter and to obtain appropriate data for modeling (LIU et al. 2008).

4. Application of Disaggregate Model

4.1 Aggregate Model and Disaggregate Model

The models in common use are divided into aggregate model and disaggregate model. Survey data is collected from different traffic zones and processed with statistical methods, and then parameter calibration of an aggregate model could be obtained. But aggregate model doesn't represent choices of individual travelers well. Therefore it's not suitable for the research of en-route travel behavior with traffic information.

Disaggregate method is developed on the basis of Probability Theory. Compared to aggregate model, disaggregate model uses survey data directly without additional processing and is able to represent the choices of individual travelers. Therefore disaggregate model is more appropriate in travel behavior research, including departure time choice, pre-trip path choice, and en-route response to traffic information (Moshe et al. 2007).

4.2 Application of MNL Model

4.2.1 Construction of MNL Model

Logit Model is a binary choice disaggregate model used for prediction of the probability of occurrence of an event. It is a generalized linear model used for binomial regression. It makes use of several predictor variables that may be either numerical or categorical. Multinomial Logit Model, i.e., MNL Model is a kind of Logit Model in common use. MNL Model has a simple form and is easy to understand. The choice probability is between 0 and 1 and the sum of choice probability of all alternative parts is 1. Therefore MNL Model is suitable for research on en-route travel choice behavior with traffic information. The model is give by the following expression:

$$P_{in} = \frac{\exp U_{in}}{\sum_{i=1}^{j} \exp U_{in}}$$

where P_{in} is the choice probability of travel behavior i by traveler n, U_{in} is the utility of travel behavior i by traveler n, j is the number of different travel behavior, $0 < i \leqslant j$。

The linear model to determine U_{in} is give by the following expression:

$$U_{in} = \theta_0 + \theta' X_{in} = \theta_0 + \sum_{k=1}^{K} \theta_k X_{ik}$$

where U_{in} means the same as above, $X_{in} = [X_{in1}, X_{in1}, \cdots, X_{ink}, \cdots, X_{inK}]$ is

eigenvector of travel behavior i by traveler n, X_{ink} is the kth eigenvector of travel behavior i by traveler n, K is the number of eigenvectors, $\theta' = [\theta_1, \theta_2, \cdots \theta_k]$ is the undetermined vector parameter, θ_k is the kth parameter of characteristic variables.

4.2.2 Definition of Numbers of Travel Choice Behavior and Eigenvector

In research of en-route travel choice behavior with traffic information, travel choice behavior is defined as following: changing destination, changing route, changing travel mode, changing departure time of next trip and canceling next trip. Thus j equals 5. The eigenvector X is defined as personal attributes collected from the RP survey, including the following eight ones: gender, age, family size, occupation, income, trip purpose, travel mode and travel time. Thus K equals 8. With the data from a RP/SP Joint Survey and a MNL Model, the following analysis could be processed successfully.

5. Conclusion

With the development of traffic information service in China, it's necessary to research residential pre-trip and en-route travel behavior with traffic information. RP/SP joint survey and disaggregate model are two suitable methods. The RP/SP joint survey is a proper method to collect necessary data and the survey scheme should be carefully designed. The disaggregate models is another effective method for modeling in the research of travel behavior. Among disaggregate models, the MNL Model is proposed in the paper. The aim of the paper is to provide theoretical and practical support for travel choice behavior research and help make better use of traffic information service and enhance the efficiency of transportation system.

A Particle Swarm Optimization Algorithm for Bilevel Programming Models in Urban Traffic Equilibrium Network Design

Hu Hui

Transportation and Economics Institute, Economics and Management School, East China Jiaotong University, P.O.Box, 330013, Nanchang; PH(086)-0791-7045027; email: hh24895@163.comm

ABSTRACT

A new algorithm is proposed to solve one usual model of bilevel programming models in urban transportation equilibrium network design. The upper model is solved by PSO and the lower model is solved by Frank-Wolfe, then iterations are continuously progressed between them so that the global optimum solution can be approximated. The algorithm is illustrated with an example and compared with other algorithms. Results demonstrate that the effectiveness of this algorithm, while iterations and extra computational burdens are not so heavy.

Key words: Equilibrium Network Design; Bilevel Programming Model; Frank-Wolfe; PSO Algorithm

INTRODUCTION

With a better understanding of urban transportation equilibrium network design problem, the bilevel programming model has been recognized as an ideal tool for transportation network design and a variety of bilevel models and solving algorithms have been developed. Gao Ziyou (2004), and Meng Qiang (2005) made a synthetic survey of its application in transportation network planning design and pointed out that the main difference among various bilevel programming models lied in constraints and upper/lower goal functions. Multiple combinations of different upper goal functions and different lower user behavior choice models make various bilevel models. Simultaneously, the solving algorithms of these models were summarized and non-numerical optimization algorithms are worth further investigations in Gao's studies. Meng attempted to give unified models and algorithms to solve bilevel programming model.

In this paper, a new algorithm based on PSO (Particle Swarm Optimization) is proposed to aim at solving a usual bilevel programming model in urban transportation equilibrium network design and it can provide reference for solving other bilevel programming models.

BILEVEL PROGRAM MODEL

One of bilevel programming models in transportation equilibrium network design is as below:Minimizing the sum of system impedance and investment in the whole

transportation network from the angle of system and decision-makers. Meeting user equilibrium principle criterion from the users' point of view. And these two rules can be expressed as the following bilevel model:

Upper model:

$$\min Z = \sum_{a \in A} t_a[f_a(y), y_a] f_a + \theta_a \sum_a G_a(y_a)$$

$$s.t. \quad y_a \geq 0, \forall a \in A$$

Lower Model:

$$\min Z \sum_{a \in A} \int_0^{x_a(y)} c_a(x, y) dx$$

$$s.t. \quad \sum_{k \in K} f_k^{ij} = q_{ij}, \forall i \in I, j \in J \qquad (1)$$

$$x_a = \sum_{ij} \sum_k f_k^{ij} \delta_{ak}^{ij}, \forall i \in I, j \in J, k \in K, a \in A \qquad (2)$$

$$f_k^{ij} \geq 0, \forall i \in I, j \in J, k \in K$$

The symbols in the above model are denoted as follows:

A: set of routes a in transportation network;

$t_a(f_a(y), y_a)$: impedance function of route a;

$G_a(y_a)$: investment function of route a,given an increased capacity y_a;

y_a: increased capacity of route a;

y: increased capacity of routes in network, they're decision variables in upper model;

θ_a: coefficient matching investment and system impedance.

K: path set from origin node i to destination node j in network;

I: origin nodes set;

J: destination nodes set;

q_{ij}: traffic demand between origin node i and destination node j;

c_a: transport cost in route a;

x_a: traffic flow volume of route a;

x: traffic flow volume of routes in network, they're decision variables in lower model;

f_k^{ij}: traffic flow volume of the path k in OD i-j pair.

δ_{ak}^{ij}: where δ_{ak}^{ij}=1 if route $a \in K_{ij}$, otherwise 0;

The constraint (1) represents the balance relationship among route traffic flow and OD demand; the constraint (2) reflects the associate linkage between route traffic flow and path traffic flow.

If one of solutions is provided (the increased vector of routes capacity) in upper model, it can be used in lower model then the lower model will become a standard user equilibrium assignment problem which can be solved using Frank-Wolfe algorithm, and the route traffic flow x will be got.

MAIN PROCEDURE OF PSO-BASED BILEVEL PROGRAMMING MODEL

It's challenging to solve the bilevel programming model, especially for the no-linear model which is a NP hard problem. The more the variables are in the model, the more difficult it is to search the global optimum solution. By analyzing and comparing various solving algorithms for known bilevel models, a new algorithm based on PSO and continuous iteration is proposed in this paper. The upper model can be solved by PSO and the lower level can be solved using Frank-Wolfe, then continuous iterations are progressed between upper model and lower model so that the optimum solution can be approximated.

PSO (Particle Swarm Optimization) is an intelligent random optimum algorithm developed by Kenndy and Eberhart who were enlightened from birds' seeking food. Although it has been used widely, PSO has its shortages, such as local minimum solutions, and convergence velocity slowing down at a later stage. So, many improved algorithms were proposed to avoid these shortcomings. One of them is based on random disturbance which can escape local optimum points and improve convergence performance.

Every solution is one of particles in searching space for optimum problems, and every particle has its adapting value (usually optimum function) which can be evaluated for the particle position. Particles in the population adjust their positions and velocities by pursuing two extreme numbers (one is the individual optimum solution Pbest, the other is the population optimum solution Gbest) in the iteration searching process. For bilevel model in urban transportation continuous equilibrium network design, the main procedures of algorithm based on PSO are as below:

Initialization Solution (increased routes' capacity). Position and velocity of Particles can be got according to population scale N, variable numbers. The random matrix is as followed:

$$\begin{bmatrix} y_{11} & y_{12} & \cdots & y_{1n} & v_{11} & v_{12} & \cdots & v_{1n} \\ y_{21} & y_{22} & \cdots & y_{2n} & v_{21} & v_{22} & \cdots & v_{2n} \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \\ y_{N1} & y_{N2} & \cdots & y_{Nn} & v_{N1} & v_{N2} & \cdots & v_{Nn} \end{bmatrix}$$

$\{y_{ij}, i = 1,2,\cdots N, j = 1,2,\cdots n\}$ denotes the position of particle i is j, in the model it's

the initial value of increased route capacity between $[R_{1j,}R_{2j}]$ ($R_{1j,}R_{2j}$ is the upper and lower limit for particle j) . v_{ij} is the corresponding velocity which can be a random number between $[v_{\min,}v_{\max}]$ or $[R_{1j}*u,R_{2j}*u]$(u is the coefficient between 0 and 1. And the current position (current solution) is set *Pi* for particle *i*, while *Pg* is set for the best position (best solution) in the initial population which can be obtained by comparing all particles goal value.

For all particles in the population, the following operations are executed:

① Positions and velocities are updated according to the following formula:

$$v_{ij}(t+1) = w*v_{ij} + c_1r_1(pbest_i(t) - y_{ij}(t)) + c_2r_2(Gbest_i(t) - y_{ij}(t))$$

$$y_{ij}(t+1) = y_{ij}(t) + v_{ij}(t+1)$$

w is a weighted coefficient, its value can be 0.1-0.9, or set a linear value between the maximum and minimum. The convergence performance can be got better if w is diminished by iteration. So, if maximum weighted coefficient and minimum weighted coefficient are set $w_{\max}, w_{\min}$ respectively and $iter, iterMax$ is the iterations and sum iterations for $iter, iterMax$, the calculation formula will be: $w = w_{\max} - iter \times \frac{(w_{\max} - w_{\min})}{iterM\,\mathrm{ax}}$.

c_1, c_2 is the learning factor, their value can be set 2; r_1, r_2 is a random number between 0 and 1.

②Solving the lower model: Using the particle i's position y_i (the solution of upper model) for lower model, the route flow volume x_i can be got by Frank-Wolfe which is a standard algorithm in traffic flow assignment.

③Using x_i , y_i in upper model, the adapting value can be got for particle i.

④If the adapting value of particle i is better than the individual optimum solution Pbest, the current position y_i will be updated while the lower model optimum solution will be x_i ; If the adapting value of particle i is better than the all particles'

best solutionGbest, then Pg is replaced by the current position y_i while the lower model best solution is x_i.

Decide whether the convergence criterion can be met. If met, the global solution is exported, the algorithm ends. Or, a random disturbance is initialized for optimum solutions so that optimum solution is updated, and return step (2) to continue.

CASE STUDY

To confirm the validity of the algorithm above mentioned, the example used in the Li Zongping's paper（2004） which confirmed his SA algorithm is selected for comparisons. The road network in the example is depicted as the figure 1:

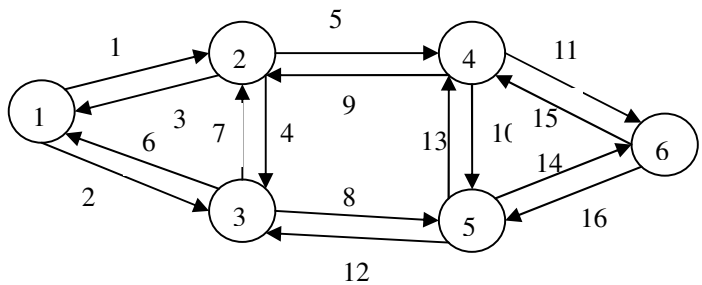

Figure 1. The Diagram of the Road Network

There're 2 OD pairs, 6 nodes, 16 routes. The OD demand is 10 between node 1 and node 6, while OD demand is 20 between node 6 and node 1. The impedance function is: $t(f_a, y_a) = A_a + B_a[x_a / (K_a + y_a)]^4$, the goal function is: $Z = \sum_a [t_a(x_a, y_a)x_a + \theta_a y_a]$, the parameters of routes are provided as the following table. The parameters of the algorithm are: population is 20, iteration is 40, learning factor c1,c2 is set 2, maximum weighted inertia value is 0.9, minimum weighted inertia value is 0.1. Concreted execution code is written in Matlab7.1 environment, the final result is given by comparing MNOS, EDO, simulation annealing algorithm as followed table 2.

Table 1 The Parameters of Road Impedance in Network

Route	A_a	B_a	K_a	θ_a
1	1	10	3	2
2	2	5	10	3
3	3	3	9	5
4	4	20	4	4

Table 2 Results Comparison of Different Algorithms

5	5	50	3	9
6	2	20	2	1
7	1	10	1	4
8	1	1	10	3
9	2	8	45	2
10	3	3	3	5
11	9	2	2	6
12	4	10	6	8
13	4	25	44	5
14	2	33	20	3
15	5	5	1	6
16	6	1	4.5	1

Route	MNOS	EDO	SA	PSO
y1				
y2	4.61	4.88		4.6175
y3	9.86	8.59	10.1740	9.8952
y4				
y5				
y6	7.71	7.48	5.7769	7.3707
y7		0.26		
y8	0.59	0.85		0.5931
y9				
y10				
y11				
y12				
y13				
y14	1.32	1.54		
y15	19.14	0.26		
y16	0.85	12.52	17.2786	20
Z	557.14	540.74	528.497	523.3811
N		12	24300	1160

Note: Z is the goal value of upper model function, N is the numbers using Frank-Wolfe solving flow assignment problem, the blank represents the increased capacity of route is zero. From the table 2, we can conclude that the PSO algorithm is better than other algorithms. Compared to SA, the iterations are less, while for EDO is not suitable for large scale transportation network although its' iteration is less.

CONCLUSIONS

A new algorithm based on PSO for a usual bilevel programming model is designed and the main procedures are developed in this paper. A study example is investigated. The calculation results are compared with other algorithms and the findings demonstrate the effectiveness of this algorithm.

ACKNOWLEDGEMENT

ABSTRACT

Due to the lack of integrated planning of interregional transportation infrastructure, the development of interregional transportation system is restricted in China. Based on qualitative analysis and quantitative forecast, this paper analyzed general methods regarding demand forecast, organization planning and infrastructure integration of Interregional Transportation Infrastructure Integration Planning in China. Also this study applied the methods into practice in Suzhou City. The evaluation showed the methods were effective and applicable. This research provides theoretical and practical support for interregional transportation infrastructure integration planning.

KEYWORDS

Interregional transportation infrastructure; Integration planning; Qualitative analysis; Quantitative forecast; Urbanization

1. Introduction

Due to the lack of integrated planning of interregional transportation infrastructure, the development of interregional transportation systems is restricted (An 2003). This problem appeared in China with the rapid socio-economic development and has attracted nationwide attention. Many researchers have achieved fruitful research findings to address this problem. QUAN Yongshen, et al. (2007) emphasized on the development of regional transportation networks to solve the fundamental urban transportation problems. YANG Junyan, et al. (2007) indicated that the coordination of interregional transportation infrastructure was an important part of regional coordination of Yangtze River Delta. Li Jiawei, et al. (2008) developed a method to emphasize the integration of urban agglomeration transportation infrastructure.

Previous research findings indicated that the integration of interregional transportation infrastructure is of great importance not only for interregional transportation systems but also for socio-economic development in China. Currently, Interregional Transportation Infrastructure Integration Planning (ITIIP) is newly emerging throughout China. Based on qualitative analysis and quantitative forecast, this paper analyzed general methods of demand forecast, organization planning and infrastructure integration of ITIIP in China. Then this study applied the methods into practice in Suzhou City. The evaluation showed the methods were effective and applicable. This research provides theoretical and practical support for interregional transportation infrastructure integration planning.

2. Content of Integration Planning

The aim of ITIIP is to achieve integration at three levels: interregional transportation development strategies, organization patterns and infrastructures (Xi et al. 2007). As shown in Figure 1, the ITIIP includes several parts. Among them, interregional transportation demand forecast, interregional transportation organization planning and interregional transportation infrastructure integration planning will be discussed in this paper.

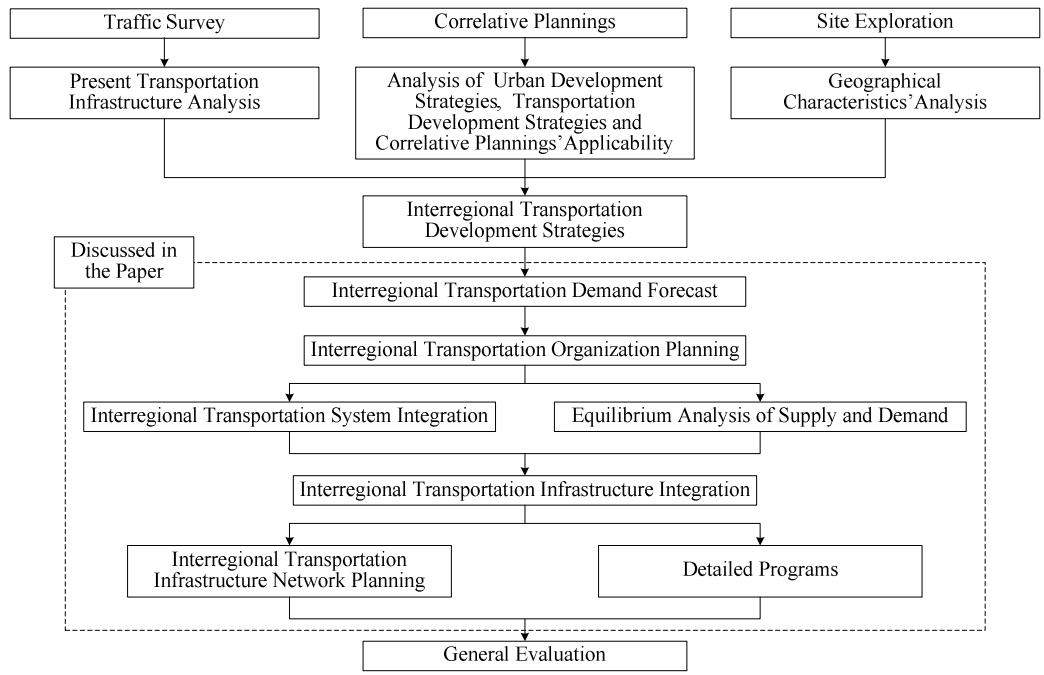

Figure 1. Flowchart of integration planning.

3. Demand Forecast, Organization Planning and Infrastructure Integration

3.1 Interregional Transportation Demand Forecast

3.1.1 Interregional Trip Generation Forecast

The ratio of interregional trip in daily trip is closely related to connection patterns of two districts. The patterns appear to be strong, intermediate or weak according to land-use, mobilization level, urbanization level, etc. When the land-use of each district is not mixed enough, it may result in a high ratio of interregional trips. When the land-use is properly mixed the ratio becomes reasonably low. As the mobilization and urbanization level is not high in China, the intermediate pattern is recommended for Chinese cities in the long run. Accordingly the ratio is about 50%. The model of interregional trip generation forecast is given by the following expression:

$$K_i = P_i \cdot F_i \cdot \alpha_i \varepsilon_i$$

where K_i is the interregional trip generation of District i on peak hour, P_i is the population of District i, F_i is the times of daily trip per capita of District i, α_i is the peak hour factor of District i, ε_i is the ratio of interregional trip generation in daily trip.

The population, times of daily trip per capita and peak hour factor could be obtained from correlative plannings such as Urban Master Planning and Comprehensive Transportation Planning. Then the interregional trip generation could be forecasted.

3.1.2 Interregional Travel Modal Split Forecast

At present, a large part of interregional trips in China are non-elastic and the options of travel mode are limited. Therefore existing methods for forecasting interregional travel modal split are not well applicable in integration planning. We recommend a forecasting method with a combination of qualitative analysis and quantitative forecast. Qualitative analysis is a macro-level method considering key factors including present travel modal split, development trends of urban layout and transportation system. Quantitative Forecast is a micro-level method based on the results of travel survey.

3.2 Interregional Transportation Organization Planning

Interregional transportation organization planning contains two parts: interregional transportation system integration planning and equilibrium analysis of supply and demand of interregional transportation infrastructure. The interregional transportation organization planning brings forward an ideal transportation organization pattern among districts to realize sustainable development of interregional transportation systems. As non-motorized traffic is still a primary composition of transportation systems in China, both motorized and non-motorized traffic should be taken into account in organization planning. The goal of equilibrium analysis of supply and demand is to examine whether the supply will

completely meet the demand and find out where the infrastructure supply is deficient. The equilibrium analysis should cover all modes of interregional transportation including non-motorized traffic, public transportation and so on.

3.3 Interregional Transportation Infrastructure Integration

The interregional transportation infrastructure integration contains two parts. The macro-level part is to determine the interregional transportation infrastructure network and the micro-level part is to put forward detailed programs. The macro-level part intends to establish overall scale and layout of interregional transportation infrastructure. The result of equilibrium analysis should be fully considered. The micro-level part puts forward programs to newly-construct or reconstruct infrastructure. The reconstruction programs contain route lines' optimization, widening alteration and key nodes' reconstruction. In addition, recommended and backup programs by stages should be included.

4. Practice in Suzhou City

The study area of an ITIIP in Suzhou City includes Gucheng District, Suzhou New District, Xiangcheng District, Wuzhong District, Suzhou Industrial Park, Changshu City and Wuxi City. The objective is to integrate interregional transportation infrastructure across the borders among these districts. The base year is 2006 and the targeting year is 2020. The strategy is to build a "New Suzhou Interregional Transportation System" in accordance with interregional transportation demand and socio-economic development. The interregional transportation demand in intermediate connection patterns in 2020 is forecasted and the O-D distribution is shown in Figure 2. The recommended interregional transportation organization is shown in Figure 3.

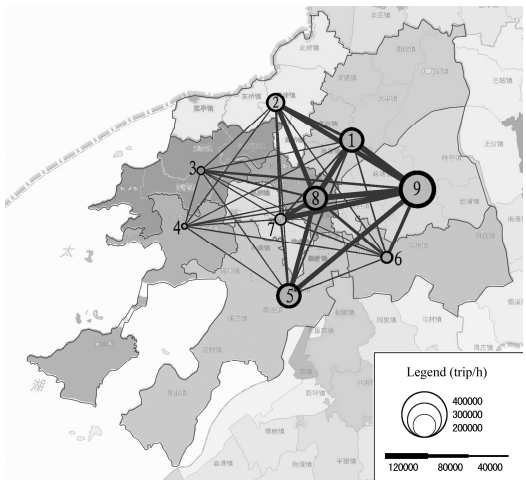

Figure 2. O-D distribution in intermediate connection pattern in 2020.

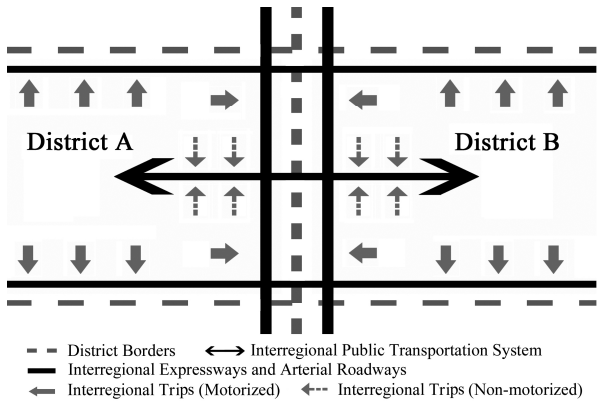

Figure 3. Recommended interregional transportation organization in 2020.

According to the equilibrium analysis of supply and demand, out of six borders, three borders' infrastructure supply will not meet the demand in 2020. The scale and layout of the infrastructure over these four borders need to be expanded. At the same time, the scale and layout of the infrastructure over other six borders need to be examined and optimized. The overall scale, layout and detailed improvement plans are listed in Table 1 and Table 2.

Table 1. Overall Scale of Interregional Transportation Infrastructure.

Borders	Railway	Rail Transit	Freeway	Urban Expressway	Arterial Road
Gucheng District-Suzhou New District	2	2	1	3	15
Gucheng District-Xiangcheng District	/	2	1	2	12
Suzhou New District-Xiangcheng District	2	1	3	5	8
Suzhou New District-Wuzhong District	/	1	1	3	23
Suzhou City-Wuxi City	3	1	4	2	3
Xiangcheng District-Changshu City	1	1	1	2	3

The general evaluation shows that the planning will raise the supply of interregional transportation infrastructure by 14.5% and improve the Level of Service (LOS) of interregional transportation systems by one grade. After the planning, the interregional transportation demand of 2020 will be well met, which will support the urbanization and socio-economic development of Suzhou City.

Table 2. Numbers of Detailed Programs.

Classification of Detailed Programs	New construction	Route lines' optimization	Widening alteration	Key nodes' reconstruction
Numbers of Detailed Programs	9	8	4	3

5. Conclusion

The integration planning includes demand forecast, transportation organization planning, transportation infrastructure integration, etc. By applying new methods, the interregional transportation demand could be well forecast. The processes of organization planning and infrastructure integration should be paid special attention to so as to adapt to the rapid development in China. A practical Integration Planning in Suzhou City provided valuable experience for further research. The practice also showed the Integration Planning would be helpful not only to interregional transportation system but also to socio-economic development in China.

Repositioning of Empty Containers in the Transpacific Market: A Case Study

Yu Zhang[1], Cristiano Facanha[2]

1. Assistant Professor, Civil and Environmental Engineering, University of South Florida, 4202 E. Fowler Ave. ENB118, Tampa, FL 33620; PH (813) 974-5846, FAX (813) 974-2957; email: yuzhang@eng.usf.edu

ABSTRACT

Although empty containers can be a great asset to a shipping company if they are strategically positioned, their transportation, handling, and storage represent considerable burdens that impact the company's profits. Trade imbalances between the U.S. and other regions of the world, especially Asian countries, have worsened the situation, and the intermodal coordination of empty containers has become a very challenging issue for shipping lines. The topic represents a very complex logistics problem with practical applications. The analysis focuses on one of the top seven shipping companies globally that is particularly strong on the transpacific trade market. The main goal was to model the operations of the company and introduce new strategies to reposition empty containers more efficiently. The concept of rail terminals should be implemented to provide economies of scale to reduce costs. Ports on the East Coast, which are currently not utilized to transport empty containers back to Asia, also played a role in the strategies considered in this study. The results indicated that the proposed repositioning plan would provide significant cost savings. Further sensitivity analysis is necessary for assessing the performance of the plan. Other complementary strategies, such as the use of a dedicated fleet of trucks to handle local transportation, could be introduced, and the cost-benefit should be compared for practical implications, as well as to improve the proposed model.

Key words: Logistics, Repositioning of Empty Containers, Shipping Line, Operational Strategy

BACKGROUND

One of the major trade problems that have arisen during the last few years, especially on the transpacific market, is the container imbalances between U.S. imports and exports. Their interference with the two-way operations has affected the finances of most shipping companies. The transportation, handling, and storage of empty containers have augmented carriers' overhead costs. The effects are even being felt in Asia, where the internal movement of containers has also suffered (Hanscom 1998). The economic growth in China has greatly contributed to this problem. During the last few years China has rapidly increased its exports to the U.S. (becoming the first source of U.S. imports), while their imports have increased at a slower pace.

An average of 250,000 containers is sent empty from North America back to Asia annually. Shipping costs related to the water portion of the trip are waived as ships have the extra capacity to carry the empty containers back to Asia. The capital

invested in this extra capacity (both in terms of containers and vessels) is not included in the previously mentioned repositioning costs. The latter are mostly composed of transportation (road and rail), handling (mainly at ports, but also at rail terminals) and inventory costs. The transpacific flow of empty containers is handled through four ocean terminals on the U.S. West Coast – Seattle, Portland, Oakland and Los Angeles.

An average container has a 10-year life span, so every year part of the container fleet is renovated while old containers are displaced. Most containers are purchased in China; therefore, new containers do not have to be repositioned. By the same token, displaced containers generally stay in North America in order to avoid repositioning costs.

CURRENT OPERATING PLAN

The selected shipping line goes through an annual "fleet sizing" exercise, which determines the containers that will be replaced and the number of new containers depending on demand forecasts. Containers can be of five different types: dry 20" and 40", which represent the fleet majority, as well as dry 40" (high-cube), dry 45" and reefer 40". On a weekly basis, a "container balancing analysis" is performed. Each location in the U.S. reports the number of containers available (supply of empty containers) and the number of containers needed (demand for empty containers). Because shippers need to book containers a few weeks prior to departure, demand for empty containers is known. This demand comes from both Asian and North American locations.

Based on transit time and rate matrices, each empty container is allocated to a point of demand. Priority is given to fulfill the demand of North American locations, as containers should be loaded as often as possible. Containers that cannot be allocated to North American loads are routed to a West Coast port (Seattle, Portland, Oakland or Los Angeles) based on the lowest cost on their way to Asia. As volumes do not change significantly from week to week, this procedure is not always used. Instead, the same pairs are usually selected, meaning that specific locations always supply empty containers to other specific locations.

In the process of repositioning empty containers, capacity constraints such as railroad equipment, railroad power, labor at ports and drayage equipment need to be considered. As full containers always have priority over empty containers, rail transit times are not always consistent (e.g., "empties" are left behind). Even though westbound vessels have extra capacity in terms of number of containers, there might be weight constraints due to the heavier nature of eastbound loads (e.g., metal scrap, garbage and other heavy goods).

Container Life Cycle

With respect to a container life cycle, it is first filled with exports from Asia, then travels by ship to the U.S. It is then sent from the arrival port in U.S. to a customer by a combination of truck and rail. Part of the empty containers will be repositioned within the U.S. to satisfy the demand of containers bound to Asia, while the remaining empty containers will need to be relocated back to Asia.

Baseline Costs

Based on the information provided by APL, baseline costs are estimated and shown in Table 1.

Table 1. Estimation of Baseline Costs.

Total feus repositioned to Asia	140,409
Total feus repositioned within U.S.	297,140
Trucking Costs	$74,567,838
Rail Costs	$73,051,908
Inventory Costs	$3,413,542
Handling Costs	$9,223,808
Terminal Costs	-
Total Cost	**$160,257,096**

LITERATURE REVIEW

A similar problem to the repositioning of empty containers is empty vehicle redistribution. Literature in that area can be traced back to 1970's. Assuming that decision-makers have complete information, Leddon and Wrathall (1967) developed deterministic models for railcar distribution. In the line of stochastic environments, various models have been developed, such as non-linear network programs (Jordan and Turnquist 1983, Beaujon and Turnquist 1991), multistage dynamic networks (Cheung and Powell, 1996), and logistic queuing network (Powell and Carvalho 1998). The other research direction pursued by researchers later is to develop control policies based on the traditional inventory control policies (s, Q) and (s, S). Literature fall into this category include a single-value threshold control policy (Du and Hall 1997), a pull-type decentralized control policy (Hall and Zhong 2002), and steady state repositioning policy (Köchel et al. 2003). Köchel et al. concluded from the literature that no closed-form solution of optimal empty container/vehicle reposition is available for the stochastic transportation service systems. Recently, Song (2005) studied a continuous-review two-depot service system and obtained an exact solution of the optimal vehicle redistribution policy by using uniformization technique and stochastic dynamic programming.

There is extensive literature in the repositioning of empty containers, called empty container allocation problem. Crainic et al. (1993a, 1993b) specifically considered the repositioning of empty containers in a stochastic environment as a mix integer program and extended it to a multi-commodity network flow model, which they solved with a Tabu search procedure. Nevertheless, their models charge a leasing cost as a fixed amount in one-off mode. Shen and Khoon (1995) then developed a decision support system to optimize container leasing decisions assuming that all demands, schedules and capacity were deterministic within the planning horizon. In their model, the leasing cost is charged according to the duration of the lease. In the line of stochastic environments, besides the models developed by Crainic (1993a, 1993b), others include a simulation model (Lia et al. 1995), a two-stage stochastic network model (Cheung and Powell 1996, Cheung and Chen 1998), a single commodity and multicommodity network model (Godfrey and Powell 2002a, 2002b, Topaloglu and Powell 2004). Lam et al. (2007) demonstrated the successful application of an approximate dynamic programming approach in deriving effective

operational strategies for the relocation of empty containers. Song (2007) found the optimal stationary policy of empty container repositioning in a periodic-review shuttle service system. Erera et al. (2007) developed a robust optimization framework using time-space networks. In their previous work (Erera et al. 2005), they also considered integrating repositioning with load assignment decisions.

Most of the models for empty container repositioning require a specified planning horizon (Crainic et al. 1993a, 1993b, Cheung and Powell 1996, Cheung and Chen 1998, Godfrey and Powell 2002a, 2002b, and Topaloglu and Powell 2004). Nevertheless, it was found that the length of planning horizon had a significant on the outcomes of those model; under a multi-modal circumstance, the longer the planning horizon, the more utilization of inexpensive and slow transportation modes. Traditional logistics solutions require tedious data collection effort, and the numerial optimization could be NP-hard to solve on some occasions (Daganzo 1999). In his monograph "Logistic System Analysis," Daganzo proposed an alternative approach for logistic system planning and analysis. With his method, "detailed data are replaced by concise summaries, and numerical methods are replaced by analytic models." He claimed that the analytic models can be solved accurately without various pieces of detailed information. This study intends to apply the methods for designing the strategies for repositioning empty containers in the continental U.S. Sensitivity analysis will also be conducted the responses of strategies to critical logistic parameters.

METHODOLOGY

Detailed data were provided for both eastbound loads (E_{ij}) and westbound loads (W_{ij}) between Asia and North America for 2002, divided in four quarters. Data were aggregated and included only major terminals (and not the first and last legs). Locations in Mexico and Canada were disregarded for simplification purposes. From this data, supply, demand, net supply, and net demand (of empty containers) in the U.S. were determined based on the above equations.

Three strategies are proposed: (1) introducing "terminals" into the shipping line's network. The investigation of current empty container management suggests that the introduction of "terminals" would increase efficiency and reduce overall cost. By adding terminals, road distance can be minimized by introducing more rail travel distances, which incur lower costs. Each terminal is assigned to an influence area that includes a fixed number of customers. Therefore, customers "belong" to a specific terminal. To simplify the modeling, terminals were assumed to handle the same number of containers. In this context, net supply refers to the difference between supply and demand at a given influence area if supply is higher than demand; net demand refers to the same difference should demand be higher than supply (net demand (ND) = - net supply (NS)). An influence area and its respective terminal belong to a region, which was chosen so that the demand and supply were slow-varying; (2) utilizing ports on East Coast. Empty containers are currently not sent back to Asia through the East Coast ports due to less frequent schedules and capacity constraints. However, we believe it is possible to reduce costs by utilizing such ports, especially for locations in the East Coast; and (3) utilizing a dedicated fleet of trucks.

Step 1: Preliminary Analysis

To account for stochastic variations in our network, the U.S. had to be divided into regions for which current supply and demand of containers were approximately uniform in each region.

Step 2: Optimization

The goal of this step was to develop a logistics cost function that could be minimized in terms of the number of terminals and the headways (decision variables). The cost function has a deterministic and a stochastic component and was divided into four levels:

- **Local Level**: This level concerns costs associated with the movement of containers from a terminal to customers in an influence area, and vice versa. It was assumed that road transportation is the only mode utilized in this level.
- **Regional Level**: This level deals with the movement of containers among terminals within the same region. It was assumed that only rail is utilized.
- **Inter-regional Level**: This level deals with the movement of containers between regions. It was assumed that the movement of containers between regions is done by rail.
- **National Level**: This includes the costs of transporting containers from terminals to seaports by rail.

Deterministic Component

a) Local Level

Local Level Parameters
c_t: Variable trucking cost ($/distance. container) $1/(mile.feu)
c_i: Inventory cost ($/time. container) $0.78/(day.feu)
s_t: Truck speed (distance/time) 1,200 miles/day
c_{ht}: Fixed trucking cost ($/container) $50/feu
– includes handling at customer and drop-off at terminal
D_L: Average local distance (miles)
A_R: Region area (miles^2)
N_R: Number of terminals in the region
MAX: Maximum between supply and demand (feu)

The local level involves the costs associated with the movement of containers between a terminal and its customers. Each terminal services one area of customers, which was approximated by a circle. A simplification could then be made for the average distance from a customer to its respective terminal. Assuming a uniform distribution of customers within an influence area, the average distance from each customer to the terminal was determined to be 2/3 times the radius of the area.

$$D_L = \frac{2}{3} \cdot (\text{Radius of area}) = \frac{2}{3}\sqrt{\frac{A_R}{N_R \cdot \pi}}$$

It has been assumed that handling costs are included in the fixed truck rate, as it was discovered that many costs are collected in contracts made for the outsourced modes of transportation. To model this level of the network, the supply and demand were paired so that the total number of round trips was the maximum of total supply and total demand for each area. It was also assumed that some of the customer

locations have simultaneous supply and demand. Thereby, we estimated that 10 percent of containers do not need to go through terminals.

Breakdown of Average Local Costs:

Transportation Cost = $c_t \cdot D_L \cdot 2 \cdot MAX \cdot 0.9$

Handling Cost = $c_{ht} \cdot MAX \cdot 0.9$

Inventory Cost = $\frac{c_i \cdot D_L}{s_t} \cdot MAX \cdot 0.9$

b) Regional Level

Regional Level Parameters
c_r: Variable rail cost with distance ($/distance. container) - 25 cents/(mile.feu)
c_{hr}: Fixed rail cost - handling ($/container) - $40/feu
c_{fr}: Fixed rail cost per dispatch ($/dispatch) - $200/dispatch
s_r: Rail speed (distance/time) - 600 miles/day
c_{fm}: Fixed cost of terminals ($/terminal) $\begin{cases} \$8000 & \text{for terminals at APL city} \\ \$80000 & \text{otherwise} \end{cases}$
c_m: Variable cost of terminal –renting ($/time.container) - 1 $/(day.feu)
D_R: Average distance between terminals in one region (distance) miles
δ_T: Terminal density, i.e. number of terminals in region/area of region (1/distance^2) 1/miles^2
H_R: Headway to transport containers among terminals (time) days
ND_R: Net demand in one area (feu)
NS_R: Net supply in one area (feu)

On the local level, containers in one area are transported from customers to a single terminal, which in turn fulfills the demand of containers within its influence area. The result will be either a net supply at the terminal (if supply > demand) or a net demand (demand > supply). The regional level cost involves the relocation of containers from terminals with net supply to terminals with net demand.

The distance between terminals in one region (D_R) was calculated based on the assumption that terminals were uniformly distributed. The constant k accounts for the fact that a rail line is never a straight line, and in this case took a value of 1.13 ($2/\sqrt{\pi}$).

$$D_R = k \cdot \delta_T^{-1/2} = k \cdot \sqrt{\frac{A_R}{N_R}}$$

Costs on the regional level were divided into transportation costs, handling costs, inventory costs and terminal costs. Transportation was only done by rail, and its costs have two components, c_{fr}, and c_r. The first one is related to the fixed cost per dispatch. The second one represents the portion that varies with distance. Note that the number of containers that have to be transported among terminals in one region is the net demand (the demand that cannot be satisfied by the supply) in the region, as containers will not be relocated unless they are needed somewhere. The handling cost involves the handling of each container from the rail storage area to the train on both origin and destination rail terminals. Last, inventory costs include both stationary and pipeline inventory. For the first one, it is assumed that, on average, containers spend

half headway at the origin rail terminal and half headway at the destination rail terminal.

$$\text{Transportation Cost} = c_{fr} \cdot \frac{1}{H_R} \cdot N_R + c_r \cdot D_R \cdot ND_R$$

$$\text{Handling Cost} = c_{hr} \cdot ND_R$$

$$\text{Inventory Cost} = c_i \cdot (H_R + \frac{D_R}{s_r}) \cdot ND_R$$

To compute the terminal costs, it was assumed that terminals were located at rail yards. As soon as containers become available at customer locations, they are shipped to the terminals, where they are stored until the next train dispatch. This assures that containers are always available at the terminals and enables economies of scale in dispatching a group of containers at once. It was assumed that each terminal serves the same number of containers, which was determined by the maximum between total supply and total demand in one region, divided by the number of terminals.

It was assumed that cities should receive priority as a terminal, and the cost there would be about $8,000 to rent a storage area. If the optimal number of terminals exceeded 56, the cost of opening a new terminal would then be $80,000. In addition, a rental cost was added. This was calculated by multiplying the rate per container times the maximum space needed by any given terminal.

$$\text{Terminal Cost} = c_{fm} \cdot N_R + c_m \cdot (\text{MAX} + 3\sigma) \cdot H_R$$

c) Inter-Regional Level

Inter-Regional Level Parameters
H_I: Headway to transport containers between regions (days)
D_I: Average inter-regional distance (miles)
L_E: Horizontal length of East region (miles)
L_W: Horizontal length of West region (miles)
ND_I: Net demand in one region (e.g., overall net demand in the East region) (feu)
NS_I: Net supply in one region (feu)

After containers are relocated among terminals within the same region, the net supply and net demand at the regional level are assessed for both the East and the West regions. It is intuitive that relocation at this level happens only if at least one region has an overall net demand. In this specific case, both East and West have overall net supply; therefore, this step was not necessary. However, this study is intended for more general cases, so the methodology for this step is as follows.

The average inter-regional distance was calculated by picturing a virtual regional terminal approximately in the middle of each of the two regions (Figure 1). As both regions – East and West – have the same vertical length, only the horizontal separation was taken into account.

$$D_I = \frac{L_E + L_W}{2}$$

Costs at the inter-regional level were divided into transportation, handling, and inventory costs, which have the same form described at the regional level. Therefore:

$$\text{Transportation Cost} = c_{fr} \cdot \frac{1}{H_I} + c_r \cdot D_I \cdot ND_I$$

$$\text{Handling Cost} = c_{hr} \cdot ND_I$$

$$\text{Inventory Cost} = c_i \cdot (H_I + \frac{D_I}{s_r}) \cdot ND_I$$

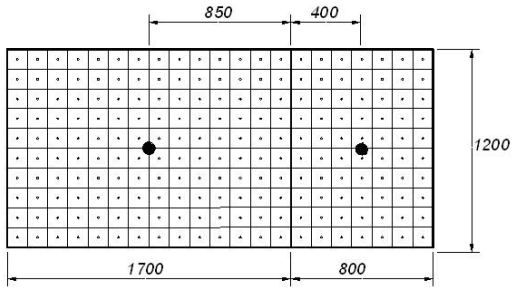

Figure 1. Average inter-regional distance.

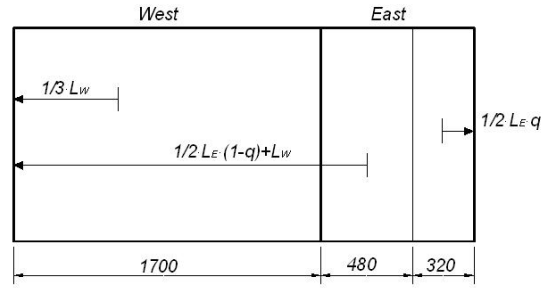

Figure 2. Average distances to ports.

d) National Level

National Level Parameters
D_{N1}: Average distance between terminals to the ports in the same region (miles)
D_{N2}: Average distance between terminals to the ports in the other region (miles)
H_{N1}: Headway to transport containers to terminals in the same region (days)
H_{N2}: Headway to transport containers to terminals in the other region (days)
$L1_R$: Horizontal length of same region (miles)
$L2_R$: Horizontal length of opposite region (miles)
V_R: Vertical length in one region (miles)
$SP1_R$: Supply that goes to ports in same region (feu)
$SP2_R$: Supply that goes to ports in opposite region (feu)

The national level is responsible for the relocation of remaining containers in the regions to the seaports on both West and East coasts after the regional net demand is fulfilled. There are additional capacity constraints on East coast ports due to fewer ship schedules bound for Asia. For simplification purposes, it is assumed that all ships provide the same proportion of their capacity to empty containers and also the same proportion at each port that they detour before they depart to Asia. From the analysis, ships at East ports can carry about 40 percent of the containers originating in East region; the remaining volume has to be transported to ports on the West Coast.

For the West region, due to the low density of containers in the Midwest, the average horizontal distance to the West Coast ports is one third of the region's horizontal length. After fulfilling the net demand of some of the terminals, the East region was divided into two subregions according to the capacity proportion. Containers in Subregion 1 were transported to East Coast ports with average horizontal distance equal to half of the subregion's horizontal length. Containers in Subregion2 were transported to West Coast ports, and the average distance was half of the subregion's horizontal length plus the horizontal-length of West region. There are four ports in each region. We assumed that the average vertical distance for each container to the ports is one eighth of the vertical length. Final numbers are presented in above Figure 2.

$$D_{N1} = L1_R \cdot q \cdot i + 1/8 \cdot V_R \qquad i = \begin{cases} 1/2 & for \quad east \quad region \\ 1/3 & for \quad west \quad region \end{cases}$$

where q is the proportion of containers transported to the ports in the same region.

$$D_{N2} = (1-q) \cdot (1-i).L1_R + L2_R + 1/8 \cdot V_R$$

For the containers transported to ports in the same region:

Transportation Cost 1 = $c_{fr} \cdot \frac{1}{H_{N1}} \cdot N_{N1} + c_r \cdot D_{N1} \cdot SP1_R$

Handling Cost 1 = $c_{hr} \cdot SP1_R$

Inventory Cost 1 = $c_i \cdot \left(\frac{H_{N1}}{2} + \frac{D_{N1}}{s_r} \right) \cdot SP1_R$

Note that the stationary inventory involves only half of the headway (inventory time at the port is not considered).

Similarly, for the containers transported to the ports in the other region:

Transportation Cost 2 = $c_{fr} \cdot \frac{1}{H_{N2}} \cdot N_{N2} + c_r \cdot D_{N2} \cdot SP2_R$

Handling Cost 2 = $c_{hr} \cdot SP2_R$

Inventory cost 2 = $c_i \cdot \left(\frac{H_{N2}}{2} + \frac{D_{N2}}{s_r} \right) \cdot SP2_R$

Stochastic Component

As the supply and demand for containers are not deterministic, stochastic variations were accounted for in this part. In the previous section, the expected number of containers was relocated within an area (local level), among areas in one region (regional level), and to the seaports (national level). This assured the whole country to be balanced. In other words, the net supply/net demand in all locations (e.g., seaports, terminals and customers) can be considered zero after the deterministic portion is solved.

Note that the deterministic component contains a term to account for the effect of demand and supply variance in the terminal renting cost, so this one is not included here. Thus, the stochastic component is concerned only with the relocation cost of containers among terminals.

The total container-distance traveled per terminal (p) was determined from a function formulated by Daganzo and Smilowitz (2003). The formula assumed that a region with an expected density of terminals (δ_R) had a net supply/net demand with zero mean and standard deviation σ, and N_R terminals.

$$p = \sigma \cdot \delta_R^{-1/2} \cdot f(N_R) = \sigma \cdot \delta_R^{-1/2} \cdot \left[0.43 + 0.02 \log_2 (N_R) \right]$$

The total cost has a similar form to that described in the regional level of the deterministic part. The number of containers in each terminal dispatch is $\sigma * H_R$, and it follows that:

Transportation Cost (regional) = $c_{fr} \cdot \frac{1}{H_R} \cdot N_R + c_r \cdot P_R \cdot N_R$

Handling Cost = $c_{hr} \cdot \sigma \cdot N_R$

Inventory Cost = $c_i.(H_R.\sigma + \frac{p_R}{s_r})$

The cost function included all costs in both deterministic and stochastic parts. Table 2 provides a summary of the cost function.

Table 2. Total Cost Function.

Deterministic Component	
• Local Level	$c_t \cdot D_L \cdot 2 \cdot MAX \cdot 0.9 + c_{ht} \cdot MAX \cdot 0.9 + \frac{c_i \cdot D_L}{s_t} \cdot MAX \cdot 0.9$
• Regional Level	$c_{fr} \cdot \frac{1}{H_R} \cdot N_R + c_r \cdot D_R \cdot ND_R + c_{hr} \cdot ND_R + c_i \cdot (H_R + \frac{D_R}{s_r}) \cdot ND_R$ $+ c_{fm} \cdot N_R + c_m \cdot (\mathrm{MAX} + 3\sigma) \cdot H_R$
• Inter-regional Level	$c_{fr} \cdot \frac{1}{H_I} + c_r \cdot D_I \cdot ND_I + c_{hr} \cdot ND_I + c_i \cdot (H_I + \frac{D_I}{s_r}) \cdot ND_I$
• National Level	$c_{fr} \cdot \frac{1}{H_{N1}} \cdot N_{N1} + c_r \cdot D_{N1} \cdot SP1_R + c_{hr} \cdot SP1_R + c_i \cdot \left(\frac{H_{N1}}{2} + \frac{D_{N1}}{s_r} \right) \cdot SP1_R$ $+ c_{fr} \cdot \frac{1}{H_{N2}} \cdot N_{N2} + c_r \cdot D_{N2} \cdot SP2_R + c_{hr} \cdot SP2_R + c_i \cdot \left(\frac{H_{N2}}{2} + \frac{D_{N2}}{s_r} \right) \cdot SP2_R$
Stochastic Component	$c_{fr} \cdot \frac{1}{H_R} \cdot N_R + c_r \cdot P_R \cdot N + c_{hr} \cdot \sigma \cdot N_R + c_i . (H_R . \sigma + \frac{p_R}{s_r})$

Constraints

The demand for empty containers in Asia did not have to be considered as a constraint. As empty containers are produced in Asia, they can be purchased there if it is more cost effective. Even though rail capacity can be an issue in practice, it was disregarded for simplification purposes. Port capacity was taken into account in order to prioritize the shipment of containers to different ports. We also assumed an infinite supply of trucks and of storage area at seaports and rail terminals. The number of terminals in the West region was constrained at 40, as it is the number of terminals served by the major rail companies.

Optimization Results

Regions were permitted to have different number of terminals and headways, so, in fact, there are two decision variables representing the number of terminals in each region and the three types of headways mentioned. The optimization model yielded the results shown in Table 3. Further analysis of such results is included in the Future Steps section.

Table 3. Optimization Results.

Optimization Results	East Region	West Region	Total
Total Cost	$58,098,500	$59,667,700	$117,766,200
Number of Terminals	53	40	93
Regional Headway (among terminals) (days)	5	4	
National Headway - to port in same region (days)	17	12	
National Headway - to port in opposite region (days)	11	-	

Step 3: Network Design

Step 2 provides the optimal number of terminals in both regions. Step 3 is responsible for choosing the location of such terminals, and determining their influence areas.

Actual Location of Terminals

Terminals for repositioning containers will be located at existing rail terminals, where yard space will be rented as needed. It was assumed that there would always be yard space available. From a list of rail terminals provided by the major rail companies, cities were ranked by the following factors (in order): (1) whether the shipping line currently has operations in such city (because there is an implicit penalty for opening a new facility), (2) number of rail routes that go through the city, and (3) number of rail companies that serve the city

The optimal number of terminals in the East, N_E*=53, matched up precisely with the number of leading cities on the ranked list. In the initial run of the optimization model output, number of terminals for the West region was 78. However, this value became unreasonable when compared to the number of existing rail terminals. A restriction was added to the model to reduce the number of terminals within the range of feasible rail terminals (Note: In the later section on sensitivity analysis, it can be seen that this restriction has a rather insignificant effect on the total costs.) The final result for the optimal value of terminals in the West was N_W*=40.

Determination of Influence Areas

Based on the actual location of terminals, it was assumed that each customer was allowed to send containers to its nearest terminal. The specific algorithm to assign influence areas to terminals assumed that demand was given by a function per square mile. Thus, we considered each 1x1 square mile to be a fictional customer with a demand for a certain amount of containers. The Voronoi Tesselation method was used to assign each fictitious customer to a terminal and thus determine the influence areas (Voronoi Tesselation 2003). Influence areas can be thought of as Voronoi regions, where all interior points are closer to the corresponding generator, or terminal, than to any other. Then, the Voronoi Tessellation is the set of Voronoi regions where no pairs of Voronoi regions have a common point. The distance is $d(z, z_i) = \|z - z_i\|$, where z is a terminal location coordinates and z_i is a 1 mile by 1 mile region representing a fictitious customer. Average distances were calculated from every $d(z,z_i)$.

Step 4: Cost Calculation

By determining the actual location of terminals, total logistics costs will be slightly different from the optimized costs. The same four levels considered will be evaluated in order to calculate the actual costs of the proposed strategies:

a) Local Level

Once the influence areas were determined, local level costs (from customers to terminals and vice-verse within an influence area) could be calculated.

For the purpose of determining the customer demand/supply density only, the 56 data points were regarded as terminals that handled containers in their own influence area. To allocate customers to terminals (to establish influence areas), it was determined that each customer was allowed to send containers to its nearest terminal. Assuming customers are uniformly located in each area and all the

customers within the same area are identical, the customer demand/supply density for each area could be obtained.

Based on this density function and on the location of terminals, the influence areas (e.g., total area, shape, and container average travel distance) could be determined through the same methodology. By combining the demand and supply of each customer within an influence area, the number of containers handled by the terminal was calculated. The local cost of transporting containers between customers and terminals was obtained as a function of the average travel distance and the volume of containers handled by a terminal.

b) Regional, Inter-regional and National Levels

Supply and demand values for each terminal were calculated by aggregating the supply and demand densities over each influence area. By regarding ports as terminals with net demand, balancing containers within the whole country was captured by a minimal cost network flow problem. The regional, inter-regional and national level costs were determined. In our specific case, inter-regional costs were not applicable as there were not any flows between both regions. Ports' demand was determined according to their capacity.

Cost Calculation Results

Based on the actual location of terminals and their respective influence areas, new costs were calculated. Table 4 compares such results with baseline and optimized costs, and it reflects that significant savings (19.07%) can still be realized by applying the proposed strategies. Additionally, the main differences between the actual and the optimized costs rely on rail costs. This is true, as rail distances are higher once the actual locations of terminals is determined, and terminals in the East region are forced to ship the remaining empty containers to the West Coast ports due to capacity constraints on the ports in the East Coast. Actual inventory costs are higher then optimized inventory costs as the maximum headway between the regional and the national was utilized to simplify the calculations. Both handling and inventory costs remain fairly constant, as they do not depend on the terminal locations.

Table 4. Cost Comparison.

Cost Item	Baseline	Optimization	Actual
Trucking Costs	$74,567,838	$42,284,200	$42,793,671
Rail Costs	$73,051,908	$45,277,987	$52,414,260
Inventory Costs	$3,413,542	$1,024,332	$5,185,021
Handling Costs	$9,223,808	$24,324,150	$24,324,150
Terminal Costs	$0	$4,825,590	$4,972,441
Total Costs	$160,257,096	$117,736,259	$129,689,443
% savings compared to baseline		26.53%	19.07%

FUTURE STEPS

The problem of repositioning empty containers has great depth. To get a more realistic view of the effects of our suggestions, the following further investigations should be considered. First, the optimization results from the previous section provided an optimal solution by minimizing total logistics costs based on several

parameters and constraints. To determine how robust the logistics cost function is to these parameters, constraints and strategies, sensitivity analyses should be performed. Second, based on the sensitivity analyses, the influence of strategies should be assessed. Third, it is important to assess the practical implications of implementing a terminal system to the reallocation of containers. These are difficult to model but are nonetheless significant. Fourth, more comprehensive research should be done on the costs of designing, implementing and operating a dedicated truck fleet for handling the local transportation. Finally, our model assumes that a rail terminal can use any headway. However, rail transportation is restricted to schedules. Synchronizing the reallocation of containers to involve the rail (and possibly port as well) schedules would provide a more practical idea of the entire system.

ACKNOWLEDGEMENT

The authors would like to thank Monica Menendez and Huifang Yin for their assistance on preliminary analysis for this study.

Institute for Traffic Engineering, Ruhr-University Bochum, 44780 Bochum, Germany; phone: +49 234 3226557, fax: +49 234 3214151; e-mail: ning.wu@rub.de, http://homepage.rub.de/ning.wu

ABSTRACT

The first version of the German Highway Capacity Manual was published in 2001. Now, a new draft is prepared and it will be published in 2011 (HBS2011). For the new German Highway Capacity Manual, the major chapters are revised and some of them are totally rewritten.

In this paper, a short overview of the major developments in the new German Highway Capacity Manual is presented. Some new ideas and field dada under consideration are introduced. For example, according to the new measurements, the values of capacity for freeway segments are revised and for the on-, off-ramps, and weaving areas a totally new procedure is developed which considers the traffic flow conditions on the freeways and at on- and off-ramps simultaneously. Also for signalized and unsignalized intersections, the procedures are revised for taking account the new developments in the past 10 years.

INTRODUCTION

Germany has been involved in traffic engineering research since many decades. Initially, the more popular calculation procedures were mainly based on deterministic considerations. Publication of the U.S *Highway Capacity Manual* (HCM) in the 1950s spurred interest in the use of stochastic elements combined with empirical research in traffic engineering. Until 2001, the different calculation procedures used in German traffic engineering applications have never been concentrated into one guideline such as the HCM. Instead, these applications were incorporated in different highway design guidelines. A new era in the development of traffic engineering guidelines for German conditions began when the Federal Department of Transportation (DOT) commissioned the Ruhr-University in 1989 to develop a prototype for a German *Highway Capacity Manual* (HBS*)*. The first draft for this manual was finished in 1993 and was published a year later by Brilon, Grossman, and Blanke (Brilon et al. 1994).

The first edition of the *German Highway Capacity manual* (*Handbuch fuer die Bemessung von Strassenverkehrsanlagen*, HBS2001) was published in 2001 (FGSV, 2001). It was introduced by the German federal DOT as the methodological basis for capacity calculations and quality assessments. Similar to the US *Highway Capacity Manual* (HCM2000), HBS2001 is based on the concept of Level of Service. An overview on the current version of HBS2001 was given by BRILON (1998).

After its publication, HBS2001 has found wide applications. Because of the importance for the professionals in the practice, the German Road and Transportation Research Association (FGSV) decided to up-date this manual. Goals of the updating work are to revise the existing chapters and to complete the contents as good as possible. In comparison to the HBS2001, the methodologies for assessment should be given in more details in the new edition.

The Institute for Traffic Engineering at Ruhr-University has provided significant contributions to the development of the new HBS2011. In this paper the proposed major revisions in the new HBS2011 are introduced chapter by chapter.

TRAFFIC DEMAND AND CAPACITY (CHAPTER 2)

The chapter 2 of the HBS deals with the fundamental concept for dimensioning and traffic quality assessment procedures. The main topic of this chapter is to provide a procedure for determining the peak hour volume for dimensioning traffic facilities and computing capacities.

In the current HBS2001, the traffic volumes for dimensioning the different traffic facilities are not exactly defined. It is suggested to use the 30th hourly volume in the year as the dimensioning peak hour volume. However, it not clearly defined how this 30th hourly volume is estimated. Thus, a modification regarding this topic is needed.

In the proposed HBS2011, the 30th hourly volume in the year will continue to be used for dimensioning the peak hour volume. However, a functional relationship between the 30th hourly volume in the year and the considered peak hour volume will be given. The use of directional peak hour volumes or aggregated peak hour volumes is recommended depending on the specific traffic conditions. The procedure for estimating the proportion of peak hour volumes to annual average daily volume (ADV) is improved.

BASIC FREEWAY SECTIONS (CHAPTER 3)

In Germany, it still lacks a general speed limit on motorways or freeways. In addition, passing on the right lane is not allowed, and this rule is generally followed by drivers. As a result, the right lane is preferred for normal driving except when passing. This rule causes a lot of lane changing maneuvers. Furthermore, the speed limit for trucks is only 80 km/h. Those rules and characteristics together generate a special traffic flow and speed relationship on German freeways where a significant influence of volume on average speed occurs.

The current HBS2001 recommends the volume/capacity-ratio (v/c-ratio) to assess the quality of traffic flow on German freeways with two or three lanes each direction. The database based on the measurements from Ponzlet (1996). The database is now extended. In the proposed HBS2011, also the freeways with 4 lanes each direction will be incorporated.

The proposed capacity in HBS2011 for different freeway sections is illustrated in the Table 2. The Level of Service (LOS) is defined depending on the degree of saturation (Table 1).

Table 1 - LOS for freeways depending on the degree of saturation

LOS	Degree of Saturation at LOS (x_{LOS})
A	$\leq$ 0.30
B	$\leq$ 0.55
C	$\leq$ 0.75
D	$\leq$ 0,90[1)]
E	$\leq$ 1.00
F	–

[1)] 0.95 for sections with Variable Speed Limit

Table 2 - Capacity (veh/h) for freeways without speed limit

No. of lanes each direction	Grade	Long distance freeways			Metropolitan traffic freeways		
		Percent of trucks			Percent of trucks		
		0 %	10 %	20 %	0 %	10 %	20 %
2	≤ 2 %	3700	3600	3400	4000	3800	3600
	3 %	3600	3500	3300	3900	3700	3500
	4 %	3400	3300	3100	3700	3500	3300
	5 %	3100	3000	2800	3400	3200	3000
3	≤ 2 %	5400	5200	4900	5800	5500	5200
	3 %	5300	5100	4800	5700	5400	5100
	4 %	5000	4800	4500	5400	5100	4800
	5 %	4600	4400	4100	5000	4700	4400
4	≤ 2 %	7400	7100	6700	8000	7600	7100
	3 %	7200	6900	6500	7800	7400	6900
	4 %	6900	6600	6200	7500	7100	6600
	5 %	6300	6000	5600	6900	6500	6000

ENTRANCES AND EXITS (ON- AND OFF- RAMPS) AT FREEWAYS (CHAPTER 4)

The capacity and performance of entrances, weaving areas and exits has been studied by Westphal (1995). Although this investigation focused on urban freeways with speed limits of 80 or 100 km/h, Westphal's procedures are also recommended by the HBS2001 for all types of freeways. In the proposed HBS2011, a totally new procedure is introduced. The procedure is developed by Wu (2008). This procedure considers the major freeways, the on- and off-ramps and the weaving areas under consideration simultaneously. The capacity for exits is expressed by the following equation:

$$q_{a,LOS} = C_{a,LOS} \cdot \sqrt[a]{1 - \left(\frac{q_h}{C_{h,LOS}}\right)^a} \qquad (1)$$

with $q_{a,LOS}$ = maximum flow of the entrance, exit, or weaving area by a given LOS

$C_{h,LOS} = C_h \cdot x_{LOS}$

$C_{a,LOS} = C_a \cdot x_{LOS}$

C_h = capacity of the major freeway section

C_a = capacity of the road section at the entrance, exit, or weaving area

a = model parameter

x_{LOS} = degree of saturation for a given LOS (Table 1)

According to the equation (1), the LOS for the on-, off-ramps or the weaving areas can be defined depending on the traffic volume on the major freeway section and the entrance/exit. Figure 1 shows a picture depicting the equation (1) for a 1-lane entrance to a 3-lane freeway with C_h=5700 veh/h, C_a=1800 Veh/h, and a=1.9. Those

pictures are constructed for all types of entrances, exits, and weaving areas in the proposed HBS2011. The users can use those pictures directly for estimating traffic flow quality.

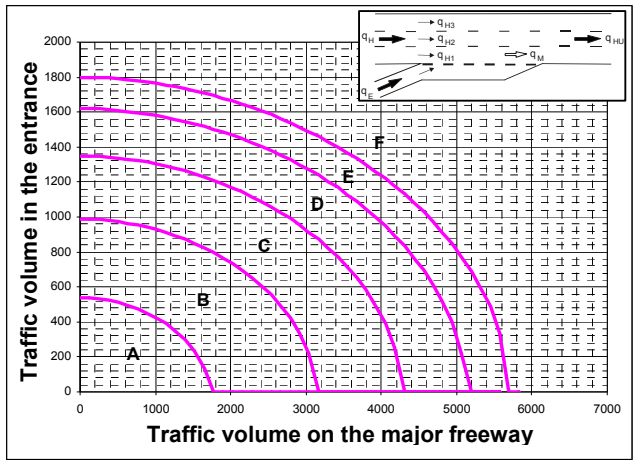

Figure 1 – An Example for the Definition of LOS (equation (1)) for a 1-lane entrance to a 3-lane freeway.

In order to ensure the downstream capacity, an extra-examination is needed for the downstream freeway section according to the Table 2 and Table 1.

TWO-LANE RURAL HIGHWAYS (CHAPTER 5)

The current procedure in the HBS2001 dealing with the capacity and traffic quality of 2-lane rural highways was introduced by Brilon and Weiser (1998, 2003). No significant changes are proposed for the new HBS2011.

SIGNALIZED INTERSECTIONS (CHAPTER 6)

This chapter will be totally revised, because some fundamental parameters and calculation procedures are not more up to date. In the new HBS2011, the chapter for signalized intersection will also be improved by avoiding overlapping with the German Guidelines for Traffic Signals (FGSV, 1992). The saturation flow rates will be recalibrated and the delay formula will be substituted by a new one which considers also the coordination and the traffic-actuated signal control. The details of this chapter are not discussed here because the revising work is still in process.

UNSIGNALIZED INTERSECTIONS (CHAPTER 7)

Calculation methods for unsignalized intersections have been developed cooperatively by American, Australian, and German researchers since many years. The new German version of the corresponding chapter tries to contribute some additional improvements in this area.

In the HBS2001 and HBS2011, the basic capacity will be calculated by Siegloch's formula. The critical gaps and follow-up times were estimated by comprehensive investigation in German (Brilon and Weinert, 2001). The problem of two-stage priorities was resolved like in the HCM2000.

Improvements that have not yet been included in the HCM2000 include:

- Impedance factors for rank 4 movements: The current HCM-solution is based on Grossmann's (1991) simulation results. Meanwhile, Wu (1998) has found a theoretical approach to that problem that enables a more precise estimation of impedance effects.

- The HCM2000 does not address the mixed and short lanes on traffic performance properly. In the HBS2000, the theoretical procedure developed by Wu (1997) is incorporated for minor approaches. In the new HBS2011, the procedure for the mixed and short lanes in major approaches is extended revised.
- Capacity calculations for roundabout entries are based on a calculation method described by Brilon, Bondzio, Wu (1997). This method is now recalibrated for taking into account the new developments in geometric design in the roundabout construction such as the mini-roundabouts, turbo-roundabouts etc.

According to those innovations, the unsignalized chapter of the HBS has a rather high standard regarding theoretical background.

URBAN ARTERIALS (CHAPTER 8)

In the current HBS2001, there is no procedure for assess the quality of traffic flow on urban arterials. In the proposed HBS2011, the procedure proposed by Baier et al. (2003) will be introduced. With this procedure, the traffic flow quality on the sections outside the influence of major intersections can be assessed.

PEDESTRIANS, BICYCLES, PUBLIC TRANSIT, AND PARKING (CHAPTER 9, 10, 11, AND 12)

Much emphasis in Germany is put on safe and comfortable operation of traffic for non-motorized road users and for public transit. In the current HBS2001, only the service quality for passengers inside the public transport vehicles (busses, trams) is considered. In the proposed HBS2011, the traffic flow of public transport vehicles on separate lanes and at (local) public transport stops are included. In this new procedure, also other road users such as taxis, cyclists, or HOV's are allowed to use the separated bus lane. The assessment of traffic flow for busses and trams mixed with the general traffic will be addressed in the other chapters. The procedures for capacity inside the public transport vehicles are excluded from the HBS2011. A separate guideline shall be developed for the public transport systems. A new chapter for bicycles is introduced in the proposed HBS2011. The existing chapters for pedestrians and parking systems are improved.

SUMMARIES

This paper illustrates the major contents of the future German HBS2011. It is intended to be published in the year 2011. Research projects are still underway for additional improvements. The new version of HBS that will be finished in the year 2011 will be comparable with the future HCM 2010 in many aspects.

The proposed paper shows the expertise of our institute in research on capacity and service quality analysis and the experience in developing highway capacity manuals in Germany and as a partner in the United States. Those expertise and experience can give the Chinese audience and institutes involving in research on capacity models and in developing capacity manuals useful knowledge and help them to speed up the developing process and avoid unnecessary errors and mistakes.

ABSTRACT

In the State of Florida, several types of exit ramps are used for traffic to exit our freeways, especially four typical types, which are single-lane exit ramp with a taper, single-lane exit ramp without a taper, two-lane exit ramp with an optional lane, and two-lane exit ramp without an optional lane. Drivers exiting freeways need to make decisions and execute maneuvers (i.e., lane change or lane merge) prior to the exit ramp in order to access cross roads at the interchanges. And different types of exit ramps lead to different driving maneuvers when exiting (fast-paced deceleration, lane changing, merging, unbalanced lane utilization), which also affects the operational performance on freeways. Bases on the facts, there are several issues and concerns that need to be addressed in selecting the most optimum types of freeway exit ramp(s) to use at a given interchange. This paper mainly focuses on different impacts of number of lane change by different types of ramp. A data collection of 24 sites were conducted to help set up a mathematical model, which could estimate the number of lane change by considering several possible independent variables. Results of the model could help choose optimal ramp type.

KEY WORDS

Operational performance; Exit ramp; Ramp type; Number of lane change.

BACKGROUND INFORMATION

There are several types of exit ramps used for traffic to exit freeways in the United States (i.e. Interstate and Turnpike Systems). Typically, four types of freeway exit ramps are most widely used in Florida, shown from Figure 1 to Figure 4. Drivers exiting freeways need to make decisions and execute maneuvers (i.e., lane change or lane merge) prior to the exit ramp in order to access cross roads at the interchanges. If the exit ramps are not sufficiently long, drivers must complete their driving maneuvers within a short distance, resulting in potentially unsafe driving actions (i.e., fast-paced deceleration, lane changing, merging, unbalanced lane utilization, etc.),

which will result in the development of shock-waves onto upstream traffic, etc. Considering these factors, there are several issues and concerns that need to be addressed in evaluating operational performance of each type of exit ramp and selecting the most optimum types of freeway exit ramp(s) to use at a given interchange.

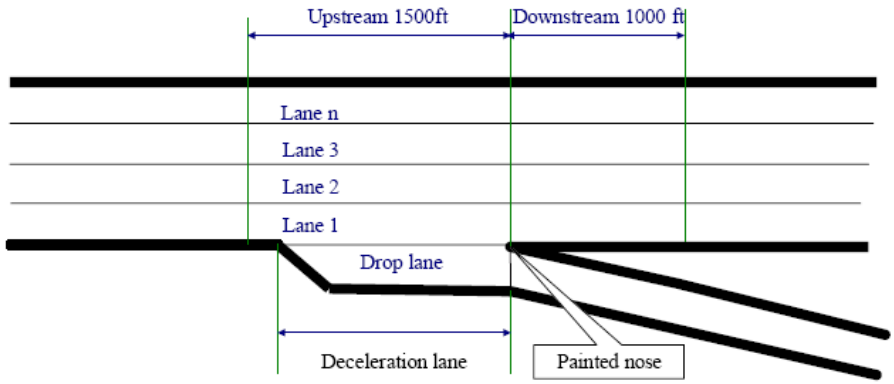

Figure 1. Type 1 exit ramp: single-lane exit ramp with a taper

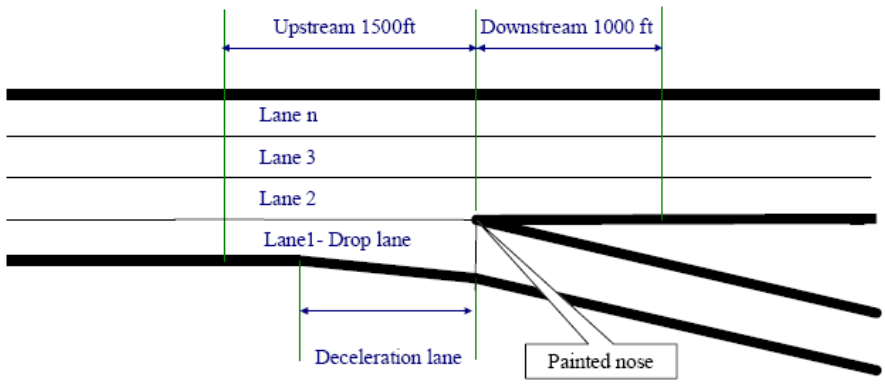

Figure 2. Type 2 exit ramp: Single-lane exit ramp without a taper

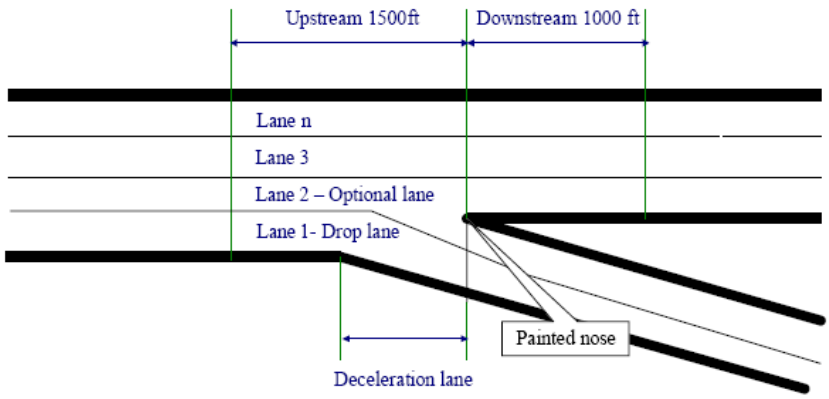

Figure 3. Type 3 exit ramp: Two-lane exit ramp with an optional lane

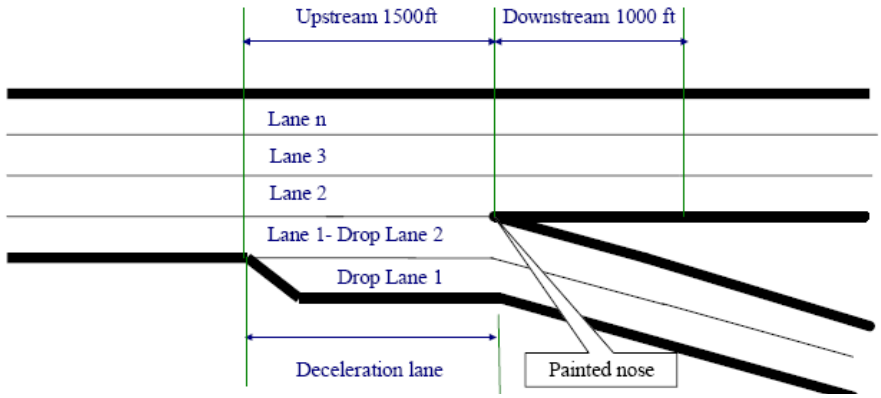

Figure 4. Type 4 exit ramp: Two-lane exit ramp without optional lane

Besides ramp type, some issues in the joint cross road of ramp can also affect safety problems, which include but are not limited to, control type of ramp terminal, downstream and upstream intersection, the distance between downstream intersection and ramp terminal, and the distance between upstream intersection and ramp terminal, shown in Figure 5. Inadequate distance for traffic to transit from the exit gore to the downstream or upstream intersection can cause complex weaving maneuver and additional rear end crash. Therefore, it is very important to present the minimal distance between these three intersections on cross road in order to prevent crashes on both exit ramp and cross road.

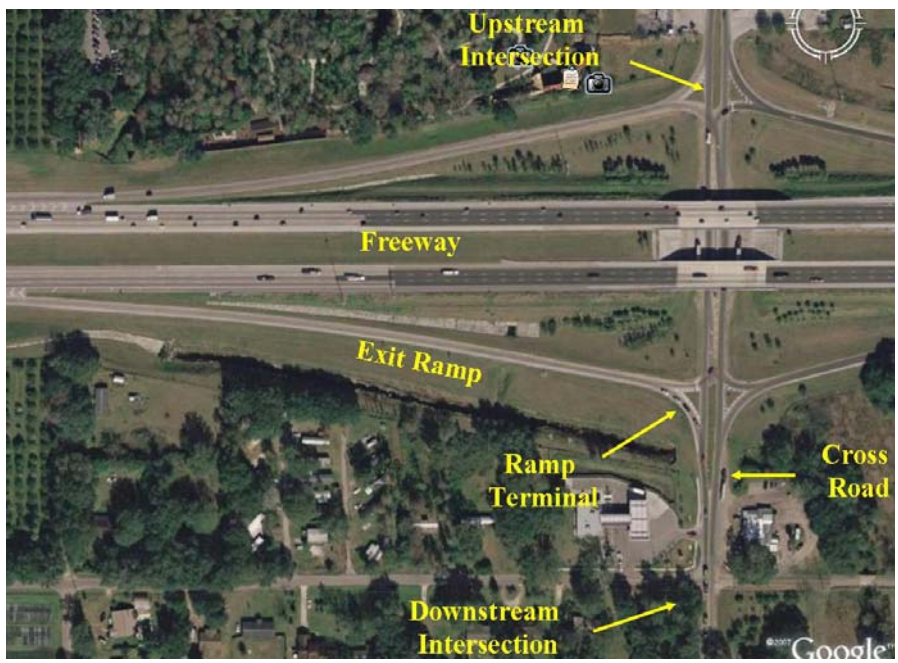

Figure 5. Exit ramp and joint cross road

All these issues have not been studied in the past and no clear guidelines,

either federal (AASHTO Green Book) or state, are currently not available in selecting exit ramp types. The Florida Department of Transportation (FDOT) in joint cooperative efforts with the local land use agencies set up a research project to determine the type of exit ramps that should be constructed at a given location considering the prevailing conditions applicable to traffic, roadway, and land-use developments.

The whole project contained three sections, freeway, ramp and cross road sections. This paper mainly focused on freeway section. Trying to find out the impacts of operational performance on freeway due to different types of ramp, and to help choose optimal ramp based on the performance.

METHODOLOGY AND DATA COLLECTION

The number of lane change on freeway is a very significant measure of effectiveness to evaluate the operational performance, which also affects safety. And number of lane change is the direct cause of potential crashes. The concept of number of lane change here refers to the changing lane maneuver that happens in the area of upstream section of painted nose (start point of exit ramp), which includes 1500 ft distance, see Figure 6. Vehicles exiting ramp need to change lane to the most right lane before entering ramp, if they are not at the right lane yet. Thus, the lane change happens from lane 1 to lane 4, lane 2 to lane 4, or lane 3 to lane 4. Lane change happening among lane 1 to lane3 will not be considered to be effective number here, because which is not the response of exit ramp. On the other hand, going through vehicles need to change to the through lane if they are on the most right lane before ramp. This is also effective number of lane change, because it is relational to ramp type.

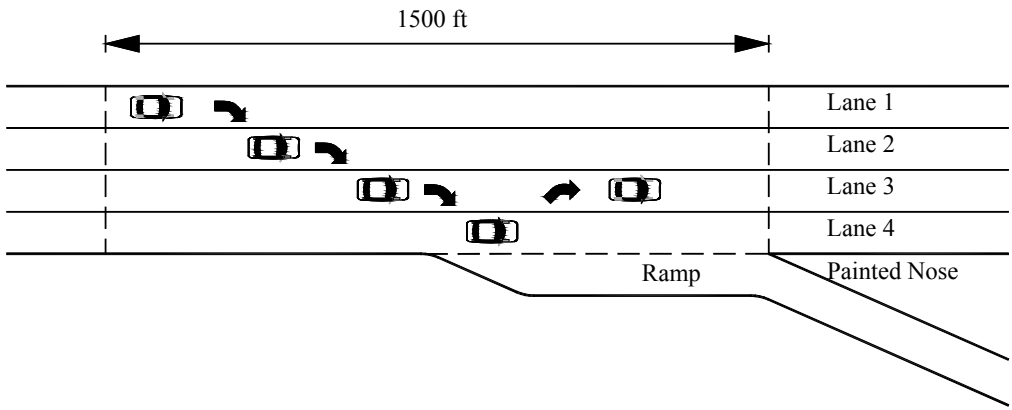

Figure 6. Number of Lane Change on Freeway

The exit ramp type is the first factor that has impacts on number of lane change. Because different types of ramps tell drivers different information and cause

different driving behavior. Besides it, other factors might also affect number of lane change. Volume on freeway is a reasonable factor because more vehicles on freeway, more vehicles exiting, and more probability of lane change. Volume on ramp has the same reason. Number of through lane on freeway also works, more lanes means more lane change. Another possible factor is operational speed on freeway, by the consideration that different speed provides diverse difficulty level of changing lane.

Data collection of totally 24 exit ramps was conducted to get all these data. Ramp type and number of through lane on freeway were known before observing. Volume on both freeway and ramp were captured by people counting in the field. The operational speed was detected in assistance of radar gun. And number of lane change was collected by setting up video cameras. All data are shown in Table 1.

Table 1. Demonstration of Lane Change

No.	Ramp Type	Number of Through Lane on Freeway	Freeway Volume (vph)	Ramp Volume (vph)	Operation Speed (mph)	Number of Lane Change
1	Ⅰ	2	1640	731	64.5	28
2	Ⅰ	3	1017	583	66.3	36
3	Ⅰ	3	2072	663	50.1	41
4	Ⅰ	3	2101	654	52.2	53
5	Ⅰ	3	2602	673	62.1	56
6	Ⅰ	4	3855	832	61.4	72
7	Ⅰ	3	3891	782	62.9	88
8	Ⅰ	2	2767	654	56.8	62
9	Ⅱ	2	5256	831	51.5	97
10	Ⅱ	3	5914	1418	48.7	214
11	Ⅱ	3	6756	966	53.8	188
12	Ⅱ	3	5139	954	62.9	176
13	Ⅲ	3	3821	1056	58.7	103
14	Ⅲ	3	3700	778	64.3	87
15	Ⅲ	3	4676	1123	53.0	164
16	Ⅲ	4	4425	1038	56.6	134
17	Ⅲ	4	6000	1852	60.2	166
18	Ⅲ	3	5157	1398	49.2	143
19	Ⅲ	3	6003	1211	60.8	158
20	Ⅲ	3	4524	845	45.6	120
21	Ⅲ	2	4519	1244	49.3	98
22	Ⅳ	3	4280	1214	49.9	143

23	Ⅳ	4	3028	784	64.5	119
24	Ⅳ	2	3933	547	55.9	117

A mathematical model was needed to be presented to evaluate and forecast the possible number of lane change based on all above data. An exponential model was selected, which fitted large number of dependent variables well. The format of the model is shown as following, including seven variables.

$$Y = \exp(a_0 + a_1X_1 + a_2X_2 + a_3X_3 + a_4X_4 + a_5X_5 + a_6X_6 + a_7X_7) \quad \text{Eq.1}$$

Where,

X_1 ——1 for ramp type II, 0 for others,
X_2 ——1 for ramp type III, 0 for others,
X_3 ——1 for ramp type IV, 0 for others,
X_4 —— Number of Through Lane on Freeway,
X_5 —— Freeway Volume (vph),
X_6 —— Ramp Volume (vph),
X_7 —— Operation Speed (mph) on Freeway, and
a_0 to a_7 —— Coefficients.

RESULTS AND CONCLUSIONS

Data of Table 1, including all variables in Equation 1 were analyzed by using mathematical software SPSS 16.0. Independent variables of ramp types are dummy variables, so ramp type I is chosen as the reference variable. In order to lower the errors, value of X_5 and X_6 were divided by 1000, and X_7 divided by 100. This made the absolute value of all variables at the same level. The distribution of error is supposed to be normal distribution, and the confidence coefficient is 95%.

Mathematical analysis showed that the absolute value of a_6 and a_7 were smaller than 0.001, which meant the ramp volume (a_6) and operation speed on freeway (a_7) had very little impacts on number of lane change (Y). Thus, variables X_6 and X_7 were eliminated to simplify Equation 1, see Equation 2.

$$Y = \exp(a_0 + a_1X_1 + a_2X_2 + a_3X_3 + a_4X_4 + a_5X_5/1000) \quad \text{Eq.2}$$

Where, all dependent and independent variables were same as Equation 1.

All coefficients in Equation 1 were calculated by non-linear regression process in SPSS, with fitting parameters, results see Equation 3 and Table 2 as followed:

$$Y = \exp(2.91 + 0.342X_1 + 0.304X_2 + 0.563X_3 + 0.139X_4 + 0.252X_5/1000) \quad \text{Eq.3}$$

Where, all dependent and independent variables were same as Equation 1.

Table 2.Mathematical Results of Equation 2

Variable	Coefficient	Std. Error	Standardized Coefficients Beta
Constant	2.910	0.195	
X_1	0.342	0.185	0.236
X_2	0.304	0.131	0.273
X_3	0.563	0.130	0.345
X_4	0.139	0.061	0.158
X_5	0.252	0.046	0.680

All Standardized Coefficients Beta showed the low fitting level of the model based on all field data. The reason might be the limited sample size of observation, as data of only 24 exit ramps were collected. And it is reasonable to believe that ramp volume would also affect the number of lane change. The number of lane change will increase with ramp volume increasing. And large sample size in the future might help find correlation ship between number of lane change and ramp volume. However, this model still demonstrated the relationships among number of lane change and all possible factors.

Compared to the coefficients of four exit ramp types, number of lane change of type I is the smallest, type IV is the largest, type II and type III are between them. If all other conditions are the same, such as volume speed and lanes, the possible number of lane change of exit ramp type I will be smaller than other three types, meaning the least probability of potential crashes. On the other hand, exit ramp IV has the highest probability of crashes. Exit ramp type II and type III are at the medium level, and type II are a little bit higher than type III. Also, the model indicates that the increasing of through lanes and volume on freeway will cause the increment of number of lane change.

All these conclusions suggest that, bases on the consideration of potential conflicts, one lane exit ramp is prior to two lane exit ramp. Ramp type I is prior to type II if one lane can provide enough capacity for ramp. Ramp type III is prior to type IV if ramp needs two or more lanes.

FUTURE RESEARCH

This research has provided statistical comparison of number of lane change among 4 types of exit ramps. The results and conclusions are benefit for the following research, which need to present quantified design guidelines of selecting optimal exit ramp under certain conditions including geometric and traffic characteristics. In addition, some design issues about the cross road should also be presented in the future.

ACKNOWLEDGEMENT

This research project was partly sponsored by the Florida Department of

Transportation. The FDOT is greatly appreciated for providing help on the information provided. The authors also would like to thank all the Graduate Research Assistants at the Department of Civil and Environmental Engineering of the University of South Florida for their assistance in field data collection and data reduction.

ABSTRACT

The change in traffic policy affects the characteristics of traffic and the direction of sustainable development of a city to a great extent. As an international metropolis, Beijing shares the same kind of traffic problems with other cities of the developed world, in its pattern of traffic development, especially in the city centre. The paper first discusses the development of the strategic transport model of Beijing based on the tool of STM (Strategic Transport Model). Then the paper presents an analysis of traffic patterns in the city centre of Beijing, and the policies that can be used to improve travel in the area. The paper presents two scenarios: cordon charge and increase in parking fee policies. The model is used to compare each scenario with a base scenario of Do Nothing, thereby enabling the relative performance of different policy choices to be assessed. Lastly, the paper provides a relative comparison of the two scenarios using travel mode, trip starts, average speeds, etc., and analyzes the effect of each policy on the environment based on NOx emissions. The numerical study testified to the validity of the model.

BACKGROUND

With the rapid economic development in Beijing, travel demand is increasing continuously. There is growing concern about the impact of the private car on our towns and cities, in terms of congestion, atmospheric pollution and associated health concerns, severance and loss of amenity, and the implications for land use policy. To assist in making informed and appropriate transport policy decisions for the city, and assess urban transport policy impacts rapidly using limited data, a strategy transport model of Beijing based on STM (Strategic Transport Model) software of TRL was developed. This paper will describe the model and how it was used to assess the potential impacts of some transport policies on the city centre (within the second ring) of Beijing to verify the validity of the model.

MODELLING MECHANISMS

The STM is a multi-modal modeling framework. It currently uses a simplified, area-based, treatment of road congestion to avoid the necessity for a time-consuming assignment process.

The basic function of STM is to predict forecast trip matrices under policy

and planning scenario assumptions. From the predicted travel costs, measures of congestion and accessibility can be derived. Using speed and traffic flow information estimates of emission levels can also be developed.

The basic STM in Beijing was derived mainly from the basic model specifications. Basic STM incorporates four main elements in the development of travel demand forecasts:

- Trip generation
- Modal split
- Trip redistribution
- Congestion calculations

It's an equilibrium model in the sense that the basic processes are iterated until the starting costs and output costs are sufficiently coincident.

DEVELOPMENT OF THE STM FOR B EIJING

Trip generation model . Trip generation is based on trip rates and related populations. So, given trip rate (r) and corresponding population (pop) we can calculate the trip generation matrix. For home-based (HB) trip generation, suppose the zone number is n, time is t, trip purpose is p, population type is l. Then trip generation of i zone is $T_i, T_i = pop_{ipl} \times r_{ipl}$.

Car ownership model . We can also use a car ownership model to predict travel demand. There has been numerous research in the use of aggregate models to predict car ownership in China. However, research on the use of disaggregate models for trip generation is currently not available even though, there has been abundant research on the use of disaggregate models in developed countries (Gerard De Jong, James Fox, 2004).

In this paper we present an analysis of cross-sectional data on car ownership at the household level, gathered from the 2000 OD survey of Beijing. The relationship of GDP and car ownership is and income is inevitably a main factor that affects private car ownership. Other factors that should be considered are numbers of drivers licenses, distance between work place and home, annual registration fee, price of car and traffic conditions. The structure of the model is as shown in Figure 1.

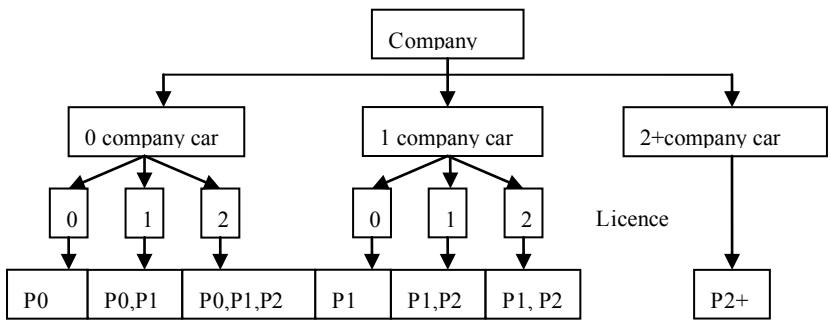

Figure 1. The structure of car ownership model

Generalized costs, calibration, modal split and redistribution . These processes fall within the iterative loop of the model. The modal shift and redistribution are driven by changes in generalized cost relative to the base. Generalized cost in STM is a combination of time and money costs (VOT). The time elements in the generalized costs include access, waiting, transferring and travel time. Money costs include internal and external costs. In this study, the traditional method (based on average income and working hours) is used to calculate VOT. The value of time is $\mathrm{VoT_j} = \alpha_{1j}\, t_j^{v} + \alpha_{2j}\, t_j^{ac} + \alpha_{3j}\, t_j^{wt} + \alpha_{4j}\, t_j^{tf}$, and the money cost is $\mathrm{Cost_j} = \mathrm{f_j} + \phi_j$.

Congestion modeling . STM does not perform an assignment calculation. A calculation is made outside of STM of the likely strategic routes between each zone pair. Each group of similar routes is converted into a zonal route. These routes are used for the purposes of estimating road speeds and journey times. STM road capacity restraint rests upon the assumption that the average traffic flow level in PCU-km within a zone is related to the average speed experienced by drivers moving within the zone according to a speed/flow curve (see Figure 2).

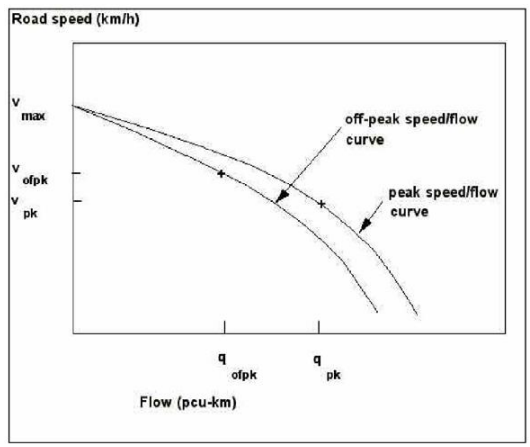

Figure 2. Speed/flow Curves (Marlow and Evans , 1978)

Several roads that represent the main network of Beijing had been surveyed. The calibration parameters of the speed/flow curve are shown in Table 1.

Tab le 1. Beijing Road Network Speed and Flow Values

Type	Max. Speed	Min. Speed	Max. Flow	Plat Flow	Road Grade(China)
1	120	25	1800	1500	Urban motorway
2	60	20	806	637	Urban artery road
3	50	18	560	410	Urban inferior artery road
4	120	50	1661	1275	Rural motorway
5	60	30	700	530	Rural first grade highway

6	50	20	460	310	Rural second grade highway

Elasticity of demand and model calibration. An elasticity of demand may be defined as: the proportional change in demand to the proportional change in the explanatory variable. The price elasticities, which were used in the STM, are as follows:

- Car trips with respect to fuel price
- Rail patronage (trips) with respect to rail fares
- Bus patronage (trips) with respect to bus fares

Basic STM uses the following elasticity values: Bus fares: -0.3, Car fuel: -0.15 and Rail fares: -0.4 (TRL Limited, 2005). For Beijing STM, a State Preference survey sheet has been designed using uniform design methods that include seven indictors (fuel price, fixed cost of commute trip, parking search time, time difference between PT and car, fare, crowding and punctuality), five levels of each indicator and ten cases. The elasticity difference of car fuel is very large from the basic STM one and the corresponding value is -0.36.

The modal split calculations used a model resembling an elasticity approach using "power law" terms. This redistributes total trips between each zone pair over the different modes in the base in accordance with the way in which generalized costs have changed from the base. The approach is incremental in the sense that it automatically reproduces the base market shares. Calibration is achieved by running the model and performing sensitivity tests for fuel price and public transport fares. The outputs demand responses for the study area as a whole are then compared with the upper elasticities. The modal split expression uses the same α coefficient, as seen in the following equation: $K_{mijpct} = \frac{k_{mijpct}(G_{mijpt}/(g_{mijpt}\cdot REI))^{-\alpha_{mpc}}}{\sum_n k_{nijpc}(G_{nijpt}/(g_{nijpt}\cdot REI))^{-\alpha_{npc}}}$ (Oldfield, 1993), where: K= proportion of trips; G= generalized cost; g= base generalized cost; k= base proportion of trips; REI = Real Earning Index relative to base year; α = elasticity calibration parameter;

The demand elasticity e_{fmpc} derived form upper equation is given by: $e_{fmpc} = -\alpha_{mpc}(1-\bar{k}_{mpc})\frac{\bar{f}_{mpc}}{\bar{g}_{mijpt}}$, where, $\bar{k}_{mpc}$, $\bar{f}_{mpc}$ and $\bar{g}_{mijpt}$ are proportions of trips, money cost and total generalized cost for mode m, purpose p, and car ownership c, respectively, and the bars denote that they are the base year values. These are origin-destination trip-weighted average value. Redistribution is based on changes in generalized costs from the base and changes in trip end factors.

EVALUATION OF CITY CENTER TRANSPORT POLICIES

Analysis of traffic in the city centre of Beijing. According to 2005 data, from traffic surveys of Beijing, the average number of person trips increased by 4%,

trips increased by 1.4 times, car trips increased from 5.02% to 23.24%, and the growth rate of private car is 27% (Beijing Government, 2005). All of these factors made the traffic in the city centre worse and lead to a series of unsustainable problems. The reasons for the worsening traffic can be due to the following three factors : 1) the areas of cultural relics are grouped in the city centre, thus limiting the adjustment and expansion of road infrastructure; 2) city construction and traffic development is not coordinated with each other; and 3) traffic is highly concentrated in the city centre and modal split is unreasonable because the quality of public transport makes it less competitive with the private car.

Policy analysis for city centre . Due to a lack of land resources and the strict restrictions imposed by cultural relic protection, from a sustainable standpoint, the road network in the city centre would be difficult to expand and modify. Thus, the main policy for the centre should be to stress public transport priority and to limit car traffic to some extent. From a strategic level, the following policies can be considered: public transport priority policy, parking policy and cordon charge policy

Scenario design. According to the policy analysis of the city centre, the following scenarios were considered in 2020:

- Do nothing;
- Charge cars for going in, out and through the second ring road (city centre boundary) at peak hour;
- Increase on-street parking fee by 100% and off-street parking fee by 30% in city centre;

Traffic policy evaluati on. Using the Beijing strategic transport model, the three scenarios were analyzed separately. To compare the effects of each policy, the cordon charge policy and the parking policy were compared with Do Nothing. We chose all regions and all purposes in a peak to compare the trip starts (person·km). The difference in traffic demand between the Do Nothing and the implementation of the cordon charge and increased parking fee policies were quite obvious. For the parking policy, average trip distance decreased by 0.188%, average speed increased by 0.028%. For the cordon charge policy, average trip distance decreased by 1.43%, average speed increased by 0.223%. The proportion of sustainable traffic modes like bus, rail, cycle and walk increased and the proportion of car travel decreased especially in the use of cordon charge policy. The whole traffic demand also decreased. Some of the results can be found in Figure 2.

Figure 3 shows the emission of NOx on the whole area of Beijing (The four middle zones consist of city centre). The darker the color, the higher the reduction in emissions. The analysis found that the cordon policy would be more effective in reducing emissions.

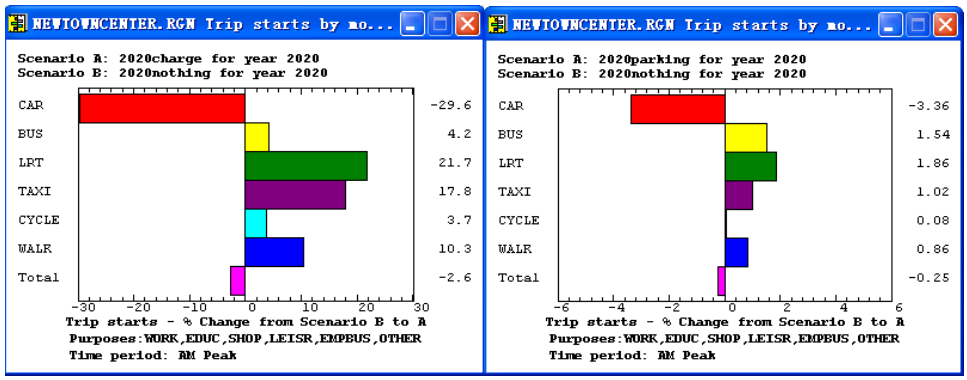

Figure 2. City centre trip starts ch ange by mode in 2020 by difference policy

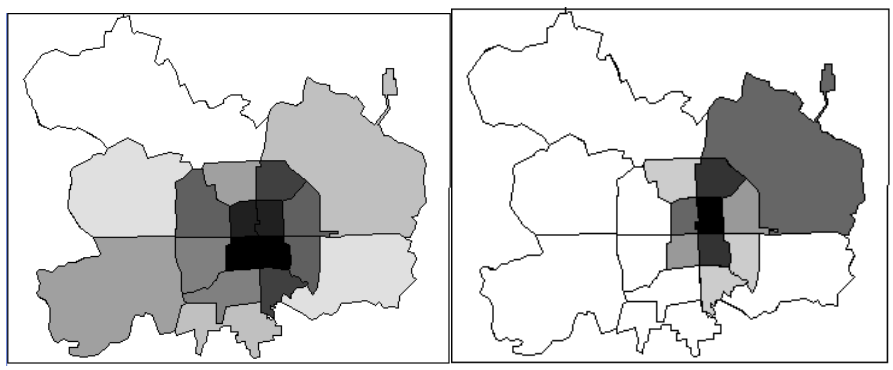

Figure 3. Emission NOx (g/hr) analysis (charge policy and parking policy)

CONCLUSION S

From the quantitative results of the Beijing strategic transport model and the qualitative analysis above, the two policies can be approved. The strategic transport model can solve the problem of inaccurate traffic forecast being caused by unsuitable policy and can be used as a computer tool for policy analysis and decision-making. The most important feature of the model is that different scenarios can be tested in a short time. The result of the model is not absolutely satisfactory right now, and there is still a need for further research in such areas as the size of the zones, the simplification degree of the road network, and in the use of elasticities of demand.

ABSTRACT

Hazardous goods logistics are very important to the national economy; this paper introduces a systems architecture of hazardous goods logistics management based on RFID, and it proposes a related model for operation and data flow. This architecture helps us to control the whole process of hazardous goods management, creating a visual transportation management system for hazardous goods based on Radio Frequency Identification (RFID). This system provides customers an advanced and scientific information management suite, and it reduces the rate of accidents during the transportation of hazardous goods.

Key words: Hazardous goods, Transportation, Identification, Visualization

1 SUMMARY of HAZARDOUS GOODS

According to the national standard *Classifying and Numbering of Hazardous Goods* (GB6944-86), hazardous goods are defined as those goods that are explosive, flammable, poisonous, perishable, or radioactive. These items require special preventive measures during transportation, handling, and storing, since they are extremely dangerous to people and the environment.

According to statistics, there are about 400 thousand tons of various hazardous goods produced every year in the world, and enormous numbers of fatalities occur during their storage and transportation. Once an accident occurs, serious outcomes are certain to follow. The chances of an accident happening during storage is usually smaller than that of transportation, since hazardous goods are usually stored far away from human living spaces. However, accidents that occur during the transportation of hazardous goods, including fires, explosions, leakage, poisoning, and pollution, do great harm to people, society, and the environment. Therefore, a greater focus on hazardous goods in transportation is needed. World governments have established many statutes and laws to ensure safety during the

transportation of hazardous goods and to standardize the logistical handling of such goods.

National and local governments have also become aware of the importance of developing of hazardous goods logistics. In 2001, the People's Republic of China passed new rules governing the transportation of hazardous goods. Local departments seriously sought to enforce requirements for three licenses and one surveillance. The three licenses include the capacity of company license, one showing the qualification of the personnel, and one verifying the technology of the vehicle. The surveillance is meant to ensure the supervision of the hazardous goods in loading and unloading, storage and transportation. Intended goals of this governance were to: ①re-censor those corporations transporting hazardous goods, ensuring that all practitioners were acting in accord with the capacity need; ② make sure that all practitioners were congnizant of their need to be qualified for transportation of the goods and to ensure that loading occurred with permission; ③ conduct across-the-board inspections regarding the technological capacity of vehicles transporting hazardous goods, with the ultimate goal of ensuring that all vehicles receive arterial technology.

However, the fact that more and more corporations and practitioners are transporting hazardous goods has still led to the destandardization of logistical operations and inadvisable management practices. We still see uneven levels in technology and logistical equipment, as well as uneven documentation levels. Accidents involving hazardous goods are still common. In addition, once accidents occur, their damage may be aggrevated by the fact that exact information about the goods cannot be immediately attained.

2 NECESSITY of BUILDING VISUAL LOGISTICS MANAGEMENT SYSTEM for HAZARDOUS GOODS

Road hazardous goods transportation is the term for the process of delivering hazardous goods by special-purpose vehicle. Road transportation, which plays an important role in hazardous goods transportation, is characterized by its numerous nodes, its ability to cover a wide area, its simple organization and flexibility, and so on. In order to ensure the safety of hazardous goods in transportation, China has established and utilized laws and regulations for road transportation, such as the "Regulations for Management of Road Hazardous Goods Transportation," "Transportation Rules of Hazardous Goods by Vehicles," "Vehicle Signs for Road Hazardous Goods Transportation," "Operation Regulation of Hazardous Goods Transportation," etc. These standards are the basis for a governing department, which should be strictly followed by corporations engaging in hazardous goods transportation. Considering the rapid development of the civil economy and rising number of hazardous goods in variety and quantity, the government cannot supervise

and control hazardous goods through traditional management methods.

Thanks to the development of certain computer technologies, the Internet, RFID, GPS and GIS can provide technical support for a Visual Logistics Management System for Hazardous Goods. Therefore, it is necessary to construct a uniform supervising plan for hazardous goods transportation and a visual logistics management system that can ensure the transmission of accurate, credible information in real-time, while preventing accidents from the start.

3 A SYSTEM ARCHITECTURE OF VISUAL HAZARDOUS GOODS LOGISTICS MANAGEMENT BASED on RFID

RFID is one kind of non-contact, automatic identification technology. Its basic principles are shown in Figure1.

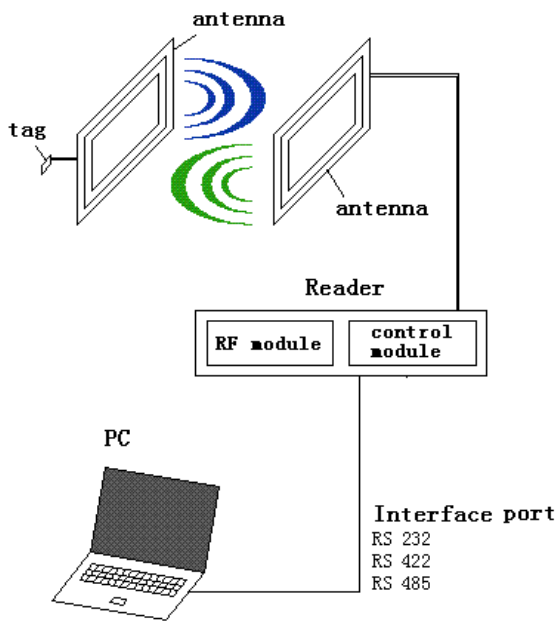

Figure 1.The basic principles of RFID

The RFID system is comprised of a reader, an electronic tag, and an antenna. The electronic tag carries information, used to store the related data and transportation information. The reader can generate radio waves through the antenna at a certain frequency. When the tag enters the broadcast area, it can broadcast the data from a tag, and data can also be written on the tag. At the same time, all data is updated by a management system. The topological structure of a visual logistics management system based on RFID is shown in figure 2.

Functions achieveable through the MIS include : ① monitoring and management of the logistical handling of hazardous goods; ②monitoring the inventory and status of the goods; ③ management and supervision of the technical

condition of vehicles transporting the goods; ④ supervision and control over the transportation route followed by vehicles, while also monitoring the position of the goods;⑤ monitoring the validity of customers receiving the goods; ⑥ the ability to create a centralized emergency response system ⑦ management of the dealers' qualifications.

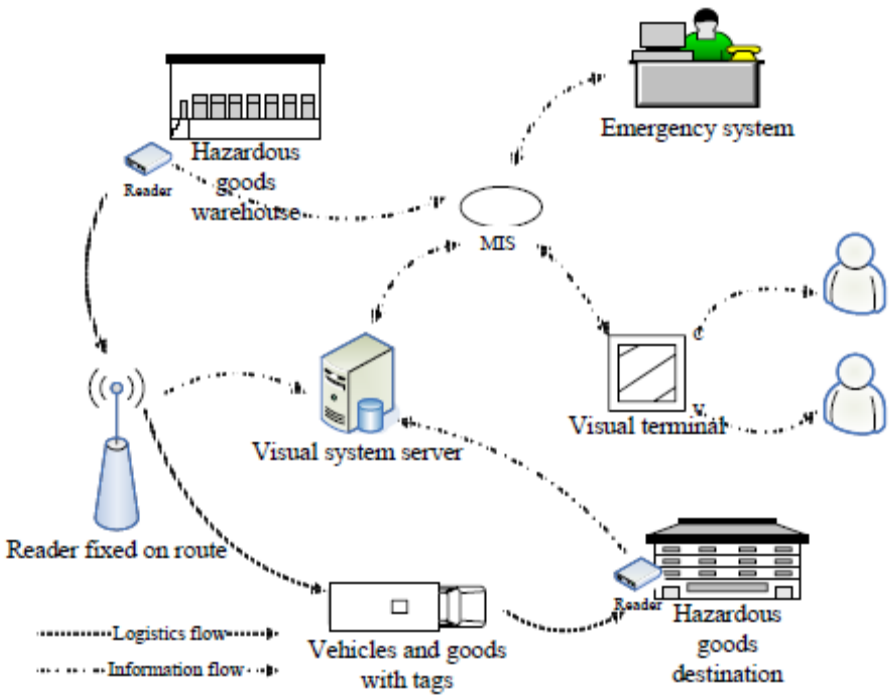

Figure 2.System Architecture of visual hazardous goods logistics management

The regional visual server system contains the perfect database for managing information such as the storage and handling processes of the hazardous goods, vehicle and route information, practitioner licenses, and emergency information. The visual device provides relevent goods information in real-time to the managers and customers.

4 OPERATIONS AND DATE FLOW OF VISUAL HAZARDOUS GOODS LOGISTICS MANAGEMENT SYSTEM BASED ON RFID

The visual hazardous goods logistics management system based on RFID enables automatic control of the whole process by identifying information stored on the tags. Its operations and data flow are shown in figure 3.

Hazardous goods should be delivered along a previously determined route. RFID readers are fixed at key points along the path, including the starting point, rest stop, and final destination point. When tagged vehicles arrive at a warehouse, the RFID reader reads the vehicle information. Every box of hazardous goods has a tag on it. After consignment at the warehouse, the PDA writes a transportation receipt

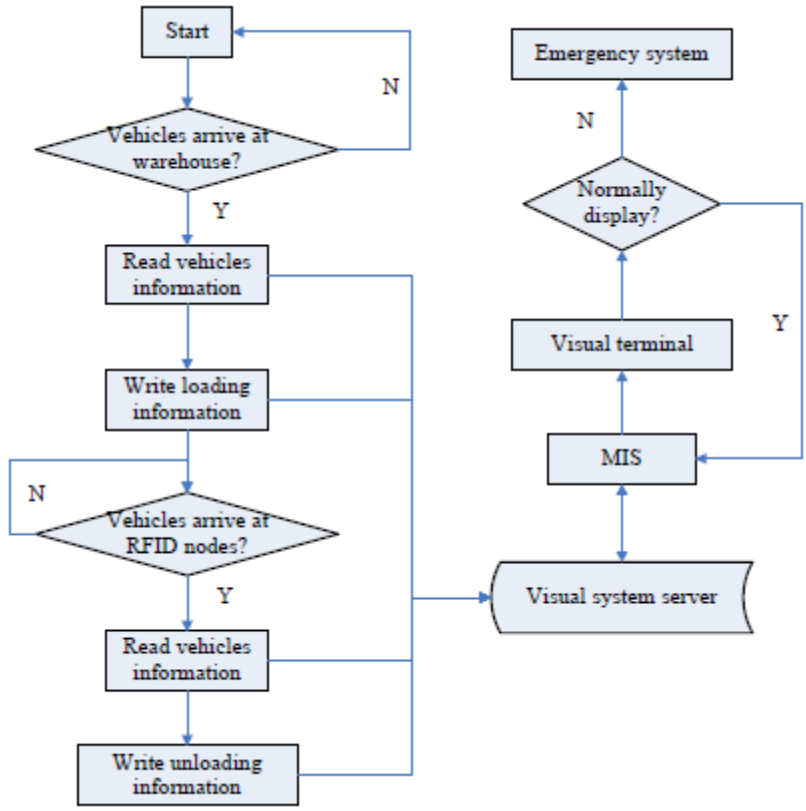

Figure 3 Operation and date flow of Hazard goods

onto the electronic tag, including the bill number, type, and serial number of hazardous goods; shipper and consignee information; normal route and so on. When vehicles and goods arrive at or depart from a rest stop or defined location, the RFID reader automatically reads the vehicle and goods information on the tags, stamping the arrival and departure times. It then sends that information to the regional visual system server, enabling system managers obtain the real time information. The visual terminal displays hazardous goods information to managers and customers. It could be the computer network terminal or portable data terminal, by which customers receive important information and control the hazardous goods. This ensures receipt of the information both visually and conveniently.

The route and condition of vehicles transporting goods is transmitted by a combination of gridding technologies, such as GIS and GPS. To keep the highways safe, 60km/h should be set as a reasonable maximum speed limit on ordinary highways, and the freeway should be limited to 80km/h. Twenty kilometers per hour should be the top speed during increment weather. The system would send a warning signal if it detects that the vehicle is exceeding the speed limit.

For some hazardous goods with special environmental requirements, like strict temperature or pressure control, related sensors are fixed on the vehicles to

detect real-time temperature or pressure, sending them to the visual system server. Once the temperature or pressure exceeds the limit, the system will immediately sound an alarm and take quick action to solve the problem.

When an accident occurs, an annunciator panel automatically sends an alarm to the visual system server, which immediately receives the accident location, vehicle information, and inventory of the hazardous goods. At the same time, an emergency response system is activated to organize responders and ensure minimum expense.

5 CONCLUSIONS

This paper presents a system architecture of visual hazardous goods logistics management. It also puts forth a model for operation and data flow. The system could supervise and control the hazardous goods logistics and state information, providing an interface for managers and customers. Development and application of the system is sure to transform the field of hazardous goods logistics, contributing to a safer society and healthy economy.

ABSTRACT

In order to reduce the running-time delay and improve the on-time arrival rate, this paper takes into consideration that most urban road networks are discrete traffic flows, combined with traffic signal control equipment and traffic flow collection device. We have used research on the public transport incident prediction model and algorithm by the road traffic delays in order to carry out an automatic prediction of the public transport incident delay making our public transportation more intelligent. This model could make a much better prediction and save much more time for dealing with the emergency, reducing the running delays and better meeting the passengers' demand for a shorter travel time.

INTRODUCTION

Compared with some developed countries, the level of public transportation service of some large and medium-sized cities in China is still relatively, mainly due to some aspects (Han, 2006): (1) Buses arriving and departing time is uncertain; (2) Informational services are nearly a blank; (3) Cannot get the information of whether or not public transportation incidences happen, there is no bus incident identification and coordination dispatching system; (4) Considering the incidents just based on the experience, there is no advanced scientific technology to ensure that we have made the right judgments, and the rapid response system dose not exist.

With the rapid development of intelligent transportation, minimization of the public transportation delay is a very important problem; bus delays have many causes, such as the road environment, traffic conditions, vehicle status, and queuing delay at signalized intersection, and so on. The four factors are interconnected, when any of the factors runs abnormally, a bus delay may happen. Therefore, in order to reduce the incidence of the delays, appropriate preventive and treatment measures should be adopted. The prediction of bus delays is based just on this principle.

PUBLIC TRANSPORT DELAYS AND FACTORS

Research shows that the public transport delay is related to lane occupancy, bus-running speed, and the queuing delay at signalized intersections. If lane occupancy becomes higher, the bus running speed becomes lower, the queue waiting time at signal intersection becomes longer, and the more bus delays will happen. Therefore, we can construct a bus delay prediction model from the three aspects.

Lane occupancy. Because of the complexity of traffic flow, the state of traffic operation in the road network varies with the time. Once traffic crowded incidents happen, the flow of the upper detector reduces; occupation rate increases; simultaneously downstream detector, the volume and occupation rate will decrease. Making judgments by the volume's or occupation rate's increase and reduction often do not reflect the substance of the process of crowding (Wang, 2005). In fact, because of the number of detected vehicles increases in unit time, the speed remains unchanged, and it will inevitably lead to the increase of the occupation rate. However, if the relative increment of volume is greater than the increment of the volume in the occupation rate, then it can judge that the traffic flow in this time is in a state of dissipation or it is in the state of crowded traffic.

In order to facilitate the discussion, we assume that the bus' length fixed L, detection coil width fixed d, according to occupation rate C's basic definition:

$$C=\frac{\sum_i (L+d)/v_i}{T}=\frac{L+d}{T}\sum_i \frac{1}{v_i}=(L+d)\frac{n}{T}\frac{1}{n}\sum_i \frac{1}{v_i}=(L+d)q\frac{1}{v}=(L+d)k \qquad (1)$$

Put formula (1) into traffic flow basic model:

$$q=k\bar{v}=\frac{C}{(L+d)}\bar{v} \qquad (2)$$

From type (2), we can see that when the speed is invariant, the traffic flow is proportional to occupation rate and their rate of change is the same, therefore, and can be:

(1) When the relative increment of flow is greater than the relative increment of occupation rate, the traffic tends to disperse;

(2) When the relative increment of flow is smaller than the relative increment of occupation rate, the traffic tends to crowd.

Public transport travel speed. Through the bus-car GPS system (Liu, 2008), we can get the real-time link travel speed $v_i(t)$, according to a large number of historical data we can get the minimum bus speed and stability bus flow, the threshold v, the crowded state discriminates is as follows:

(1) If $v_i(t)$ smaller than the established threshold v, then think section i

being crowded.

(2) If $v_i(t)$ greater than the established threshold v, then think section i unobstructed.

Queue delay at signal intersection. When it is a single lane, the capacity of intersection is limited; therefore, the queuing model belongs to a limited capacity system model, and the queue is a single row, so it is in accord with model M/M/1/N ^{j} /∞ (Han, 2003). Particularly, under steady-state conditions, the probability $P_{ij}^{(k)}(t)$ that there are k vehicles queuing at an intersection is unrelated with the moment.

The vehicles queued at a downstream intersection at section j during period i, to every vehicle, transfer probability is $\lambda_j(t)P_{ij}^{(0)}$, where $\lambda_j(t)$ is a vehicle arriving rate, $\lambda_j(t)$ is the vehicle arriving rate of entrance of section j at t moment which got from the detector, which means $\lambda_j(t)$ is a function related with t, take $\lambda_j(t)=\lambda_{ij}$;the maximum capacity of downstream intersection of section j in unit time is denoted by $\mu_j(t)$, let certain direction split g_{ij}, the effective service rate take $g_{ij}\mu_j(t)$,then suppose in any period i, the capacity in unit time is the same; so take $\mu_j(t)=\mu_j$, as one queuing vehicle bears off, the transfer probability is $g_{ij}\mu_j$.

List out the steady-state equation:

$$\begin{cases} g_{ij}\mu_j P_{ij}^{(1)} = \lambda_{ij}P_{ij}^{(0)} & \\ g_{ij}\mu_j P_{ij}^{(k+1)} + \lambda_{ij}P_{ij}^{(k-1)} = \left(\lambda_{ij}+g_{ij}\mu_j\right)P_{ij}^{(k)} & k \le N_j - 1 \\ \mu_j P_{ij}^{(N_j)} = \lambda_{ij}P_{ij}^{(N_j-1)} & \end{cases} \tag{3}$$

According to $\sum_{k=0}^{N_j} P_{ij}^{(k)} = 1$, let $\rho_{ij} = \dfrac{\lambda_{ij}}{g_{ij}\mu_j}$ then we can get

$$P_{ij}^{(k)} = \begin{cases} \dfrac{1}{N_j+1} & \rho_{ij}=1 \\ \dfrac{1-\rho_{ij}}{1-\rho_{ij}^{N_j+1}}\rho_{ij}^{k} & \rho_{ij}\neq 1 \end{cases} \qquad k=0,1,2,\cdots,N_j \tag{4}$$

Then queuing vehicle number at section *j* at i is

$$L_{ij}^{(q)} = \begin{cases} \dfrac{N_j(N_j-1)}{2(N_j+1)} & \rho_{ij}=1 \\ \dfrac{\rho_{ij}^2}{1-\rho_{ij}} - \dfrac{(N_j+\rho_{ij})\rho_{ij}^{N_j+1}}{1-\rho_{ij}^{N_j+1}} & \rho_{ij}\neq 1 \end{cases} \tag{5}$$

$$T_{ij}^{(q)} = \frac{L_{ij}^{(q)}}{\lambda_{ij}\left(1 - p_{ij}^{(N_j)}\right)} = \begin{cases} \dfrac{N_j - 1}{2\lambda_{ij}} & \rho_{ij} = 1 \\ \dfrac{\rho_{ij}}{\mu_j - \lambda_{ij}} - \dfrac{N_j p_{ij}^{(N_j)}}{\mu_j\left(1 - \rho_{ij}^{N_j}\right)} & \rho_{ij} \neq 1 \end{cases} \tag{6}$$

where, $P_{ij}^{(k)}(t)$ is the probability of the k queuing vehicles at intersection, N_j is capacity of section j, λ_{ij} is the vehicle average arrival rate of section j the during i period, g_{ij} is running direction split of the downstream intersection at section j during i period, u_j is the biggest capacity of the downstream intersection of section j in unit time, ρ_{ij} is traffic intensity.

When $T_{ij}^{(q)}$ becomes greater, the bus will be prone to have delays, rather than less prone to have delays.

MODEL CONSTRUCTION

According to the selected characteristic index, we construct the following model:

$$\min f = \alpha(\Delta q_{ij} - \Delta C_{ij}) + \beta(v_{ij}(t) - v) - \gamma T_{ij}^{(q)} \tag{7}$$

Where, $\alpha + \beta + \gamma = 1$, i is the time period (i=1, 2……n), j is section (i=1, 2……n), Δq_{ij} is relative increment of the flow in time i section j, ΔC_{ij} is relative increment of occupation rate in time i section j, $v_{ij}(t)$ is bus running speed in time i section j, v is the minimum speed under stable bus traffic flow, and $T_{ij}^{(q)}$ is queue delay at signal intersection in time i section j.

The greater f becomes, the greater the chance of delay. We can get the value of the threshold k based on historical data. When $f < k$, the delay incident will happen, when $f \geq$ k, the delays will not happen.

Before prediction, the test data should be calculated first, we get Δq_{ij} ΔC_{ij}, $T_{ij}^{(q)}$ and other data, then we can make the prediction. The prediction flowchart of the model is shown in Figure 1.

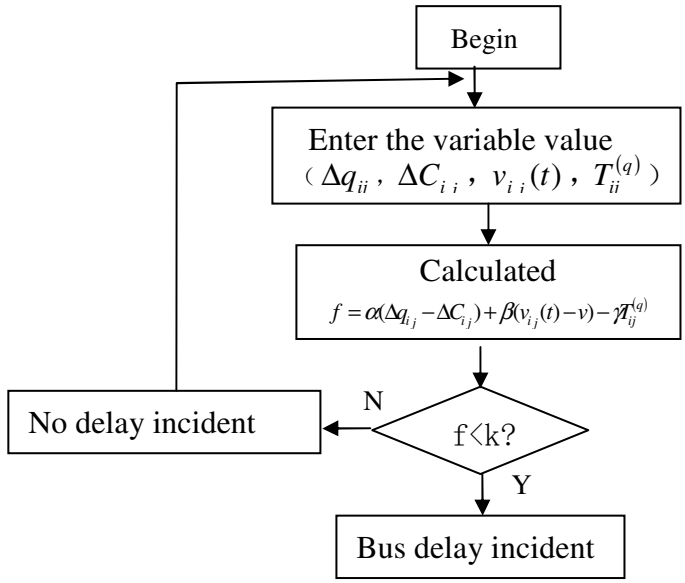

Fig.1 Bus delay incident prediction flowchart

MODEL SIMULATION

In order to survey the testing effect of the model, in the conditions that actual data is hard to collect, we often get the large number of incident and non-incident state test data by way of simulated methods (Wen, 2005). In this text, we choose a segment with three intersections and two bus stops (see Figure.2). Let $\Delta q_{ij} = \Delta C_{ij}, v_{ij}(t) = v$, Queue delay time $T_{ij}^{(q)}$=1(minute), $\alpha = \beta = 0.25$, $\gamma = 0.5$, so threshold $k = -0.5$. We input 100 groups of data, 60 of which are delay incident data, 40 of which are not delay incident data, to evaluate the model.

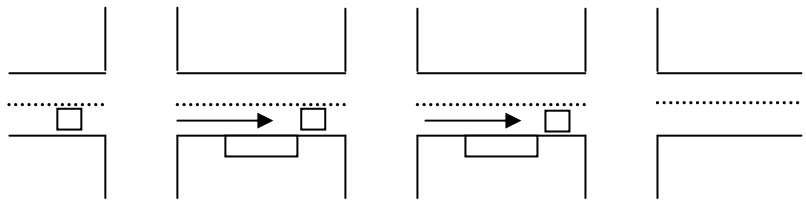

Figure 2 Traffic simulation map

Performance indexes usually used to evaluate incident detection algorithm are detection rate, false alarm rate and average detecting time. 100 groups' data are used to test the model. Calculate and output *f*. If $f < -0.5$, it is identified as the delay incident.

Test results are: detection rate is 96.3%, false alarm rate is 3.12%, and average detecting time is 40s.

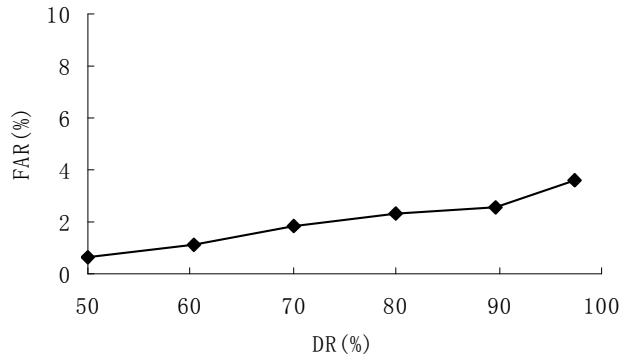

Figure 3 Relation between detection rate and false rate

Figure 3 shows the relation between detection rate and false rate, the results show that the model made a good prediction for the public transport delay incident. Through the test simulation, the model can effectively detect the occurrence of delays in public transport. Therefore, the prediction of the bus delay incidents can make a scheduling department to have advanced preparation to reduce bus delay time and shorten bus travel time.

CONCLUSION

A bus delay incident identification model was built on the testing data from annular induction coil, in-car GPS returns, and a vehicle random queuing model. Through test simulations, it can effectively identify the occurrence of bus delays in public transportation, the method and model has a great applicability.

Because public transportation incident forecasting is still in its infancy, if a model is to be applied to practice, further research needs to be done, for example, determining the parameter values such as α, β, γ and determining the average queue delay time.

ABSTRACT

If there is a catastrophic event in a city, it is necessary to provide the suffering people with shelters to get a refuge. Based on the analysis on the city shelters planning principles, the covering area of the shelter should be big enough and should maximize the coverage level of the demand points. At the same time, it should consider the capacity of shelters, and this paper is aimed to modify the maximal covering location problem (MCLP), which based on the P-median model to get a capability limitative MCLP-P. The analysis of an example finds that the shelter layout has more applicability and also proves that the trimmed model is reasonable. Furthermore, it is expected to offer some reasonable evidences to build catastrophic facilities in the future.

1 INTRODUCTION

In the modern world, cities are more easily threatened by catastrophic events. If a serious natural disaster occurs in a city, especially an earthquake, it is impossible to evacuate all the residents to the suburban safe area. The aim is to build shelters to provide suffering people with safe places and prevent the harm of a secondary disaster. At the same time, it should ensure daily life, iatrical rescue and communication. In the preventable disaster system of the entire city, if emergency shelters can be planned and built, it will be a good measure in decreasing the casualty and economy losses of a fatal paroxysmal event, such as an earthquake, fire, flood, etc. The big earthquake of Wenchuan, in the southwest of China, brought serious disaster to the Chinese and revealed the importance of building shelters reduce the harm of a disaster.

2 PRINCIPLES OF SHELTERS LAYOUT

The main problem of a city shelter layout is: in a city, the density of the population is determined and evacuation routes are limited. Because of the shortage of funding and the restriction of the environment, few locations can be selected to be used as shelters (Huang et al., 2004).

2.1 Requirement for city shelter scale

There are two kinds of shelters (Su et al., 2004): permanent and temporary. A temporary shelter is a small, temporary facility that makes use of a sub-district park, small public square, etc, which, next to the residents' housing, averages 1~2m^2 for each person, totaling more than 1000m^2, and its service radius is 300~500m. A permanent shelter is a park, school, public square, playground, or stadium used for setting up tents and temporary buildings that can hold more than 1000 residents, averaging 2~3m^2 for each person, totaling not less than 15000m^2 with service radius is 500~2000m.

2.2 The confirmation of the shelter number and capacity

Before a shelters layout, it must take a risk analysis of the city to confirm the distribution of dangers, which is based on geographical factors, natural factors and the past years' statistics of the disaster dates (Zhou et al., 2007). Combining the economic level, it can confirm the shelter area of every person, at the same time, based on the incidence, it can confirm the appropriate region of the preliminary building shelter. Statistically, the location distribution within the region which can be used to build shelters, such as large gymnasium, park, school, church and so on. However, the population and its distribution in the city can confirm the number and the capacity of the rebuilt shelter.

3 ESTABLISHMENT OF THE SHELTER LAYOUT MODEL

Shelters belong to the public ministrant facility, so residents demands should considered to ensure the optimum shelter layout. At present, there are few mathematical models for city shelter layouts, so shelter layouts usually depend on the facility location problem (Yin, 2007). The facility location problem is ensuring one or more optimal facility locations with the optimum aims, such as the minimum distance, the lowest transportation cost, and the maximum market share (Sherali, 1991). Because of the particularity of shelters, this paper chooses the maximal covering model of partial coverage (MCLP-P) to make shelter layouts.

3.1 The maximal coverage and partial coverage model in the location problem

A basic assumption in almost all of the maximum covering location problem

(MCLP) formulated to date is that the demand points are assumed to be covered completely, if located within the critical distance of the facility and not covered at all outside of the critical distance, and rebuild P emergent facilities to cover most of the demand points within the stated critical distance (Orhan, 2004). Such an assumption is not always reasonable provided that the coverage does not change in a crisp way from "fully covered" to "not covered" at the critical distance. In some situations, it may not be possible to guarantee the full coverage of the demand points depending on the distance between the demand point and the facility site. The partial coverage, which is defined as a function of the distance of the demand point to the facility. We assume that the demand point can be fully covered within the minimum critical distance, partially covered up to a maximum critical distance, and not covered outside of the maximum critical distance.

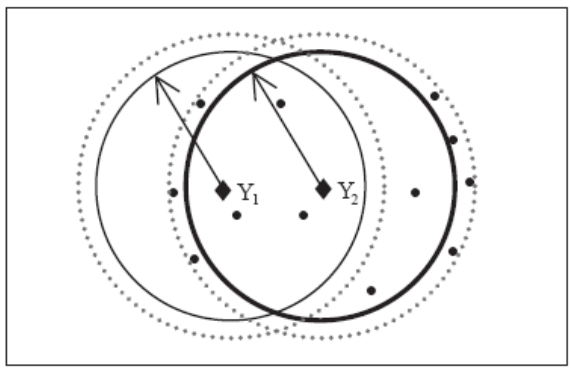

Fig 1 the maximal coverage and partial coverage.

Fig 1 depicts the partial coverage model to solve the location problem. Suppose that there are two potential facility locations and only one will be chosen. The solid line shows the radius of the full covered and the dotted line shows the partial covered. Within the full coverage range, location Y_1 can cover 6 demand points and Y_2 can cover 5 demand points. So, the MCLP will choose Y_1 as the optimal choice. If we employ the partial coverage idea, we may choose Y_2 instead of Y_1, because location Y_2 covers 5 demand points fully and an additional 7 demand points partially, but location Y_1 covers only 6 demand points fully.

3.2 The MCLP-P model

This MCLP-P model is based on the classical p-median model. However, the aim of this model is not the minimal critical distance but the maximal coverage of demand points. The model of the MCLP-P is as follows:

$$Z = Max \sum_{i \in I} \sum_{\notin M_i} C_{ij} x_{ij} \tag{1}$$

$$\text{s.t.} \quad \sum_{j \in J} y_j = P \tag{2}$$

$$x_{ij} \le y_j \qquad \forall i \in I, j \in M_i \tag{3}$$

$$\sum_{j \in M_i} x_{ij} \le 1 \qquad \forall i \in I \tag{4}$$

$$y_j \in \{0,1\} \qquad \forall j \in J \tag{5}$$

$$x_{ij} \in \{0,1\} \qquad \forall i \in I, j \in M_i \tag{6}$$

where I is the index set of all demand points, J is the index set of all potential facility sites, P is the number of facilities to be sited, M_i is the set of facility sites that can either fully or partially cover the demand point i, S is the maximal radius of full covered, T is the maximal radius of partial covered ($T > S$), D_{ij} is the travel distance between the facility j and the demand point i, C_{ij} is the level of coverage provided by the facility j to the demand point i.

$$C_{ij} = \begin{cases} 1 & D_{ij} \le S \\ f(D_{ij}) & S < D_{ij} \le T, (0 < f(D_{ij}) < 1) \\ 0 & \text{otherwise} \end{cases} \tag{7}$$

$$y_j = \begin{cases} 1 & \text{if a facility is sited at j} \\ 0 & \text{otherwise} \end{cases} \tag{8}$$

$$x_{ij} = \begin{cases} 1 & \text{if the demand point i is either partially or fully covered by a facility j} \\ 0 & \text{otherwise} \end{cases} \tag{9}$$

The objective function (1) maximizes the coverage level within the maximum critical distance T. Constraint (2) ensures that the total number of facilities sited equals P. Constraint (3) shows that if facility j is not sited, all x_{ij}'s associated with facility j will be forced to become 0. The constraints of type (4) require that the demand point will be covered by at most one of the facility locations sited. The constraint sets (5) and (6) impose binary restriction on the decision variables. In this paper, $C_{ij} = f(D_{ij})$, where $S < D_{ij} \le T$ and $0 < f(D_{ij}) < 1$. Based on the experience, we expect the function to be monotone decreasing with the increase in the distance between facility site and demand point and be zero at the distance T. $A = 5$

$$f(D_{ij}) = 1/(1 + e^{A(D_{ij} - (S+T)/2)}) \tag{10}$$

3.3 The trimmed MCLP-P model

When we have a shelter layout, the capacity of each shelter is limited if the population reaches to the upper limit. We can think that the shelter cannot offer refuge

service and the other people who need to be evacuated should be arranged to the nearest shelters. Therefore, it is better to build a location model with the capacity limitation when we have shelter layouts, so we can append restriction as follows: each shelter can only meet the refuge demand of a limited number of residents, limiting the capacity of each shelter. In this paper, we mainly consider the distance and the capacity between demand points and potential facilities. Based on the crucial degree to confirm the corresponding power coefficient, we apply different power coefficients to the objective function and calculate the maximal numerical value to confirm the final layout result. Suppose the capacity of the fixed shelter is V, the potential shelter's capacity is U, order $\omega_j = \begin{cases} 1 & U > V \\ 0 & U < V \end{cases}$, $\forall j \in J$, $W = r_1 C_{ij} + r_2 \omega_j$. Suppose the two power coefficients of distance and capacity are equal, namely: $r_1 = r_2$, so $W_1 = C_{ij} + \omega_j$. Hence, the objective function of the trimmed MCLP-P is:

$$Z = Max \sum_{i \in I} \sum_{j \in M_i} W_1 x_{ij} \tag{11}$$

4. ANALYSIS OF THE SHELTER LAYOUT

In this paper, we have a shelter layout with the standard of a fixed shelter. The fixed shelter is a place where refugees can live a long time; it needs to be big enough to provide the refugees sufficient space. In this paper, the population concentrative places are abstracted to a demand point, such as a residential area, marketplace, and recreation ground, etc.; the places that are suited to be a shelter are abstracted to a potential facility, such as a square, playground, and greenbelt. Based on the foregoing correlative requirement and experience, suppose S=1000m, T=1100m, V=6000, and the facility 1, 3, 6 is less than 6000, facility 2, 4, 5 is more than 6000, P=3. Based on the trimmed MCLP-P, Fig 2 depicts the shelters layout results.

Fig 2 shows that using different models can bring on different shelter layout results. The number of covered demand points is equal by using the capacity limitative MCLP and the no capacity limitative MCLP. Howver, the layout result by using the capacity limitative MCLP can accommodate more stricken residents. The number of covered demand points by using the capacity limitative MCLP-P is 1 fewer than by using the no capacity limitative MCLP-P, but the capacity of facility 2 is bigger than facility 1, which can accommodate more stricken residents and offer more refuge service. In addition, it can incarnate the function of shelters. Considering from the aspects of security and applicability, we choose the shelter layout result by using the capacity limitative MCLP-P. Therefore, it is necessary and important to consider the capacity of the shelter when we have a shelter layout, which can reduce the disaster loss and bring more value.

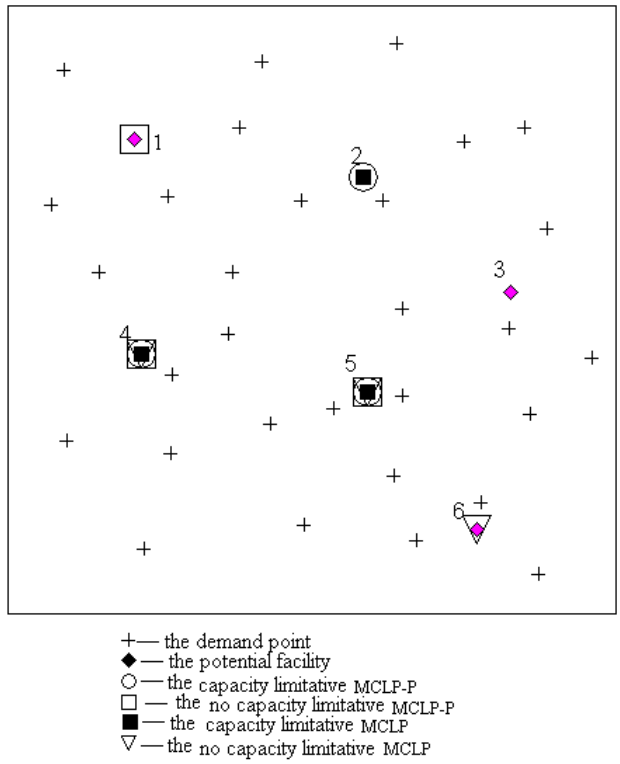

Fig 2 shelter layout results with different models

5 CONCLUSION

In this paper, we consider the capacity limit when we use the MCLP-P to plan a shelter layout and set up the capacity limitative MCLP-P. Through analyzing this example, we can see that the shelter layout results by using that model have more applicability, improving the value of shelters. But, in this paper, the trimmed MCLP-P only considers the capacity of the shelter and the distance between demand points and potential facilities, many other restrained factors are not involved, and they should also be ameliorated.

ABSTRACT

To deliver emergency materials and evacuees to the destination within a limited amount of time, various traffic management and control measures must be employed to manage numerous traffic flows. A Freeway Emergency Traffic Organization Scenario (FETOS) is one of various combinations of traffic management and control measures. A framework of simulation system for the FETOS is presented in this paper. It consists of function modules of the simulation system, core models of the simulation system, and key technologies of implementing the simulation system. The simulation models include a freeway infrastructure model, a data model of the FETOS, a dynamic traffic flow model under the FETOS, FETOS simulation indexes, and their respective statistical models. Function modules include modules of modeling freeway networks, modules of modeling the FETOS, modules of system parameters configuration, module of simulation execution and control, module of visualizing simulation running process, module of generating and printing simulation reports, modules of open data interface, and modules of data backup and recovery. The key technologies of system implementation are also discussed.

INTRODUCTION

Emergency management can be divided into four periods (McLoughlin. D.1985): mitigation, response, relief and recovery. During the response period, a large number of people and materials need to be transported from one place to another (Henry X.Liu, Jeff X.Ban, Wenteng Ma, Pitu B. Mirchandani, 2006). In some cases, people and materials transportation must traverse multiple cities or provinces and freeway transportation is one of the main means of transportation (Henry X.Liu, Jeff X.Ban, Wenteng Ma, Pitu B. Mirchandani.2006). To ensure that the operation of emergency traffic flow on a freeway is efficient and orderly, effective traffic management and control measures must be taken. A FETOS can be

defined as one of various combinations of traffic management and control measures, and simulation is one of the main methods to optimize the FETOS. Through analyzing elements consisting of the FETOS and function requirement of a simulation system for the FETOS, a framework of simulation system for FETOS is presented in this paper.

FUNCTION MODULES OF THE SIMULATION SYSTEM FOR THE FETOS

Function modules of the simulation system for the FETOS consist of three parts: input module, simulation execution and control module, and simulation output module. Relationship among the modules is illustrated in Figure 1.

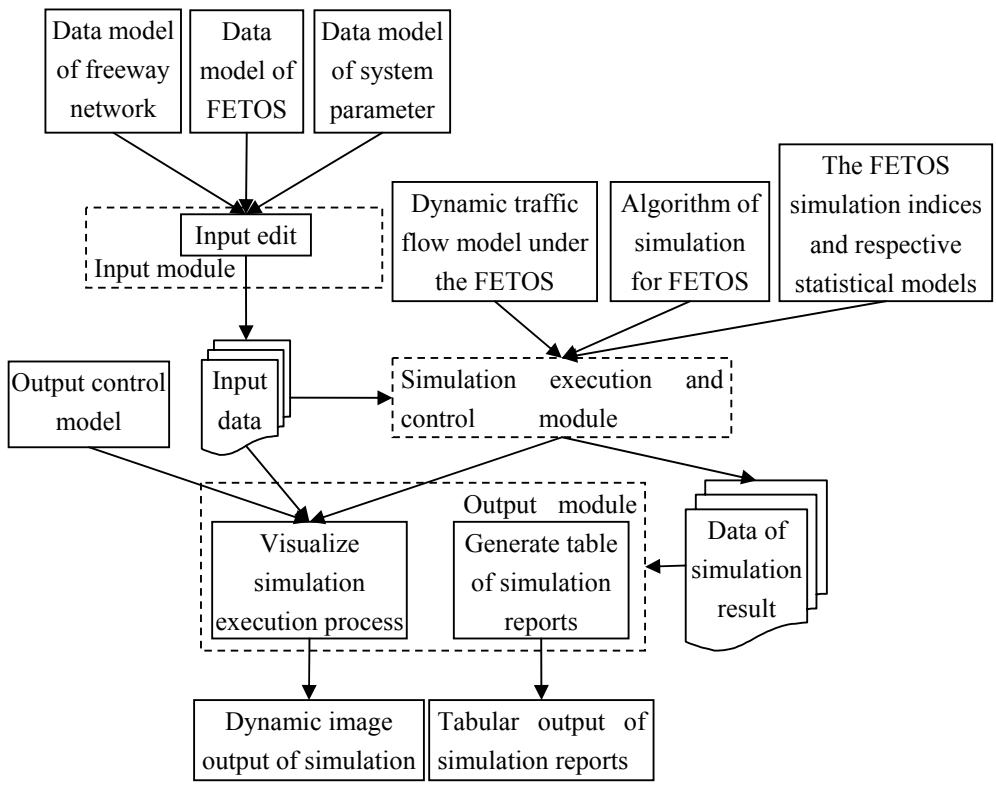

Figure 1. Relationship among modules of simulation system for the FETOS

Input module provides an interactive modeling environment for the simulation of the FETOS. Users can visually edit freeway networks, visually edit the FETOS, and visually configure system parameters, such as simulation running, controlling parameters, the vehicular operating parameters, etc. Models corresponding to the functions are a data model of freeway networks, a data model of the FETOS, and a data model of system parameters, respectively.

Simulation execution and control module, according to the FETOS data and system parameters (such as vehicular operation parameters, start and end time of

simulation, etc.) entered by a user executes the simulation algorithm generates vehicles, loads the vehicles into the freeway network, generates traffic flow data in accordance with dynamic traffic flow model under the FETOS, and logs files of the simulation execution and computes simulation indexes.

Output module submits both data of the simulation execution process and data of the simulation execution result produced by the simulation execution and control module to the user in two forms: dynamic images output of simulation execution process and tabular output of the simulation execution result.

THE CORE MODELS AND RESPECTIV FUNCTION MODULES

Core models of the simulation system for the FETOS include a data model of freeway networks, a data model of the FETOS, a dynamic traffic flow model under the FETOS, simulation indexes of the FETOS, and respective statistical models.

Data model of freeway networks and respective modeling module A data model of freeway networks abstracts the freeway network in the real world to describe the geometric characteristic of a freeway, location and properties of freeway infrastructures, and topological structures of a freeway network. During the simulation execution period, a data model of a freeway network function as a space reference frame of simulation execution, which describes boundary constraints of simulation execution, records and stores state information and statistical information of dynamic and static parameters, defining logic models and logical rules of driving vehicles (such as topological traces of vehicles travel) according to the geometric shape of the road, effective scope of the controller, and conflict rules at junctions. Quality of a data model of freeway networks has a direct impact on efficiency of simulation system execution. The entities that a data model of freeway networks describe includes segments of a freeway, functional lanes of a freeway, junctions between two freeways, ramps of freeways, and tollbooths, etc. A data model of freeway networks can be represented as relation tables corresponding to a module of modeling freeway networks, which is a component of the input module of the simulation system for the FETOS.

Data model of the FETOS and respective modeling module The function of the FETOS model describes organization and storage of data on the FETOS. A data model of the FETOS can be represented as relation tables. Data about the FETOS that users input to start a simulation execution is stored into the relation tables, which are built based on data model of the FETOS. A data model of the FETOS corresponds to the module of modeling the FETOS, which is also a component of the input module of simulation system for the FETOS. Through the module of modeling the FETOS, users can visually input data on the FETOS, such as ramp control data, control-flow control identification, etc.

The dynamic traffic flow model under the FETOS This is built based on the

Cellular Automaton (CA) (R. Jiang, Q. S. Wu.2003) to describe temporal and spatial evolution regularity of traffic flow under the FETOS. That is, the most important of core models of a simulation system for the FETOS. Although the Cellular Automaton model^0 is a kind of micro-model, efficiency of a CA model is better than a car-following model and the CA model avoids the "discrete-continuous-discrete" approximate process. Based on the shortcomings, analysis of the existing models for freeway traffic flow, the improvements of the NaSch model (K. Nagel and M. Schreckenberg.1992) for freeway traffic flow will be given in the future research, and multi-lane changing rules (M. M. Pedersen and P. T. Ruhoff.2002) for freeway traffic flow will be introduced to the coming model of freeway traffic flow. Further, the evolution rules of traffic flow, under various emergency traffic organization measures, will be developed, and, finally, a dynamic traffic flow model under the FETOS will be built.

Simulation indexes of the FETOS and respective statistical models Simulation indexes of the FETOS can be used to evaluate the FETOS. These indexes include traffic volume on all lanes and ramps, average speed of vehicles on the main lines, delay at tollbooths, average speed and average delay of vehicles, empty time of emergency traffic flow, freeway network load, freeway network reliability, ratio of emergency traffic flow and normal flow, and comprehensiveness and feasibility of emergency transport organizations plan. A number of important indexes, such as traffic volume, average speed, traffic density, average delay and emptying time, can be derived by calculating the road load. The road network reliability, such as flow through the above-mentioned indexes, can also be embodied in an intuitive visual display of the performance.

Output Control Model The compositions and functions of output control models are as follow. First, in dynamic presentations, the users intuitively feel the vehicles traveling on the freeway and changes the color and dynamic presentation at the network based on the types and speed of vehicles, dynamically displays the current means of transport organizational measures, the visual output of simulation results, the flow of segments nodes, and saturation distribution networks can observe a crowded bottleneck. Second, in output indexes, through the simulation process, in accordance with the above-mentioned statistical model, obtain statistical data, such as indexes that show the average speed and density of vehicles and other information.

KEY TECHNOLOGIES

User interface of the simulation system for the FETOS can be interactively implemented within the visual studio development environment. A data model of freeway networks and a data model of the FETOS can be interactively built in a relation database (such as MS SQL server, Oracle, and Sybase etc.). Off course, they also can be implemented by VC++ programming.

Dynamic traffic flow models under the FETOS and simulation algorithms can be implemented by VC++ programming. Visual C++ adopts an object-oriented programming idea and the mechanism that data packages and their operations are shaped into categories, objects and methods. Through derivatives, inheritance, overloading and other characteristics of VC, software can be reused and procedures for implementation can be automatically generated.

In order to visualize the process of simulation execution, component development technology is adopted to integrate arc objects with dynamic traffic flow models under the FETOS. Traffic states on a freeway network can be identified by colors (for example, red represents congestion state of traffic, and green represents fluent state of traffic). Traffic states on a freeway network can be obtained from dynamic traffic flow model under the FETOS.

CONCLUSION

This paper presents, through the analysis of the elements consisting of the FETOS and requirement of a simulation system for the FETOS, a framework of a simulation system for the FETOS and discusses function modules of the simulation system and correlation among modules, core models of the simulation system, and the key technologies of implementing the simulation system. The framework proposed has significance on guiding the development of a simulation system for the FETOS, which is our on-going work.

ABSTRACT

The exact locating of emergency and rescue resources is not the only precondition for implementing rescue work, but also the input data for optimizing vehicle dispatching. In this paper, locating technology is applied to determine the location of emergencies in the highway emergency response system. According to the alarm information, such as road name, stake number and traveling direction, the algorithm of locating emergencies has been designed by the comprehensive use of the variable length subsection mode and the interpolation method. This study has been applied to the actual scheduling platform. The results show that the proposed algorithms achieve the precise position of emergencies and improve the performance of the emergency response system.

1 INTRODUCTION

Advanced algorithms can help to quickly and automatically detect incident. However, the status of national highway makes this manner difficult to be promoted. In general, when unexpected events happen on a highway, most of the information for assistance or alerts are derived from mobile phones, emergency telephones, traffic police and road patrol vehicles. Mobile phone alarms have obvious advantages. When emergency personnel have not yet arrived at the scene, command dispatching personnel can facilitate self-help or a police officer conducting an initial treatment. The biggest disadvantage of mobile phone alarms is difficulty determining the exact location of the incident, and more repeat alarms easily lead to police confusion. As an input parameter, the exact locating emergency is the precondition for implementing rescue work. So, it is necessary to research the exact locating of emergencies based on mobile phone alarms.

2 LOCATING TECHNOLOGY ANALYSIS

Traditional event locating is expressed by the relative positions (Gu Mingchen, 2005), which is more suitable for city streets. But for highways, the

marker positioned on both sides of the road is relatively simple and not easy to be confirmed. Some researchers have proposed to realize automatic locating by integrating the alarm telephone, electronic maps and GPS systems (Huang Tongyuan, 2003). Based on fuzzy information from alarm phones, patrol vehicles are dispatched to the scene of the accident. Then, according GPS coordinates, the feedback data can be displayed on the electronic map. Such locating means can precisely locate incident, but will inevitably lead to a lag time in making a decision because the site of the incident must be located after the patrol vehicles have rushed to the scene. Automatic Alarm System of America links private telephone companies and public service institutions together. China has not provided such a service of a private telephone company, but this will be the development trend of future locating systems.

Taking into account the specificity of the highway, alarm information can be described by a stake number. In this paper, the line used to calculate can be generated by using the variable length subsection mode on the highway, and then, in accordance with the alarm information of the road name, the stake number and the traveling direction, the interpolation method is used to calculate the exact location of incident.

3 KEY TECHNOLOGIES

3.1 Linear Reference Methods

The location of any unknown points can be determined by the distance and direction of known points on the linear characteristics, this method is known as Linear Reference Methods (LRM) (Li Qingquan, 2004). As an effective means for describing the location information of events, LRM has settled the expression of incident points in the transport network. Highway traffic incidents must occur or exist at a certain point or on a certain period in the road network. This phenomenon can be seen as one-dimensional, linear distribution rather than conventional two-dimensional, spatial distribution. To a single system with small amount of data, plane coordinates of the reference system are feasible for incident locating. But in the long run, highway GIS-T will be the integration of different types of traffic data; therefore, the conventional coordinate reference system is not suitable for the establishment of enterprise-level GIS-T. LRM can unify the integration interface of traffic information data and simplify the query method, which has been recognized as the best location reference method for traffic information systems.

Common LRM includes road stake number reference, road signs reference, node reference, and geodetic coordinate reference, as well as other extended ways. This article relates to the highway GIS-T, its line features decide that stake number reference is a more suitable method. Stake number is the main reference standard unit of highway measurement and is the locating method commonly used in transport industries, especially the road sector. Based on the stake number of a given point, such as the starting point of a route, the so-called “road-stake

number" reference method converts accident location and characteristics of road sections to the distance, in relation to the starting point, and determines the specific location. After recording the attribute information of incident location and confirming the LRM, the mapping for the information of unexpected events requires the use of virtual technology to determine the relative position of incident in the road entities, and an incident point diagram is finally generated in the electronic map automatically.

3.2 Linear Section Technology

Space geographical distribution of a highway has obvious linear features. Property information is collected by taking mileage piles, similar to a Linear Referencing System. In GIS, linear features are saved and managed with arc as the basic unit. All locations on the same arc have the same attributes. The multiplicity of highway attribute data determines that all the attributes are divided into multiple attribute sets in accordance with a certain standard and are set-up in a database separately. Each attribute set contains a number of characteristics of the highway. If the attribute data changes, the corresponding mileage of the attribute database changes. For highway data processing with these linear characteristics, GIS has provided three ways: isometric subsection method, variable length subsection method and dynamic segmentation method (Fu Zuoliang, 1994).

The variable length subsection method organizes data according to the start and finish of a variety of attribute changes in the road. The relative isometric subsection method, with small data redundancy, easy data updating and maintenance, is able to accurately reflect the real situation of all the relevant road attributes. For example, a pavement can be divided into several sections by both road types and road conditions. The variable length subsection mode can only deal with an attribute data set each time. The disadvantage is that the start and finish of the road sections require manual input, the same data will be duplicate saved when the road is delineated as different attributes of data sets and the various attribute data sets can not be integrated into spatial analysis and display.

4 ALGORITHM DESIGN

The initial incident information is obtained by alarm response staff. The contents of inquiry normally include sections, stake number, the directions of traffic, the availability of casualties, the impacted number of lanes, vehicle type, etc. Automatic locating of highway incidents just needs to consider the location-related alarm information.

The significant signs along the highway include toll stations, variable information boards, service area, and so on. The intervals between these signs are relatively distant, so they are unfit for describing the initial reference of incident location. Stake number is the unique identification information of highways, along the distribution-intensive, easy identified and reported. In addition, road names and directions of traffic could be accurately reported by police personnel. The

above-mentioned three elements constitute the input parameters of automatic locating.

The following steps are the design idea of the automatic locating incident algorithm:

(1) First, based on the stake number of highways, the line used to calculate a certain road section is constructed. The variable length subsection mode is used to divide this line into segmentations. At the same time, the data sets of stake number, road name, traffic direction and segmentation length are generated.

(2) Secondly, a mileage information table is built by the corresponding mileage of digital stake numbers. For vector stake numbers, a corresponding mileage value can be extracted by searching mileage information tables.

(3) Third, a MapObject point set is defined to store section name and traffic direction of alarm information. According to the contents of the object, the appropriate record of section attribute set is determined.

(4) Through cumulating the subsection length in the record, the current located section of stake number from alert information can be judged.

(5) The located section contains the stake numbers which are used for vectoring a highway. These discrete points can be seen as the start and finish of attribute changes; therefore, some more detailed subsections are automatically generated. The accumulation of these small subsections can judge the current located section of stake numbers from alert information. The start and finish coordinate of this current section is known and can be used to calculate the coordinate of the stake number by taking advantage of the interpolation method. Finally the point is located in an electronic map.

5 ANALYSIS OF TECHNOLOGY APPLICATION

(1) The line used to calculate

In order to clearly indicate the incident location, regional elements are used to store highway data in map scale 1:2000. Because of the obvious linear features of the highway, the locating algorithm needs to produce the line used to calculate which is connected by all vectors of stake numbers.

(2) Stake number description

The form of stake numbers is general described as “K*+***,” which needs to be converted to the specific numeral for program recognition. For example, if the stake number is “K2 +100,” then the mileage value is “2100m,” such data is necessary to calculate the location of the incident. For vectoring of stake number, the coordinates can be found by cumulating the subsection length. As for non-vectoring of stake number, the interpolation method is used to calculate the coordinates.

(3) Variable length subsection mode

The determination of incident location is the only target in this paper. The attributes of all sections include the code of section name, the code of traffic direction, the section length, as well as some fields automatically generated by the

attribute table. That is, we need only work with one attribute data set. The variable length subsection mode is selected to describe linear features. The selection of variable sections is based on linear features. The larger the arc curve is, the longer the section takes value.

For example, part of the attribute data sets of the Changji highway and Changyu highway is shown in Table 1. Field LENGTH is the section length, field CODE is the road code, field DIRECTION is the code of traffic directions, and other fields are automatically generated. Among them, 001 on behalf of Changji highway, 002 on behalf of Changyu highway, 0011 on behalf of the direction of Changchun to Jilin, and 0012 on behalf of the direction of Jilin to Changchun. Changyu highway is divided into four sections and Changji highway is divided into ten sections.

Table 1. Attribute data sets of Changji highway and Changyu highway

ID	FNODE_	TNODE_	LENGTH	CODE	DIRECTION	SHAPE
1	13	2	27027.77	002	0021	1
2	3	2	53174.97	002	0021	2
3	5	3	49604.38	002	0021	3
4	5	7	13713.09	002	0021	4
5	4	3	8431.051	002	0021	5
6	6	3	7931.204	001	0011	6
7	9	6	6130.557	001	0011	7
8	12	9	8100.018	001	0011	8
9	14	12	9875.148	001	0011	9
10	21	15	5170.029	001	0012	10

(4) Combination of variable length subsection and interpolation method

The variable length subsection method is used to describe the linear features of highway, and interpolation method is used to calculate coordinate values. If the division of sections is based on road linear, the distance between the start and finish of the section is not too short to adopt an interpolation method. As shown in Figure 1(a), if the coordinate of point E is solved by the coordinate of point A and point B, a large error will be produced through the interpolation method. This also explains why the section needs to be further divided. If the section is accumulated fully in accordance with the stake number, there is a larger calculation volume. As shown in Figure 1(b), before the interpolation between point C and point D, all the subsections require calculation. Therefore, the most suitable approach is the combination of these two variable length methods. As shown in Figure 1(c), in the first instance, the large section where the incident located should be calculated, then the subsections above this large section are cumulated, then the start and finish of the subsection where the incident located can be determined.

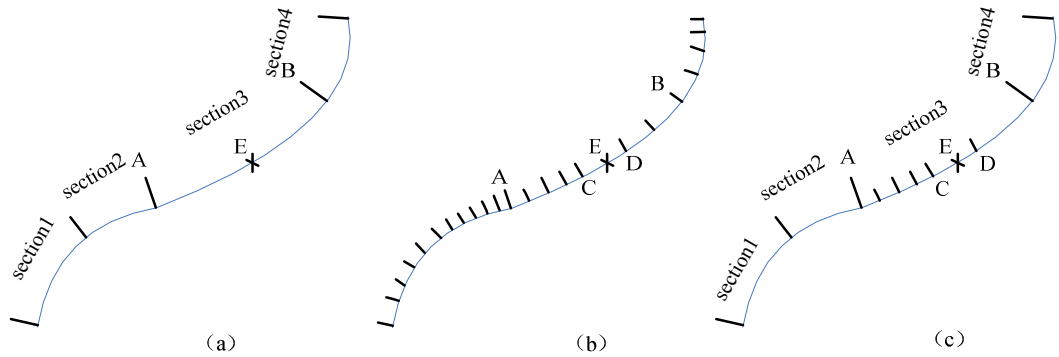

Figure 1. Variable length subsection for highway linear features.

5 CONCLUSIONS

The algorithm of locating emergency has been designed and the definition of the line used to calculate is put forward, which is produced by the variable length subsection mode. Based on the alarm information, the precise location of incident can be calculated by the interpolation method. This algorithm achieves accurate locating of incident on an electronic map after receiving a police alarm. However, the use of the variable length subsection mode needs to re-sub the road when the data is updated. The future research should concentrate on the dynamic segmentation method.

ABSTRACT

As the special section of a highway, the tunnel driving environment is poor. Accidents occurring in highway tunnel typically have the characteristics of high damage and difficult transaction. Taking the Xue Gong-Ling highway tunnel as the example, this paper discuses combining the advanced technique of intelligent transportation system (ITS) used in accident prevention and evacuation strategies of long highway tunnels, and solves the evacuation problem of drivers, passengers and vehicles when accidents or dangers occur. Under the state detection of traffic flow and environment in or out of the highway tunnel, a corresponding prevention scheme was executed for accident prevention. Once a single point accident or fire occurs in the highway tunnel, the threshold value h was stetted, waiting time T and minimum (diffuse time between fire and induced vehicle appropriative crossing, h) were compared, the Inducement Strategy was executed based on comparable results. Due to the long length of a highway tunnel, once there were both accidents happening in the same time, combined with the single point accident inducement strategy, a corresponding prevention scheme was executed according to different positions of accidents. Type and characteristics of accidents being considered, traffic can be evacuated rapidly through open or close induced vehicle appropriative crossing and people appropriative crossing. As a result, secondary accidents were avoided and the safety of driver and passengers can be ensured. Based on tunnel impact and a control development flat-form, the guiding strategy is simulated showing that this guiding strategy is a good way of controlling and inducing.

1. INTRODUCTION

As the highway workers have paid more and more attention on the environment, oil consumption, driving time and economic benefit, in many countries, especially in mountainous areas, more highway tunnels have been employed to conquer the landform limitation, optimize road linearity, and shorten traveling length. Therefore, characteristic accidents, such as a fire or a traffic accident, would be the ineluctable issue coming up with the tunnels. Related data show that the rate of fire or accident in tunnels is about 5 times per billion kilometers (Zhang Z D, 2003; Zhang H Y, 2003; Chen L D, 2003). Although the probability of fire and accident is very low, the after-effect is usually serious, especially in long highway tunnels (LU Mao-cheng, 2003). Therefore, an effective measure is the only way to keep the tunnels safe. The intractable issue to be solved now is to find a method that can play an important role

in preventing fires and accidents from occurring and can provide inducement information to drivers and passengers in time further avoiding secondary accidents.

2 SCHEME FOR ACCIDENT PREVENTION

It is well known that prevention is better than a cure. Not only accident management, but also prevention, should be provided in a perfect tunnel monitor control system. Preventatives can eliminate accidents during the germination phase and ensure the running safety of a tunnel. Therefore, the accident rate will fall, loss in calamities will decrease, the service life of the tunnel will be prolonged, and the road service level will be improved. Safety prevention includes two parts: outside and inside prevention (Chen J F, 2002).

2.1 Outside prevention

Some equipment, such as a video hard disk recorder, sensor, vehicle detector and video frequency monitor equipment, was set outside of the tunnel to avoid latent danger entering into the tunnel. All of the vehicles, which will enter into the tunnel, should be detected, and the system will distinguish whether or not there is latent trouble and give the corresponding directive. The judgment comes from the comprehensive analysis considering such factors as air cleanliness degree, fire, illuminative degree and video frequency data.

2.2 Inside prevention

Over-speed and overtaking vehicles are forbidden in tunnels and vehicles should drive in the given lines. By placing that equipment in the locale tunnel, monitoring systems acquire traffic flow information, including volume, temperature, brightness, etc. Data will be transmitted to a monitor center by a field control network then the monitor center would set out inducible information (Shen A Z, 2002). Relevant measures will be taken based on the degree of crowdedness in the tunnel.

(1) Speed-down adjustment

When micro-accidents occur, some vehicles will be blocked and an occasional crowd may appear in tunnel. In this instance, a tunnel can provide service as before with the help of inducement information shown on various message signs (VMS) given by the monitor center (NIU Yong-liang, 2006). The system indicates vehicles to slow down to the given speed limitation. If the traffic volume is too crowded, the monitor center can predict, according to data from the equipment set in the locale, the development trend of traffic flow and calculate the reasonable velocity and announce it.

(2) Closing line or lane temporarily

When there is serious jam in the tunnel caused by a small accident, the tunnel is still at the service-offering condition; however, the concentration of some harmful gases, such as CO, exceeds the regular provision. At this time, one line or lane should be closed until the harmful gas concentration decreases to a normal degree after ventilation for a period of time.

(3) Closing lane

If traffic is so crowded that, even though all ventilators work well, the

concentration of gases is still over the provision, or the converse wave caused by an accident happening in a downstream road, transmits into the tunnel, there will probably be a traffic jam or even an accident. Under this situation, we should close the whole lane or tunnel and induce vehicles to avoid the tunnel through vehicle appropriative crossing.

3. EVACUATION STRATEGY

However, even if the prevention monitor system works well, accidents in a tunnel cannot be completely avoided. Inducement projects will always play a very important role in the monitoring system. The system will enter the preparation phase when the scheme of an accident (including accident and fire in the paper) meets the condition for traffic inducement (including traffic accident, traffic jam, fire accident, lower air circumstance, abrupt power failure, ice and snow road surface, etc.) (JIANG Gui-yan, WEN, 2001; DAI Guo-ping, 2002; WANG Jin-guo, 2005). Manipulation interface of monitoring systems can give reference, but artificial confirmation will be necessary before entering the evacuation program. Some long and large highway tunnels are apt to have more accident spots, so it is probable that two or more accidents may happen at the same time (Pan Z, 2003). The evacuation scheme is often diverse enough for the different location and number of accidents.

3.1 Single point accident

According to Figure 1, provided that the accident or fire happens in the right lane, after confirmed by a manager, with the help of detecting system, alarm system and video monitor system, the position and the type of the accident can be estimated, and then the relevant control scheme will be executed (Ding Heng, 2008). Signals of control system forbid vehicles to enter both the left and right lanes. Closing the left lane prepares for inducing vehicles in the right lane going through vehicle appropriative crossing. Signals inside the left lane induce local vehicles driving continuously. At the same time, the system opens relative vehicle appropriative crossing, to induce the vehicles ahead of an accident point to turn left and pass through the inducement place, and finally avoid the tunnel by the left lane entrance. In this situation an obvious collision at the inducement place between induced vehicles and those had entered tunnel should be well disposed. In order not to affect regular performance of the latter passing through inducement place, the control scheme would give waiting time T and intercalate a threshold value h (value is advised 50s～60s) for induced vehicles. According to the compared result between T with $\min[(t-t_1), h]$, the system determines the entering time for induced vehicles(ZHAO Zhong-jie,2007).

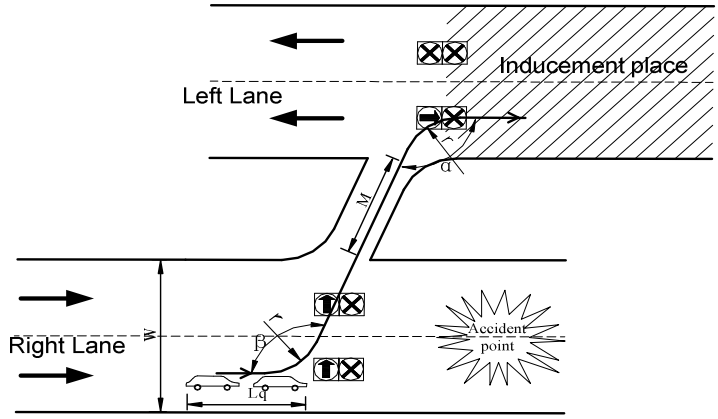

Fig. 1 Accident inducement.

Waiting time:

$$T = \frac{L - L_1 + d_1}{\overline{V}_a} - \left(\frac{M + \frac{W}{2\sin\beta}}{\overline{V}_v} + \frac{(\alpha+\beta)r + L_q}{\overline{V}_s} \right) + t_f + t_t + t_d \qquad (1)$$

L -the length of vehicle appropriative crossing (m);

d_1 -average vehicle length (m);

$\overline{V}_a$ -average velocity (m/s);

$\overline{V}_v$ -average velocity of vehicle running in vehicle appropriative crossing (m/s);

$\overline{V}_s$ -velocity of vehicle swerve (m/s);

t_f -response time (advice estimation time 1.5s+ response time 1.0s);

t_t -transmission time (s);

t_d -information dealing with time (s)。

In the formula (1), $d_1 \le 10$, d_1 can be ignored compared with L, t_t, t_d can be ignored too; t_f is about 2.5s, so formula (1) can be predigested as:

$$T = \frac{L - L_1}{\overline{V}_a} - \left(\frac{M + \frac{W}{2\sin\beta}}{\overline{V}_v} + \frac{r(\alpha+\beta) + L_q}{\overline{V}_s} \right) + 2.5 \qquad (2)$$

Compare result:

$$R = CMP\{T, \min[(t - t_1), h]\} \qquad (3)$$

R -result;

CMP -compare symbol;

t -the diffuse time between fire and induced vehicle appropriative crossing (normal traffic accident is $+\infty$.);

t_1-the shortest length of time driver can bear (advise 10～15s,fire accident, 0s for not fire accident.);

h-setting threshold value.

When the value of waiting time R is "<", those vehicles coming from the right lane are forbidden. After detecting all vehicles in the left lane heading away from inducement place, the system opens vehicle appropriative crossing and correlative pedestrian crossing, inducing blocked vehicles to get away. If R is ">", driveway indicator forbids vehicles in the inducement place in the left lane driving forward, and induces vehicles in the right lane to run away immediately. The left lane cannot work in a bi-directional way until all blocked vehicles in the right lane are evacuated; at the same time, the right lane is closed to undertake accident disposal and succor task. The traffic information "Frontage accident, please wait" is shown on the VMS at the entrance of the right lane.

3.2 Two-point accidents

It is more complex to induce vehicles when two-point accidents happen. Actually, the probability of a two-point accident is very low, but it cannot be eliminated, especially when the drivers may be scared by a previously occurring accident, which will probably result in a secondary one. The longer the tunnel is, the higher the rate of an accident happening. The evacuation strategy of a two-point accident in a long highway tunnel is significantly complex. Usually such accidents can be divided into two kinds: two accidents happening in the same lane and the two accidents happening in different lanes.

When two-point accidents happen in the same lane (Fig. 2), the system would forbid all vehicles from entering the tunnel, so vehicles ahead of the accident point avoid the tunnel through the first crossing ahead of the accident point. Before a driveway indicator sends out a signal to turn left, the control system uses formulas (2) and (3) to compare waiting time with threshold value separately. If R is "<", the system gives the waiting time induces vehicles to turn left and reach the other lane. When R is ">", waiting time will not be given and the system induces vehicles to run away from tunnel through vehicle appropriative crossing and inducement place directly. Cooperating with driveway indicator traffic signal does relevant manipulation, and VMS inside tunnel shows the relational information and the outside ones show waiting information.

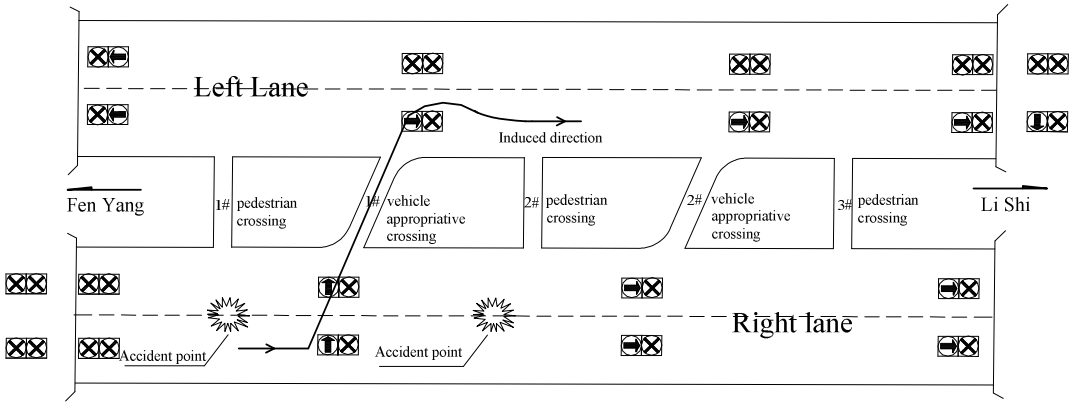

Fig. 2 Two-point accidents happen in the same lane.

When two-point accidents happen separately in different lanes, the first thing is to forbid all vehicles entering the tunnel too, then control system estimates whether or not the vehicles behind accident point can be induced. The rule is whether there is an accident point in the other lane in front of the crossing. If there is no accident point, crossing inducement is valid; otherwise, crossing cannot used for inducement. The situation of invalid crossing inducement in all traffic accidents is exceptive and the result is to close both lanes and induce drivers and passengers to abandon vehicles and run away.

If vehicles can be induced by crossing, the next step is to estimate the vehicles of both lanes, which may be induced by one or two vehicle appropriative crossing. There is no need to acquire the value of *R* when using one crossing inducing vehicles in two lanes (Fig. 3) because the shorter-length team has the priority to be induced. If vehicles need to be induced by two crossings (Fig. 4), the monitoring system should compare the threshold value separately and decides whether or not to give the waiting time, then shows information based on the value of *R*. Inside, VMS shows inducement information of current, the outside one shows running information inside the tunnel and provides estimative time and a displacing road to waiting vehicles.

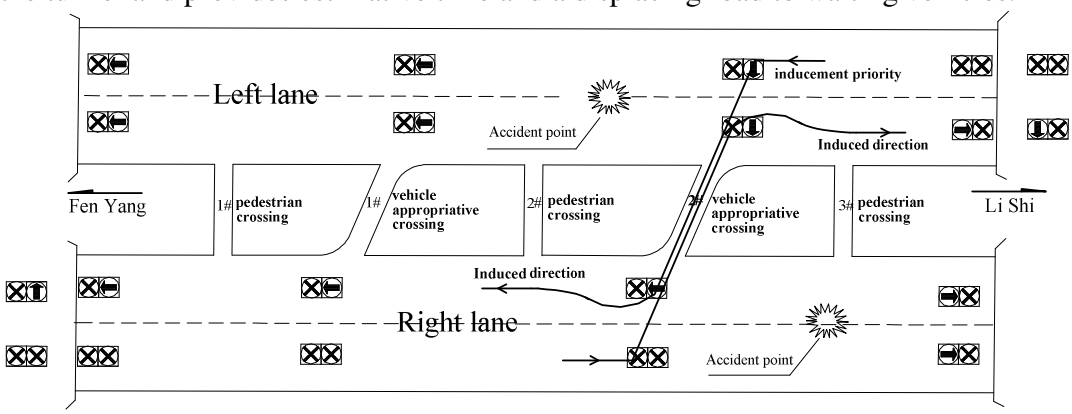

Figure 3 Inducement through the same vehicle appropriative crossing

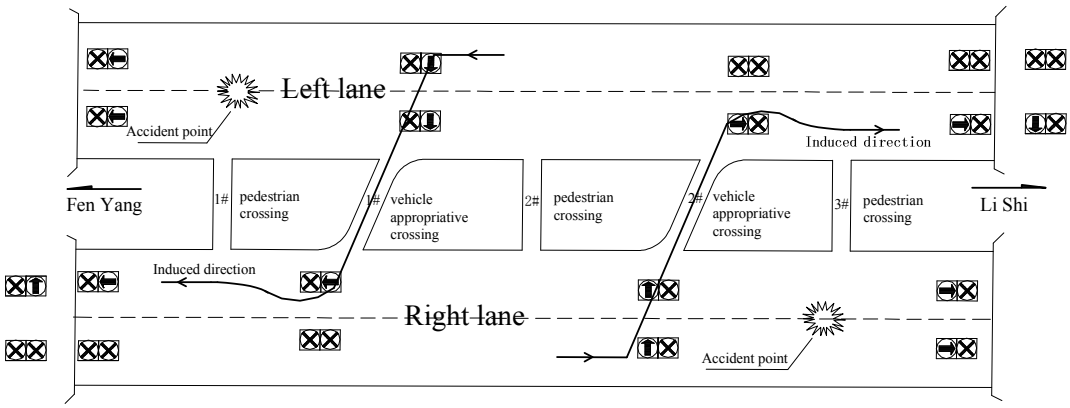

Figure 4 Inducement through different vehicle appropriative crossings.

By implementing evacuation and inducement strategies, control systems can be united with broadcast sub-systems, Route Guidance System, Vehicle Navigation System, etc., to ensure that passengers and drivers are induced safely and quickly, avoiding a secondary accident from occurring. When an inducement sub-system is executing its assignment, fire-fighting and alarm subsystems and an exigency succor sub-system must be started. After accidents are disposed, all of the correlative index should be checked, if the circumstances meet the need of normal exertion, both lines should resume.

4. CONCLUSION

(1) Practice tells us that the Scheme for Accident Prevention can reduce the accident rate about 83%.

(2) Aiming at accidents happening in different positions, using relevant and effective inducement strategies can shorten rescue time and increase rescue efficiency, consequently, ensuring the safety of drivers and passengers.

(3) The setting of threshold values reduces the difficult of establishment of rescue schemes and accelerates the rescuing procedure.

(4) Referring to the inducement strategy of this paper, control software has been developed and simulation control tests have been performed on the tunnel impact and control development flat-form. The results prove that an inducement scheme and the advice of waiting threshold values are feasible.

ABSTRACT

This paper studies the emergency response facility location problem. It is assumed that the demand of a roadway segment is concentrated on its midpoint and the number of the emergency response facilities and candidate location sites are known. An optimization model considering the uncertain coverage probability and rescue effect for emergency response facility location and network design is developed. The objective is to maximize the total expected demand node covered, with the decisions being where to locate the response facilities and how to dispatch emergency response teams to demand nodes. A genetic algorithm is designed to solve the model, and the application of the model shows that the optimization model can improve the robustness of the emergency response facility location by considering coverage probability and rescue effect.

INTRODUCTION

It is one of the important problems in emergency management to locate emergency response facilities and design specialized emergency response networks. The quick arrival of specialized response teams at an accident site can expedite the emergency response process and increase the chances of avoiding or impeding the consequences of the accident. This facility location and network design problem has attracted significant research efforts resulting in some models being proposed to solve the problems. The existing models for locating response teams can be classified into four categories.

The first category model is the location set covering model (LSCM) whose aim is to minimize the number of facilities needed to cover all demand points or the expected response time of response teams (Konstantinos G. Zografos, Konstantinos N. Androutsopoulos, 2008). The second is the maximal covering location problem (MCLP), whose aim is to maximize population coverage subjected to limited response facilities and teams availability (Church R., C. ReVelle, 1974). The third is the maximal expected covering location problem (MEXCLP) with response team

availability and response time uncertainty (Ingolfsson A., S. Budge, E. Erku, 2008). A team that is responding to a call is unavailable to respond to a subsequent call. Response time is uncertain due to factors such as pre-travel delays, traffic congestion and weather (Daskin M. S., 1987). The fourth is the maximal arc-covering problem, involving locating facilities to maximize the total weighted arc length covered (Berman O., Verter V., Kara B.Y., 2007).

Once an accident occurs with the transportation of hazardous materials, the released hazardous materials can be harmful to the environment, property and human health. The undesirable consequences can be mitigated by the timely arrival of the response teams. Different response times lead to different emergency response effects and degrees of satisfaction.

In view of this, based on the assumption that the demand of a roadway segment is concentrated on its midpoint, an optimal model for locating emergency response facilities with stochastic response time is developed, where the uncertain emergency response effects, probabilistic coverage, population exposure, accident rate, equal workload constraints and response time constraints are considered. The objective is to maximize the total expected demand covered, with the decisions to be made being where to locate the emergency response facilities and how to dispatch emergency response facilities to demand nodes.

THE PROBLEM AND MATHEMATICAL FORMULATION

The roadway network can be transformed into a mathematical graph $G = (N, A)$, where every node represents the midpoint of a roadway segment while any arc denotes the connection between two successive midpoints. Assume that m is the number of demand nodes, n is the number of candidate locations, and q is the number of facilities to be located. Note that d_i denotes the population exposure in the accident, p_i denotes the accident rate, t_c denotes the threshold value of the maximum response time between any demand node and the corresponding response facility, and t_{ij} denotes the response time from candidate location j to demand node i with mean r_{ij} and standard deviation σ_{ij}. Let p_{ij} designate the probability that facility j covers demand node i, and let f_{ij} designate the emergency response effect and satisfaction degree. x_j is a binary variable that takes value 1 if a emergency response facility is located at node j and 0 otherwise, and y_{ij} is a binary variable that takes value 1 if demand node i is covered by the emergency response facility located at node j and 0 otherwise.

The mathematical formulation for the emergency response facility location problem can be expressed as follows:

$$\max \sum_{i=1}^{m} d_i p_i \sum_{j=1}^{n} p_{ij} f_{ij} y_{ij} \tag{1}$$

$$s.t. \quad \sum_{i=1}^{m} y_{ij} \le m x_j \tag{2}$$

$$\sum_{j=1}^{n} y_{ij} = 1 \tag{3}$$

$$\sum_{j=1}^{n} x_j \le q \tag{4}$$

$$\sum_{i=1}^{m} y_{ij} d_i p_i \le W \tag{5}$$

$$\sum_{j=1}^{n} y_{ij} r_{ij} \le t_c \tag{6}$$

$$x_j \in \{0,1\}, \quad j = 1,2,...,n \tag{7}$$

$$y_{ij} \in \{0,1\}, \quad i = 1,2,...m, \quad j = 1,2,...,n \tag{8}$$

Objective function (1) maximizes the total expected demand nodes covered. Constraint (2) implies that the demand at node i can be serviced by node j if only a response facility is located at node j and requires that at most m demand nodes can be serviced by node j. Constraint (3) implies that the demand of any node is covered by a single response facility. Constraint (4) requires that at most q candidate locations can be selected. Constraint (5) implies that the workload assigned to each response team should not exceed W, where $W = (1+\varepsilon)\sum_{i=1}^{m} d_i p_i \Big/ \sum_{j=1}^{n} x_j$. Constraint (6) implies that the maximum response time from a emergency response facility to a demand node should not exceed the threshold time t_c. Constraint (7) and Constraint (8) establish binary restrictions on the decision variables. As in MCLP, each response facility houses only one response team.

COVERAGE PROBABILITIES AND EMERGENCY RESPONSE EFFECTS

The facility location model presented in the previous section requires input values of the coverage probability p_{ij} and the emergency response effect f_{ij}. Response time includes pre-travel delay, including time spent on obtaining the address, time spent on deciding which team to dispatch, time to contact the response team crew, and time for the crew to reach the facility and start it, and travel time. Travel time is uncertain because of factors such as bad weather and traffic congestion. The model includes the parameter p_{ij}, the probability that facility j covers demand node i. Let t_{ij} denote the response time from candidate location j to demand node i with mean r_{ij}, standard deviation σ_{ij} and coefficient of variation $c_{ij} = \sigma_{ij} / \mu_{ij}$. The response time can be lognormally distributed, exponentially distributed, log-logistic distributed and gamma distributed.

If t_{ij} is lognormally distributed with the parameter a_{ij}, then

$$\mathrm{E}[\ln(t_{ij})] = \ln(r_{ij}) - 0.5\ln(1+ c_{ij}^2), \tag{9}$$

$$\mathrm{var}[\ln(t_{ij})] = \ln(1+c_{ij}^2), \tag{10}$$

$$p_{ij} = \Pr\{t_{ij} \le t_c\} = \Phi\left(\frac{\ln(t_c) - \ln(r_{ij}) + 0.5\ln(1+ c_{ij}^2)}{\sqrt{\ln(1+c_{ij}^2)}}\right). \tag{11}$$

where Φ is the cumulative standard normal distribution function and t_c is the coverage time threshold.

The uncertainty of emergency response effect and satisfaction degree can be expressed by a function f_{ij}. The usual function for emergency response effect can be expressed as follows:

$$f_{ij} = \begin{cases} 1 & t_{ij} < a_i \\ 1 - \left(\dfrac{t_{ij} - a_i}{b_i - a_i}\right)^k & a_i \le t_{ij} \le b_i \\ 0 & t_{ij} > b_i \end{cases}, \tag{12}$$

where a_i, b_i and k are constant parameters, t_{ij} is the response time from candidate location j to demand node i, and f_{ij} is the rescue effect of emergency response.

AN EXAMPLE

An example will show how the model presented in this paper can be used to optimize the emergency response facility location. The roadway network is shown in Figure 1, with 5 candidate emergency response facility sites and 5 demand nodes. The maximum number of emergency response facilities is 2, and the population exposure at node 1, 2, 3, 4 and 5 are 1000, 950, 800, 1080, 1900, respectively. Without loss of generality, we may assume $p_i = 1$ and $\varepsilon = 20\%$, and the values of $t_{ij}, \sigma_{ij}, t_c, p_{ij}$ and f_{ij} are shown in Table 1.

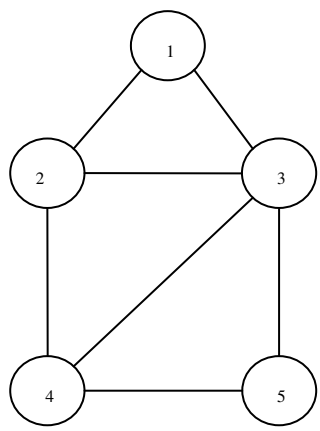

Figure 1. A simple network.

Table 1. The network parameters

Roadway Segments	t_{ij}	σ_{ij}	c_{ij}	t_c	p_{ij}	f_{ij}
1—2	530	10	0.019		0.841	0.717
1—3	515	30	0.058		0.801	0.747
2—3	535	5	0.009		0.841	0.709
2—4	510	30	0.059	540	0.842	0.757
3—4	535	10	0.019		0.694	0.712
3—5	500	5	0.010		1.000	0.766
4—5	520	10	0.019		0.976	0.710

The model of this example belongs to the class of NP-hard problems and can be solved using a genetic algorithm. If the workload constraint (5) is ignored, the optimal objective value is 5553.086 and the optimal solution is to locate response facilities at node 1 and node 5, to allocate demand node 1 and 2 to facility 1, and to allocate demand node 3, 4 and 5 to facility 5. If the workload constraint (5) is taken into account, the optimal objective value is 5418.196. The results show that the model can allocate relatively equal work loads to every response facility and avoid improper resource configuration by considering the equal workload constraint.

If the response time uncertainty is ignored, then the optimal objective value is 5730 and the optimal solution is to locate response facilities at node 2 and node 5, to allocate demand node 1, 2 and 4 to facility 2, and to allocate demand node 3 and 5 to facility 5. If the coverage probability and emergency response effect are considered, the optimal objective value is 4754.91 and the optimal solution is to locate response facilities at node 2 and node 5. We get optimal solution by considering not only the coverage probability but also the emergency response effect, which ensures robustness and effectiveness of this facility location model.

CONCLUSIONS

In this paper we investigated the response facility location problem. Based on the assumption that the demand of a roadway segment is concentrated on its midpoint, an optimal model for locating emergency response facilities with stochastic response time has been developed, where the uncertain emergency response effect and the probabilistic coverage are taken into account. The example result has shown that the model can allocate relatively equal workload to every response facility, ensure robustness and effectiveness of this facility location model.

ABSTRACT

The rail break emergency treatment device (RBETD) for railway switches has been developed to temporarily allow trains to pass through in case the stock rail of the railway switch cannot be replaced immediately after a break occurs. In order to test the soundness and reliability of its design so as to guarantee the safety of the running train, a field test was conducted with the emergency treatment device. The main components of the test include: the stress of the bottom edge of the common or frozen jointbar and the stress of the rail foot top at the center of the rail joint under different train speeds, the stresses of the vertical bearing plate of the device and the rail foot hook, the forces of the fastening screw, the transverse displacement of the rail head, and the sinking of the rail foot. Test results and subsequent calculations show that the emergency treatment device is safe as long as the train passes through at a speed less than 25 km/h with the help of the device.

INTRODUCTION

In the event that the stock rail of the railway switch cannot be replaced immediately after a rail breaks, Beijing Railway Bureau has designed an RBETD in order to guarantee the safety of the train while passing through at a limited speed (see Figure 1). In order to verify the reliability of the design and guarantee the safety of the running train, Shijiazhuang Railway Institute and Beijing Railway Bureau jointly

conducted a field test of the device at Handan Railway Station.

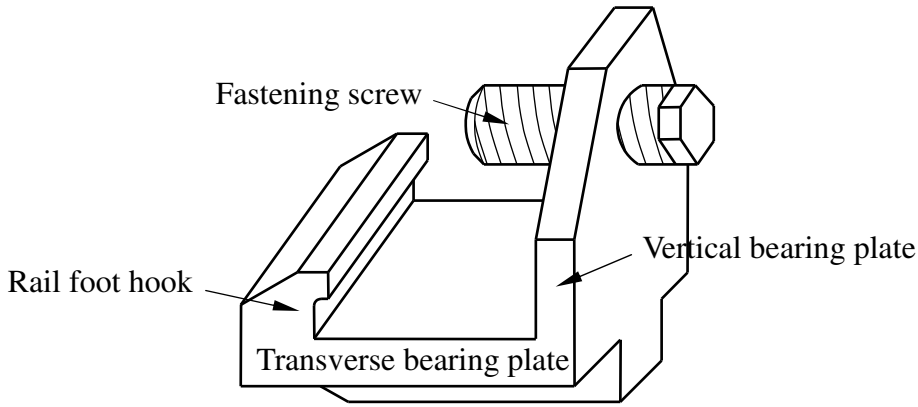

Figure 1. Rail break emergency treatment device

GENERAL DESCRIPTION OF THE TEST

Information on the railway line. The test was conducted on Track No.6 at Handan Railway Station (K431+650～K431+675 on Jing-Guang Railway). The segment lies in a curve with a 1000 m radius and 20 mm super-elevation of the outer rail. The track is constructed of 60 kg/m 25 m-long rail, 1760 pieces/km 69-type sleepers, and 300 mm-thick lime crushed stone ballast with good elasticity and no hardening. For test Section 1 (K431+650 of Jing-Guang Railway), the rail joint is 21 mm and close to the left sleeper's edge. For test section 2 (K431+675 of Jing-Guang Railway), the rail joint is 23 mm and is located at the middle of the span.

Operating conditions. The Dongfeng-7 dispatching locomotive was adopted in the test and the test speeds varied from 9.8 km/h to 44.0 km/h (measured by ground speed meter). It was tested 22 times, 16 times with common jointbar, and 6 times with frozen jointbar.

TEST PLAN DESIGN

Contents of test: (1) The stress of the bottom edge of the common or frozen jointbar and the stress of rail foot top at the center of the rail joint under different train speeds; (2) The stresses of the vertical bearing plate and rail foot hook, and force of the fastening screw of RBETD for railway switch; and (3) The transverse displacement of the railhead and the sinking of the rail foot, from which the dynamic change of track gauge and the dynamic joint stagger (horizontal and vertical) can be derived

Test method: Strain sensors were adopted for stress testing. Single-piece strain sensors were directly placed on appropriate positions on the structure and formed half-bridges with the corresponding temperature-compensation strain sensors (Cao, 2004; Wu, 1991). The stress was calibrated on the spot with the equal-strength beam.

The rail displacements were measured by leaf displacement meters, which adopted variable-sections but uniform-strength beamed copper leaf-springs as sensors. Strain sensors were symmetrically placed on both sides of the copper leaf to

form a half-bridge. A 1.5m-long steel rod with a diameter of 32 mm was driven into the subgrade to affix the displacement meter (Cao, 2004; Wu, 1991). The displacement sensor was affixed to the upper end of the rod and the displacement was measured with feeler gauge.

Arrangement of test points. Two sections were tested. Ten test points were arranged at Section 1, one point for the stress at the bottom edge of the common jointbar ($_A$), one point for the stress at the rail foot top ($_B$), one point for the stress of the vertical bearing plate of the emergency treatment device ($_C$), one point for the stress at the rail foot hook of the device ($_D$), one point for the inner force of the fastening screw of the device(P_G), and five points for rail displacement; Eight test points were arranged at Section 2, one point for the stress at the bottom edge of the common jointbar ($_A$), one point for the stress at the rail foot top ($_B$), one point for the stress of the vertical bearing plate of the emergency treatment device ($_C$), and five points for rail displacement.

Depending on the field test result in the case of a frozen jointbar, one test point was arranged at both Section 1 and 2 for the stress at the bottom edge of the frozen jointbar ($_A$). The arrangement of the Test Sections is shown in Figure 2.

Figure 2. Arrangement of test sections

Criterion for appraisal. Stress: less than the allowable stress for each part. Dynamic track gauge change: no more than (+8, -4) mm. Dynamic joint stagger: 3 mm.

TEST RESULTS AND ANALYSIS

Stress values. Table 1 shows the maximum stress values observed as the test train passed the test sections at different speeds. In Table 1, only the stresses with maximum absolute values are included, "-" for compressive stress and "+" for tensile stress. Test points No.1-16 are for the common jointbar, and points 17-22 are for the frozen jointbar. The test results show that:

(1) All stresses were less than the allowable value and had a sufficient margin of safety. The stress at the rail foot hook of the emergency treatment device was

especially far bellow the allowable value.

(2) There was no obvious relationship between the stress values and the speed of the test train, and the stress values were scattered to some extent. However, the stress values seem to be related to the position of the wheels and direction of the train, possibly due to the impact of the wheels on the rail joint. When the train was running in the same direction, the stress values increased with the train speed.

(3) Before the running test, the relation between the compressive force of the fastening screw (P_G) and the torque moment of the bolt (T) was determined through test: $T=KDP_G$, in which K is the torque coefficient ranging from 0.26～0.37 and adopted 0.30 practically in the test. The field test shows that a bolt torque moment of 400-500 N·m can meet the performance requirement.

Test result analysis of the geometric shape and position. Table 2 shows the maximum observed values of the transverse displacement of the rail head, the sinking of the rail foot, the dynamic track gauge change, and the dynamic joint stagger. In Table 2 only the data with the maximum absolutes are included. For rail head transverse displacement, "+"indicates the displacement is toward the outside of

the rail, "-"indicates the displacement is toward the inside of the rail. For rail foot sinking; "+"indicates the displacement is downward; "-"indicates the displacement is upward. For track gauge change, "+"indicates the gauge is increased;"-"indicates the gauge is decreased. The test data shows that:

Table 2. Maximum observed values of displacement

Speed ($km \cdot h^{-1}$)	Section1 / Section2 (mm)					
	Transverse rail head displacement	Rail foot sinking	Gauge change		Joint stagger

33.9	+2.27/+1.67	+4.67/+4.20	+3.37/+2.76	-0.06/-0.50	1.65/1.32	1.23/1.26
40.3	+1.26/+2.87	+4.27/+4.26	+2.05/+4.38	-0.62/-0.52	**1.97**/1.91	1.39/**1.58**
36.9	+2.36/+1.63	**+4.79**/**+4.58**	+3.43/+2.71	-0.14/-0.40	1.83/1.11	1.23/1.02
44.0	+1.27/**+3.05**	+4.37/+4.35	+1.99/**+4.49**	-0.72/-0.33	1.77/1.84	1.34/1.41

(1) All the observed data in both sections were less than their allowable values. It should be noted that a few of the observed data were close to their allowable value.

(2) The observed data of the rail head transverse displacement, rail foot sinking, dynamic track gauge change, and joint stagger were not obviously influenced by the speed of the test train and were scattered to some extent, possibly due to the limited range of the speed change. As with the stress test, the running direction of the train had an effect on the observed data. With the same train speed, the data had greater values when the train was running southward rather than northward, possibly due to the impact of the wheels on the section of the rail joint. When the train was running in the same direction, the values of the observed data increased with the train speed.

Comparison between calculation result and observed data. The mid-span bending moment and vertical displacement of the jointbar were calculated with the railway engineering numerical calculation software, adopting the following parameters values: The elastic modulus of the rail and jonitbar E=2.1×10^5 MPa., the

inertia moment of 60 kg/m rail against the horizontal axis I_1=2879 cm^4(allowing for 6 mm vertical wear), the inertia moment of the common jointbar against the horizontal axis I_2=496.3 cm^4, the inertia moment of whole-section-frozen jointbar against the horizontal axis I_3=709.1 cm^4 and the elastic coefficient of the rail supporting point D=300 kN/cm (Goenraad, 2001; Gu, 2005, Hao, 2002).

The comparison between the calculation results and observed data shows that the calculated bending stress at the bottom edge of the jointbar is greater than the observed value while the calculated displacements are smaller than observed. However, both are less than their allowable values, which indicates that the bending strength of the jointbar is not fully utilzed due to the contact displacement between the rail and the jointbar.

CONCLUSIONS AND FUTURE RESEARCH

(1) The test analysis shows the train can temporarily pass through the broken section of rail at a speed under 25 km/h after the rail is strengthened with the railway switch RBETD combined with single-side jointbar. All the major safety indexes are below their allowable values, hence it is verified that the design and strengthening method of the device are reasonable, safe, and reliable.

(2) According to the test results, the maximum compressive force of the fastening screw is about 60 kN, hence the value of 66 kN adopted in the design is appropriate. The initial torque moment of 400-500 N·m of the fastening screw can meet the requirement to ensure the good performance of RBETD.

(3) The safe operation of RBETD can be assured with a common jointbar, hence a frozen jointbar is not necessary.

(4) The vehicle used in the test is the dispatching locomotive of Dongfeng-7 Model. It should be noted that in order to make a comprehensive appraisal of the running safety and railroad stability, the vertical and horizontal wheel-rail forces should be tested to obtain such important indexes as derail factor and wheel load decrement ratio.

ABSTRACT： Under adverse weather conditions, both traffic system and physical environment have strong uncertainty and road network capacity is also changing and has strong fuzziness under dynamic situations. Based on analysis of the concept and meaning of road network capability, which has uncertain meaning, the capacity reliability of road network is taken as a fuzzy and random variable, therefore, fuzzy probability was applied to study it. The calculation and simulation method for reliability with random traffic flow and fuzzy road network capacity are discussed. The Bootstrap method based on experiential data was introduced to analyze reliability with fuzzy road network capacity. The area of fuzzy variable was given based on form and relative parameters in consideration of the practical requirements of traffic management.

Keywords: adverse weather, fuzzy theory, capacity reliability of road network

Reliability generally can be defined as the probability of completing the stipulated functions and tasks and it has extensive applications in computer system, correspondence and electric power engineering. However, research introducing the road network capacity reliability into the road network is still nearly a 10-year thing. Chen (Chen, 2000) set up a double-layer mathematical programming model of the capacity reliability, which can solve problems based on sensitivity analysis and Monte Carlo technique. Lo (2003) proposed PUE (probability user equilibrium) model to reflect the traveler's route choice behavior in stochastic road network and to calculate the road network capacity reliability. Bell (2000) took into account the difficulties of traffic data acquisition and made use of game theory to estimate the road network reliability. This paper will use fuzzy random theory to generate a city road network capacity reliability study.

1 Road network uncertainty analysis under adverse weather

The operation of a city transport system is affected by manifold factors under adverse weather and has a strong uncertainty. Urban transportation networks are closely related to traveler's activities, so it has more uncertainty. On the one hand, it is the fuzzy traffic change and there are some uncertainty factors to change the supply status of road network such as road status, visibility and traffic management situation and so on. On the other hand, the random change of traffic demand is affected by the travelers' path selections such as travel cost, personal preference, the status of road network, etc.

City road network capacity can be described with the fuzzy variables under adverse weather. The case or concept itself is described by fuzzy variables is ambiguous, whether an object is accord with vague concept is not clearly determined, but can only describe the possibility of the certain concept with the

subjection degree. Road network capacity is difficult but should not be simply divided into reliable or unreliable. Road network capacity is changing continuously and has strong ambiguity under dynamic situations.

Traffic demand can be described randomly under adverse weather. The randomness of cases or phenomena themselves is clear and the collection of random events demonstrates its clear extension.

The change of traffic demand has certain effects on the road network reliability which is the ability to adapt to the change of traffic demand. The change of traffic demand has fixed rules under adverse weather conditions and road network capacity has different reliability demands.

Road network reliability is a fuzzy random concept under manifold uncertainty. Generally, either the road network is in a normal situation or it is in an abnormal situation, and it does not have the transition situation in middle. But in fact road network has ambiguity, and it can also be regarded as the process from normal situation to abnormal situation. The control parameters of reliability which are in a limited state can be expressed with threshold cost. Therefore, it is statistically independent that the fuzzy random theory is used to study the change of road network capacity. The system will obtain new balance during this time.

2 The analysis of road network capacity reliability about fuzzy road network capacity of random traffic demand

For the fuzzy road network capacity $\tilde{C}$ and random traffic demand D,we can record fuzzy road network capacity as $\tilde{A} = \left\{ D \le \tilde{C} \right\}$; for any fixed threshold value, we can obtain interval $\tilde{C}_\lambda = [a_\lambda, b_\lambda]$. According to the concept of λ-cut set, we can think that any values are chosen about the posibility of the road network capacity is the same between a_λ and b_λ, when the threshold value of fuzzy road network capacity is λ, it is subjected to a uniform distribution of random variables between a_λ and b_λ. Therefore, the reliability problem of fuzzy road network can be converted into the probability problem of $\tilde{A}_\lambda = \left\{ D \le \tilde{C}_\lambda \right\}$. The probability of $\tilde{A}_\lambda = \left\{ D \le \tilde{C}_\lambda \right\}$ can be calculated with traditional reliability design theory.

Considering the above information, we can regard traffic demand and road network capacity as random variables to calculate the probability of the road network capacity reliability $\tilde{A}_\lambda = \left\{ D \le \tilde{C}_\lambda \right\}$,that is the following:

$$R_\lambda = P(\tilde{A}_\lambda) = P(D \le \tilde{C}_\lambda) \quad (1)$$

In the above formulas, $\tilde{C}_\lambda$—when the threshold value λ is given, the membership function $\mu_{\tilde{C}_\lambda}(C)$ of fuzzy road network capacity $\tilde{C}$ can determine the interval which is between a_λ and b_λ; and it can be determined according to the relation formula $\mu_{\tilde{C}_\lambda}(C) \ge \lambda$. Road network capacity in the above interval is subjected to the uniform distribution of random variables. R_λ—when the threshold value is λ, it is the probability of fuzzy road network capacity reliability. $P(D \le \tilde{C}_\lambda)$—when the threshold value is λ, when the fuzzy road network capacity is converted into random

road network capacity, random road network capacity outweighs the probability of random traffic demand.

When the general expression of the probability R_λ of λ-cut set of reliability of fuzzy road network capacity is obtained, the probability of fuzzy road network capacity reliability is the following:

$$R = P(D \le \tilde{C}) = \int_0^1 R_\lambda d\lambda = \int_0^1 P(D \le \tilde{C}_\lambda) d\lambda \qquad 2$$

In the above formula, $P(D \le \tilde{C})$ —it is the probability of fuzzy road network capacity reliability.

In formula 1, for any given threshold value λ, when we get the interval $\tilde{C}_\lambda$ of fuzzy road network capacity, the probability density function of road network capacity is the following:

$$f_{\tilde{C}_\lambda}(C) = \begin{cases} \dfrac{1}{b_\lambda - a_\lambda} & C \in [a_\lambda, b_\lambda] \\ 0 & other \end{cases} \qquad 3$$

Therefore, λ-cut-set probability of fuzzy road network capacity reliability is the following:

$$R_\lambda = P(D \le \tilde{C}_\lambda) = \int_{-\infty}^{+\infty} f(D)[\int_D^{+\infty} f_{\tilde{C}_\lambda}(C) dC] dD \qquad 4$$

In the above formula, $f(D)$ —the probability density function of traffic demand.

When fuzzy road network capacity $\tilde{C}$ is equal to threshold value λ, the interval which it belonged to obeys the random variable of uniform distribution, so we just consider the value between a_λ and b_λ when we calculate the integral value $\int_D^{+\infty} f_{\tilde{C}_\lambda}(C) dC$. Therefore, the value of traffic demand D is less than a_λ, traffic demand will not more than road network capacity, the integral value is 1; when the value of traffic demand D is more than b_λ, the traffic demand is always greater than the capacity of road network, the integral value is 0; the integral value is $(b_\lambda - D)/(b_\lambda - a_\lambda)$ when the value of traffic demand D is between a_λ and b_λ. From the above analysis, let us substitute formula 4 into the following:

$$R_\lambda = P(D \le \tilde{C}_\lambda) = \int_{a_\lambda}^{b_\lambda} \frac{1}{b_\lambda - a_\lambda} [\int_{-\infty}^{C} f(D) dD] dC = \int_{-\infty}^{a_\lambda} f(D) dD + \int_{a_\lambda}^{b_\lambda} \frac{b_\lambda - D}{b_\lambda - a_\lambda} f(D) dD$$

$$= \int_{-\infty}^{+\infty} f(D) \cdot \max[\min(\frac{b_\lambda - D}{b_\lambda - a_\lambda}, 1), 0] dD \qquad 5$$

where

$$\max[\min(\frac{b_\lambda - D}{b_\lambda - a_\lambda}, 1), 0] = \begin{cases} 1, & D \le a_\lambda \\ \dfrac{b_\lambda - D}{b_\lambda - a_\lambda}, & a_\lambda < D < b_\lambda \\ 0, & b_\lambda \le D \end{cases} \qquad 6$$

Formula 5 is used for the road network capacity reliability when the city road network is equal to the threshold value λ. Then, when the road network capacity reliability is equal to the threshold value λ, the integral value between 0 and 1 of the

reliability R_λ is the following:

$$R = P(D \le \tilde{C}) = \int_0^1 R_\lambda d\lambda = \int_0^1 P(D \le \tilde{C}_\lambda) d\lambda$$
$$= \int_0^1 \int_{-\infty}^{+\infty} f(D) \cdot \max[\min(\frac{b_\lambda - D}{b_\lambda - a_\lambda}, 1), 0] dD d\lambda \quad (7)$$

$P(D \le \tilde{C})$ is the probability of fuzzy road network capacity greater than or equal to the traffic demand D.

3 The way of Bootstrap about fuzzy random reliability analysis

When we analyze the reliability of fuzzy random road network capacity, we can use the λ-cut set concept of fuzzy collection and obtain the relation formula of fuzzy random road network capacity and analyze the fuzzy capacity reliability of road network through the ways discussed in the second section. Comparatively speaking , it is more measurable with the actual situation if we give an interval of fuzzy variables than if we use the direct form of its membership function and its parameters. When we analyze the fuzzy reliability, we can regard every interval as a λ-cut set of membership function of fuzzy variables. We can get the probability of fuzzy road network capacity reliability when experts give enough intervals (Dong , 2007).

Bootstrap is a simple and effective non-parametric statistical method which is proposed by Professor Efron in Stanford University in the United States (Efron, 1979). This method is widely used in engineering practices as it can make a statistical simulation on the basis of traditional mathematical statistics and create confident parameter intervals on the basis of small samples. Meanwhile, the method makes full use of information of sub-samples themselves so it does not need any assumptions for the overall distribution. Its basic principle is the following:

We assume there is a independent distribution sub-sample $X = (X_1, X_2, \cdots, X_n)$, which is from the unknown overall distribution R, but $\theta = \theta(R_n)$ is the unknown parameter of overall distribution. We suppose that R_n is the experience distribution drawn from sub-sample X, $\hat{\theta} = \hat{\theta}(R_n)$ is the estimation of θ. Estimation error is the following:

$$E_n = \hat{\theta}(R_n) - \theta(R) \quad (8)$$

According to the R_n,we can carry out sample by means of simulation, we assume that $X^* = (X_1^*, X_2^*, \cdots, X_n^*)$ is regeneration sample obtained from samples. Experience distribution R_n^* from X^* is the following:

$$E_n^* = \hat{\theta}(R_n^*) - \hat{\theta}(R_n) \quad (9)$$

According to the theory of Professor Efron, we can simulate E_n distribution by means of E_n^* distribution. E_n^* is self-assist statistics of E_n. When determining the parameters θ, we can make a close affinity between E_n^* and E_n

in formula 9, so we can get $\theta(R) \approx \hat{\theta}(R_n) - E_n^*$ and sample $\theta(R)$ of θ through single sampling X^* of R_n. From the above principle, we can get multiple $\theta(R)$ samples, therefore, we can get eigenvalue and its distribution of θ .

4 Analysis of Examples

It is inaccurate to express the road network capacity with defined data under adverse weather conditions. We suppose that "under adverse weather road network capacity of about 4304" is a fuzzy case $\tilde{C}$ where its membership function is expressed as a drop- ridge shaped distribution, as follows:

$$\mu(C) = \begin{cases} 1, & \text{当} C \le 4099 \\ \frac{1}{2} - \frac{1}{2}\sin\frac{\pi}{430}(C - 4304), & \text{当} 4099 \le C \le 4519 \\ 0, & \text{当} 4519 \le C \end{cases} \quad 10$$

Owing to the randomness of traffic demand (Yue, 2001), we can regard it as a random variable of normal distribution where its density function is the following:

$$D(x) = \frac{1}{200\sqrt{2\pi}} \exp(\frac{-(x-3857)^2}{80000}) \quad 11$$

We can calculate 10^4 according to the membership function of road network capacity. The result obtained is equal to $R = 0.9427848$ which is used as the theoretical value of city road network capacity reliability under adverse weather conditions. At this point, the road network capacity can satisfy the requirements of the traffic demand. We will get eight intervals according to these supposed eight different λ values and membership function of road network capacity and the concept of λ cut-set of fuzzy collation, meanwhile we can regard these λ value and its corresponding interval as a group of empirical data. We will estimate road network capacity reliability by means of different methods on the basis of eight different λ values and their corresponding intervals. After six repetitions, the results are shown in table 1:

Table 1 Count results of road network capacity reliability

serial number	λ value	R_n	Bootsprap method	
			average	95% confidence interval (M=1000)
1	0.1,0.2,0.3,0.4,0.5,0.6,0.8,0.9	0.945258	0.940503	[0.915349 , 0.965657]
2	0.05,0.1,0.3,0.4,0.55,0.60,0.75,0.95	0.945097	0.935551	[0.905865 , 0.965237]
3	0.05,0.15,0.25,0.4,0.5,0.8,0.85,0.9,	0.942266	0.940445	[0.915409 , 0.965482]
4	0.2,0.3,0.45,0.5,0.6,0.7,0.85,0.95	0.939388	0.932273	[0.905701 , 0.958844]
5	0.15,0.2,0.3,0.4,0.45,0.5,0.6,0.7	0.950494	0.948643	[0.935693 , 0.961593]
6	0.05,0.2,0.3,0.4,0.55,0.7,0.8,0.95	0.943177	0.942692	[0.905256 , 0.965038]

We see from table 1 that the Bootstrap method is obtained by means of the method of obtaining R_n. Even though it is aiming at self-assist sample $R_{w,l}$, its final result is closer to a theoretical value than R_n. Not only can it effectively reduce the fluctuation caused by interval change but it also can get the corresponding confidence interval according to different confidence limit. Meanwhile, it has certain practical significance.

5 Conclusion

Road network capacity reliability analyzes the city road network service capabilities from a macroscopic angle. The supply capacity of city road network and traffic demand is uncertain. We can regard traffic supply as the variable of fuzzy change and regard traffic demand as the variable of random change. Therefore, we can study road network capacity reliability by means of fuzzy random theory; that is, road network capacity reliability is regarded as a fuzzy random variable and to study the theoretical calculation method of random traffic flow of fuzzy road network capacity reliability analysis. The Bootstrap Method based on the experience data is introduced to analyze fuzzy road network capacity reliability. The fuzzy variable intervals obtained from empirical data become more affordable to the practical requirements of traffic management than its form of membership function and parameters.

ABSTRACT

The purpose of this paper is to build an effective mode for the dispatching and routing of emergency vehicles during disaster response. In this paper we consider the conditions of an earthquake disaster, for example, there are a large number of injuries which require medical treatment. The given conditions, including the injuries, casualties, roads, and traffic conditions, were utilized to dispatch and route emergency vehicles to the injured persons and then delivery them to the appropriate treatment center. In this paper, a real-time scheduling of the mathematical programming model is built for emergency vehicles to quickly select a reasonable route to save injured persons, and we utilize a case study to evaluate the performance of the proposed methodology. This is a highly effective mode for improving the emergency response capacity of the vehicle, improving rescue time and providing a theoretical basis and technical support for emergency rescue work.

1 INTRODUCTION

China is one of the most disaster-stricken countries in the world. An important element in post-disaster rescue is the emergency rescue of the injured persons. When an emergency situation arises, data including reports about injured persons, structural damage, road conditions, and traffic situations begin to flow to the Emergency Response Centers. ITS can monitor the real-time status of the roads and estimate the travel time of emergency vehicles. In the case of a major disaster, the discovery rate of casualties is extraordinary high. Therefore, an effective strategy for dispatching and routing is necessary for the decision makers involved in emergency rescue procedures.

There is limited research on the routing of vehicles in a disaster environment, although dynamic vehicle routing problems have been studied in the past. Afshin et al. (2003) provided an urban emergency transportation network to reduce loss of life based on the principles of minimized travel time and maximization of the capacity of rescue services. Yi and Kumar (2007) built a multi-stage model of network flow by

disassembling the rescue vehicle scheduling problem into the path of the vehicle structure and multi-item dispatching. Linet et al. (2004) discussed emergency material transportation scheduling in 2004, which describes dispatch orders for vehicles as consisting of sets of "broken" routes. Barbarosoglu and Arda (2004) proposed a two-stage multi-mode transport network model, and simulated the transport plan of relief materials. In such problems, a set of vehicles is routed over a particular timeline while new services are occurring in real time. To our knowledge, such a scenario has not been studied within a dynamic disaster environment.

2 POST-EARTHQUAKE ROAD CAPACITY

Road traffic capacity is influenced by many factors, such as lane width, lane number, and road surface conditions. The road capacity in disaster is impacted by the collapse of buildings along the street, displaced persons and vehicles, and the damage to the road itself. In the current study, the effects of damage to the road are not considered because urban roads have better seismic performance. The effects of the displaced persons by a stringent post-earthquake traffic management can also be ignored analogously.

Post-earthquake road capacity should be amended based on the actual road damage and the practical capacity in good condition, as shown in table 1. The value parameter denotes the increased travel time in different degrees of damage. The practical travel time is denoted by $t_{ij}(t)$ which is calculated by $\sum_n t_n^0(t) \cdot \xi_n$, where $t_n^0(t)$ is travel time in good condition.

Table 1. Value of ξ_n in different degrees of damage

Probability of buildings collapse	High	High	Low	Low
Probability of occupation road	High	Low	High	Low
The increase of travel time ξ_n	∞	2	1.7	1.0

3 MODEL DEVELOPMENT

In this paper, real-time information and the linked travel time estimates are used to calculate the dynamic shortest path. Mathematical programming models are used to find the best scenarios of emergency vehicle dispatching and routing. The final objective is to send the appropriate emergency vehicles to injured persons, and then deliver those persons to the appropriate hospitals. Thus, the problem can be divided into two parts: the vehicle dispatching problem and the vehicle routing problem.

3.1 VEHICLE DISPATCHING PROBLEM

The information on injured persons includes both their location and injury

classes. There are two injury classes: moderately injured and severely injured. The casualties are distributed randomly across the space affected; if a certain number are concentrated in a particular region, they then form clusters, which can be considered a small geographic region where a certain number of casualties are aggregated (Arun et al., 2009).

In the vehicle dispatching problem, an emergency vehicle is dispatched to an individual or cluster of casualties. Preference is given to the latter since it is more efficient to process groups than to serve individual casualties. This is the case since the emergency vehicle is likely to find some casualty for pickup within the cluster. If no clusters are present, the idle emergency vehicle is sent to the nearest high severity casualty.

3.2 VEHICLE ROUTING PROBLEM

Once injured persons have been picked up, the next task is to deliver them to appropriate hospitals. At each point, the dispatcher makes a dispatching decision for the emergency vehicles so that the system can use its resources with maximum efficiency. We assume at this point the travel time for each link is calculated and the shortest path for each pair of nodes is known based on the historical information.

While trying to minimize the total response time, the route and the destination of the emergency vehicles could change frequently. Too many and too frequent changes in the destination or route can be confusing and counter-productive. For example, before the reassignment vehicle 1 is assigned to an incident at node A, and vehicle 2 is assigned to an incident at node B. Under new demand conditions, if $t_{1,A} + t_{2,B} > t_{1,B} + t_{2,A}$, the result of reassignment could be that vehicle 1 is assigned to node B and vehicle 2 is assigned to node A. If the increase in travel time t_{1A} and t_{2B} are minor (for example less than 5%), $(t_{1,B} + t_{2,A}) - (t_{1,A} + t_{2,B})$ is a very small amount and perhaps less than the assignment before. This kind of route change should be avoided. The drivers should not change routes even if the destination is the same unless significant improvements could be achieved (Haghani et al., 2004).

3.3 MATHEMATICAL FORMULATION

The mathematical formulation for the real-time emergency vehicle dispatching problem minimizes the overall response time subject to vehicle availability and service constraints and is as follows:

$$\min a\sum_{i=1}^{N_v}\sum_{n=1}^{N}\sum_{j\in w^1,w^2} x_{ij}t_{ij}(t)\alpha_n + b\sum_{i=1}^{N_v}\sum_{n=1}^{N}\sum_{k\in w^2} x_{ik}t_{ik}(t)\alpha_n$$

S.T.

$$\sum_{j\in w^1,w^2} x_{ij} + \sum_{k=1}^{N_k} x_{ik} = 1 \quad \forall i \tag{1}$$

$$\sum_{j \in w^1, w^2} x_{ij} = 1 \qquad \forall i \in V^2 \tag{2}$$

$$\sum_{k=1}^{N_k} x_{ik} = 1 \qquad \forall i \in V^3 \tag{3}$$

$$\sum_{j=1}^{N_v} x_{ij} = 1 \qquad \forall j \in W^1, W^2 \tag{4}$$

$$\sum_{i=1}^{N_v} \sum_{n=1}^{N} \sum_{j \in w^1, w^2} x_{ij} t_{ij}(t) \le T_{j(t)} \tag{5}$$

$$-\left(\sum_{j \in w^1, w^2} x_{ij}^0 t_{ij}(t) - \sum_{j \in w^1, w^2} x_{ij} t_{ij}(t) - \varepsilon \right) \le M \cdot y_i \qquad \forall i \in V^2 \tag{6}$$

$$1 - \sum_{j \in w^1, w^2} x_{ij}^0 x_{ij} \le M \left(1 - y_i\right)$$

$$t_{ij}(t) = \sum_n t_n^0(t) \cdot \xi_n \tag{7}$$

Where:

i = The index of vehicles within No. i

N_v = The total number of emergency vehicles

j = The index of casualties within No. j

N_j = The total number of casualties

k =The index of hospitals within No. k

N_k = The total number of hospitals

N = The total number of paths

α_n = 1 if the a path was chosen; =0 otherwise

x_{io} = 1 if the a vehicle i is idle ; =0 otherwise

x_{ij} = 1 if the a vehicle i is dispatched to casualty j ; =0 otherwise

x_{ik} = 1 if the a vehicle i is dispatched to hospital k; =0 otherwise

$t_{ij}(t)$ = The travel time for vehicle i to arrive at casualties j while at time t

$t_{ik}(t)$ = The travel time for vehicle i to arrive at hospital k while at time t

$T_{j(t)}$ = The required response time for casualties j at time t

W^1 = The subset of casualties with moderately injured

W^2 = The subset of casualties with severely injured

V^1 = The subset of emergency vehicles with “idle” status

V^2 = The subset of emergency vehicles moving to casualties

V^3 = The subset of emergency vehicles moving to hospital

ξ_n = The increase of travel time of path n

$t_n^0(t)$ = The travel time in good condition of path n

a、b = The weight of two problems

The total travel time is the objective function of this formulation. The total travel time includes: the travel time to the casualties and the travel time to the hospitals. Constraint 1 states that every emergency vehicle must have a destination after assignment at time t. Constraint 2 ensures that emergency vehicles are dispatched to a destination. Constraint 3 states that the vehicles driving to hospitals can change their destination. Constraint 4 states that one vehicle must be dispatched to a casualty. Constraint 5 ensures that every casualty is treated justly. Constraint 6 is a mathematical expression of the reassignment conditions. Constraint 7 calculates practical travel time.

The model is solved by Flody's shortest path algorithm at every step during the dynamic solution process. The process is characterized by the concept that when faced with a new rescue request, the system recalculates the best path of each emergency vehicle and considers whether the reassignment conditions of real-time adjustments is satisfied, until a satisfactory solution is obtained.

4 CASE STUDY

In order to illustrate the advantages of the real-time vehicle scheduling model compared to the conventional scheduling model, the model is used in a road network which is abstracted from Changchun city, and compared with the conventional scheduling model. As shown in Figure 1, there are 26 nodes and 60 paths. Parameter values of the road travel times are shown in Table 2.

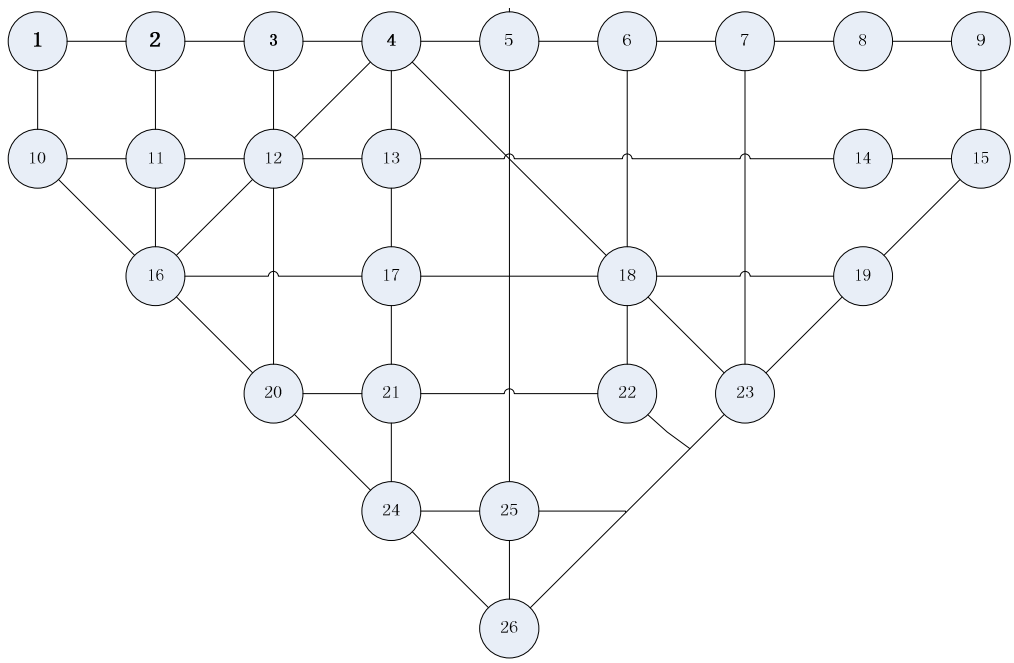

Figure 1. Emergency rescue network diagram

Table 2. Parameter values of the road travel time.

path	$t_n^0(t)\cdot\xi_n$	path	$t_n^0(t)\cdot\xi_n$	path	$t_n^0(t)\cdot\xi_n$	path	$t_n^0(t)\cdot\xi_n$	path	$t_n^0(t)\cdot\xi_n$	path	$t_n^0(t)\cdot\xi_n$
1	3.0	11	1.5	21	3.0	31	4.5	41	3.3	51	3.4
2	4.5	12	6.0	22	1.5	32	4.5	42	3.1	52	5.7
3	6.0	13	3.0	23	3.0	33	9.0	43	4.8	53	6.9
4	6.0	14	4.5	24	3.0	34	3.0	44	4.8	54	4.0
5	1.5	15	1.5	25	4.5	35	7.5	45	3.4	55	5.2
6	4.5	16	4.5	26	6.0	36	6.0	46	5.8	56	5.8
7	9.0	17	4.5	27	3.0	37	10.5	47	6.3	57	8.5
8	4.5	18	9.0	28	1.5	38	1.5	48	3.1	58	5.4
9	3.0	19	3.0	29	3.0	39	6.0	49	3.3	59	5.1
10	6.0	20	7.5	30	7.5	40	6.0	50	7.5	60	7.3

It is assumed that: hospitals are in nodes 11 and 23, there are two emergency vehicles at each hospital's location, relief demand generated by the system are A and B whose locations are nodes 17 and 24 with time interval 6 minutes. The required response times for A and B are 10 minutes and 9 minutes. The calculated results of the real-time model and are traditional model are shown in Table 3.

Table 3. Results of Emergency Vehicle Scheduling.

Scheduling strategy	Real-time	Traditional
Vehicle 1's mission and travel time	A, 11.7min	A, 11.7min
Vehicle 1's destination and travel time	Node 11, 11.7min	Node 11, 11.7min
Vehicle 2's mission and travel time	B, 14min	B, 14min
Vehicle 2's destination and travel time	Node 11, 6.3min	Node 23, 14min
Total travel time	43.7min	51.4min

As what can be seen from the results, response time of the real-time model is much less than the traditional scheduling model. This is because the real-time model ensures that emergency vehicles are always working efficiently. The model shows advantages in that when there is increased demand, the model can handle them in a more timely fashion and reduce response times.

5 CONCLUSION

This study concentrated on developing a dynamic dispatch strategy, by dividing the problem into two parts: the vehicle dispatching problem and the vehicle routing problem. An integer programming formulation was proposed for developing the real-time dispatching strategy. The formulation uses the shortest paths in as the routes for vehicles. A case study demonstrates that the real-time scheduling model,

compared with the traditional model, can significantly reduce the response times.

ABSTRACT

In recent years, with the rapid development of the national economy, frequent construction accidents on mountainous freeways result in a great loss of national property and become the focus of the nation's attention. It is urgent that we establish a construction safety early-warning system for freeways in mountainous regions in order to radically improve the situation of safety management. Major hazard identification and risk assessment is still lacking in the field. In order to solve this problem, a construction safety early-warning system for mountainous freeways was established. The targets, function, input and output of system were analyzed. The safety early-warning indicator system was made up of people, materials, environment, and management factors. The weights of factors were calculated by an analytic hierarchy process. The safety status grade was determined by a safety early-warning model. Results revealed that the safety early-warning system can reflect the safety status in freeway construction of mountainous regions objectively.

0 INTRODUCTION

Safety in mountainous freeways is needed for the sustained, healthy, stable development of the construction industry and essentially guarantees steady politics, stable society, and people living and working in peace and contentment. It is necessary to establish an early-warning system in freeway construction in mountainous regions for long-term and standard safety management. It helps to take corresponding measures quickly and efficiently to improve safety management in the event of accidents. The system monitors and controls the construction safety status. On one hand, it can take established management measures for restoration if accident

signs are recognized. On the other hand, it adopts corresponding emergency relief methods to reduce casualties and economic loss when accidents occur (Fan Hong 2005,Zhang Shilian 2006,Li Shirong 2004).

In foreign countries, the origin of economic early-warning methods was traced back to the Statistic General Assembly in Paris in the late 19th century. In the mid-30s of the 20th century, a diffusion index was applied. In the 50s, it came into practice. A synthetic index appeared in the 60s. Early-warning methods came to be mature in the 70s. Its theoretical research and application began in the mid-1980s. It has been used in everything from macroeconomics to corporation early-warnings, from qualitative analysis to combining qualitative and quantitative analysis, from point to status. But its development is far from mature. It belongs to the area of economic mutation (Wu Mingxia 2007, Zhu Jianjun 2007, Ren Hong 2005). In the field of freeway safety, early-warning system research is at a stand-still. Firstly, it is lacking advanced theory to support it. Secondly, it lacks the comprehensiveness, objectivity and dynamism needed to achieve full functionality of the early-warning system. Above all, applications of qualitative and quantitative analysis, forecasting methods and assessment means are insufficient (Choi H.H. 2004, Chua D. K. H. 2004,Sangoub Lee 2003,Osama Ahmed Jannadi 2003). Because of these problems, a safety early-warning system in freeway construction in mountainous regions was based on an unclear comprehensive assessment.

1 MODELING FRAME OF SAFETY EARLY-WARNING SYSTEM

1.1 Targets of system

The safety early-warning system in freeway construction in mountainous regions is used to determine whether the construction site is safe or not and take appropriate management measures. It can monitor, forecast and, warn various subsystems and adopt corresponding countermeasures.

1.2 Components, functions and input-output of system

The safety early-warning system is formed of three subsystems. The superior system is a database management system, and also is the input system. The mid-level system is comprised of a control system and also core processors including control system and convergence. The lower-level system is a generation subsystem consisting of graphics, conclusions, and recommendation output system.

The database management system is an integrated information system composed of entered qualitative and quantitative indicators. It contains all kinds of information which the mid-level system can order to call, query, add, delete and modify. The control system contacts the database management system with the generation subsystem, combining the functional requirement of subsystems according to the process of the safety early-warning system. It controls and manages subsystems. It also implements the man-machine dialogue interface and dynamic

management. The output system relates to the control system and generates corresponding graphics, conclusions and recommendations. The input of the safety system is the value of inspected indicators. The output is the warning degree.

Referencing the five-color warning system of the U.S. Department of Homeland Security as well as four-color warning of China's frame and guidance of contingency plans for public emergencies for relevant State Council departments and units, the system adopts three colors: red, yellow and blue. They correspond to three evaluation grades respectively. A red warning is adopted when safety status is poor. A yellow warning corresponds to general status. A blue level indicates a good status.

2 CONSTRUCTION OF SAFETY EARLY-WARNING SYSTEM MODEL

The safety system for freeway construction in mountainous regions is quite a complex, multi-level and nonlinear system. It has plenty of influencing factors, and many key factors cannot be carried out through quantitative analysis. A comprehensive assessment can solve qualitative factors and is appropriate for a multi-indicator and multi-layer system. Thus, the comprehensive assessment model of the safety early-warning system is established according to the characteristics of mountain freeways.

The construction safety status is divided into several grades. Evaluation grade set V is built:

$$V = \{v_1, v_2, \cdots, v_m\} \tag{1}$$

According to indicators in the system, bottom indicators are regarded as factors of safety comprehensive evaluation. Set U of evaluation factors is:

$$U = \{U_1, U_2, \cdots, U_n\} \tag{2}$$

Indicators' weight of various levels is determined according to a classification of evaluation factors and their importance to evaluated targets. Weight vector A is formed:

$$A = \{a_1, a_2, \cdots, a_n\} \tag{3}$$

The subjection degree of evaluation is determined using subjection function. Based on the model of comprehensive assessment, evaluation vector B is gained through determined weight vector A and relationship matrix R.

$$B = A \square R = (b_1, b_2, \cdots, b_n) \tag{4}$$

$$B = \sum_{j=1}^{n} b_j^2 \square j / \sum_{j=1}^{n} b_j^2 \tag{5}$$

The evaluation vector is changed to a single value though weighted mean., and eventually a safety grade is determined by comprehensive assessment.

3 CASE STUDY

Hubei Hurongxi Expressway is a major framework at home and an important part of the "six horizontal, five vertical and one ring" high grade highway network in Hubei province. It is also a fast-track of Shanghai-Chengdu's national highway from Yichang to Enshi connecting Chongqing, Chengdu and other major cities in the southwest. Hurongxi expressway is 320 kilometers long and the total investment is 204.5163 billion. It is divided into the Yichang-Enshi and Enshi-Lichuan projects. It was started on August 20, 2004. The project is expected to be completed in 2009.

Hurongxi expressway is located in a mountainous region of western Hubei province on Yunnan-Guizhou Plateau's northeast edge. Due to its special topography, complex technology, and difficult construction conditions, it is by far the largest investment, the most arduous project, the most complicated geologically, and the longest construction cycle expressway in Hubei province. The main line has four-lanes with the closed freeway building standard. The traffic speed is 80km/h.

Hurongxi expressway is currently one of the key high-risk projects in the country's transport infrastructure construction. It is also an important project of highway construction supervision. In order to ensure construction safety in production, the safety early-warning system of freeway construction in mountainous regions is built. A certain project is illustrated to evaluate the construction safety status using the early-warning system.

The construction safety status is divided into three grades. Corresponding evaluation grade set V is built:

$$V = \{v_1, v_2, \cdots, v_3\} = \{\text{safety grade, general safety grade, danger grade}\} \quad (6)$$

The indicators system is built based on basic principles of analytic hierarchy process as shown in Figure 1. The bottom twenty-four indicators are regarded as factors of safety comprehensive evaluation.

$$U = \{U_1, U_2, \cdots, U_{24}\} \quad (7)$$

According to features of mountain freeway construction and experts' advice, e each factor is compared to determine its relative importance and give corresponding value using 1-9 scale method created by Professor Satie. It constructs a judgment matrix of all levels. Then, it calculates weight vector and tests consistency. Due to limited space, only results are presented. Weight vector is given:

$$A=(0.1396062\quad 0.0504664\quad 0.0504664\quad 0.0504664\quad 0.0273645\quad 0.0532271$$
$$0.0170045\quad 0.0170045\quad 0.0108649\quad 0.1199108\quad 0.0951733\quad 0.0755389$$
$$0.0339422\quad 0.0339422\quad 0.0207853\quad 0.0478032\quad 0.0478032\quad 0.0203231$$
$$0.0110199\quad 0.0101616\quad 0.0340505\quad 0.0168001\quad 0.0118795\quad 0.0043959) \tag{8}$$

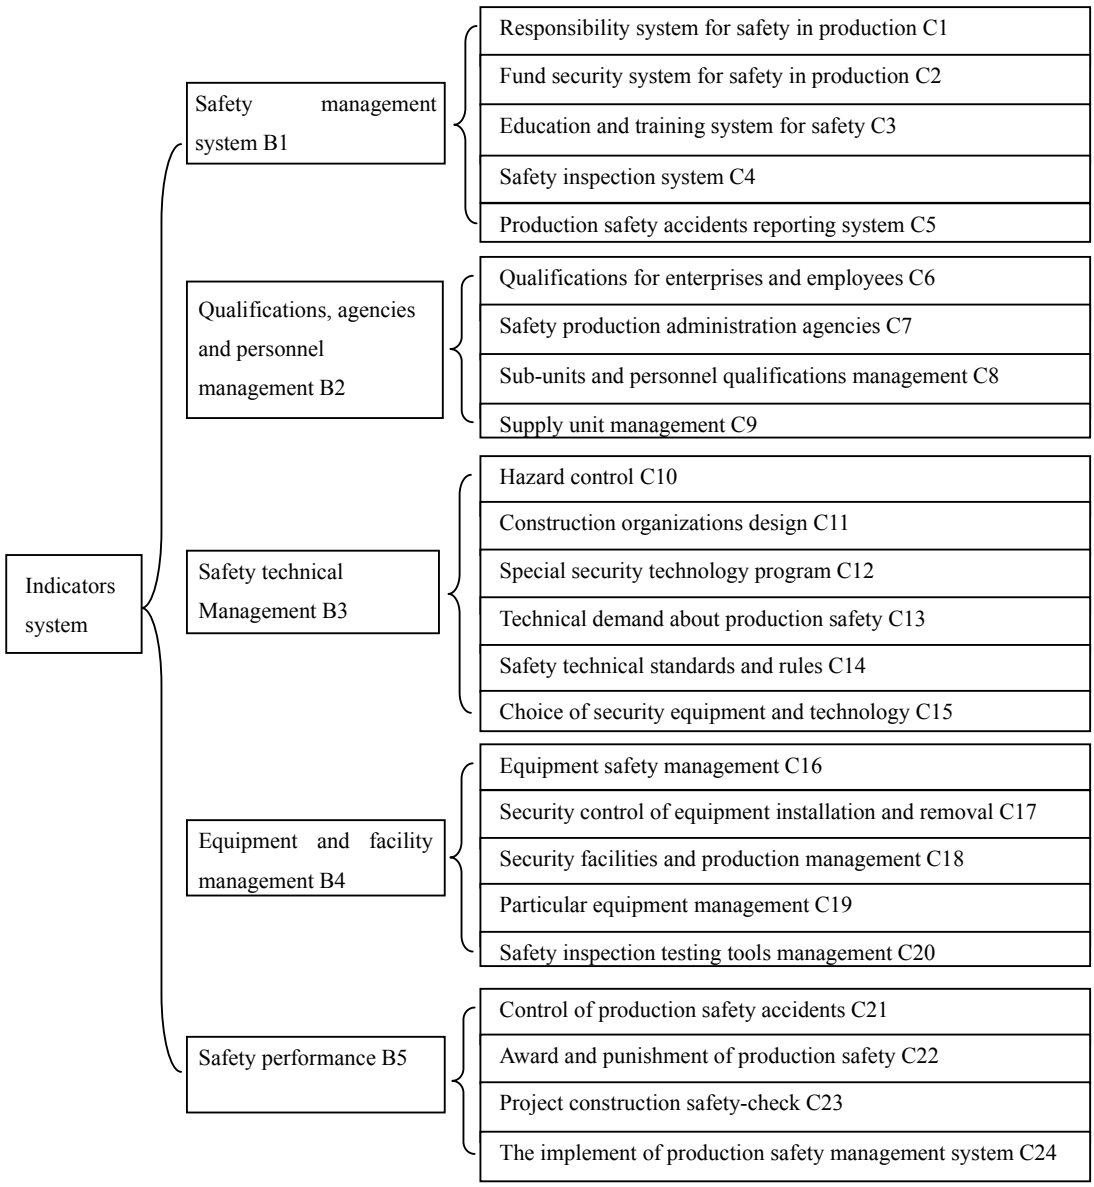

Figure 1: Indicators system of construction early-warning system of mountainous freeways

A score sheet is designed for each factor. Scores of factors are determined according to actual status in freeway construction of mountainous regions. Every factor is assumed to have x point. Subjection functions are built respectively:

$$\mu_{v1}(x)=\begin{cases} 0 & 0\le x<85 \\ \left(\dfrac{x-85}{10}\right)^2 & 85\le x\le 95 \\ 1 & 95<x\le 100 \end{cases} \tag{9}$$

$$\mu_{v2}(x)=\begin{cases} 0 & 0\le x<65 \\ \left(\dfrac{x-65}{10}\right)^2 & 65\le x<75 \\ 1 & 75\le x<85 \\ \left(\dfrac{95-x}{10}\right)^2 & 85\le x<95 \\ 0 & 95\le x\le 100 \end{cases} \tag{10}$$

$$\mu_{v3}(x)=\begin{cases} 1 & 0\le x<65 \\ \left(\dfrac{75-x}{10}\right)^2 & 65\le x\le 75 \\ 0 & 75<x\le 100 \end{cases} \tag{11}$$

Points are given by experts according to the score sheet. The subjection degree of evaluation is determined using the above subjection function. The relationship matrix R was also determined:

$$R=\begin{bmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ \vdots & \vdots & \vdots \\ r_{241} & r_{242} & r_{243} \end{bmatrix} \tag{12}$$

Based on the model of comprehensive assessment, B is determined through determined weight vector A and relationship matrix R .

$$B=A\circ R=(a_1,a_2,\cdots,a_m)\circ\begin{pmatrix} r_{11} & r_{12} & \cdots & r_{1n} \\ r_{21} & r_{22} & \cdots & r_{2n} \\ \vdots & \vdots & \cdots & \vdots \\ r_{m1} & r_{m2} & \cdots & r_{mn} \end{pmatrix}=(b_1,b_2,\cdots,b_n)=(0.172438,0.556829,0) \tag{13}$$

Using weighted mean, B is determined $B=1.91$ (14)

Thus, the freeway project is at the level of general safety. The results show that in order to raise the safety level, we need to establish and improve a responsibility system for production safety and strengthen hazard control. Because of the high risk

and many uncertain factors, it is difficult to evaluate the safety of a construction site accurately and objectively.

The system can understand and grasp overall construction site safety, find hidden causes of accidents and management shortcomings to establish early-warning system of construction safety. Also, it can improve the quality of information technology of safety management in freeway construction in mountainous regions.

4 CONCLUSION

It is urgent that we establish a safety early-warning system for mountainous freeways. Major hazard identification and risk assessment is still lacking in the field. A safety early-warning system for freeway construction in mountainous regions is established based on principles of comprehensive evaluation by studying factors of construction safety.

This system can reflect the safety status in freeway construction in mountainous regions objectively. Its interface is friendly for man-machine dialogue so as to provide the basis for construction safety evaluation and management decisions. Also, it can improve the quality of information technology of safety management for mountain freeways.

ABSTRACT

Salt spreading is a common practice in wintertime in many countries, and involves the spreading of salt on roads when ice or snow has made them slippery. The progress of optimization models of vehicle and materials depot locations can increase the efficiency or effectiveness of this practice, and also result in significant savings and reduced environmental and societal impacts. However, it is obvious that the depot location problem at the strategic level should be considered in conjunction with the vehicle routing problem at the operational level. As a result, this paper takes a Location-Routing Problem (LRP) based approach to the problems of depot location and vehicle routing with the purpose of aiding winter road maintenance planners. A two-stage TABU search algorithm is applied to solve the model.

INTRODUCTION

A chemical method is one of the winter road maintenance techniques used to clear roadways of snow and assumes a major role in winter road maintenance because of the effective performance and relatively low cost in comparison to alternatives. As highlighted by Perrier et al (2007), in recent years new technologies have been implemented in many agencies to help control the total costs associated with spreading materials, while also enhancing their effectiveness. However, the progress of optimization models of depot location not only increases the efficiency or effectiveness, but also results in significant savings, improved mobility, and reduced environmental and societal impacts. Unfortunately most agencies in China still rely in large part on decision rules dictated by field experience when making depot location decisions.

Perrier et al (2006) sorted the decision-making problems related to the materials spreading into strategic, tactical, operational, and real-time levels. Figure 1

shows the planning structure of winter road maintenance. The depot location problem is often solved by choosing a preset number of depots to open from a set of candidate sites based on some predefined strategic and operational objective. A number of different depot location models have been proposed in recent years. These models tend to take into account a large variety of characteristics of the problems arising in real-world applications (Muyldermans et al. 2002).

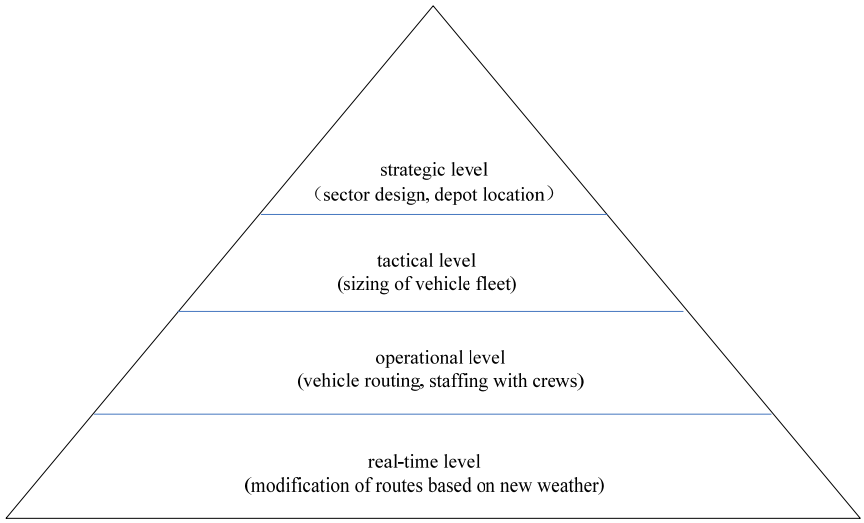

Figure 1. The planning structure of winter road maintenance

The vehicle routing problem requires that a set of routes is determined to optimize some performance criteria, such that all required road segments are serviced and all the operational constraints are satisfied. The proposed models for spreader routing generally assume a predetermined depot location and corresponding sector (Waddell B. 1994, Haghani A. 2002). Webb (1968) first pointed out that it is extremely undesirable to ignore the routing problem in the question of depot location. Some combined models for winter road maintenance have been proposed (Lotan et al 1996). However, there is not enough research that solves the combined problems of depot location and vehicle routing in an efficient manner. Most of the existing research on combined location routing problems assumes that the number of routes is equivalent to the number of vehicles.

The complexities involved in each of the problems of depot location and vehicle routing need careful analysis to determine the significant aspects of each problem in order to unify them in an integrated approach. In spite of the difficulty of the problem, recent developments of location-routing problems (LRP) in modeling and algorithms, and the increased performance of computers, all motivate the optimization models. As a result, this paper takes an LRP based approach to the integrated problems of depot location and vehicle routing with the purpose of aiding

winter road maintenance planners. The paper is organized as follows. In Section 1, a mathematical formulation of the problem is presented. Section 2 describes the solution methods. Computational experiments are performed in Section 3, and conclusions are given in the last section.

MATHEMATICAL FORMULATION

The Location-Routing Problem is proposed to optimize the location and quantity of depots, and solve the VRP at the same time. The problem of LRP for salt spreading operations is defined on a connected graph $G = (V, A)$. Before giving the mathematical formulation, we define some other notations:

V	The vertex set $\{v_1, \cdots v_k, v_{k+1}, \cdots, v_{k+n}\}$
A	The arc set $\{(v_i, v_j) : v_i, v_j \in V \text{ and } i \neq j\}$
V_t	The set of candidate depots $\{v_1, \cdots v_k\}$
V_c	The set of other vertex $\{v_{k+1}, \cdots, v_{k+n}\}$
k_i	The capacity of the depot
g_i	The fixed investment of establishing a depot
d_{ij}	The demand of arc (v_i, v_j)
C	The expense of unit demand
R	The set all routes which satisfy the demand of the arc
Q_c	The maximum capacity of the service vehicles;
m	The number of service vehicles;
H_i	The set of vehicle scheduling $\{S_{i1}, S_{i2} \cdots, S_{ih}\}$;
y_{ijs}	1 Only if arc (v_i, v_j) is assigned to S
	0 Otherwise
x_{ijr}	1 Only if the route r from the v_i to v_j
	0 Otherwise
u_{ri}	1 Only if v_i is the end point the route r
	0 Otherwise
o_i	1 Only if v_i is the depot location
	0 Otherwise

The formulation is then as follows:

Minimize

$$\sum_{i=0}^{n+k} \sum_{j=0}^{n+k} \sum_{b=1}^{m} d_{ij} x_{ijr} c + \sum_{i=1}^{k} o_i g_i \tag{1}$$

Subject to

$$\sum_{i=1}^{k} o_i k_i \geq \sum_{i=1}^{n+k} \sum_{j=1}^{n+k} d_{ij} \tag{2}$$

$$\sum_{i=1}^{k} o_i \leq P \tag{3}$$

$$\sum_{s \in H_i} y_{ijs} = 1, \quad (i = 1, \cdots, n) \tag{4}$$

$$\sum_{i=0}^{n+k} \sum_{j=0}^{n+k} x_{ijr} d_{ij} \leq Q_c, \ (r \in R_i) \tag{5}$$

$$\sum_{v_i \in S} \sum_{v_j \in S} x_{ijr} \leq |S| - 1, \ (b = 1, \cdots, m; S \subseteq V_t \cup V_c; |S| \geq 2) \tag{6}$$

$$\sum_{r \in R} u_{ri} - o_i \geq 0, \quad (i = 1, \cdots, k) \tag{7}$$

$$x_{ijr} \in \{0,1\}, \ (i = 0, \cdots, n+k; j = 0, \cdots, n+k; r \in R) \tag{8}$$

$$y_{ijs} \in \{0,1\}, \ (i = 0, \cdots, n+k; S \in H_i) \tag{9}$$

$$z_{ijr} \in \{0,1\}, \ (i = 0, \cdots, n+k; j = 0, \cdots, n+k; b = 1, \cdots, m) \tag{10}$$

$$o_i \in \{0,1\}, \ (i = 1, \cdots, k) \tag{11}$$

$$u_{ri} \in \{0,1\}, \ (\forall_r \in R; i = 1, \cdots, k) \tag{12}$$

The objective function (1) minimizes the total cost of the vehicle routing and depot location. Constraints (2) require that the capacity of all depots meet the materials requirement of all roads. Constraints (3) state that at most P materials depots are to be located. Constraints (4) require that every arc (v_i, v_j) is assigned to H_i. Constraints (5) state that the demand of every route is less than the capacity of the vehicle. Constraints (6) are the branch-eliminate constraints. Constraints (7) require that every depot has service vehicles. Constraints (8)-(12) require that the variables are integers.

HEURISTIC SOLUTION

Because of the complexity of the LRP, the problem is usually NP-hard. We apply the two-stage TABU search algorithm. Figure 2 describes the TABU-based algorithm.

(1) First, we establish the initial solution of the depot location. We randomly select a depot whose state is “open”.

(2) We apply two types of “moves” to construct the neighborhood of the current solution. One is the “exchange” move, and the other is the “increase” move. The “exchange” move is to open a depot and close a depot at the same time. The “increase” move is to increase the number of the depots.

(3) After every move at the stage of depot location, it is time to modify and search the optimal route.

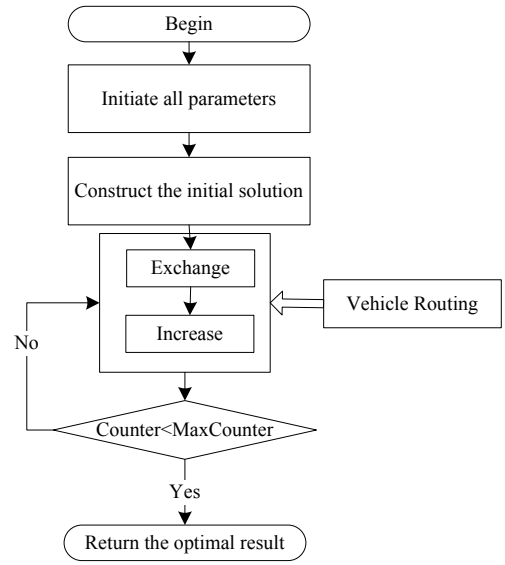

Figure 2. The description of the TABU-based algorithm

CASE STUDY

This section provides a case study to illustrate the models proposed in the previous sections. The test traffic network is the central part of the Changchun city which has been illustrated in Figure 3. Table 1 gives the parameters of the case.

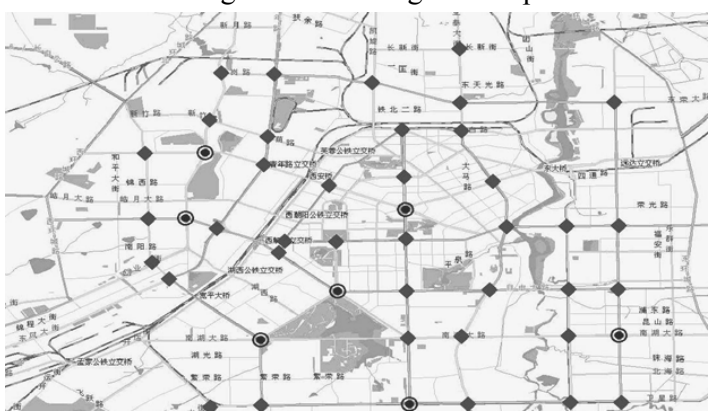

Figure 3. The test network

Table 2. The parameters of the case

Parameter(unit)	Value	Parameter(unit)	Value
road section(ind)	321	g_i (yuan)	10000
candidate depots(ind)	20	C (yuan/kilometer)	30
the number of spreader	13	Q_c (ton)	6

This paper compiles the algorithms program with the C++ language. The value of the parameters is as follows: $\alpha = 1, \beta = 1,\ \delta = 0.5, \eta = 1000$. The result is

shown in Table 3.

Table 3. Comparison of Results

Parameter	LRP	ARP
number of depots	7	8
the investment of depots	70000	80000
the cost of all routes	48563	46251
the total cost	118563	126251

CONCLUSION

The objective of this research was to develop a systematic optimization approach to integrate the winter road maintenance planning decisions for depot location and vehicle route design. The solution methodology achieves the objective of a more integrated and less sequential approach to the problems considered. Although there is much opportunity for further integrating the decisions studied in this research, the proposed methodology shows progress from the traditional sequential approach to winter road maintenance planning problems towards the eventual goal of a fully integrated approach. Since the solution methodology proposed in this research is heuristic solution based, there is no guarantee that an optimal or near optimal solution will be achieved.

ABSTRACT

Recently, meteorological disasters have had an expansive and complicated influence on city transportation networks. The reliability of travel time during adverse weather has gradually become the primary consideration before making travel decisions. Through the analysis of the impact of adverse weather on the transportation network, we adopt a disaster degree system to quantifiably describe the impact of weather on the transportation network. By combining the road network travel time reliability model and algorithm, we obtain the route travel time reliability and road network travel time reliability during adverse weather. Finally, we verify the effectiveness of this model through the calculation and analysis of an example.

1 INTRODUCTION

The transportation network is easily influenced by meteorological disasters. The problem of how to keep a transportation network working normally and functioning becomes important during adverse weather conditions. Travel time reliability is a typical index which can signify the uncertainty of the network and is a means to test random transportation network behaviors during adverse weather.

Travel time reliability is generally defined as an arrival possibility for travelers between a given origin and destination on time (Asakura, 1996). In Bell's (1997) paper, travel time reliability change was analyzed by sensitivity analysis to estimate travel time fluctuation with traffic demand changing. Hiroshi Wakabayashi (2000) built the framework of travel time reliability arithmetic during rain and snowy weather, which was applied to expressway networks. Stephen Clark et al (2005) analyzed transportation network travel time reliability with stochastic user demand. Until now, the majority of reliability research has been for normal transportation networks, so it is important to analyze transportation network travel time reliability

during adverse weather.

2 DYNAMICS OF EFFECTS ON TRANSPORTATION NETWORK TRAVEL TIME DURING ADVERSE WEATHER

In this paper, adverse weather is defined as rain, fog, snow, or dust storm disasters. The influence of adverse weather on a transportation network is similar to other disasters which have different effects in different terrains, different traffic facilities, etc.

The disaster degree system is used to denote how severely adverse weather affects transportation networks in cities. Adverse weather influences drivers' sight distance, friction on roads, and drivers' mental and emotional states. If these were to signify the degree, they create some difficulty in determining results. Two quantifiable factors were chosen: the number of traffic accidents (or traffic delays) and direct economic loss.

The calculation method of disaster degrees adopts a logarithm function to denote disaster (Feng Li-hua, 2000), which is:

$$\xi = \lg(DE) + \phi \tag{1}$$

Where ξ is degree; D is traffic accident numbers (or traffic delay); E is direct economic loss; ϕ is constant. The state of the transportation network is classified by four precautionary grades based on the disaster degree. The logarithm function is used to confirm the grade of emergency status:

$$N = a' \ln(\theta T) + b \tag{2}$$

Where N is precaution grade; θ is a possibility of degree to the mean ($\theta = \left| [\xi(t) - \bar{\xi}] / \bar{\xi} * 100\% \right|$, where ξ is degree; $\bar{\xi}$ is mean of degree); T is last time of disaster; a' and b are undetermined parameters. The range of N can be divided into four intervals according to the past data from the weather department:

(1) The fourth precaution grade. The degree reported by the meteorological department is minimal. The control mode of the transportation network is to release information and remind travelers to drive safely and slow down.

(2) The third precaution grade. When adverse weather occurs, the traffic information system must tell travelers suggested travel time and route by putting out information continuously. Relevant departments should prepare to manage the running of traffic on site.

(3) The second precaution grade. Alerting travelers to adjust their routes to avoid delay. The accident-prone locations should be supervised by traffic

management personnel.

(4) The first precaution grade. Remind travelers to avoid driving in these conditions. Begin emergency planning.

The effects of adverse weather on transportation networks is a stochastic process, which can be treated thusly: divide the last time of adverse weather effect into many periods of adverse weather, and each period has a mean of degree. We can determine the course of adverse weather effects.

3 PRESENTATIONS OF CAPABILITY AND FLOW FOR TRANSPORTATION NETWORK DURING ADVERSE WEATHER

Using the capability to describe a transportation network under adverse weather, the vector of every path in network is a state. That is $\tilde{c} = \{c_1, c_2, \cdots c_A\}$, so:

$$c_a(t) = \bar{c}_a - \delta_a(t) \tag{3}$$

Where c_a is real capacity of path a under adverse weather; $\bar{c}_a$ is capacity of path a in normal state; $\delta_a(t)$ is index function of emergence rank N:

$$\delta_a(t) = ce^N + d \tag{4}$$

Where c and d are undetermined parameters. So the network volume is:

$$x_w^k = \bar{x}_w - \frac{\lambda}{n} \sum_{a \in q, \not\in w} \delta_a^k \tag{5}$$

Where $\bar{x}_w$ is mean volume on route w(OD) under fine weather; δ_a^k is variable quantity of path a's capacity under adverse weather; λ is a constant; n is path number on route w(OD), so δ_a^k is:

$$\delta_a^k = h(\theta T)^{a'} + d \tag{6}$$

The possibility distribution of degree to the mean can be known by formula derivation, to get the possibility p_{at} of the real capacity c_a. Supposing c_{a0} is max capacity of path a under adverse weather, therefore:

$$p\{c_a = c_{at}\} = p_{at} \quad t = 0,1,\cdots,T_a - 1 \tag{7}$$

$$p_{at} \geq 0, \forall t \quad , 0 \leq c_{at} \leq c_{a0}, \quad t = 0,1,\cdots,T_a - 1 \tag{8}$$

The mean of whole path capacity change is $\bar{\delta}_a^k$ ($\bar{\delta}_a^k = \frac{\lambda}{n} \sum_{a \in q, \not\in w} \delta_a^k$) among route w on t period, and its possibility is p_{wt}.

4 THE TRAVEL TIME RELIABILITY OF TRANSPORTATION NETWORKS DURING ADVERSE WEATHER

4.1 Route travel time reliability

A transportation network is described by the real capacity $\overline{c}$, and the flow also describes the state of transportation network. The vector of actual capacity in all paths is called system state, which is $s=\{x_1,x_2,\cdots x_A\}$. Once traffic distribution mode (*TA*) is confirmed, the system state is known as:

$$s=\mathrm{TA}(\overline{c},x) \tag{9}$$

Travel time is the time superposition of every path chosen by travelers. Given that $\tilde{c}_0$ is ideal capacity of network under adverse weather; $\overline{x}_w$ is volume of w among OD in precaution stage; $\overline{x}$ is the vector of mean flow among OD:

$$\overline{x}=(\overline{x}_W, w\in W) \tag{10}$$

Supposing $t_{wq}(\tilde{c}_0,\overline{x})$ is the shortest travel time on route q among w(OD) under adverse weather; $t_{wq}(\overline{c},x)$ is actual travel time on route q among w(OD) in given state. So the route travel time reliability is defined as a ratio between $t_{Wq}(\overline{c},x)$ and $t_{Wq}(\tilde{c}_0,\overline{x})$ in acceptable level τ_{wq}, which is as follows:

$$R_{Wq}(\tilde{c},x)=P\left[t_{Wq}(\overline{c},x)/t_{Wq}(\tilde{c}_0,\overline{x})\le\tau_{Wq}\right] \tag{11}$$

Where τ_{wq} is a level of route with flow and weather effects fluctuating.

4.2 Transport network travel time reliability

The route travel time is the mean of a path's travel time, assuming city transportation network distribution is under user optimization control. So the mean of travel time on route w among OD is:

$$\overline{t}_W=\sum_{q\in P_W}\left[\left(x_{Wq}t_{Wq}\right)/x_W\right] \tag{12}$$

Since it is a problem to enumerate routes, it can be simplified. Supposing the possibility of choice of route q is p_{Wq}, and the travel time on path a is t_a, and γ_{waq} is 0 or 1(it's 1 if path a were chosen, or 0). According to equivalence substitution of the traveler route choice model, the travel time on w among OD is:

$$\overline{t}_W=\sum_{q\in P_W}\left[\left(x_{Wq}t_{Wq}\right)/x_W\right]=p_{Wq}\left(\sum_{q\in P}t_a\gamma_{waq}\right) \tag{13}$$

The transportation network's travel time reliability is defined as a weighted average of each OD, based on OD travel time reliability. That is as follows:

$$R_S(\tilde{c},x)=\sum\left[\overline{t}_W(\overline{c},x)R_W(\overline{c},x)\right]/\sum_{w\in W}\overline{t}_W(\tilde{c},x) \tag{14}$$

Adopt approximation algorithm to solve the route travel time reliability.

5 NUMERICAL ANALYSIS

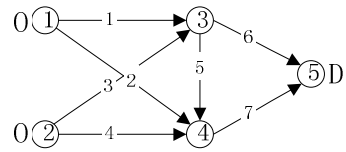

Figure 1. Test road network

The transportation network in Figure 1 has 5 joints and 7 paths, 2 OD s, and six routes. Assuming every path volume is changing with adverse weather on the third precaution stage, and the path's actual volume is x_k on k period, its possibility is p_{ak} shown in Table 1.

Table 1. Actual capacity and possibility of path under adverse weather

Path 1		Path 2		Path 3		Path 4		Path 5		Path 6		Path 7	
$\tilde{c}_{1k}$	p_{1k}	$\tilde{c}_{2k}$	p_{2k}	$\tilde{c}_{3k}$	p_{3k}	$\tilde{c}_{4k}$	p_{4k}	$\tilde{c}_{5k}$	p_{5k}	$\tilde{c}_{6k}$	p_{6k}	$\tilde{c}_{7k}$	p_{7k}
23	0.80	18	0.75	20	0.75	16	0.80	20	0.70	22	0.75	23	0.85
18	0.15	14	0.15	16	0.20	12	0.10	15	0.20	18	0.15	19	0.10
13	0.05	10	0.10	12	0.05	8	0.10	12	0.10	12	0.10	14	0.05

In the traveler route choice model (logit-model), suppose drivers choose route $q_3(2 \to 7)$ among OD $(1 \to 5)$. Select 20 transport network states in the third precaution stage, and show the volume x_k and possibility p_{ak} in Table2.

Assuming the acceptable level τ_{wq} of travel time is 0.6, so acceptable volume of route q_3 is 29, and acceptable volume of path 2 is 12, and path 7 is 15. Therefore the travel time reliability of route q_3 is as shown in Figure 2.

Table 2. Traffic flow and possibility of route q_3 in third precaution stage

Network state		Possibility	cumulative probability
State	Path 2	Path 7		
1	20	15	0.432	0.432
2	12	24	0.098	0.530
3	18	20	0.080	0.610
4	15	14	0.065	0.675

5	11	18	0.060	0.735
6	14	13	0.050	0.785
7	11	15	0.030	0.815
8	13	15	0.025	0.840
9	10	19	0.018	0.858
10	15	16	0.015	0.873
11	10	16	0.010	0.883
12	13	10	0.009	0.892
13	9	17	0.008	0.900
14	15	9	0.008	0.908
15	8	16	0.008	0.916
16	14	9	0.006	0.922
17	8	10	0.006	0.928
18	13	8	0.006	0.934
19	6	17	0.006	0.940
20	15	7	0.005	0.945

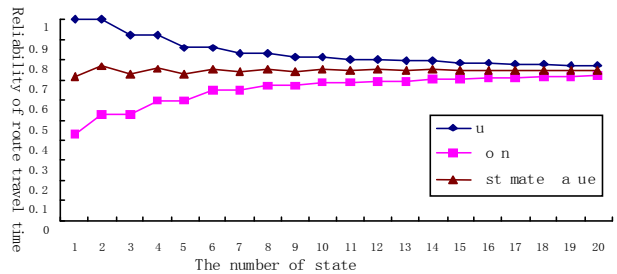

Figure 2. Estimated travel time reliability of route 3 in the third precaution step

Table 2 shows the travel time reliability estimated value of route q_3 in the third precaution stage. Given the acceptable volume of travelers, the estimated value of route travel time reliability quickly tends to be convergent with the number of network states increasing from Figure 2. The whole transportation network's reliability must be known according to each route's travel time reliability on one precaution stage, which is will allow the traffic department to improve the structure of the transportation network and guide travelers to choose the optimal route.

6 CONCLUSIONS

In this paper, the route and transportation network reliability are analyzed during adverse weather. Based on a system of weather degrees, the emergency transportation network is divided into four precaution grades, which will be helpful to traffic organization and management officials. However, because of fluctuations in adverse weather, the data collected here are not universally applicable, and the effects of adverse weather on the transportation network needs further study.

ABSTRACT

This research focuses on identifying optimal evacuation routing plans in public transit networks during various extreme events in urban road networks. The public transit evacuation system is modeled by a time-expanded network, based on a dynamic network flow model, and aims to minimize the total evacuation clearance time. This model transforms the public transit evacuation scheduling problem into a mixed-integer linear program (MILP). Also, a heuristic TABU-based search algorithm is used to find a high-quality solution in a reasonable amount of time. Finally, a case study is conducted using the central road network of Changchun city in China. Many numerical experiments are implemented in CPLEX 9.0 and the results show that time-expanded networks can effectively represent transit evacuation dynamics and the heuristic TABU-based algorithm can make an appropriate trade-off between solving efficiency and accuracy.

INTRODUCTION

In general, emergency evacuation of urban areas has gained prominent attention from both practitioners and researchers in the last three decades in the world (Wolshon et al. 2005, An et al. 2008, Liu et al. 2006). Among available modes of transportation, the use of public transit in evacuation situations is not well studied or understood (Liu and Hu. 2008). The use of public transit during evacuation is more crucial and should be well studied in some developing countries such as in China, as the population of transit-dependent citizens is very large. In addition to people without vehicles, the indigent, the elderly, the infirm and tourists also rely on the public transit system for evacuation. Accordingly, the purpose of this study is to make the existing transit system viable in emergency situations by developing a

practical "Public Transit Routing Plan" to deliver evacuees from the danger zone to safe destinations.

TIME-EXPANDED NETWORK OF PUBLIC TRANSIT EVACUATION

Here, we use a time-space network structure to present the schematic of the transit network. Let $G=(V,E)$ be the undirected graph of the city, where V and E stand for the set of nodes and the set of arcs, respectively. The set V is decomposed as $V=I\cup I^{'}\cup N$, where $I=\{s_1,s_2,...,s_n\}$ is the set of stations, $I^{'}=\{sh_1,sh_2,...,sh_l\}$ is the set of shelters, and N is the set of intersections.

Accordingly, the graph G is transformed into the time-expanded network $G^*=(V^*,E^*)$, where $V^*=I^*\cup I^{'}\cup S^*$ denotes the node set and E^* denotes the arc set. The network G^*, which is illustrated in Figure 1, consists of $T+1$ layers, and each layer represents a time period. The time-space network contains three types of nodes: *StatNodes*(I^*), *ShelterNodes* ($I^{'}$), and *SinkNodes* (S^*). The StatNodes are the set of station nodes with two attributes: location and time. The location of the stations is defined based on the existing transit system. Time is partitioned into equal-length time intervals (*intertime*). Let the time period set be defined as $\Re=\{0,1,2,...,T\}$. Nodes of the set I^* correspond to the copies of each station nodes $i\in I$ in each time period $\alpha\in\Re$; in other words, the *StatNodes* corresponds to the set $I\times\Re$. An element of this set is denoted by i_α, where $i\in I$ and $\alpha\in\Re$.

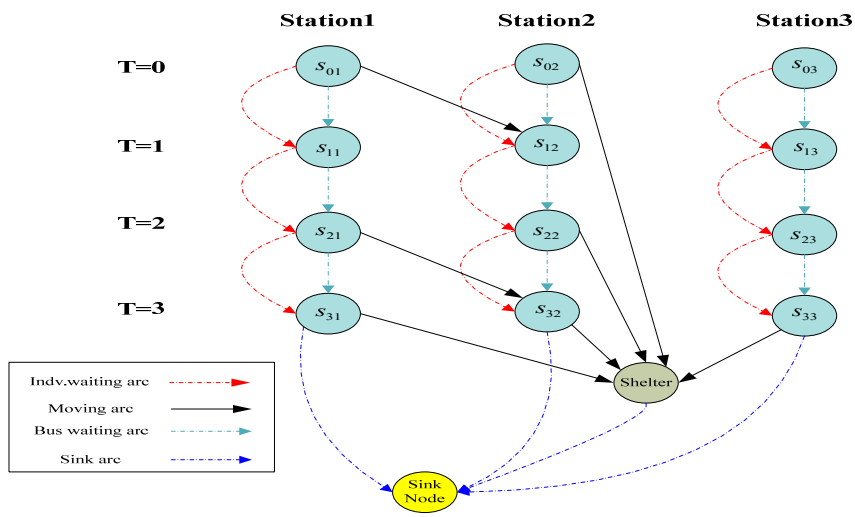

Figure 1.Topographical of a network.

The *ShelterNodes* set corresponds to the set of shelter nodes in which evacuees are accommodated temporarily. An artificial *SinkNode* is introduced, and its supply is set to the total demand on nodes in *StatNodes*.

The set E^* of arcs is decomposed into 4 subsets: movement arcs (M), individual waiting arcs (W_p), transit vehicle waiting arcs (W_b), and sink arcs (S).

The arcs in the set of movement arcs emanate from nodes in the *StatNodes* and enter nodes in *StatNodes* or *ShelterNodes*. To model a possible arc from station i at time period α to station j, we create an arc from node i_α to node j_β, where $\beta = \alpha + r_{i_a j} / \text{int}\, ertime$ and $r_{i_a j}$ is the travel time between station i and station j at time α. The movement arc between any pair of nodes is selected out of *k*-dissimilar paths between nodes. The capacity of movement arcs is equal to the capacity of transit vehicles, and their cost is equal to the time required to traverse the path.

The set of individual waiting arcs (W_p) includes the arcs from node i_α to node $i_{\alpha+1}$. Individuals at station i who are not picked up by any transit vehicle at time period α will move to the subsequent copy of station i at the next time period ($\alpha+1$) using the individual waiting arc. The individual waiting arcs have unlimited capacity and they can flow an infinite number of individuals from one time period to the next time period. Also, we introduce transit vehicle waiting arcs (W_B) from node i_α to node $i_{\alpha+1}$. Unlike individual waiting arcs, the transit vehicle waiting arcs are constrained in volume, and their capacity is limited to the vehicle capacity. The traverse time on both types of waiting arcs is equal to the length of the time interval (*intertime*).

The arcs in the set of sink arcs (S) emanate from the last copy of stations (i_T) in *StatNodes* and *ShelterNodes* and enter the *SinkNode*. The sink arcs between nodes in *StatNodes* and the *SinkNode* are unconstrained, and their traverse time is set to a big number to discourage the individuals to move to the *SinkNode*. The sink arcs between the shelter nodes and the *SinkNode* are also unconstrained in capacity; their traverse time, however, is set to be zero.

PUBLIC TRANSIT EVACUATION ROUTE PLANNING MODEL

Here the network flow formulation is used along with side constraints to formulate the public transit evacuation problem:

$$\min \sum_{(i,j)\in E^*} t_{ij} x_{ij} \tag{1}$$

$$\sum_{\{j:(i,j)\in E^*\}} x_{ij} - \sum_{\{j:(j,i)\in E^*\}} x_{ji} = \begin{cases} \delta_i & i \in I^* \\ 0 & i \in I' \\ -\sum_{n=1}^{|I^*|} \delta_n & i = s^* \end{cases} \tag{2}$$

$$x_{ij} - u y_{ij} \le 0 \qquad (i,j) \in M \tag{3}$$

$$\sum_{\{i:(i,j)\in M\}} \sum_{j\in I'} y_{ij} = \omega \tag{4}$$

$$\sum_{\{j:(i,j)\in\{M\cup W_B\}\}} y_{ij} - \sum_{\{j:(j,i)\in\{M\cup W_B\}\}} y_{ji} = b_i \tag{5}$$

$$-x_{ij} + u y_{ij} - M z_{il} \le 0; (i,j) \in M; (i,l) \in W_p \tag{6}$$

$$x_{il} - M(1 - z_{il}) \le 0; (i,l) \in W_p \quad (7)$$

$$y_{ij} \in \{0,1\}; (i,j) \in M \quad (8)$$

$$z_{il} \in \{0,1\}\ ; (i,l) \in W_p \quad (9)$$

$$x_{ij} x_{il} \ge 0;\ (i,j) \in E^*; (i,l) \in W_p \quad (10)$$

Where, I^* = *StatNodes*; I' = *ShelterNodes*; s^* =*SinkNodes*; M =set of movement arcs; W_p =set of waiting arcs for individuals; W_B =set of waiting arcs for transit vehicles; S = set of sink arcs; $E^* = \{M \cup W_P \cup W_B \cup S\}$; ω =total number of available transit vehicles; U =capacity of a transit vehicle; δ_i =supply at node $i \in I^*$; b_i =number of transit vehicles that start their trip from node $i \in I^*$; x_{ij} = flow of evacuees on movement arcs from node $i \in I^*$ to node $j \in \{I^* \cup I'\}$; x_{il} = flow of evacuees on individual waiting arcs from node $i \in I^*$ to its subsequent copy (node $l \in I^*$); y_{ij} = a binary variable related to the movement arcs that takes the value 1 if there is a flow of evacuees from node $i \in I^*$ to node $j \in \{I^* \cup I'\}$ and takes the value 0 otherwise; z_{il} = a binary variable related to the individual waiting arcs that takes the value 1 if there is flow of residents from node $i \in I^*$ to its subsequent copy (node $l \in I^*$) and takes the value 0 otherwise.

The objective function (1) aims to minimize the total system travel time as well as the waiting time. Constraint set (2) is comprised of 3 sets of constraints. Each set provides the standard flow conservation constraints for the nodes in *StatNodes*, s*helterNodes* and *SinkNodes*. Constraint set (3) determines the transit vehicle capacity constraint. These constraints guarantee that, at any time, transit vehicles cannot move more individuals than their capacity. These constraints also connect the binary variables y_{ij} to their corresponding x_{ij} variables. Constraint set (4) limits the total number of transit vehicles to the number of available transit vehicles. Constraint set (5) indicates that, for a given time period, the total number of vehicles that leave a station deducted from the number of vehicles that enter the same station is equal to the number of vehicles that start their trip from that station at that time period. Constraint sets (6) and (7) ensure a vehicle does not leave a station with positive residual capacity while there are individuals waiting at the station. Constraint sets (8) and (9) are the binary constraints, and the constraint set (10) is the non-negativity constraint.

TABU-BASED SOLVING ALGORITHM

The large amount of decision variables and constraints in the model suggests the application of an approximate solution approach. The TABU search algorithm is currently one of the most effective local search algorithms designed to find a near-optimal solution to many optimization problems that contain numerous permutations and combinations.

As shown in Figure 2, the TABU search algorithm is implemented for a fixed number of iterations (*MaxCounter*). At any iteration, the parameters are initialized

and a random construction procedure is used to build an initial feasible solution. Then, the 2-exchange search mechanism starts with this initial solution and iteratively identifies the most appropriate neighbor to move. Next, in order to diversify the search, the 3-exchange search mechanism is performed. The TABU mechanism allows neighbor S' to be selected (bad move) even if it is not a better solution compared to S. By operating this way, the search mechanism explores the solution space beyond the local optimal. Finally, the algorithm terminates by reporting the best found solution over all iterations (S^*).

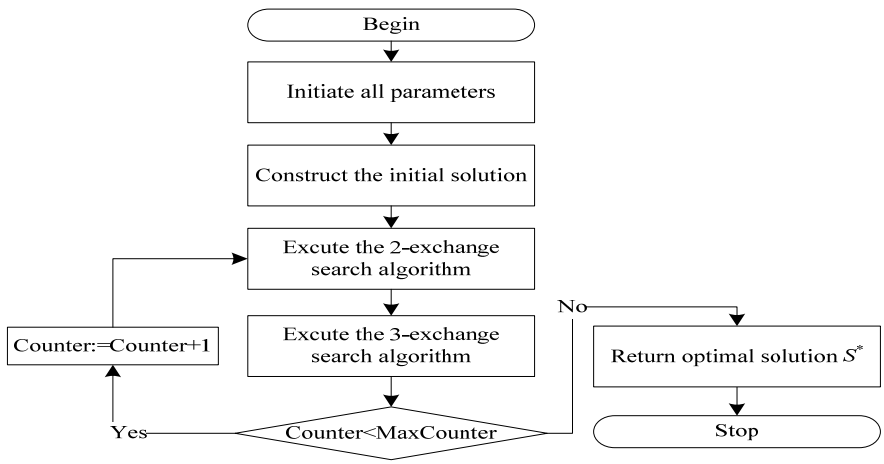

Figure 2.The description of the TABU-based algorithm.

CASE STUDY OF CBD IN CHANGCHUN CITY

This section provides a case study to illustrate the modeling techniques discussed in the previous sections. The test traffic network is the central part of the urban area in Changchun city, China, which has been illustrated in Figure 3. Regarding the transit system, there are 20 stations (represented by the *star* symbol).

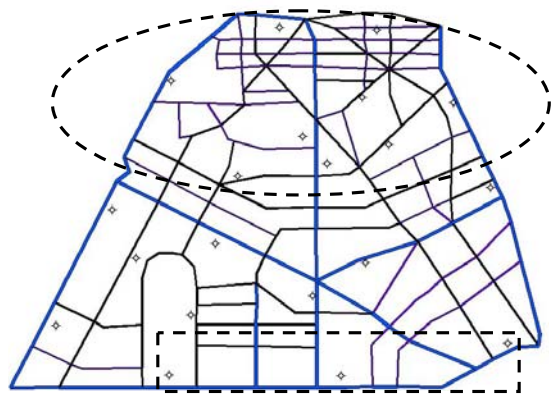

Figure 3. Sample line art illustration.

A hypothetical event is developed to test the public transit evacuation modeling strategy. Here, the evacuation area involves the metropolitan area with a radius of 3

miles around the incident location (enclosed by dotted ellipse in Fig.3) and 3 end points of the network (enclosed by dotted rectangle in Fig.3), which are sufficiently far from the incident location, to be considered shelter locations.

CPLEX 9.0 is used to get the exact solution and TABU-based algorithm is used to get an approximate solution. We introduce 3 measures of effectiveness for evaluation purposes: the computational time, the evacuation time (ET) and the evacuees' gap (EG). The evacuation time is the time that the last transit vehicle reaches the safe location. The evacuees' gap is calculated as $(P_{\%saved} - A_{\%saved})$ $/ P_{\%saved} \times 100$, where $A_{\%saved}$ is the actual percentage of evacuees who are evacuated safely from the incident location. Given the number of available transit vehicles (ω), the value $P_{\%saved} = (\omega \times U) / \ number\ of\ evacuees$, is the percentage of evacuees who are planned to be saved.

A comparison of computational performance on 4 sub-problems is illustrated in Table 1 for a 1-hour evacuation operation horizon.

Regarding the computational time, the average CPU time of the heuristic TABU search is significantly lower than that of CPLEX. Also, based on the comparison of *ET* and *EG* between the CPLEX and TABU search, we can conclude that the evacuation time derived from the heuristic TABU search is very close to that of the CPLEX. In addition, for a given evacuation time, the evacuees' gap reached by the heuristic TABU search is comparable with the evacuees' gap derived from CPLEX. It should be noted that, for no-notice evacuation modeling, the developed model shall be solved efficiently to get the solution quickly after the incident occurrence by TABU heuristic search algorithm which can make a good trade-off between the computational efficiency and solution accuracy.

Table 1. CPLEX vs. TABU search algorithm for 1-hour evacuation horizon.

Problem		CPLEX9.0			TABU

CONCLUSION

The primary objective of this research is to improve the service level for transit dependent citizens in emergency situations. Based on the existing transit system, we developed a public transit routing plan (PTRP) model for an urban area to move residents from the danger zone to the safe location. The main assumption underlying

the model is that the locations of station points and shelters are known a *priori*. The problem follows the structure of the network flow problem with additional side constraints. A mixed integer linear programming formulation is used to model the problem. The no-notice characteristics of the emergency situation necessitate a solution approach that generates the solution in a short amount of time. We proposed a heuristic TABU search algorithm that demands significantly smaller computational effort compared to CPLEX to generate comparable results.

ABSTRACT

To better understand the traffic management and control needs under urban emergency evacuation situation caused by a non-notice disaster, two zones and three evacuation routes are in general identified to simplify the evacuation network planning. Two zones are referred to harm zone and buffer zone. Three types of evacuation routes are identified as: *harm-zone evacuee path* – the shortest path for evacuees from the target to evacuee-loading sites within the harm zone serviced by evacuation vehicles; *harm-zone vehicular path* – the shortest path for evacuation vehicles and on-road regular traffic within the harm zone to harm zone exits; and *buffer-zone vehicular path* – the shortest routes from harm zone exits to target shelters or outside of the buffer zone. However, a challenge rises in dealing with the mixed traffic of evacuation and regular vehicular flows in the buffer zone when modeling the *buffer-zone vehicular path*. In this study, the **I**ntegrated **A**rterial **S**ignal and **A**ccess **C**ontrol (IASAC) system is proposed with attempt to provide an alternative solution to buffer-zone traffic control. In the IASAC, SCOOT and BOTTLENECK systems and algorithms are coordinated together for traffic control along major corridors within the buffer zones. The algorithm embedded within the IASAC system is capable of predicting time-dependent demands of an urban corridors and coordinating signal control, and mid-block access metering control. A PARAMICS simulation-based test bed is designed for evaluating the IASAC system. A case study of two scenarios with and without IASAC control shows the potential benefit of the IASAC.

ITRODUCTION

When an unexpected disaster in an urban area like human-caused or terrorist-induced emergencies occurs without advance notice, the concentration of

population at the harm zone and the surge for evacuation can quickly congest existing transportation networks (Sbayti et al. 2006; Wolshon et al. 2005). Special traffic control plans are therefore necessary for specific evacuation routes (Alshih et al. 2003). A network "redesign" problem due to specific control requirements for evacuation has been emerged. The existing network "redesign" problem is actually confined to contra-flow problem due to lane traffic flow reversibility.

Our research (Yang et al. 2006; Wei et al. 2006; Wei et al. 2008) disclosed a broader scope of such a "redesign" problem and the emergency evacuation backbone network (E^2 Backbone Network) is proposed to provide an effective "platform" on the basis of which relationships between a harm zone, buffer zone, potential shelters, evacuation routing and travel behaviors, evacuation communication, and deployment of intelligent transportation security and management systems could be dealt with in a coordinated manner in the evacuation planning. Figure 1 shows an example of physical harm zones, buffer zones, and shelters, which are connected by the E^2 Backbone Network. The E^2 Backbone Network consists of major roadway arteries constituting the shortest routes among all potential targets and shelters.

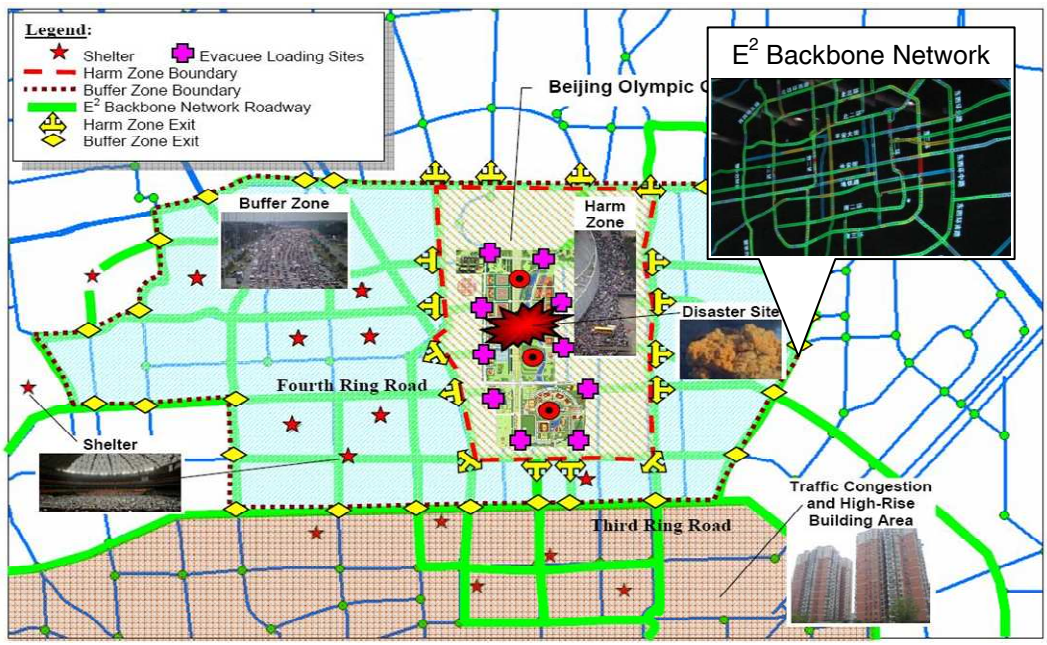

Figure 1. Exemplary Key Components of the E^2 Backbone Network.

On the basis of configuration of the E^2 Backbone Network, the network problem transforms to the optimization of the routes from the harm-zone exists to destinations, namely, specified shelters or boundary of the buffer zone. The calculation of such an optimum route bases the roadways over the E^2 Backbone Network while small local streets and other minor roadways will not be considered as the evacuation routes. In this way, the calculation becomes simpler

than traditional network routing optimization calculations that consider all the roadway segments over the network.

BUFFER-ZONE TRAFFIC CONTROL PLANNING OBJECTIVE MODEL

Arterial priority traffic control plan is considered to the buffer-zone routes; for example, SCOOT and BOTTLENECK systems and their algorithms could be used and coordinated together for traffic control along major corridors within the buffer zones (Perugu et al. 2007), which is termed as the **I**ntegrated **A**rterial **S**ignal and **A**ccess **C**ontrol (IASAC) system. The algorithm embedded within the IASAC system is capable of predicting time-dependent demands of an urban corridors and coordinating signal control, and mid-block access metering control. The IASAC algorithm can be adopted as an alternative solution to controlling the evacuation traffic of the buffer-zone routes (which are usually major urban corridors over the E^2 Backbone Network), and other traffic from crossing roadways and mid-block accesses. Top priority will be given to the flows on the evacuation routes while minimizing the delays of flows at crossing roadways and mid-block accesses. The algorithm keeps comparing the actual state and predicted traffic states at each designated time slice while the inputs are updated frequently. Assuming that a whole concerned corridor is divided into "*M*" segments, i.e., *i = 1 to M,* and destination segment is denoted by *j*. The number of time slice intervals are "*N*", i.e., *k = t to t+N.* The buffer-zone traffic control planning objective model is recommended as the following.

Objective: $Min.\ U_{br}(i) = \sum_{k=1}^{N}\sum_{i=1}^{M}\{TM(i,k)Q(i,k) + ERD(i,k) + MRD(i,k)\}$ (1)

s.t.: $ERD_i(k) = Min\{(q_i(k)G_i(k)\Delta T), (q_{i-1}(k)\Delta T + \lambda_i(k-1))\}$ (2)

$MRD_i(k) = 0.5T[\tau_i(k) + \tau_i(k+1)] = 0.5T[2\tau_i(k) + Q_i(k) - X_i(k)]$ (3)

Where,
- U_{br}(i, k) = Delay utility of ith segment;
- $TM(i, k)$ = Travel time on ith segment during kth time interval;
- $ERD(i, k)$ = Signal delay on main line at downstream intersection of ith segment during k*th* time interval;
- $MRD(i, k)$ = Signal delay at crossing road at the downstream intersection of ith segment during k*th* time interval;
- $q_i(k)$ = Approaching traffic flow at downstream intersection of ith segment during k*th* time interval;;
- K = discharge headway time during kth time interval;
- $G_i(k)$ = g/c (traffic signal green time to cycle length) ratio for downstream intersection of ith segment= $q_i(k)/(q_i(k)+q_{i'}(k))$;
- $q_i(k)$ = traffic demand of crossing street at downstream intersection of ith segment;
- T = Length of time interval;
- λ_i = queue length

$$\lambda_i(k+1) = \lambda_i(k) + \Delta T[(1-\beta_i)Q_i(k-K_{ij}) + q_i(k) - q_{i+1}(k)]$$

$_i$= turning ration at downstream intersection of ith segment;
$_i(k)$ = queue volume of crossing street at downstream intersection of ith segment;
$X_i(k)$ = Outflow rate of crossing street at downstream intersection of ith segment;

BUFFER-ZONE EVACUATION ROUTE TRAFFIC CONTROL

Concerning mixed regular and evacuation traffic existing in the roadways in the buffer zone, control along an evacuation route, is performed by selecting one of a set of patterns previously generated by the SCOOT signal optimization program. The objective of this module is to control both traffic flows on the roadways and traffic coming from the access points adjoining the corridor. The BOTTLENECK algorithm, used to be a coordinative ramp metering algorithm, is used for coordinated access meters for controlling conflict of the access traffic with the evacuation traffic.

The SCOOT model is based on the use of "cyclic flow profiles (CFP)." A CFP is a measure of the average one-way flow of vehicles past any chosen point on the road during each part of the cycle time of the upstream signal. The average flows in each part of the cycle can be taken over many cycle times and updated every 4 seconds. This CFP records can be easily generated using vehicle sensor data. With CFP central control unit can estimate how many vehicles will reach the downstream signals when they are red-hence both the size of the queue, and how long it will take to clear the intersection, and corresponding alterations in the signal timings are predicted. A SCOOT-prepared control plan is selected to match most closely the predicted traffic pattern in each section during the upcoming control period (Robertson et al. 1991).

BOTTLENECK algorithm is *coordinative* as well as *competitive* metering, in which two metering rates are computed for each access based on either local traffic conditions or system conditions; and the restrictive one is chosen. The bottlenecks can be identified on network using two types of criteria. The first is the capacity criterion to checks if the occupancy of a section exceeds a pre-determined occupancy threshold. The second is the vehicle storage criterion for identifying bottleneck sections. If a bottleneck is identified, the corresponding section is marked as a bottleneck section. A reduction of traffic demand from upstream accesses in the next control step is then needed to reduce its congestion. At this moment, the amount of demand reduction can be calculated for each bottleneck section (Chu et al. 2004).

The integrated algorithm consists of different steps for corridor control. Initially, all traffic variables are synthesized from raw data. A pre-defined "diversion policy" is established. Based on the diversion policy, a diversion

volume is assumed. For actual traffic volumes on mainline and alternate routes "Cyclic Flow Profiles" from SCOOT algorithm is used. Utilizing these volumes, access meter rates are estimated. Access meter volumes are estimated using the occupancy criterion in BOTTLENECK algorithm. For its capability of identifying bottleneck position on a particular section on the corridor, the algorithm can be also used for non recurrent congestion due to incidents. Based on the objective function, the diversion volumes are recalculated and they are compared. If the algorithm control comes out from inner loop, then the cycle lengths and metering rates are computed. Actually, this function establishes cycle length, offsets, and splits for a set of signal controllers along a section of arterial roadway. As the time control step is furthered, actual traffic variables are re-estimated from sensor data, and iterations are continued (Chang et al. 1993).

The core of implementing the integrated corridor control is the algorithm embedded within the central computer system that operates the corridor control system. Figure 2 shows the flowchart of steps for implementing the algorithm.

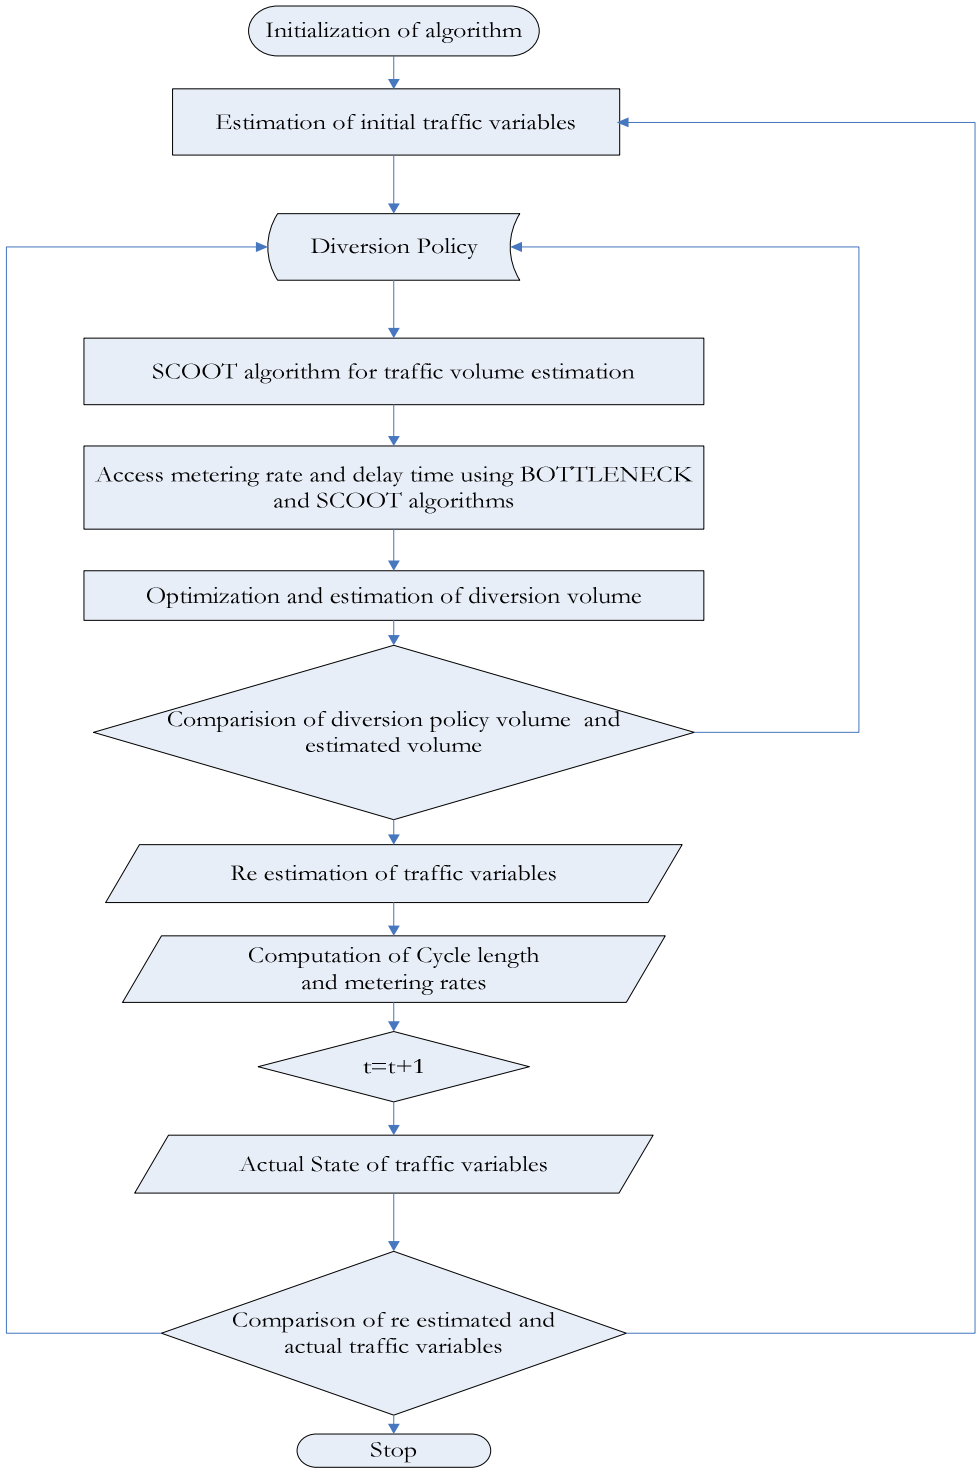

Figure 2. Flowchart of IASAC Algorithm.

The IASAC algorithm is developed to carry out major functions of the system that utilizes the interoperability of the traffic responsive signal strategy and access metering controls. The algorithm keeps comparing the actual state and predicted traffic states at each designated time slice while the inputs are updated frequently. Assuming that the total corridor is divided into "*M*" segments, i.e., *I* =

1 to M, and destination segment is denoted by *j*. The number of time slice intervals are "*N*", i.e., *k = t to t+N*.

KEY SUBMODELS INVOLVED IN THE IASAC SYSTEM

Corridor Traffic Demand Model

Using the discrete choice model (Chang et al. 1993; Reiss et al 1991), the traffic demand on the corridor is described as the following

$$Q(i, j) = \Theta_1 + \Theta_2 TM\ (i, j) + \Theta_3 \lambda_i + \varepsilon_1 \quad (4)$$

$$D(i, j) = \Theta_2 TPR\ (i, j) + \varepsilon_2 \quad (5)$$

Where: $Q(i, j)$ = the traffic demand between origin segment i and destination segment j on mainline;

$D(i, j)$ = the traffic demand between origin segment i and destination segment j on alternate route;

$TM\ (i, j)$ = expected travel time on streets for origin i to destination j;

$TPR\ (i, j)$ = expected travel time on parallel streets for origin i to destination j.

$\Theta_1, \Theta_2, \Theta_3$ are parameters;

ε_1, ε_2 error factors to capture unobserved factors.

Estimating Traffic Flow on Main Arterials

Traffic flow on the segment *i* of main arterial depends on the actual traffic demand that should be traveled on main line from *i* to *j* and the traffic joining from access points. Let us suppose there is an access point in every segment on mainline. Because of the traffic from access meters, there exists a significant time delay between the demand change at one segment and subsequent effects on downstream segments. The flow on main line is represented as below (Papageorgiou 1980).

$$Q_i(k) = \sum_{i=0}^{j} B_{ij}(k - K_{ij} + 1) X_i(k - K_{ij} + 1) \quad (6)$$

Where, K_{ij} = constant travel time in terms of number of intervals (k) from i to j;

B_{ij} = the traffic flow should be traveling from segment *i* to destination j or farther which includes diverted flow from arrival intersection as well as existing flow;

$X_i\ (k)$ = the access metering rate.

As the access points also have exiting flows, for true prediction of traffic flow on main line should include their effect. Using same theory and assumptions of Papageorgiou (1980), the exiting flow from mainline is given by the equation:

$$E_j\ (k) = \sum_{i=0}^{j} X_i(k - K_{ij} + 1)[B_{ij}(k - K_{ij} + 1) - B_{ij+1}(k - K_{ij} + 1)] \quad (7)$$

Then the actual demand on the mainline is given by expression

$$Q_i(k) = \sum_{i=0}^{j} \{B_{ij}(k - K_{ij} + 1) X_i(k - K_{ij} + 1)\} - E_{ij}(k) = \sum_{i=0}^{j} B_{ij+1}(k - K_{ij} + 1) X_i(k - K_{ij} + 1) \quad (8)$$

Estimating Access Metering Rate

To find the access metering rate, the queue volumes of each access should be known. Based on queue length, the queue volume is used as input variable to find the access metering rate. Each of access is assigned with weightage factor and all the access meters are coordinated and based on Bottleneck algorithm (PATH 2001). The access metering rate is given as:

$$X_i(k) = \tau_i(k-1) - \sum_{i=0}^{j} \left(Q_i(k - K_{ij} + 1)(\frac{WF_i(k)}{\sum WF_i(k)} \right) \quad (9)$$

Where, τ_i (k) is queue volume at i^{th} access meter; and $WF_i(k)$ is the weightage factor for i^{th} access meter.

For better access of the vehicles from surrounding land use to main arterial the gap of green times between intersection and access meter should be less than the travel time required for i^{th} section on main line. So, the access meter should satisfy following relation (PATH 2001).

$$TM_i(k) - \quad _i(k) > 0; \forall i \in M, k \in N \quad (10)$$

Where, κ is the discharge headway in terms of time interval k; τ_i (k) is queue volume at i^{th} access meter; and $TM_i(k)$ is travel time for i th segment on main line.

Signal Delay

To design the algorithm better, it is assumed each signalized intersection consisted by only one segment. And intersection should be located at the end of the segment in which the traffic flows comes from the access points, cross-streets and upstream sections. As this model is based on SCOOT algorithm for traffic responsive signal control, the under lying Platoon dispersion model (Hunt et al. 1982) is used to estimate the signal delay on mainline. This delay includes offset found earlier to facilitate the flows from access points.

$$SDM_i(k) = Min\{(q_i(k)G_i(k)\Delta T), (q_{i-1}(k)\Delta T + \kappa \hat{L}_i(k-1))\} \quad (11)$$

Where, $SDM_i(k)$ = signal delay on main line;

$q_i(k)$ = approaching traffic flow at intersection i and interval k in the direction of mainline;

κ = the discharge headway in terms of time interval k;

$G_i(k)$ = g/c ratio for i th intersection,= $q_i(k)/(q_i(k) + q_{i'}(k))$;

$q_{i'}(k)$ = traffic demand of crossing street;

T = the sample time interval of time horizon; and

λ_i = the queue length.

Queue length in the above expression depends on the turning ration at that particular intersection, which can be found using historical origin- destination studies. Thus, given by the expression

$$\lambda_i(k+1) = \lambda_i(k) + \Delta T[(1-\beta_i)Q_i(k-K_{ij}) + q_i(k) - q_{i+1}(k)] \quad (12)$$

Where, $_i$ is turning ratio. Similarly to find signal delay on parallel route same expression can be used.

$$SDPR_i = Min\{(d_i(k)G_i(k)\Delta T), (d_{i-1}(k)\Delta T + \lambda_i(k-1)\} \quad (13)$$

And queue length at intersections on parallel route is given by following equation

$$\lambda_i(k+1) = \lambda_i(k) + \Delta T[(1-\beta_i)D_i(k-K_{ij}) + d_i(k) - d_{i+1}(k)] \quad (14)$$

Access Meter Delay

If metering rate is $X_i(k)$ at access meter I, then average queue length can be approximated by taking average of queue lengths at k and $k+1$ intervals (Chang et al. 1993).

$$AMD_i(k) = 0.5T[\tau_i(k) + \tau_i(k+1)] = 0.5T[2\tau_i(k) + Q_i(k) - X_i(k) \quad (15)$$

SIMULATION-BASED EVALUATION OF IASAC SYSTEM

Building Simulation Environment for Case Study

The Colerain Avenue, Cincinnati, Ohio is selected as the case study site, which is a congested corridor connecting major residential areas with commercial areas and consists of numerous driveways and parkways. The microscopic simulation software is used as a simulation environment for building the test bed. Using the Modeller tool embedded within PARAMICS, a new network can be created through entering node, link, zone data and Origin/Destination demand matrices (Quadstone 2005). Then traffic is assigned using different assignment techniques, simulation runs are carried out to get results. Among all tools in PARAMICS suite, the *Programmers*' Application Programming Interface (API) is most valuable as it enables users to customize the simulation. The customization of functionality can be achieved through "plug-ins" (Jacob et al. 2005). The PARAMICS simulation program calls different functions for vehicle release, position update for vehicles, or to interface with other programs or data at every time step. These functions used for decision control, retrieving information or carry-on the simulation. Using API, these functions can be modified, replaced or added using any high level languages like C, C++ (Doshi et al. 2006).

Embedding IASAC Algorithms into Simulation System

In this study the intersections are coordinated with SCOOT signal control

system on mainline and alternate routes. The Split Optimization component in the algorithm minimizes the maximum degree of saturation on links at a node. The cycle length optimization component attempts to adjust the cycle time to maintain 90% link saturation at each node by changing the cycle length in 4 seconds increment. The algorithm is to find out the degree of saturation for each lane served by each phase. The cycle length optimization component decides to extend or shorten the green time for each phase based on degree of saturation. Initially it is necessary to know initial green time for each phase for each intersection, lane groups in each phase and corresponding detector numbers. This information can be stored in data structures during the *api_setup ( )* function call. the *net_post_action ( )* function is called at every time step during simulation, so that it is possible to check if the current phase is about to end within 5 seconds or if the last cycle length optimization was done before 300 seconds (Doshi et al. 2006). For access control, the Bottleneck algorithm requires two overriding PARAMICS API functions (which replaces existing ramp metering functions). The first one is *void api_setup (void)*, which is to read the data from input files. The second function is *net action (),* which is actual control logic of the algorithm and carried out at each ramp control cycle (PATH 2001).

Validation of the IASAC System Model

A 2.4 mile stretch of the Colerain Avenue in Cincinnati, from Blue Rock Road intersection and Poole Road intersection (see Figure 3), was found to be a good section to test the proposed control methodology. Actually there are 18 driveways on each side of the mainline in addition to 6 signalized intersections. For validation of the IASAC System Model the driveways traffic flow is controlled by limiting them to 6 access metering points. Figure 3 shows the Colerain Avenue with one possible alternate route. Blue Rock Road intersection and Poole Road intersection are traffic bifurcation points.

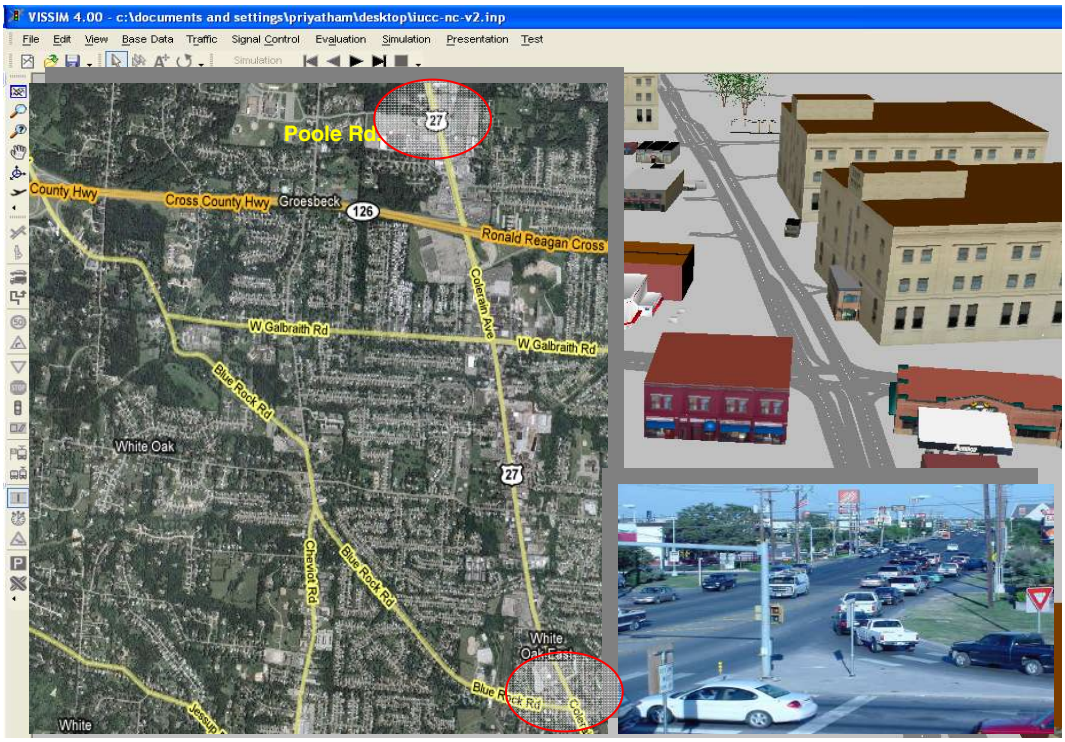

Figure 3. Colerain Avenue Corridor Network for Case Study.

All access meters are coordinated and each of them assigned equal weightage factor. The main line is divided into 10 segments and alternate route is divided into 4 segments. Each of segments contains an access point or a signalized intersection, u/s and d/s detectors, and a far downstream detector located at the end of the section. The access point is also provided with a detector, which will provide information about traffic entering the main line from the access point. The IASAC algorithm "plug-in" will receive the input data like speed, volume or occupancy, as well as the current metering rate from detectors. This algorithm also tries to find the best metering rates and green timings under different traffic and congestion scenarios. In this simulation the traffic volumes at access points are considered to be at least 150 vehicles/hr. The signal settings, access metering rates and optimum diversion rates are achieved by implementing the required code in the *Programmer* by using *call back functions* and *set functions* for the signal (Quadstone 2005).

Comparison of Two Scenarios with and without IASAC Control

In this simulation model, the input control variables are occupancies at the intersections and access points, signal green timings and current metering rates. Using these variables the algorithm can estimate demand on the main line, alternate route and access points. In order to evaluate the feasibility of the approach, the results obtained from the IASAC algorithm implementation have been compared with the results obtained from the base scenario – without control. As the objective is to assess the overall effectiveness of the control measures, the

mean travel time, vehicle miles traveled and mean speed between an origin/destination pair (Blue Rock Road intersection (zone 1) and Poole road (zone 2) , were used for evaluation. Table 1 provides the results obtained from the simulation of the proposed approach and base case.

Table 1. Comparison of Scenarios with and Without IASAC Control in Case Study

Parameter	Without IASAC CONTROL		IASAC CONTROL	
	North Bound	South Bound	North Bound	South Bound
Mean travel time in *sec* *(improvement %)*	850.1	1163.7	382.8 *(55 %)*	384.0 *(67%)*
Vehicle miles traveled in 1 hr *(improvement %)*	1548.1	1796.9	2385.1 *(54%)*	2745.2 *(53%)*
Mean speed in *mph* *(improvement %)*	14.9	10.9	33.1 *(122%)*	33.0 *(202%)*

From these results it is evident that the mean travel time in both directions on the corridor is drastically improved due to implementation of the IASAC control strategy. The increase in Vehicle Miles Traveled suggests that the corridor is more accessible to the vehicles. Improved average speed results shows that the recurrent congestion on the corridor is relieved. This case shows that the IASAC traffic control strategy performs much better than no control. When more detailed network information is provided using input control variables, the reliability of the system can be further increased.

CONCLUSION

This research proposes a framework for integrating arterial and access controls for evacuation routes in buffer zones. The application of IASAC traffic control strategy was examined for the arterial or express/collector traffic corridor using traffic simulation software PARAMICS. The results from the simulation analysis showed that it is very effective alternative to carrying out control plan for mixed regular and evacuating traffic. Using Application Programming Interface the algorithm has been developed and it is very adaptable to the field in the ITS framework. ABSTRACT

The development of Intelligent Transport Systems (ITS) is a key enabling technology to prevent traffic accidents, enable road charging, and reduce congestion. However, the deployment ITS is limited by positioning and wireless communication technologies. Global Navigation Satellite Systems (GNSS) can provide positioning and timing services globally but requires good visibility of navigation satellites that is difficult in urban area where ITS systems were deployed. Currently, only the Global Positioning System (GPS) operates at an accuracy of about 10 m. Advanced GNSS provides more navigation satellites and signals improving the visibility and positioning accuracy to sub-metre even centimetre level in real-time. Additional integrity information will be described for safety-critical applications. Potential improvements of current and new ITS applications enabled by the modernization of GNSS are presented in this paper. In addition, Precise Point Positioning (PPP) using only one GNSS receiver and wireless communication network is much more cost-effective as it removes the need of reference receivers and relative positioning used in current applications. The advantages of using PPP technology in ITS will be demonstrated in this paper.

INTRODUCTION

Intelligent Transport Systems (ITS) improve transport safety, reduce congestion and reduce air pollution.. In figure 1, the services shown in rounded rectangles and objectives shown in ellipses of ITS are summarized. *Emergency vehicle management* involves locating the accidents and informing the nearest and enough available emergency vehicle. For example, the European Community has planned to fully roll out a system named eCall (the pan-European in-vehicle emergency call) by 2010 (COM, 2007). This system could save up to 2,500 lives every year and reduce the corresponding congestion (COM, 2007). However, eCall has been rejected by the UK and some other countries because of the concern of high costs comparing with the benefits. *Advanced Vehicle Control and Safety Systems* (AVCSS) can increase safety by avoiding intersection collisions. The Cooperative Safety Systems (CSS) warns drivers when other vehicles are approaching at an intersection or when a driver should apply braking. Such warnings could be generated on-board and transmitted directly from one vehicle to another (VV), and/or generated by fixed monitoring systems and transmitted to the vehicle from a roadside sensor (R-V). Such systems have been demonstrated successfully, but their deployment is hindered by the need for different stakeholders; drivers, the government and –private industry to cooperate.. In addition, AVCSS can also

provide lane departure warning to prevent a vehicle drifting out of its lane and blind spot warning to assist drivers in changing lanes. However, these services require high accuracy of positioning in real-time that is not guaranteed by current GPS or any other positioning technique in urban area with existing GPS technology. Due to cost, the deployment of such systems is likely several years away (POSTnote, 2009).

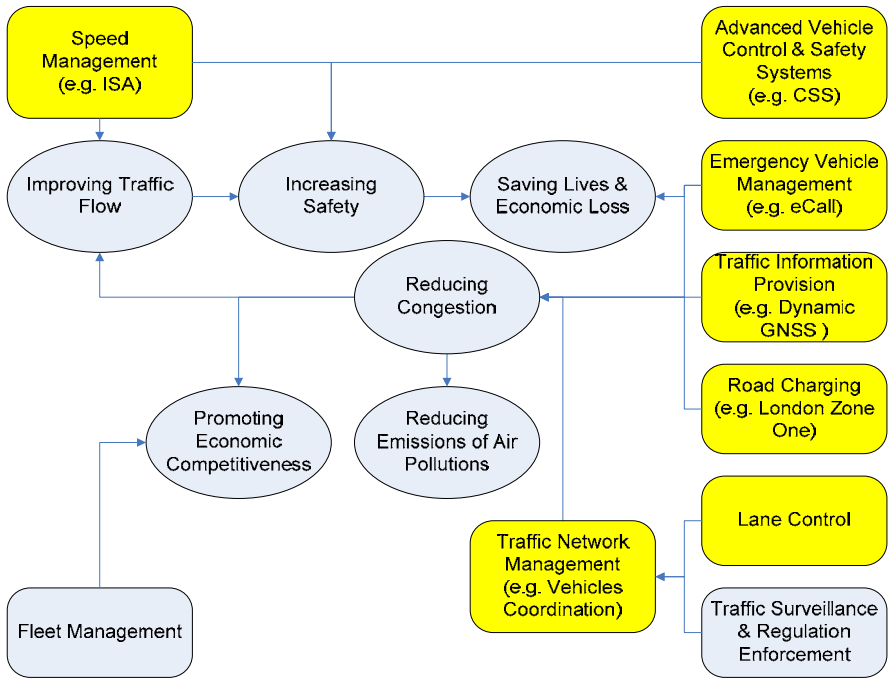

Figure 1. ITS Services and Objectives.

Speed Management applications such as Intelligent Speed Adaptation (ISA) and Adaptive Cruise Control (ACC) can improve traffic flow and increase safety by assisting drivers to stay within the designated speed limits. Many GPS devices, (e.g. TomTom), already provide warnings when the speed limit is exceeded. To exclude the drivers' influences, ISA may also be achieved by automatic intervention to slow down the vehicle. Recent research suggested that fatal accidents may be reduced by 42% if all vehicles were fitted with automatic governed ISA (ISA-UK, 2008). However, public acceptance of ISA is uncertain and no public traffic policies involving ISA was published. In addition, identifying the prevailing speed limit for ISA is also difficult. Unlike ISA, ACC does not vary the speed based on the digital speed map but on the separation from the vehicle in front. *Traffic Information Systems*, provide pre-journey and en-route traveller information, and route guidance, An *Traffic network management* collects and analyzes the vehicle coordinates in real-time. Based on the results, this management system can reduce congestion by controlling traffic signals and other methods. Again, the timing and accuracy of the collected vehicle coordinates and the costs of the system are key issues that must be addressed for the system to be useful.

The technologies required for ITS are near real-time on-board positioning and wireless communications. Among different positioning techniques, the satellite

positioning and navigation systems have obvious advantages such as the global coverage, no limitation of the network capacity, relatively high accuracy, real-time positioning, small size of on-board device and no roadside infrastructure required. However, the current limitations of GNSS systems highly limit the current and future ITS services highlighted in figure 1. This paper concentrates on the benefits of ITS from the modernization of GNSS consuming the wireless communication network is available that is usually the case in urban and rural area globally.

THE MODERNIZATION OF GNSS

GNSS including American GPS, Russian GLONASS, European GALILEO and Chinese BeiDou II has drawn huge interests and investments over the past ten years. Currently, only NAVSTAR GPS is operational with providing global coverage. The advancement of GPS technologies and infrastructures continues in improvement. In 2010 a new civil navigation signal is expected be available and the undifferenced code-phase based stand-alone positioning (using only one receiver) will be able to provide 3D accuracy at 2m (2σ). The carrier-phase based double-differenced (DD) real-time kinematic (RTK) positioning (using at least two receivers) 3D accuracy is 3cm (2σ) and the 3D accuracy of post-processed static positioning is 5mm (2σ). GALILEO is expected to reach its full operational capacity (FOC) around 2013 (EC, 2008). In this paper, only the free services including the Open Service (OS) provided by GALILEO and the modernized Standard Positioning Service (SPS) provided by GPS are considered.

PRECISE POINT POSITIONING (PPP)

PPP provides sub-metre level accuracy using only one receiver. Compared with conventional DD RTK positioning techniques, PPP does not reference stations. However, errors mitigated by 'differencing' in differential algorithms need to be properly modelled and estimated. Conventional PPP requires several tens of minutes (static mode) to hours (kinematic mode) to converge to a positioning accuracy at the decimetre to centimetre level. This research builds on GNSS modernization to achieve RTK PPP that has the advantages of global coverage, cost-effectiveness, high accuracy at decimetre level and improved availability.

TRIPLE-FREQUENCY RTK PPP

Conventional PPP is based on processing dual-frequency navigation signals. This paper developed RTK PPP based on processing triple-frequency code-phase and carrier-phase navigation signal observables. The satellite clock and orbit errors are eliminated by using precise products provided by International GPS Service (IGS) (IGS, 2009). The ionosphere delay is cancelled by linearly combining the observations based on the nature of this error (Kaplan, 2006). The troposphere delay is modelled following Hofmann-Wellenhof (1997) theory. The cycle slips and multipath are detected and corrected with methods suggested in Leick (2004) and Sauer (2003). Therefore, the triple-frequency observation equations applied in this research are given by:

$$\begin{cases} PR^s_{r,IF,GS}(L_1) = 0.5(PR^s_r(L_1) + \Phi^s_r(L_1) \\ PR^s_{r,IF,GS}(L_2) = 0.5(PR^s_r(L_2) + \Phi^s_r(L_2) \\ PR^s_{r,IF,GS}(L_3) = 0.5(PR^s_r(L_3) + \Phi^s_r(L_3) \\ \Phi^s_{r,IF,12} = \dfrac{f_1^2}{f_1^2 - f_2^2}\Phi^s_{r,f1} - \dfrac{f_2^2}{f_1^2 - f_2^2}\Phi^s_{r,f2} \\ \Phi^s_{r,IF,13} = \dfrac{f_1^2}{f_1^2 - f_3^2}\Phi^s_{r,f1} - \dfrac{f_3^2}{f_1^2 - f_3^2}\Phi^s_{r,f3} \end{cases} \quad (1)$$

where $PR^s_r(L_i)$ and $\Phi^s_r(L_i)$ are the measured code phase pseudo-range and the calculated carrier phase pseudo-range on carrier L_i respectively. For n satellites, there are $5n$ equations used to estimate $5+3n$ unknown variables. The unknown variable are the 3D receiver position coordinates, the receiver clock offset, the wet troposphere delay, and three real-value ambiguity in carrier phase for each satellite. Simulated GALILEO observations and corresponding IGS satellite orbit and clock corrections were generated by the GALILEO System Simulation Facility (GSSF) and used to test this model.

RESULTS

To simulate the urban environment, a high level of multipath is added onto the simulated GALILEO signals. The dual-frequency PPP using E1-E5b observations and the triple-frequency PPP observing six satellites were implemented. For both cases, the convergence performance are recorded and compared in Figure 2.

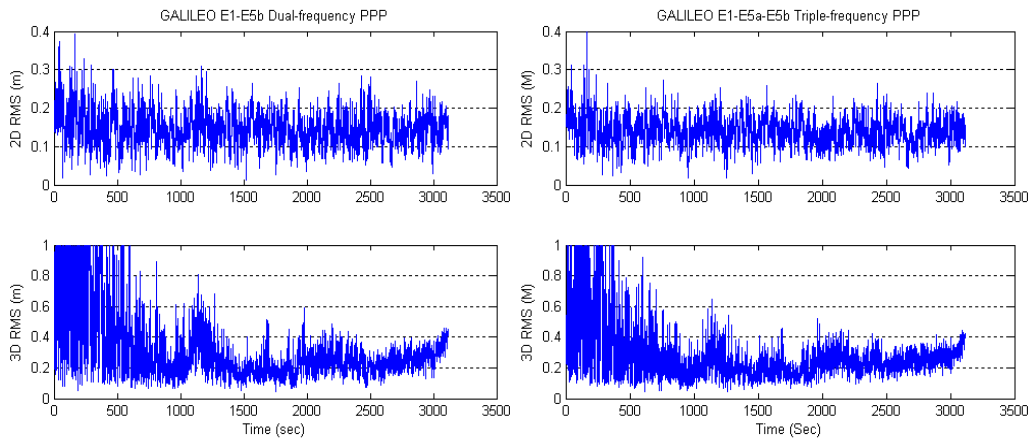

Figure 2. E1-E5b Dual-frequency and Triple-frequency PPP Observing Six Satellites.

As seen in Figure 1, there is almost no difference between these two processes, using all available observables may not lead to any improvements in PPP. In addition, the 2D RMS immediately converged to 40 cm precision. This performance is good enough to enable many 2D position required ITS services in real time. However, it did not converge to better precision due to the relatively high residual error bias mainly the multipath bias ranging from -40 cm to +40 cm. For services requiring 3D positioning, a very long initial waiting time of less than an

hour was inevitable. However, by checking the residual, satellites with relatively higher noise level can be identified and removed from the constellation. After removing the two noisiest satellites, the PPP performance is shown in Figure 3.

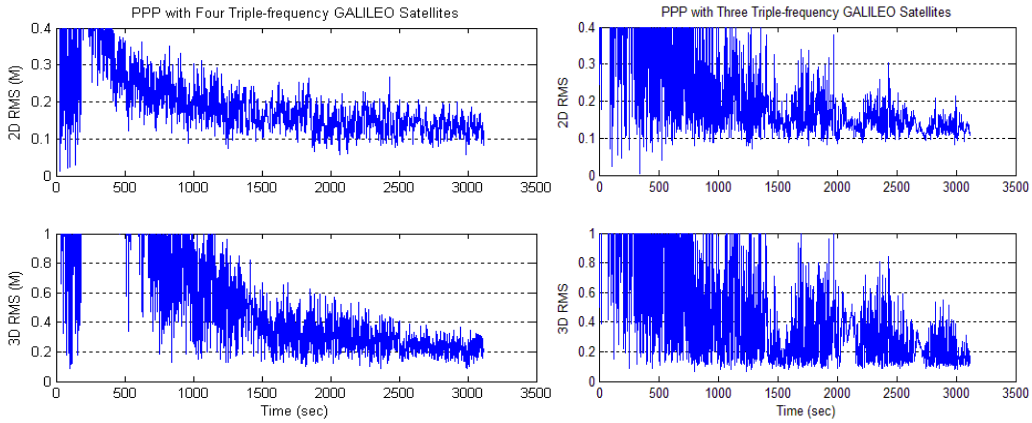

Figure 3. Triple-frequency PPP Observing Four or Three GALILEO Satellites.

By observing four satellites with relatively lower noise levels, both 2D and 3D RMS converged slower to sub-metre level than using observations from all six visible satellites and the 3D RMS initial waiting time was reduced to within 2500 seconds. If only three satellites with the lowest noise were observed, the PPP processing converged more slowly then observing four satellites. The 2D RMS and 3D RMS converged to 20 cm and 40 cm precisions with about 3000 seconds. The position convergence is determined by not only the residual error level but also the satellite geometry, using the smallest number of satellites with the lowest noise level does not guarantee the shortest convergence time of PPP.

CONCLUSION

This paper reviewed the main technical GNSS technology including positioning accuracy, GNSS availability. GNSS technology advancements were summarized and free GNSS services were evaluated to be used in ITS applications. With these free GNSS navigation signals, RTK PPP algorithms were developed and tested with simulated triple-frequency GALILEO signals in urban area. The results have shown acceptable real-time on-board processed positioning results with sub-metre level accuracy within an acceptable time for 2D applications. This new PPP algorithm has improved the GNSS availability by reducing the number of necessary visible satellites from four to three.

The developed triple-frequency PPP has shown many advantages that can benefit ITS application. First, it was designed to use free navigation information and only one GNSS receiver without the need of building the expensive reference station network. The deployment costs can be greatly reduced benefitting emergency vehicle management systems and other ITS applications. The global coverage of PPP and elimination of required fixed reference stations also greatly benefit emergency systems like eCall.

Second, the new PPP achieved 2D RMS positioning accuracy better than 040 cm immediately and 3D RMS sub-metre accuracy with about 10 minutes waiting

time. This high 2D accuracy can enable AVCSS such as lane departure warning and CSS. However, the waiting time for 3D precise positioning is still too long. As the positioning accuracy has been improved, the speed estimations have also become more accurate benefitting the speed Management applications such Intelligent Speed Adaptation (ISA) and Adaptive Cruise Control (ACC). In addition, better than the current road charging systems based on cameras, PPP can enable more detailed and reasonable charging policies such as multi-entry charges or even travelling route charging eliminating the need for additional costly roadside infrastructure to detect vehicles. Obviously, real-time accurate vehicle positions can improve the performance of Traffic Information Provision and Traffic network management.

Third, the developed PPP algorithm has proved to successfully cope with the higher level of navigation signal noise and smaller number of visible satellites due to high buildings and narrow roads in urban area then rural area and remote area. This is important because most of the ITS applications are utilized densely populated areas

The next step of this research may be strictly identifying the requirements of the ITS applications including the accuracy, integrity, and availability of the sensors. The integrity algorithms of PPP will be developed and the waiting time of PPP convergence will be further reduced by examining and eliminating the residual errors in GNSS observables.

ABSTRACT

It is commonly agreed upon that car-following only takes place when the separation between two vehicles is within some threshold value. This threshold has been studied but most of the work focuses on highway or motorway traffic and does not consider car-following in intersection areas. This paper studies the car-following threshold criteria in a signalized intersection area. The close-range photogrammetry system is built to collect and analyze traffic data at a signalized intersection in Beijing. The speed difference analysis method and K means the cluster method is employed to distinguish the car-following status and to obtain the critical headway and spacing for car-following. The results show that the critical headway of car-following at the signalized intersection is three seconds and the critical spacing is 20 meters. The main contributions of the paper are the close-range photogrammetry system developed for data collection, and the speed difference analysis or judging the car-following status at a signalized intersection.

Keywords: car-following; signalized intersection; headway

INTRODUCTION

Micro traffic flows play an important role in the analysis of existing traffic facilities needing modification and also in the design of new facilities. It is of great importance to make sure that these traffic flows are able to reflect real traffic situations accurately. One important sub-process in micro traffic flows consists of the modeling of car-following behavior. Car-following phenomenon is concerned with the relationship between driver-vehicle systems and inter-vehicular dynamics in a single stream of traffic.

A traffic flow theory book (Daniel 1975) stated that car-following starts when spacing between the leading vehicle and the following one is less than 100m or 125m. The HCM 1994 (TRB 1994) defined that car-following criterion on highways is 5 seconds. The HCM 2000 (TRB 2000) defined car following criterion

on two-lane highways is 3 seconds. Paker (Paker 1996) used 5-second headway to research car-following behavior of heavy goods vehicles on a motorway. Weidman (Widedmann 1992) studied that car-following occurs when vehicle spacing is less than 150m. All these studies focused exclusively on highway or motorway traffic.

For the car-following data collection, Chandler, Herman and Montroll (Chandler 1958) used wire-linked vehicles. Ozak i(Ozaki 1993) collected data by using video taken from the 32th floor of a city office building. Treiterer and Myers (1974) used a helicopter as a tool to observe a platoon of 70 vehicles. Hoogendoorn (Saskia 2005) took pictures of freeway A2 in Utrecht from a helicopter. One of the main advantages of these last approaches was that the observation did not disturb normal traffic flow.

Headway and vehicle spacing are important to calculate the capacity of a signalized intersection and signal timing plan. It is obvious that at a signalized intersection, the traffic flow is restricted. But headway and vehicle spacing are not determined. One reason is that the past work foundation is located on a highway or motorway segment. Another reason may be that the traffic flow in a signalized intersection is complex and observation is difficult. This paper aims to research the car-following criterion in a signalized intersection.

DATA COLLECTION PROCESS

Unlike the helicopter observation method that is typically expensive, a close-range photogrammetry method is used in this study. Close-range photogrammetry technique is an old method, but is seldom used in traffic observation. It is easy to implement, and it is a low-cost method. It also does not require specialized training (ARIAS 2002). The method uses a common video tape recorder to obtain data and reference points (coordinates origin point), and analysis software to analyze the collected data. This paper does not intend to interpret the close-range photogrammetry method and its history. The important thing to be introduced here is the data collection system and field work used in this study.

FIELD WORK

The video data collection site is a signalized intersection named Jiang Zhaikou in Dongcheng District of Beijing City. The intersecting streets at the intersection are An-Dingmen Avenue and He Pingli North Street. The north-south An-Dingmen Avenue is the arterial.

The traffic signal control mode at this intersection is fixed time, three phase operation.

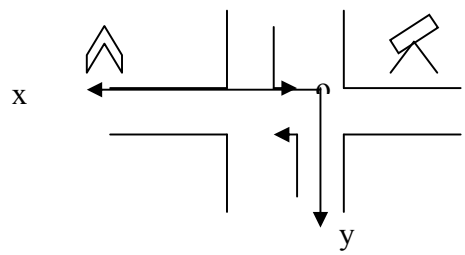

Figure 1 The ground reference system of the intersection named Jian Zhaikou

The date of video collection was April 16, 2006. The weather was fine. Video recording time was from 16:00 pm to17:00 pm. The video tape recorder was installed on the 11th floor of a neighboring residential building. The building is located at the north leg of the arterial. The coordinates of the observation system are calibrated by using tapeline measure and laser range finder. The reference frame is shown in the Figure 1. The X-axis is the stop line of the north approach. The origin point of the observation system lies in the base of a pole standing on the separated strap between the automobile lane and non-automobile lane. The area of the intersection which the video tape recorder shoots is 53m * 40 m. The left turn lane is the inner lane.

The recorded video film is fed into the computer and the dedicated analysis software is used to extract data from the video. The following information of each vehicle can be directly provided (at 0.02s intervals)——(1) x-y coordinates of the vehicle; and (2) speed of the vehicle (m/s). After filtering out data with pedestrian and bicycle interruptions, 200 pairs of vehicles were selected for the car-following analysis.

CAR-FOLLOWING DATA ANALYSIS AT A SIGNALIZED INTERSECTION

Whether a vehicle is in a car-following mode is determined in this study based on the difference of the speeds between the leading car and the following car in the traffic stream. Generally speaking, if the speed of the leading vehicle is less than the desired speed of the following vehicle, the follower is in car-following mode. However the desired speed of a vehicle cannot be determined by observation of the oscillation process and the chaos phenomenon of the vehicles (Widedmann 1992, Yu 2007). During the continuous acceleration and deceleration process of the vehicle, it may reach the desired speed, but only momentarily. Therefore, it is impracticable to judge whether a vehicle is in car-following mode based on the vehicle speed with respect to the desired speed. The speed difference between the leader and the follower can reflect the response of the follower to the leader and reveal whether the follower is in car-following mode.

For a leader-follower pair, the speed of the leading car may be greater or less than that of the following car, so the speed difference may be positive or negative. With the coordinates for both vehicles collected from the data acquisition system described earlier, the spacing between the vehicles can be determined using Equation 1.

$$s_{lf,t}=\sqrt{\left(x_{l,t}-x_{f,t}\right)^2+\left(y_{l,t}-y_{f,t}\right)^2} \quad (1)$$

Where， $s_{lf,t}$ = vehicle spacing between the leading vehicle and the following vehicle

at time t; $x_{l,t}, y_{l,t}$ = coordinates of the leading vehicle at time t; $x_{f,t}, y_{f,t}$ = coordinates of the following vehicle at time t; The speed difference can be determined using Equation 2.

$$v_{lf,t} = v_{l,t} - v_{f,t} \quad (2)$$

Where, $v_{lf,t}$ = speed difference between the leading vehicle and the following vehicle at time t; $v_{l,t}$ = speed of leading vehicle at time t; $v_{f,t}$ = speed of following vehicle

The headway between the vehicles can be estimated using Equation 3.

$$h_{lf,y} \approx s_{lf,t} / v_{f,t} \quad (3)$$

$h_{lf,y}$ = headway between the leading vehicle and the following vehicle at the location of y axle.

Table 1 Vehicle spacing of through vehicles

Particular leader-follower pair sample	No. of data points for sample pair	Minimum spacing (m)	Maximum spacing (m)	Mean spacing (m)	Std.Deviation
Sample1	461	5.98	13.74	9.3899	2.03958
Sample2	361	8.77	20.55	14.2250	3.24984
……	……	……	……	……	……
Sample 14	351	7.84	21.88	16.4822	3.77541
Sample 15	289	13.85	22.47	17.4573	2.06810

Table 1 shows part of the data collected. Sample i means particular leader vehicle i-follower vehicle i+1 pair sample. Analysis software shows 0.01s step results of through vehicle data points. Trajectories are recorded of 34 through vehicles during one cycle. These 34 vehicles all ran through the intersection. All 10154 data point records of vehicle spacing are collected.

At time t with equations one through three, we get headway, spacing and the speed difference of leader-follower pairs. A graph of scattered points of speed difference and headway is shown in Figure 2. Because it is not clear to see the order, we choose a display mode named Sun-Flower in SPSS software. It is shown in Figure 3.

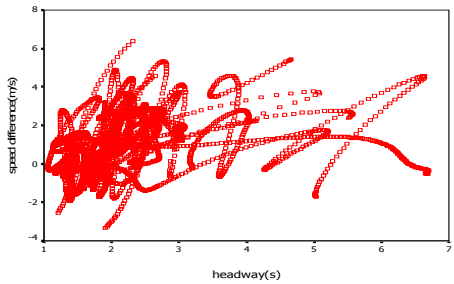

Figure 2. scattered points of speed

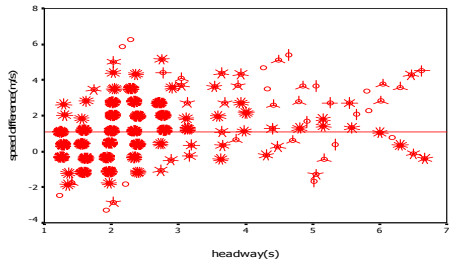

Figure 3. the sun-flower graph of scattered points.

It is clear that most points aggregate between 1s to 3s headway whether the speed difference is positive or negative. In the area with headways exceeding 3s, the points scatter. It is evident there is a critical point at 3s. K means the cluster method is used to analyze the headway data. Valid sample sizes are 31125 headway data, the value is 3s. Table 2 is the ANOVA analysis result. The table shows that the cluster effect is good. The graph of speed difference and spacing shows it is good as well. It is shown in Figure 4. Also does the graph of sun-flower display mode in Figure 5.

Table 2 the ANOVA table of the headway

	Cluster		Error		F	Sig.
	Mean Square	df	Mean Square	df		
Headway	14054.355	2	.258	31122	54403.419	.000

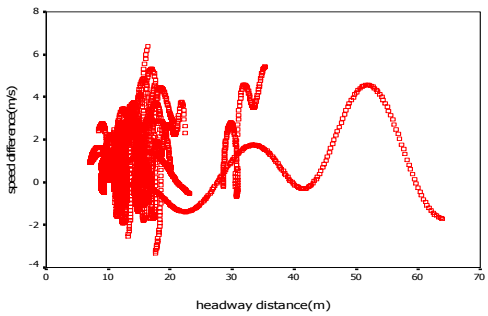

Figure 4 speed and vehicle spacing

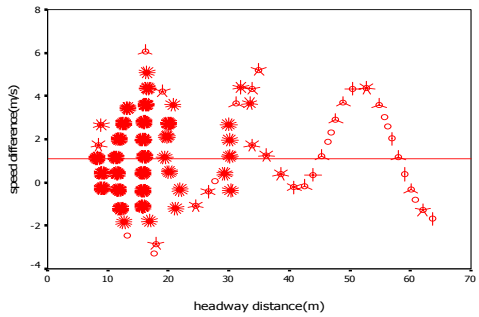

Figure 5 the sun-flower graph of scattered points

The vehicle spacing is from 10m to 30m so that the critical vehicle spacing is 20m. K means cluster method is used to analyze the vehicle spacing data. Valid sample sizes are 37482. We choose the second class vehicle spacing as the car following headway criteria at the signalized intersection, the value is 20m. Table 3 is the ANOVA analysis result. The table shows that cluster effect is good.

CONCLUSION

The car-following phenomenon has been observed in highway, expressway or motorway road segments in particular. This paper studies the car-following in a signalized intersection by the low-cost close-range photogrammetry method. By

speed difference analysis, the critical headway of 3s and the vehicle spacing of 20m are identified. With 3s headways, the saturation flow rate of through lanes in the signalized intersection is 3600/3=1200 vehicles. This paper does not intend to touch the car-following models, but introduces a feasible observation method to observe vehicles in a signalized intersection, and gives out the critical headway and vehicle spacing when there is car-following at the signalized intersection. This study should be beneficial to capacity and timing plans as well as signalized intersection safety.

Table 3 the ANOVA table of the vehicle spacing

	Cluster		Error		F	Sig.
	Mean Square	df	Mean Square	df		
Vehicle spacing	967068.701	2	13.936	37479	69394.061	.000

ABSTRACT

A driver is a principal part of traffic, and a driver's state is related to traffic safety, such as in the case of a driver's dangerous emotional state, fatigued state, or drunken state. According to scientists' study, an Electroencephalogram (EEG) can reflect his different states more accurately. In the modern Intelligent Transportation Systems which consists of the network and information, if the driver's EEG information could be gathered in real-time, and the transportation system could be adjusted to this, then the driver could be alerted or measures could be taken by the car's safety equipment which is designed according to the drivers' EEG information. Compared to the traditional transportation system, this kind of system which uses the drivers' EEG information can greatly reduce traffic accidents.

By using the car simulation driving instrument and the EEG measuring instrument, the EEG measuring experiment was developed. The experiments of fatigued driving, drunken driving, and driving while emotionally unstable were designed, and drivers' EEG signals were measured when they were in normal, fatigued, drunken, excited, tense, and sad states. FFT and Wavelet Analysis signal processing methods were used to extract the characteristics of the EEG signals.

The EEG characteristics of the fatigues state were found by these methods, and the drunken state's characteristics were distinct, and the excited, tense and sad states' were also found. The EEG characteristics of drivers in different states can reflect drivers' state in real-time, so they can be applied to the Intelligent Transportation Systems.

INTRODUCTION

The rapid development of modern traffic has brought us convenience, but it also has given us a serious problem: traffic safety. If you search on the internet for traffic-related deaths, you would find that there were 50,000 to 60,000 deaths due to traffic accidents every year. How to reduce the number is a problem faced by many countries.

Now, the Intelligent Transportation Systems (Westin et al. 1999; Lu Huapu et al. 2003) mainly utilizes the information about the road and car, but of the factors related to traffic accidents, the driver is the most important. (Wang Yanzhong et al.

2007) If the state of the driver could be gathered and taken to the center of the Intelligent Transportation Systems, the traffic information would be full-scale and more exact.

According to research, the EEG, which is the signal recorded from people's scalps, can reflect information about the people accurately. Therefore, in this paper, the EEG of the driver was studied. First, the experiment system in this research is given, second, the experiment process is explained, next are the experiment results and the analysis of them, the last are the conclusions.

1 EXPERIMENT SYSTEM

Fatigued, drunken, excited, tense and sad: these five states are the most dangerous factors which may influence driving. While in these states,, the driver may make some mistakes in driving, so in this paper, the EEG characters of drivers in these five dangerous states were studied.

The experiment system includes the car simulation driving system, the dangerous state inducement system, the EEG measurement instrument, and the data analysis system (see Figure 1).

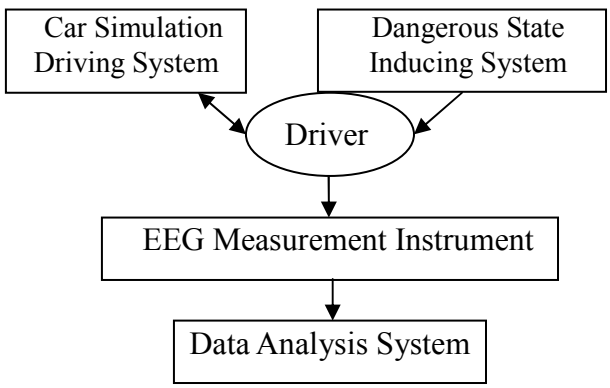

Figure 1. Frame of Experiment System.

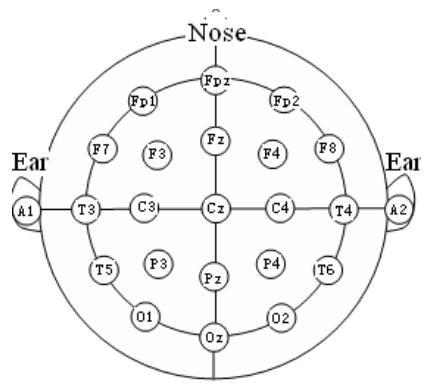

Figure 2: Location of Electrodes.

The car simulation driving system was chosen from the car driving school's teaching system. It is composed of a car cabin and a scene simulation system which can simulate many kinds of different scenes. The dangerous state inducing system can induce the experiment subject into the five kinds of dangerous states. The EEG measurement was chosen from the Japan Photoelectricity Company, type is EEG1100, which has one hundred and ninety two channels, and is one of the most advanced EEG measurement systems available.

2 EXPERIMENT PROCESS

To cover each of the five kinds of dangerous states, the experiments mainly were made of three parts: driving while fatigued, driving while drunk, and driving while excited, tense or sad .

Experiment subjects included graduate students, in good health, between 22 and 30 years of age.

Location of electrode: the electrodes were placed according to a 10-20 system standard which is the international standard. The referenced electrodes were A1 and A2 which were located on the ear. The EEG signals were recorded from the electrodes F3 and F4, C3 and C4, P3 and P4, O1 and O2, T3 and T4, which corresponded to the prefrontal area, frontal area, parietal area, occipital area and temporal area respectively (see Figure 2).

2.1 Experiment of fatigued driving

The experiment process was showed by figure 3.

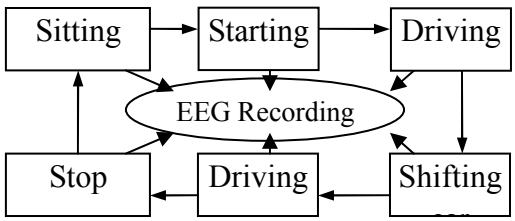

Figure 3. Experiment of Car Driving

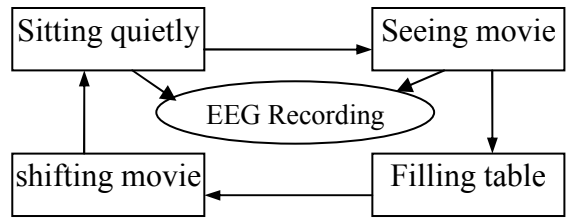

Figure 4. Experiment of Inducing Emotion

The high-speed road scene was chosen, the other cars and passengers were in normal mode, and the experiment was done five times following the process in figure 3 for every experimenter. At the same time, the subject's EEG was recorded by the EEG1100.

For the sake of contrast, first the subject drove in the normal state, and then drove the car following the experiment process, when he was in a fatigued state.

Five subjects participated in this experiment

2.2 Experiment of drunken driving

Experiment process: the subjects drank together, then they drove in the car simulation driving system. At the same time, their EEG was recorded. This experiment had some damage to the subjects' bodies, so only four experimenters participated in it.

2.3 Experiment of driving in a dangerous emotional state

This experiment's key point was the inducing of a dangerous emotion state: excited, tense, and sad. Now there are mainly three kinds of methods, such as picture inducement, movie inducement, and scene inducement. The movie inducement was chosen, for this method can arouse more obvious emotions, and the operation was simpler.

Before the experiment, many movie excerpts were compared, from them, the movie section which could induce the subjects' emotions more obviously was

selected. The process was as shown in Figure 4, first, sitting quietly for two minutes (the aim was recording the normal EEG as reference EEG), second, play the movie section (the aim was inducing the experimenter's emotion), third, the subject filled in the table of self-evaluating emotion (aim was to estimate the degree of the emotion). The emotion was divided into five degrees: zero (never), one (a little). two (normal), three (more), four (much).

In this experiment, twelve subjects participated.

3 RESULTS AND ANALYSIS

In the experiment, of all the EEG data from all the channels, the EEG of the frontal area is the most representative, so in this paper, the entire EEG signal was coming from the channel F3. More than four subjects had done the experiments, and the results in this paper were the same for every subject, so the entire EEG signal came from one representative subject.

The condition of the EEG signal used in this paper was as follows:

Time: 6 seconds. Sampling frequency: 500Hz. Number of data: 3000. In the figure, the x-coordinates were time, and unit was second(s). The y-coordinates were value of EEG signal, and unit was microvolt (μ v).

3.1 EEG characteristicss of fatigued driving

The EEGs of normal driving and fatigued driving were are shown in Figures 5 and 6.

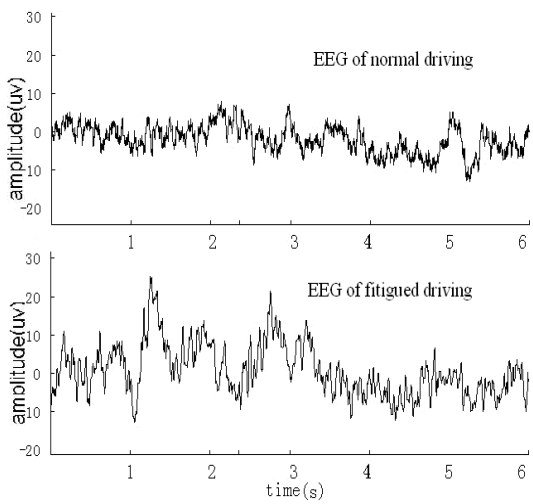

Figure 5. EEG of Normal Driving Fatigued Driving

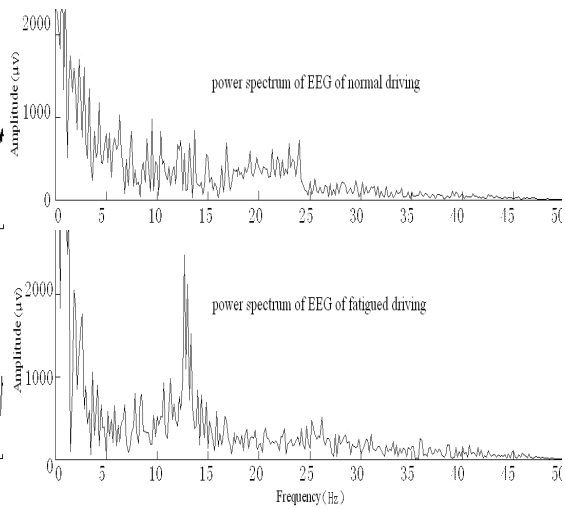

Figure 6. Power Spectrum of of Normal and Fatigued Driving

From Figures 5 and 6, we find that the energy of EEG when the subject was fatigued mainly focused in α-wave, of which the frequency was 10 to 13Hz, and the β-wave reduced much more, of which the frequency was 18 to 22Hz.

By using the method of power spectrum analysis, the characters of fatigued

driving can be obtained (Lin Chinteng et al. 2004). Because the EEG signal was non-linear and the value of correlation dimension was correlative closely to the complicated degree of the EEG signal (Jinghua et al. 1988), we found that when the subject was fatigued, the correlation was smaller than that of normal driving. The reason was that when people are fatigued, their ability to process thoughts is reduced. The value of correlation dimension can also be one EEG characteristic of fatigued driving.

3.2 EEG characteristics of drunken driving

Due to the degree of drunkenness, the EEG of drunken subjects appeared as different shapes and characters. EEG signals are shown in Figure 7.

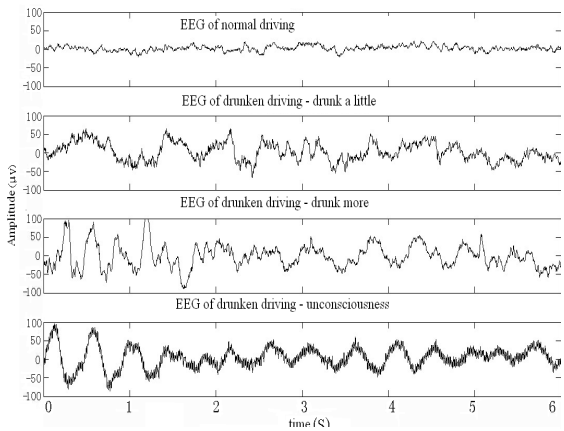

Figure 7. EEG of Drunken Driving

From Figure 7, we find that the EEG signal of drunken driving was different from that of normal driving. When the experimenter had drunk a little, when he was more excited and clear, the value of EEG signal increased much more, both in the low-frequency and high-frequency. But along with the increment of drunkenness, information on the subjects's brain received would decrease, and the random action of the nerve cells in brain would increase. From Figure 7 we find that the δ-wave, of which the frequency was 1 to 2 Hz, can be one EEG characteristic of drunken driving. Two methods of power spectrum analysis and wavelet analysis both can exstract the EEG characteristic. In this paper, the db6 wavelet was used to decompose the EEG signal into 6 parts, the sixth part ca6 represented the δ-wave , which power was as Table 1.

Table 1. Power of ca6 wave of Subjects

experimenter	Normal s	Drank a little	Drank more	Unconscious
1	4.01	12.91	17.70	18.52
2	3.06	13.92	18.73	20.50
3	3.95	15.89	18.65	19.55
4	4.96	13.90	19.66	22.57
mean	3.99	14.16	18.69	20.29

As seen in Table 1, the power of δ -wave of drunken driving was greater than that of normal driving, and along with the increment of drunkenness, the power of δ -wave was even greater. So the power of δ -wave can be taken as one EEG characteristics of drunken driving.

3.3 EEG characteristics of driving in a dangerous emotional state

The EEG signal of one subject in an excited state is shown in Figure 8 and that of the subject in tense and sad state is shown in Figure 9.

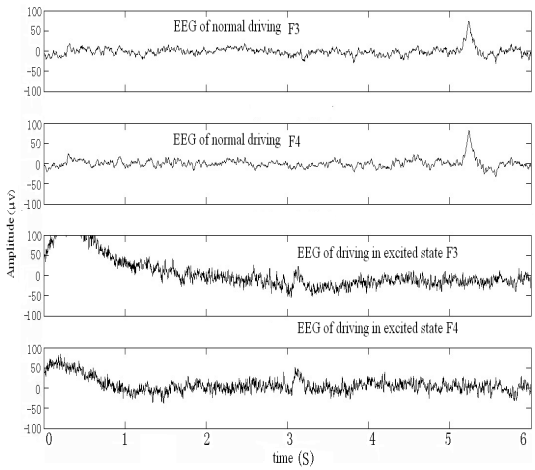

Figure 8. EEG of Normal Driving and Driving in Excited State

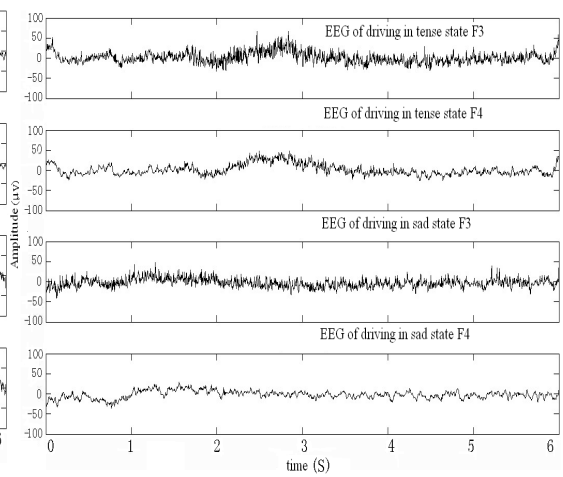

Figure 9. EEG of Driving in Tense and Sad State

As shown in Figure 8, when the subject was in the excited state, both the value and frequency of the EEG signal increased, among that, the β -wave increased more noticeably. As shown in Figure 9, when the subject was in a tense or sad state, the value of the EEG signal from the left frontal area was greater than that from right frontal area.

Table 2 shows the power of β -wave from channel F3 (left frontal area) and F4 (right frontal area), the computing method was wavelet analysis.

Table 2. Power of β-wave in Normal, Excited, Tense and Sad

Experimenter	normal		excited		tense		sad

As shown in Table 2, when the subject was in an excited state, the power of the β-wave was greater than that of when the subject was in normal state. But when the subject was in tense or sad state, the power of β-wave showed asymmetry between the left and right frontal area, and the power of β-wave from the left frontal area was greater than that from right frontal area. So the power of β-wave can be taken as one EEG signal characteristics of driving in dangerous emotional state (Musha et al. 1997; Coan et al. 2003).

CONCLUSION

In this paper, the EEG characteristics of drivers in five dangerous states, fatigued, drunken, excited, tense and sad, were studied. Several EEG characteristics which can reflect the driver's state were discovered.

The research is limited to the lab now, and the experiment results need to be verified by more experiments and more subjects. For the application of EEG information of drivers in ITS, many problems need to be researched, such as how to measure a driver's EEG without influencing the driving, as well as how to abstract and recognize the EEG characteristics in real-time.

Along with the more research on the relation of EEGs to driving and traffic, the ITS will need more useful EEGs of drivers to optimize the traffic network.

ABSTRACT

Short-term traffic flow forecasting is considered to be the core of intelligent transportation systems and the advanced technical support including traffic information service, traffic control, and guidance. Previous traffic information is on current or predicted traffic states, which are still deterministic and difficult to show with the uncertainty of the road network. Therefore, the analysis of reliability of short-term forecasting is proposed to deal with the uncertainty of traffic.

The reliability of short-term forecasting is described as a range of forecast values which show the deviation between forecast value and the measure. A state space model is used in this paper and the Monte Carlo method is performed to deal with uncertainty, where a random sample of traffic flow within a probability distribution is generated until at a steady state. Results show that the proposed model can reduce the disturbances between the forecast and actual traffic.

INTRODUCTION

Even though intelligent transportation systems are developing quickly all over the world, there is no comprehensive theory to support the intelligent transportation system (ITS) which affects the development of ITS technologies and the efficiency of travel. Based on modern information, communication, networking, and computer technologies combined with the conventional traffic flow theory, a comprehensive theory can be obtained which is suitable for ITS. Short-term traffic forecasting determines the traffic state in the next time window, based on the current time window or previous time windows and is a theory-supported practice in the field of traffic information service, traffic guidance, traffic management and relaxing traffic congestion.

Earlier attempts to obtain short-term traffic states primarily depended on linear models, such as historical trends, time series, and the Kalman filtering

approach. Next, wavelet and fractal theory emerged which are used to handle complex and nonlinear optimization problems. Forecast models based on artificial intelligence, such as neural networks evolved rapidly and a combination of two or more methods was created. Various approaches have been developed to forecast traffic states, but they usually obtain only a single future value rather than a range. However, transportation networks are disrupted by natural or man-made disasters or more commonly by routine events, such as congestion, collisions, and road maintenance. The uncertainty of travel exists due to these unexpected things. Traffic states at a given location may vary from day to day and a single value is difficult to show with certainty.

Therefore, a range of forecast values is proposed to show the comprehensiveness of the forecast model in dealing with such uncertainty. The Monte Carlo method is joined with the forecast model to deal with both the day-to-day recurrent traffic patterns and the real-time fluctuation, while the state space model is performed iteratively to obtain the range of forecast values and show the variability of the road network. The proposed model can generate traffic forecast values with reasonable accuracy.

SHORT TERM FORECAST BADED ON STATE SPACE MODEL

The state space model by R.E. Kalman is widely used in the field of traffic flow forecast. The forecast value can be obtained by the recursive relation of system state x_n and transfer equators between x_n and the observed y_n. It is expressed as:

$$x_n = F_n x_{n-1} + G_n v_n$$

$$y_n = H_n x_n + w_n$$

where x_n is the k dimension system state vector of n period of time and unable to be observed directly; u_n is r dimension system input vector of n period of time; v_n is system noise of n period of time and a zero mean white noise source with m dimension variance matrix Q_n, $Q_n = E(v_n v_n^T)$; y_n is j dimension observation vector; w_n is observed noise and a zero mean white noise source with j dimension variance matrix R_n, $R_n = E(w_n w_n^T)$; F_n, T_n, G_n and H_n are $k \times k, k \times r, k \times m, j \times k$ dimension coefficient matrix, state transfer matrix, input coefficient matrix, noise transfer matrix and observed matrix respectively.

The relationship between any period of time and previous p periods of time exists in time series $\{x_t\}$ made of observed sample $x_1, x_2, \ldots, x_N$ and can be

described by the state space model. The Kalman filtering algorithm is an efficient way to solve the state space model based on the linear minimum variance estimation theory. See references (Brockwell and Davis, 2001; Deng, 2005; Yao, 2007) for a complete description.

The algorithm can be shown as follows: (1) Identify initial coefficient matrix, initial system state x_0 and variance matrix V_0. Because the statistical distribution of system states are difficult to gain in practice, an autoregressive parameters estimation of the AR model which is made of observed samples is used to get these initial values by the Yule-Walker estimation and AIC criterion. For details see attached reference (Digalakis , Rohlicek and Ostendorf, 1993; Sun, Chen and Liu,2002). (2) Perform recursive relation of system state as previously mentioned. (3) Revise system state according to observed vector filter. (4) Determine convergence and output; otherwise, return to step 2.

UNCERTAINTY OF SHORT TERM FORECAST

The deviation of actual versus forecast values exists because of numerous factors, primarily imperfect data, model errors, and road network variability. With the development of traffic science and technology, automatic acquirement devices set on the roads have improved constantly, which makes it possible to perform short-term traffic flow analysis and forecasting accurately. Various models are dedicated to reducing error. However, the uncertainty of the road network is seldom considered in the process of performance and the forecast values are unable to show the comprehensiveness of the model in dealing with such uncertainty. Previous attempts to perform short-term forecasts make sure to fit the actual value. But the forecast value is not consistent with the actual value, no matter how accurate the model or perfect the data are. Therefore, reliability of forecast is proposed to show the ability of the model to deal with uncertainty, which is defined as the forecast value within the given range under uncertainty.

The day-to-day variations in travel demand and supply are disrupted by many sources ranging from daily fluctuation to unexpected events. If the variation can be assumed, the performance of the road network under uncertainty can be easily determined. Traffic volumes obey normal distribution which was demonstrated by Bell and Iida (1997) according to numerous detective data. The reliability is the probability of traffic volume not exceeding its capacity. The relation between its mean and variance is recommended (Yamada, Yoshimura and Mori, 2003):

$$\sigma = h_1 \times \mu^{h_2}$$

where $h_1 = 0.360, h_2 = 0.821$ is parameter respectively, μ, σ is mean and variance of

any link traffic volume.

RELIABILITY OF FORECAST

The MC method is usually used in reliability analysis. When multiple trials are performed, the range of measure value can be obtained by its probability distribution. To give an accurate range to show the reliability of forecasts, 95 percent traffic volume is recommended. It can be considered as the tolerance range not allowing to be exceeded and showing the probability that traffic volume may be within the range is 95 percent. That is to say, the traffic volume can only exceed the range once in twenty times.

The algorithm to determine the forecast reliability is as follows:

Step 0: Initialization. Set n=1.

Step 1: Establish short-term forecast model. The state space model is proposed as before.

Step 2: Perform state space model. A value that used to be the forecast value can be obtained which is only an initial value in the process of reliability analysis.

Step 3: Generate the stochastic variable. Traffic volume is assumed to be at normal distribution. Its variance can be obtained according to the analysis of uncertainty. A forecast value is made of the initial and the stochastic term.

Step 4: If $n < n_{\max}, n = n + 1$ go to Step 1.

Step 5: Obtain the upper and lower value of the forecast range, which is 95 percent of the statistics after many experiments.

ILLUSTRATION

To illustrate the reliability of forecast, we used traffic volume data from an expressway form 09/01/2007 to 09/11/2007, where time interval is 2 minutes. Data is divided into two parts, one from 09/01/2007 to 09/10/2007 to establish a forecasting model, the rest to fit the outputs of the forecasting model.

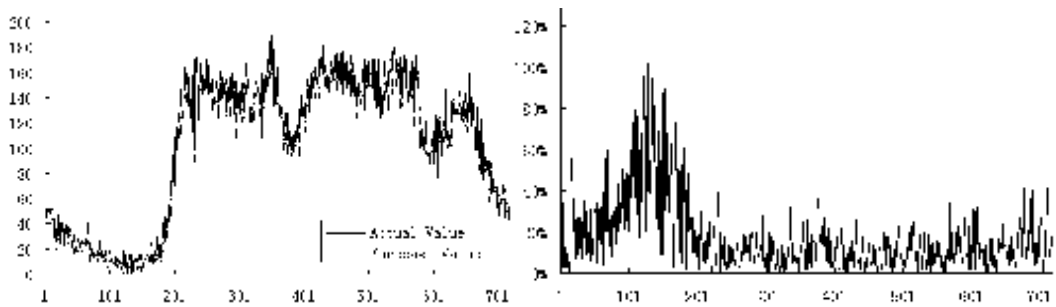
There is a time interval on the x axis which represents the whole day (24 hours) and traffic volume is shown on the y axis. The outcome of the state space model is shown in Figure 1(a). Mean absolute percentage errors (MAPE) of the model are shown in Figure 1(b). We can see that MAPE are high, especially in the first half of the x-axis when there were fewer vehicles because it was late at night.

The difference between a measured value of performing MC 500 times and the value of 1000 times is shown in Figure 2. The formula of measure value can be expressed as:

$$Transition = \begin{cases} 0, if \quad Lower < True < Upper \\ \min(abs(Upper - True), abs(True - Lower)), \quad other \end{cases}$$

$$Measure \quad value = \frac{Transition}{Ture} \times 100\%$$

where Upper and Lower is 95 percent traffic volume from MC trials and True is the actual value.



(a) (b)

Figure 1. Forecast value of state space model

Monte Carlo circulating frequencies (500 and 1000) can influence the accuracy of the forecast. It shows that the range was closer to actual values with the number of MC trials increasing.

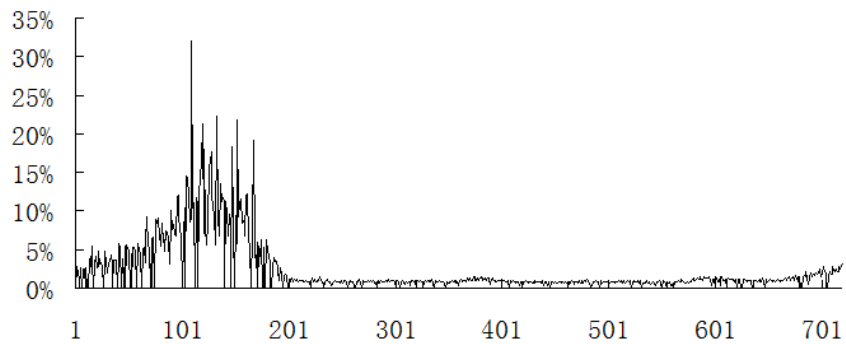


Figure 2. The effect of circulation frequency

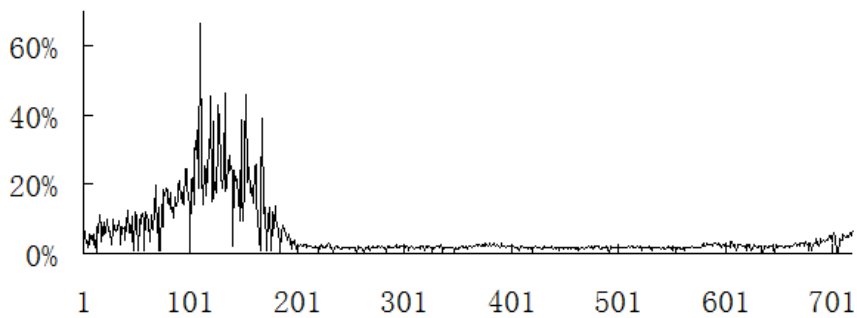

Figure 3. The effect of two methods

Figure 3 reflects the measure value of two methods. One is the MC method and the other is the traditional state space model. The MC approach performs better than traditional one, especially in the early time of day. Therefore, the proposed way to give an accurate range of forecast values may be more accurate than the traditional models and can show the capacity of the model dealing with uncertainty.

CONCLUSION

Short-term traffic state forecasting is one of the most critical aspects in ITS. Traditional methods seldom take the uncertainty of the road network into consideration. An accurate range of forecast values can be obtained by the MC method to show the uncertainty of the road network. The proposed approach performs better than the traditional one. More research is needed to verify the reliability of short-term forecasts.

Dynamic Model of Transit Signal Priority on Colored Time Petri Net

Ciyun Lin[1], Zhaosheng Yang[1], and Bowen Gong[1]

[1] Department of Traffic and Transportation, Jilin University, Changchun, Jilin, China, ST 130022; PH (+86) 0431-85095767; FAX (+86) 0431-85095767; email: linciyun@email.jlu.edu, yangzs@jlu.edu.cn, gongbowen1982@gmail.com

ABSTRACT

A dynamic coordination strategy model of the transit signal priority and traffic signal control cooperative system is created by using Colored Time Petri Nets (CTPNs). To extend the coordination from isolated intersections to the arterial network of intersections, a multi-level and multi-group computer supported cooperative system is described based on CTPNs. Then inter-intersection and cross-intersection coordination strategy for busses and vehicles was proposed to model transit signal priority in urban networks.

INTRODUCTION

Traffic management systems address the problem of reducing congestion, vehicle delay time, fuel consumption, and pollution. The most common technique to regulate and manage urban traffic areas and surface street networks is traffic signal control (Dotoli and Fanti 2006). Traffic signal control plays a central role in modern urban traffic management (Dotoli et al. 2003).

Public transit, with the advantages of large capacity, reduced road occupancy, low fuel consumption and so forth, is considered to be one of the most effective ways to solve urban transportation problems (Han and Liu 2008). Transit signal priority (TSP) is a direct way to improve public transit service levels and attract residents to use public transit.

In traffic control systems, general vehicle signal control and transit signal priority control share resources, resource conflicts, a tendency to deadlock and overflow, and require well-planned synchronization and scheduling. They are controlled to achieve satisfactory performance which includes reduced travel time for transit customers, improved schedule adherence and side-street traffic, and the smooth flow of traffic. (Dotoli et al. 2006). Therefore, it is of practical importance to develop, verify and, validate simple, yet powerful models that help to design and improve the safety and efficiency of traffic signal control systems. Petri nets have been proven to be a powerful modeling tool for various kinds of discrete event systems (Chung and Huang 2007). Compared with other analytical and simulation methods, Petri nets have the following advantages (Dos Santos Soares and Vrancken 2007; Wang et al. 1999):

1) Petri nets can easily express concurrency, competition, and synchronization activities among traffic, TSP and traffic control

2) Petri net modeling allows easy changes to be made to the network configuration, the traffic signal control logic, timing and coordination, and the assumptions on intersection physical layout, vehicle flow rate, turning movement,

pedestrian movement, etc.

3) Petri net models are mathematically defined, which makes it possible to verify that the control logic enforces all required, ensuring that capacities are not exceeded and that gridlock will not occur as a result of the logic and timing.

In this paper, a dynamic coordination strategy model of the transit signal priority and traffic signal control cooperative system is created by using Colored Time Petri Nets (CTPNs). To extend the coordination from isolated intersections to arterial networks of intersections, a multi-level and multi-group computer supported cooperative system is described based on CTPNs. Compared to isolated intersections, it not only provides coordination strategy and priority plan for inter-intersection relations, but also coordination priority strategy and signal plan for cross-intersection relations.

THE DESCRIPTION OF THE BASIC COLORED TIME PETRI NET

A CTPN is defined as a bipartite directed graph represented by $CTPN = (\sum, P, T, A, N, C_o, G, E, R, I)$. Where $\sum$ is a finite set of non-empty types, called color sets; P is finite a set of places; T is finite a set of transitions; A is a finite set of arcs, such that $P \bigcap T = P \bigcap A = A \bigcap T\varnothing$; N is a node function. It is defined as $N : A \to (P \times T \bigcup T \times P)$; C_o is a color function that associates with each element in $P \bigcup T \neq \varnothing$ a set of colors in the set of possible colors Cl. C_o maps each place $p_i \in P$ to the set of possible token color $C_o(p_i) = \{a_{i,1}, a_{i,2}, \cdots, a_{i,ui}\} \subseteq Cl$, where $u_i = |C_o(p_i)|$ is the number of possible colors of tokens in p_i. Analogously, C_o maps each transition $t_i \in T$ to the set of possible occurrence colors $C_o(t_j) = \{b_{j,1}, b_{j,2}, \cdots, b_{j,uj}\} \subseteq Cl$ with $u_j = |C_o(t_j)|$. $G : T \to$ is a T guard function and $E : A \to$ is an arc expression function. R is the set of time values $R = (r_i / p_i \in P)$; I is an initialization function (Tian et al. 2003) . The detailed description of $CTPN$ can be seen in (Hrúz and Zhou 2007).

MODELING TRAFFIC SIGNAL CONTROL WITH TSP BASED ON CTPN

Urban Traffic Networks

In urban traffic networks, signalized intersections, links, vehicles and traffic signal lights whose signal plan is controlled by a traffic signal control system are the fundamental components. In CTPN model, a place $p_i \in P$ denotes a resource, corresponding to link cells and intersection cells. Five types of links are considered:

1) input links $L_i \in L_{in}$, which vehicles input to the traffic signal control network

2) intermediate links $L_i \in L_{\text{int}}$ which join two successive signalized intersection

3) output links $L_i \in L_{out}$, which vehicles exit the traffic signal control network

4) signalized intersection $I_i \in I_{sig}$

5) un-signalized intersection $I_i \in I_{unsig}$

In addition, transitions from T are timed transitions and model the flow of

vehicles into the system between consecutive cells. Five types of transitions are considered (Dotoli et al. 2004):

1) input transitions $t_{o,i} \in T_I$, modeling the arrival of a vehicle in a link from the outside of the considered intersection

2) output transitions $t_{i,o} \in T_O$, modeling the departure of a vehicle from a link to the outside of the considered intersection

3) flow transitions $t_j \in T_F$, modeling the flow of vehicles between two consecutive link cells

4) intersection transitions $t_j \in T_C$, modeling vehicles entering or leaving a cross section. The intersection transitions that model a vehicle entering the crossing sections are regulated by a multi-phase traffic signal or transit signal priority plan

5) lane changing transitions $t_j \in T_L$, modeling vehicles that change lanes in the road

The value of FT_j assigned to each $t_j \in T_O \cup T_F \cup T_C$ is equal to the average time interval in which a vehicle passes from a cell to the subsequent one or occupies an intersection cell. This depends on the average vehicle speed in the considered traffic scenario.

A colored token in a place represents a vehicle. The color of each token is the routing assigned to each vehicle indicating the different paths that a vehicle can follow starting from a particular position. For instance, a priority bus has a different color than a general vehicle. Their paths across the intersection also have different respective colors.

Matrices $Pre(p_i,t_j)$ and $Post(p_i,t_j)$ are determined by physical layout of the intersection, traffic organization, and signal phase numbers at intersection.

Inter-intersection Coordination Strategy for Busses and Vehicles

Transit signal priority is taken into account to achieve efficient performance. But this does not mean that transit signal priority is allowed to provoke perturbations in the normal traffic signal plan without any consideration. It makes sense to optimize the performance indices of the overall traffic, for instance, shortening and equalizing the queues at the intersections. The aim of inter-intersection coordination strategy is to coordinate busses and vehicles reasonably to share and use the limited resources of signal time and intersection space. We use a controllable time-sharing strategy to coordinate bus and vehicle signals (Ni et al. 2001).

The basic idea is that if bus traffic or vehicle traffic wants to obtain or occupy the signal resource and intersection's place resource, it must have a public token. The number who can obtain the token is defined as a focus point which can use the resource at a specified time without interruption unless it abandons the token voluntarily. The token's application and availability are determined by a coordination chair. If the token is in effect, insert into the FIFO application queue. If the token runs out of time and the queue is not empty, the token turns to queue lead

and lets the lead member occupy the resource. The coordination strategy process is demonstrated in Figure 1.

The problem of managing a transit signal priority request in inter-intersection relations is solved by a simple control algorithm described as follows (Di Febbraro et al. 2004):

Step 1: let T_{ask} be the instant at which a bus requests for signal priority and T_{arr} the time the bus is expected to arrive at the intersection.

Step 2: if at T_{arr}, the signal phase for the direction of priority comes from is expected to be green, then there will be no need for intervention. Exit the algorithm.

Step 3: if the red signal is expected, the local controller has to decide (Lin 2007)

Step 3.1 Green Extension: extending the current green time until the bus crosses the intersection

Step 3.2 Early Green: anticipating the next green time, shortening the current red one accordingly

Step 3.3 Phase Insertion: bus forward direction inserting a phase which can be used for bus and vehicle

Step 3.4 Actuated Bus Phase: inserting a phase which can only be used for the bus

Step 3.5 Phase Rotation: changing the signal phase sequence accordingly

Step 3.6 Phase Skipping: jumping a signal phase, and switching to implement the phase so that the bus can cross the intersection

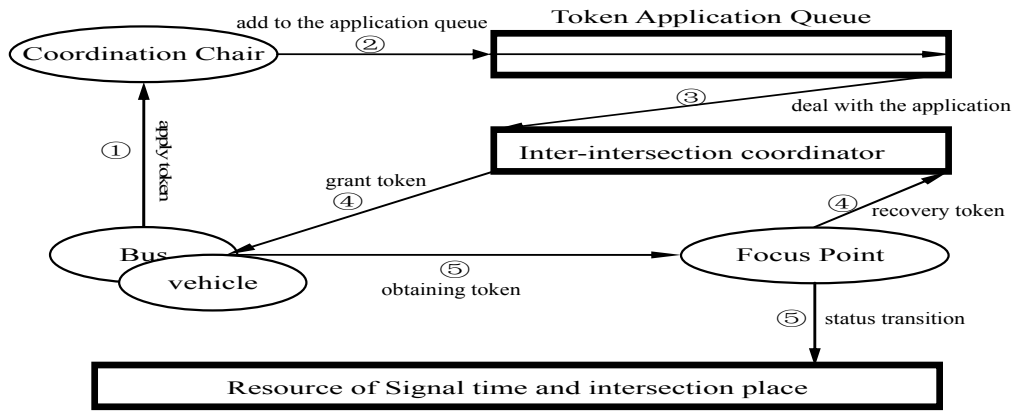

Figure 1. Processing of inter-intersection coordination strategy.

Note that above strategies are subject to (Long 2008):

$$\min d_p = \sum_{i=1}^{n}\sum_{j=1}^{m_i}(d_{ij}Q_{ij}^{V}P_V + d_{ij}Q_{ij}^{B}P_B) / \sum_{i=1}^{n}\sum_{j=1}^{m_i}(Q_{ij}^{V}P_V + Q_{ij}^{B}P_B)$$

$$S.T.\begin{cases}\sum_{i=1}^{n} g_i + L = C \\ C_{\min} \le C \le C_{\max}\end{cases} \tag{1}$$

Where d_p is the average delay per passenger; d_{ij} is the average delay per vehicle at approach j and phases i; Q_{ij}^V Q_{ij}^B are the traffic volume of general vehicles and bus respectively at approach j and phase i; P_V, P_B are the average passengers loaded on vehicle and bus respectively. n is the phase number of intersection, m_i is the number of approach during phase i; g_i is green time for phase i, L is the loss time, C is the cycle time, $C_{\min}$ and $C_{\max}$ is the minimum and maximum value of cycle time.

Cross-intersection Coordination Strategy for Bus and Vehicle

We now address cross-intersection coordination strategy of controlling traffic in an urban transportation network so as to increase the performances of public transit. The main objective is to minimize the travel time from the bus origin station to the destination, in order to maximize the efficiency of the bus. The basic idea is that the supervisor divides the task into several sub-tasks, and delegates the sub-tasks to different local controllers. The local controller uses inter-section coordination strategy for cooperation, optimization of the signal plan, and implementation of priority requests. The role of supervisor is to coordinate the work flow of sub-tasks, control resource access, and resolve conflicts. The procedure is described as follows:

Step 1: when a priority vehicle requests, at T, for signal priority, it communicates its location, direction and schedule to the supervisor; then, the supervisor deliberates, through knowledge of the traffic conditions over each arc of the arterial and bus status at T.

Step 2: the supervisor asks the corresponding priority controller to solve the priority control problem, providing guidance on whether or not to provide signal priority and decide when (the time instant) and how (priority strategy) to provide priority for the bus.

Step 3: each local controller solves the local problem described and determines its own optimal timing plan due to the minimize cost function:

$$\min R = (\sum_{i=1}^{n} D_i^{SP} - \sum_{i=1}^{n} D_i^{Int}) / \sum_{i=1}^{n} D_{Int} < \delta \tag{2}$$

Where R is delay ratio, D_i^{SP} and D_i^{Int} is i^{th} intersection's total vehicle delay with and without bus signal priority respectively, δ is a constant defined by traffic control manager.

Step 4: the supervisor computes the real travel time T_{bus} on the basis of the traffic conditions and the traffic signal timing plans determined in Step 3. If $T_{bus} > T_{plan}$, then go to Step 2. Otherwise, go to Step 5.

Step 5: among all the possible priority strategies, the supervisor chooses the best priority strategy. Then it communicates to the responding local controller and the priority bus.

SIMULATION

For the purpose of analysis, a simple simulation of an urban traffic network is used to verify the model. The traffic network consists of four signalized intersections. For simplification, all signalized intersections have four basic phase transition and

six priority phase strategies which are described above.

The TCPN model is implemented and simulated by CPN Tools. CPN Tools are tools for editing, simulating, and analyzing Colored Petri Nets (CPN Group 2007). Figure 2 shows a snapshot of a CTPN model of this paper in CPN Tools. In order to compare model performance of this paper, the priority logic is simulated in PARAMICS V6 which is a famous microcosmic simulator in traffic engineering.

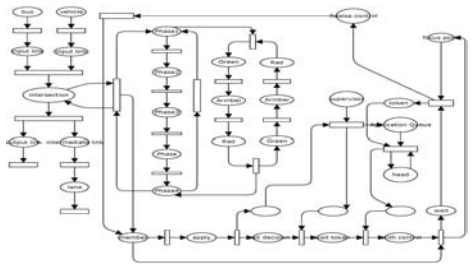

Figure 2. A snapshot of the CTPN model in CPN Tools

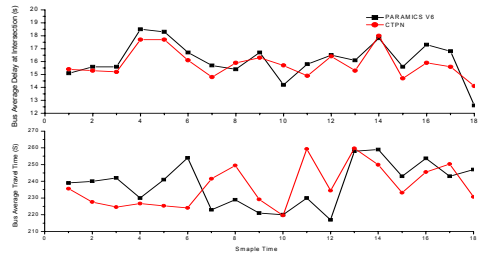

Figure 3. Bus average travel time, delay at intersection in CTPN and PARAMICS

In summary, the simulation results are similar to the PARAMICS results. Figure 3 shows the bus's average travel time and signal delay at the intersection in CTPN and PARAMICS V6.

CONCLUSION

This paper describes the processing of transit signal priority control in urban traffic networks based on CTPN models. A coordination model of the multi-level and multi-group system using CTPN is proposed, which worked when using inter-intersection and cross-intersection cooperation. CTPN was applied to four successive signalized intersections of simulated urban traffic networks. Finally, the CTPN model's performance was compared with the simulation of PARAMICS V6. Briefly, we can conclude that the traffic signal control system with transit signal priority can be implemented by the CTPN model and perform successfully..

ABSTRACT

We introduce a systematic design plan for an urban bus location display system based on GPRS. It adopts special APN transmissions as a GPRS communication project. The system consists of four modules: bus wireless terminals, bus-location display terminals, bus company data center, and GPRS network. In this paper, the development of the database and data processing key algorithm of the bus data center are introduced, and the development of wireless terminals as well as communication protocols between the bus data center and the wireless terminals are presented. An innovative data-sending algorithm of bus location information based on the bus's sequence is presented. Tests show that this system can display the location of the nearest bus in each bus station which indicates how far the closest bus is from this site. This system can be used as a subsystem for a bus scheduling system.

INTRODUCTION

With the rapid development of ITS and popularization of new technology in China, the bus location display system is used more and more as an important component of ITS (*Tang Xin-zhou, 2006*), especially for the bus transportation systems in small and medium-sized cities. As a result of low road network density and long time interval between regular buses, it is necessary that the bus location display system provides the location of the nearest bus to the station.

Owing to the bus's constant movement, wireless communication technology is the key to creating the bus location display system. GPRS (General Packet Radio Service) is a kind of data service for wireless data transmission based on GSM. It can provide continuous and timely information service, which makes the spatial data from the bus unit packed to send and receive (*Zhang, 2006*). GPRS wireless networks provided by Mobile Company covers every city, so it is a better choice to use GPRS as a communication link of the displaying system.

SYSTEM ARCHITECTURE AND PRINCIPLES

The system functions are as follows: displaying the location of the nearest bus in each bus station, which indicates that how far the most recent bus is from the site. If necessary, voice prompts can be addd according to the condition. It can be used as a subsystem of a bus scheduling system.

System Architecture. The overall structure of the system is shown in Figure 1.

The system consists of four modules: bus wireless terminals, bus-location displaying terminals of bus station plates, bus company data center, and GPRS Network (APN private network) (*Motorola Engineering Institute, 2005*). Current bus location information is sent to the data center by the bus wireless terminal through the GPRS network, processed by the data center, and sent to the bus-location displaying terminals of bus station through the GPRS network. Bus wireless terminals and bus-location displaying terminals of bus stations are called wireless terminals.

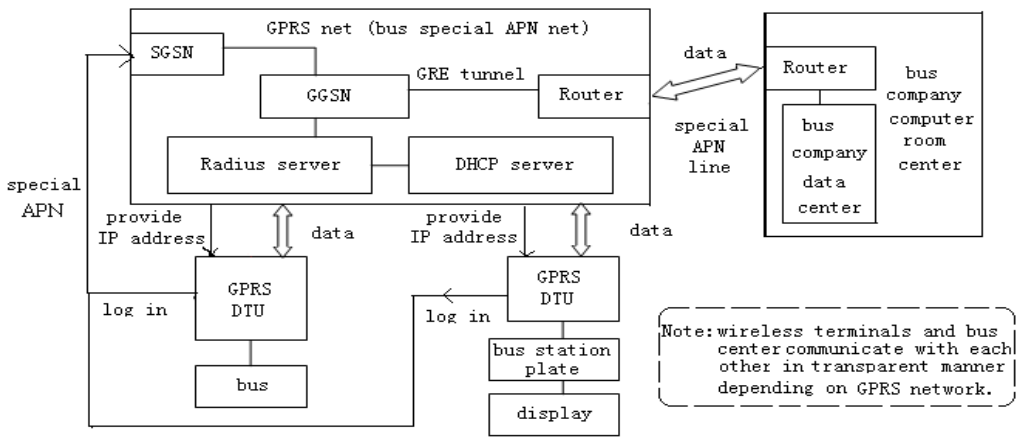

Figure 1. Overall block diagram of the system

GPRS is a kind of advanced mobile data communication. It has some special advantages compared to other data communication, for example: it has wide coverage, high transfer rate, short accessing time, it is always on, and charged by data flow. A vehicle monitoring system has frequent data flow in small amounts and requests rapid responses. Therefore GPRS is very suitable for data transmission for the vehicle monitoring system.

GPRS Communication Project. APN (Access Point Name) is a kind of wireless DDN service provided by China Mobile Company for GPRS users. APN consists of public the APN and special APNs. The consumers, who do not apply for special APN, only log onto the public APN by common SIM card. They log on the CMNET or CMWAP domain, and receive IP address 10.xxx.xxx.xxx. However, they cannot transmit data each other.

When one has applied for a special APN, he will obtain the accounts of the special APN from Mobile Company and a domain on GGSN (Gateway GPRS Support Node) nodes. Special SIM cards, for the service, are bound in this domain. When the consumers logs in, GGSN needs to check the accounts for the SIM card. If they are all right, a designated IP address would be allocated to SIM card. They can transmit data each other. One cannot call a special APN using public SIM card.

In this system, the special APN is adopted. The bus company would apply for a special APN which only could be used for the bus company, and is linked to the GPRS network of Mobile Company by the special APN line. The mobile company provides a private IP address for the bus center which is connected by special cable to the GGSN equipment of GPRS network. Wireless terminals would use the accounts of the special bus APN to log onto the GPRS net and obtain an IP address. In this way, the bus data center communicates with wireless terminals in the GPRS network.

Wireless terminals would make use of unified GPRS SIM card of Mobile Company, and the information is registered by the bus data center in order to identify them.

System Principles. Depending on GPRS networks, the wireless terminals and the bus center are linked in a wireless local area network, which has no distinction from wired LAN. They transmit data with each other relying on Socket and TCP/UDP technology.

The bus data center operates as the monitoring server (TCP/UDP) in the system, which establishes TCP connections with all wireless terminals. The center collects location information from all buses depending on their TCP program, and classifies the data to insert into the database, then processes the data by a data processing algorithm. At last the system sends the results to the terminals of bus stations which display the nearest bus location information.

Before bus departure, each wireless terminal is initialized, and the wireless terminal's information such as IP address is inserted into the data center's database. After departute, the bus location information from the same bus route is put into the same data table. Bus location information data sheets are associated with station data sheets through the station ID number. Bus location information of the same bus route is sorted according to its current location with station ID in each route table. The driver will press the arrival button when the bus has arrived at a station, so we can know the bus's location. Every time bus stops at a station, the bus terminal will send information to the data center, and the data center sorts the bus information by location or running sequence. The location information is displayed by LED in the bus stations.

In order to use this network effectively, Mobile Company does not require the GPRS to be on always. If there is no GPRS data exchange for some time, users will drop out of the GPRS network. The re-dial-up will bring additional data traffic,

which will have an impact on the real-time transmission. So "heartbeat packet technology" is carried out in the system, which sends a number of bytes of data to the GPRS network from time to time to ensure that it is always on (*Liu, 2006*).

BUS DATA CENTER DEVELOPMENT

Database Design of Bus Data Center. The database of the bus company data center includes two static data tables: bus route station name table (see Table 1) and bus route vehicle table (see Table 2), two dynamic tables: bus location collection table (see Table 3) and bus location station table (see Table 4). The contents of static data tables will not be changed until the amount of vehicles and station terminals are changed.

In order to facilitate the realization of the system, the system sorts the bus station terminal of each route by ascending serial number (see Figure 2). Because the bus is traveling in two ways, the serial numbers of bus station in diffirent directions are sorted together. In Figure 2, except the starting and terminal station, the intermediate stations are in pairs. Although they have the same station name in Figure 2, due to the different direction, the bus station terminal and SIM card number are different.

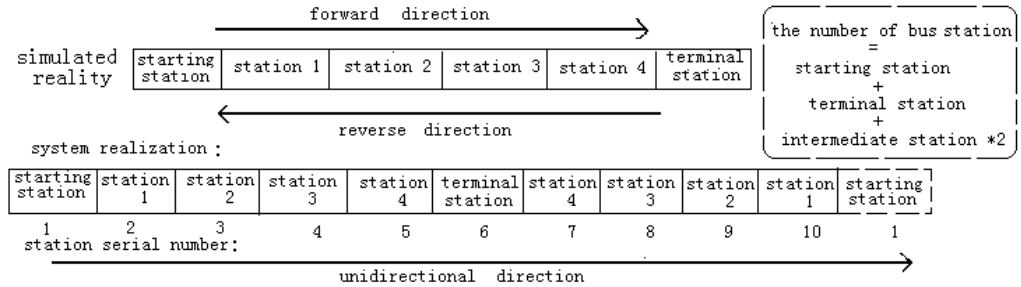

Figure 2. Compositor method of bus station

The abbreviations of database fields are shown in Table 5.

Table 1. Bus Route Station Name.

BR	SS	TS	AS	S1	SS1	S2	SS2	S3	SS3	S4	SS4	S5	SS5
2	A	C	4	A	13X	B	13X	C	13X	B	13X	A	13X

Table 2. Bus Route Vehicle.

BR	AB	BI1	SB1	BI2	SB2	BI3	SB3	BI4	SB4	BI5	SB5
2	5	XX	13X	XX	13X	XX	13X	XX	13X	XX	13X

Table 3. Bus Location Collection.

Running Sequence	BR	SB	CSN	BTIP	Time	WU
1	2	13X	1	10.X.X.X	9H30M	N
2	2	13X	3	10.X.X.X	9H31M	Y
3	2	13X	5	10.X.X.X	9H30M	Y

Table 4. Bus Location Station.

BR	SN	SS	STIP	MSRBS	Time	WSS
2	1	13X	10.X.X.X	2	9H31M	N
2	2	13X	10.X.X.X	3	9H31M	Y

When the system is working, the number of records remains unchanged in Table 3 and in Table 4, and the contents of the first three fields are also invariable, but the contents of other fields may be updated at any moment.

Table 5. Field Abbreviations.

Field abbreviation	Signification
AB	amount of buses
AS	amount of station
BI(X)	identification number of bus X
BR	bus route
BTIP	IP address of bus wireless terminal
CSN	current station number
MSRBS	how many stations the recent bus is from current station
SB(X)	SIM number of bus X
SN	station number
SS	starting station name
S(X)	station X name
SS(X)	SIM number of station X
STIP	IP address of station wireless terminal
TS	terminal station name
WSS	whether has been sent to the wireless terminal of station
WU	whether the information has been updated in the bus-location-station table

Data Processing key Algorithm of Bus Data Center. Considering the requirements of real-time, economics, and technical feasibility, it is not advisable to transmit the location information of each bus to the correlative wireless terminals of the bus station.

Since buses run in an orderly sequence, all buses of each route can be ordered in running sequence and be stored by records (see Table 3). Depending on Table 3, the system only sends the current bus location to the "empty" station terminal between two buses, as shown in Figure 3. A bus "parked" at a certain station, means the bus is stopping at the station, or has been driven out of the station, but has not yet reached the next station.

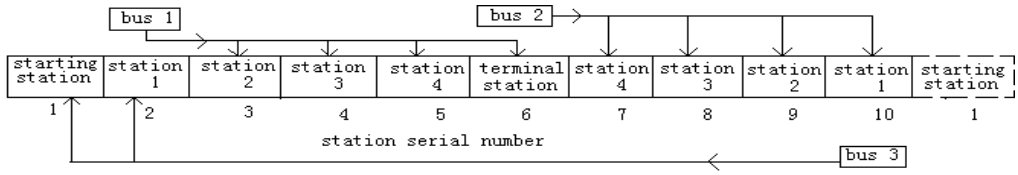

Figure 3. Sending algorithm of bus location information

The driver presses the button of arrival when bus arrives at a station. The bus terminal stores all the correlated information of each station terminal in memory orderly, so we can know the location of the bus by checking the button signal. After collecting the arriving signal, the bus terminal will send the current location to the bus company data centers.

DEVELOPMENT OF WIRELESS TERMINAL AND COMMUNICATION PROTOCOL

Development of Wireless Terminal. **The** wireless terminal controls the GPRS module with an 8 or 16 bit microcontroller via AT commands to achieve SOCKET communication (*Wang, 2006*), and outputs to an LED display module through parallel ports. The communication steps are introduced as follows (Siemens MC55 GPRS modules).

- Log on GPRS network by the special APN of the bus system.

  AT^SICS=0, conType, GPRS0<CR>

  AT^SICS=0, apn, "special APN"<CR>

- Establish SOCKET connections. Connect IP address XXX.XXX.XXX.XXX and port number PORT-S of bus data center server.

  AT^SISS=1, srvType, socket<CR>

  AT^SISS=1, conId, 0<CR>

  AT^SISS=1, address,"socktcp://XXX.XXX.XXX.XXX:PORT-S"<CR>

- Open TCP connection, and gain IP addresses 10.XXX.XXX.XXX and local port number PORT-C.

  AT^SISO=1<CR>

  AT^SICI=0<CR>

  ^ SICI: 0, 2, 1,"10.XXX.XXX.XXX"

  AT^SISO? <CR>

  ^SISO:1,..,"10.XXX.XXX.XXX:PORT-C","XXX.XXX.XXX.XXX:PORT-S"

Read *n* bytes of data; *n* is not more than 1500.

AT^SISR=1, *n*<CR>

Write *m* bytes of data; *m* is not more than 1500.

AT^SISW=1, *m*<CR>

<*m* bytes of data><CTRL+Z><CR>

Design of Communication Protocols between Bus Data Center and Wireless Terminal. Communication protocols between the bus data center and wireless terminal are divided into three kinds of data types: IP address and port number of wireless terminals are sent to the data center, wireless terminal of sends its location information to the data center, and the information from the data center is sent to the wireless terminal of the station. The protocols are shown in Figure 4.

1. protocol that IP address and port number of wireless terminals are sent to the data center.

beginning character					end character	
@	identification(bus/stop)	SIM NO.	IP address	port number	time	%

2. protocol that wireless terminal of bus sends its location information to the data center.

beginning character					end character	
$	bus SIM NO.	bus route number	current location	IP address	time	&

3. protocol that information data center has processed is sended to the wireless terminal of station plate.

beginning character					end character
#	stop SIM NO.	bus route number	the recent bus location	time	*

Figure 4. Communication protocols

CONCLUSION

Tests show that the plan for the urban bus location display system based on GPRS is correct. The bus wireless terminals, bus location displaying terminals, bus company data center, and GPRS Network can run stably. The key algorithm of data processing and the communication protocols between the data center and the wireless terminal is efficient.

The bus location displaying system can display the location of the nearest bus in each bus station which indicates that how far the closest bus is from this site. GPRS is a kind of wireless communication with a high data transfer rate, low error rate, low cost, and is free from the impact of bad weather.

ABSTRACT

An approach to short-term traffic flow prediction based on empirical mode decomposition (EMD) and artificial neural network (ANN) is proposed. The traffic flow is decomposed into different modes by EMD, and these different modes are predicted by appropriate ANNs. The predictive traffic flow is obtained by adding up all predictive values. This method is used to predict traffic flow with the actual measurement data. The results show that the proposed method has high predictive accuracy, and is more successful than the outcome of directly using ANN prediction.

INTRODUCTION

Traffic flow forecast has been a popular research topic in the field of intelligent transportation systems (ITS). Real-time and accurate traffic flow forecast is the premise and key of traffic control(Gao et al.2008; Liu et al.2004). Short-term traffic flow prediction analyzes traffic data and predicts the future traffic status within minutes, so that appropriate and timely traffic control measures are taken to provide real-time and effective road information for travelers. Dynamic path induction is used successfully to save travel time, ease road congestion, reduce pollution, and save energy (Gao et al.2008). Therefore, the traffic flow forecast is the premise of real-time control, and also is the theoretical basis of intelligent transportation systems.

In the 1960s, people began to use prediction models of other fields for short-term traffic flow forecasting, and a variety of prediction models and methods were developed. Generally speaking, there are four types of forecasting methods: based on traditional statistical theory approach, based on ANN approach, based on non-linear theory methods, and methods based on emerging new technologies (Gao et al.2008; Liu et al.2004). But the transport system is a giant time-variable, non-linear, uncertain, and complex system. Therefore, the prediction accuracy of

existing models have not achieved satisfactory results, and their accuracy and real-time usability need be improved.

In this paper, an approach to short-term traffic flow prediction based on empirical mode decomposition (EMD) and artificial neural network (ANN) is proposed. This method is used to predict traffic flow with actual measurement data. The results show that the proposed method has high predictive accuracy, and is more successful than the outcome of directly using ANN prediction.

EMD AND ANN TRAFFIC FLOW PREDICTION MEODEL

EMD is a new method to deal with non-linear and non-stationary signals. Non-stationary signals can be broken down into a number of intrinsic mode functions (IMF) by different scale level fluctuations or trends with EMD. Each component contains a different composition of the signal from high to low frequencies, and the EMD method is an adaptive decomposition based on the inherent characteristics of the signal itself (Huang N E et al.1998; 2003; Xuan et al.2008). The traffic flow is a typical non-stationary signal, therefore if it is decomposed by EMD, each component can better reflect the nature of the traffic flow and potential trends.

EMD algorithm. IMF is an innovative concept proposed by Huang (1998) in empirical mode decomposition, which is defined as a function that satisfies the following conditions: in the entire data set, the number of extrema and the number of zero crossings must either be equal or differ at most by one, at any point, the mean value of the envelope defined by the local maxima and the envelope defined by the local minima is zero. Then the sifting process is:

(1) For a given signal $x(t)$, construct its upper envelope and lower envelope by connecting all local maxima and local minima with cubic spline functions, respectively.

(2) Compute the envelope's mean $m(t)$ and extract the detail $h(t) = x(t) - m(t)$. Regard $h(t)$ as new $x(t)$ and repeat the operation above until $h(t)$ satisfies the IMF conditions, then obtain the first order IMF $c(t) = h(t)$.

(3) Let the residual $r(t) = x(t) - c(t)$ be a new signal, repeat (1), (2) and (3), obtain the other orders' IMFs.

Finally, we can obtain

$$x(t) = \sum_{j=1}^{n} c_j(t) + r_n(t)$$

Then, the signal $x(t)$ is decomposed into n intrinsic modes and a residue $r_n(t)$.

ANN model. The ANN model is a parallel processing technique inspired by the desire to emulate human learning activity. The back propagation (BP) network is the most commonly used learning algorithm and the initial connection weights of the nodes change during the training process to minimize the overall network errors (Kuang et al.2004; Xiang et al.2006). By dividing the nodes into different groups, an ANN model generally consists of an input layer, one or several hidden layers, and an output layer, each of which includes several nodes. In this paper, the number of hidden layers is one. The input vector is n measured traffic data of k moment ago $(x_{k-1}, x_{k-2}, \cdots, x_{k-n})$, the output is the predictive traffic flow value of k moment, and transfer functions and the nodes number of hidden layers are choose according to the different IMFs.

EMD and ANN traffic flow prediction model. At first, the signal of traffic flow is decomposed to obtain a number of IMFs and a residue. The random interference component is removed, and each IMF and residue is predicted by the appropriate artificial neural networks. Finally, the traffic flow is obtained by adding up all predictive values.

The specific algorithm is as follows:

Step 1: Carry out the traffic flow decomposition with EMD

Step 2: Analyze the IMFs, and remove the random interference

Step 3: Normalize all useful components of the traffic flow

Step 4: Establish different neural network models to predict the useful components

Step 5: Anti-normalize all predictive outcomes

Step 6: All anti-normalized data are accumulated to obtain the result of traffic flow prediction

Evaluation index. In order to evaluate the performance of the proposed method, following four indicators are selected as the basis for evaluation in this paper [8].

(1) Mean Absolute Error

$$MAE = \frac{1}{N}\sum_{t=1}^{N}\left|y_t - \hat{y}_t\right|$$

(2) Mean Square Error

$$MSE = \frac{1}{N}\sqrt{\sum_{t=1}^{N}\left|y_t - \hat{y}_t\right|^2}$$

(3) Mean Absolute Percent Error

$$MAPE = \frac{1}{N}\sum_{t=1}^{N}\left|\frac{y_t - \hat{y}_t}{y_t}\right|$$

(4) Mean Square Percent Error

$$MSPE = \frac{1}{N}\sqrt{\sum_{t=1}^{N}\left|\frac{y_t - \hat{y}_t}{y_t}\right|^2}$$

TRAFFIC FLOW PREDICTION WITH EMD AND ANN

To assess the performance of the proposed method, a measurement data of 30 second traffic flow with 660 points is used as the test data, the first 510 data are used as training samples of ANN, the last 150 data are used as test samples. The waveform is shown in Figure 1.

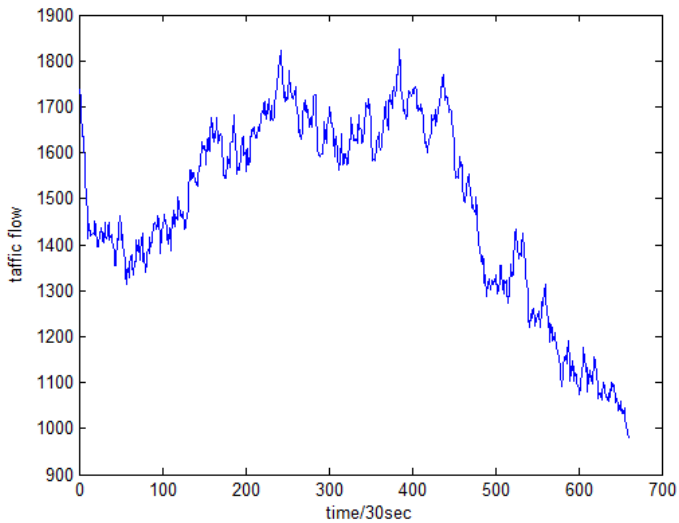

Figure 1. 30 second traffic flow data

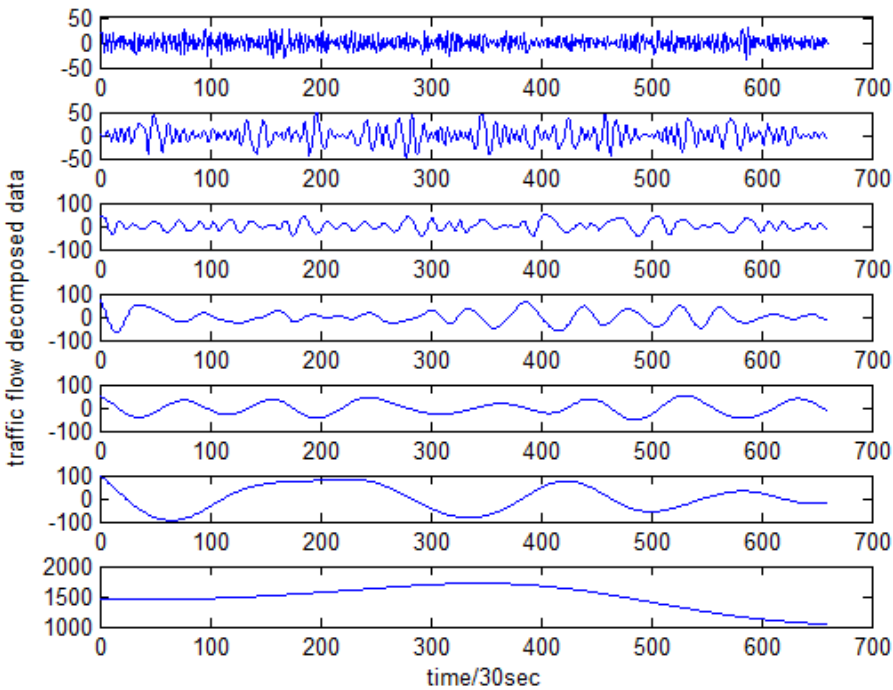

Figure 2. Traffic flow decomposition with EMD

According to the EDM algorithm, the traffic flow data is decomposed, and the result is shown in Figure 2. The traffic flow data is decomposed into 6 IMFs and 1 residue. In Figure 2, from top to bottom, the waveforms are IMF1 to IMF6 respectively, and the last is residue. Through the EMD, fluctuations of various components of traffic flow data are reduced. We can see that the first IMF is mainly random interference, so IMF1 is removed directly as random noise, while the other 5 IMFs and residue are predicted using different ANN models. All the predictive value of ANN models is accumulated, and the ultimate predictive value of traffic flow can be obtained. The result is shown in Figure 3.

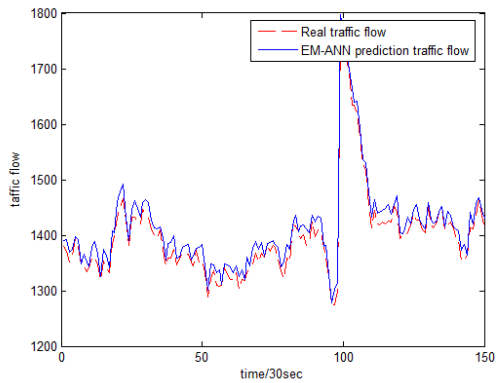

Figure 3. The forecast and the actual value with EMD-ANN

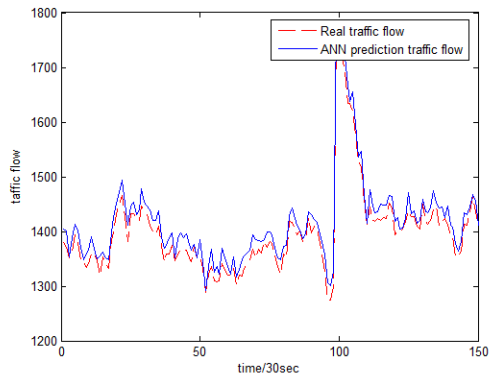

Figure 4. The forecast and the actual value with ANN

Table 1. Performance index of EMD-ANN and ANN

Performance Index / Prediction Method	MAE	MSE	MAPE	MSP
ANN	21.8906	6.287	0.0531	0.0346
EMD-ANN	12.3267	3.1530	0.0336	0.0121

In order to illustrate the superiority of the EMD-ANN method, the traffic flow is predicted directly using ANN. The result is shown in Figure 4. The prediction error of the EMD-ANN and ANN method is shown in Table 1. From Table 1, we can see that the EMD-ANN method has higher predictive accuracy than the ANN method.

CONCLUSION

In this paper, the method on the short-term traffic flow prediction is studied using EMD and ANN models. The traffic flow is decomposed into different IMFs and one residue by EMD. The random interference IMF is removed directly, and the useful IMFs and residue are predicted by appropriate ANN models. The traffic flow

is obtained by adding up all predictive values. This method is used to predict traffic flow with actual measurement data. The results show that the proposed method has high predictive accuracy which is higher than the accuracy of directly using the ANN model. The predictive method based on EMD and ANN is an effective prediction method of short-term traffic flow.

ABSTRACT

The design of phase sequence is very important to signal control timing. The research embodied in this paper presents a new method of designing the phase sequence of the signal control, based on the conglomeration of pedestrians and bicycles in our country. Firstly，we present a new definition of the conglomeration of pedestrians and bicycles at the first phase after analyzing the two phases of the releasing characteristics of the signalized intersection.

Next, we present a new method which is based on suppositional grids to describe the conglomeration. Then, we present a new method to optimize the phase sequence based on the time-space resource usage of the intersection. In order to optimize the phase sequence quantitatively, we found the model of conflict timing between the conglomeration and the vehicles. As for estimating the optimal phase sequence, we used the model of conflict timing.

Finally, the application of this method is illustrated with the signalized intersection of Pingleyuan in Beijing. Under the simulation, the method gives an optimized result.

1. INTRODUCTION

Mixed traffic phenomena are one of the most remarkable characteristics in Chinese cities, which can cause traffic congestion and accidents in urban intersections. The optimization of the phase sequence of the signal control is the basis for the signal timing optimization. In view of the mixed traffic phenomena in China, this paper presents a new definition of the conglomeration of pedestrians and bicycles, and it presents a new method to optimize the phase sequence based on the time-space resource usage of the intersection. By optimizing the signal timing, we can cut down on traffic congestion and accidents at intersections.

There is some past research on signal phase sequences. In the HCM 2000

example, the vehicles were considered to be the main object for optimizing the phase sequence, while pedestrians and bicycles were seen as the affection coefficient for the saturation flow of the vehicles (HCM, 2000). In the "Manual of Traffic Signal Design", optimization advice is presented for the left and right turning phase without considering the pedestrians and bicycles (James H.Kell, 1991). Shladover proposed a method for the bicyclist phase, creating the signal phases by synchronizing the traffic signal with video images (Shladover, 2009).

In China, Yang Xiaoguang presented the combination phases for pedestrians, bicycles and vehicles (Yang, 2003). Wang Dianhai suggested setting the left turn bicycle phase and end bicycle phase and pedestrian phase ahead of time (Wang, 2004). Xu Liangjie proposed the method of dynamic ordinal samples cluster algorithms to optimize the phase sequence (Xu, 2005). Generally, these researchers mainly focus on the vehicle or consider the pedestrians and bicycles separately to optimize the phase sequence. This paper will present a new method to calculate the phase sequence based on the conglomeration of pedestrians and bicycles.

2. CONGLOMERATION OF PEDESTRIANS AND BICYCLES

Before giving the definition of the pedestrians and bicycles conglomeration, it is necessary to analyze the releasing characteristic in the green time of the signalized intersection. Then we will present a new method which is based on the suppositional grids to describe the conglomeration.

2.1 The releasing characteristic in the green

In China, there are many pedestrians and bicycles crossing intersections. Because of the red light of the controller, there are often a lot of pedestrians and bicycles assembled at the stop line. When the green light shows, the assembled pedestrians and bicycles begin to enter the crosswalk together (Figure 1). After the assembled pedestrians and bicycles all enter the crosswalk, the remaining pedestrians and the bicycles will enter the crosswalk randomly (Figure 2).

Based on the method of video analysis, we analyzed the releasing characteristic quantitatively and found the results shown in Figure 3, the time-space curve of the pedestrians and bicycles. One curve stands for a pedestrian or a bicycle. The x-coordinate stands for the green time, and the Y-coordinate stands for the displacement of the pedestrian or a bicycle. From the figure we can see that, in the first 8 seconds, the curves are very dense, it shows that the pedestrians and bicycles are clustered densely. After the 8th second, the curves are sparse, it shows that the pedestrians and bicycles are spread out. We can consider the first 8 seconds as the first phase of the releasing time, and the green time after the 8th second is considered the second phase.

Figure 1. the conglomeration mode.

Figure 2: the individual mode.

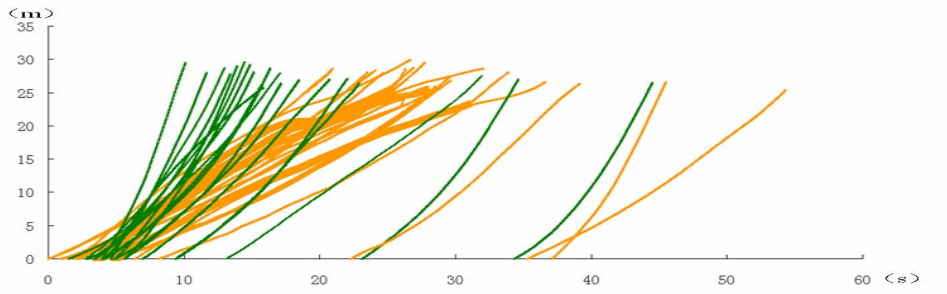

Figure 3. Time-space curve of the pedestrians and bicycles in one cycle

From these results, we can determine the definition of the conglomeration of pedestrians and bicycles: In the first phase of the releasing time, the pedestrians and the bicycles enter the crosswalk densely like a pack, and then they keep the shape of a pack to get through the crosswalk. This is considered to be the conglomeration of pedestrians and bicycles. The conglomeration of pedestrians and bicycles is the most distinct characteristic of the releasing process.

2.1 THE METHOD OF SUPPOSITIONAL GRIDS

In order to describe the conglomeration of pedestrians and bicycles, based on the occupation space of the pedestrians and bicycles and the crosswalk criterion, we present a method of suppositional grids to calculate the occupation, and the detailed method is described below.

In the HCM 2000 example, the space of the pedestrians walking in the crosswalk is $0.3\,m^2/P$. When the establishment of the road was evaluated, the space of the pedestrians walking in the crosswalk is $0.75\,m^2/P$ (HCM, 2000). In China, the research of the space of the pedestrians walking in the crosswalk is $0.35\text{-}1.2\,m^2/P$, the space of the bicycles in the crosswalk is $2.0\text{-}4.0\,m^2/B$ (REN, 2003).

In the crosswalk criterion (GB5768-1999) of China (GB5768-1999), the width of one zebra crossing is 0.45m, and the length of one zebra crossing is at least 3.0m which can be added 1.0m as one grade. The spacing of the two zebra crossings is 0.60m.

By way of calculating the occupation of the conglomeration of pedestrians and bicycles, we consider the pedestrians and bicycles as one unit, and the space of this unit is $0.3\text{-}4.0\,m^2/unit$.

In view of the research of the space of the pedestrians and bicycles and the

crosswalk criterion (GB5768-1999), we present the method of suppositional grids to divide the crosswalk. The width of the suppositional grid is 1.0m, and the length of the suppositional grid is 1.05m. Figure 4 shows the division of the crosswalk.

Based on the definition of suppositional grids, we can determine the size of the conglomeration of the pedestrians and bicycles. If the spacing of the projection area of the unit is less than one suppositional grid, and the quantity is more than two suppositional grids, the number of the suppositional grids is the quantity of the conglomeration of pedestrians and bicycles.

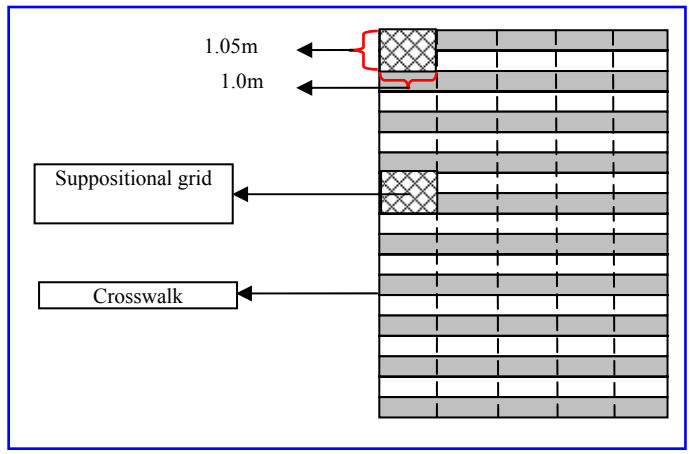

Figure 4. the suppositional grids of the crosswalk

3. THE METHOD OF THE PHASE SEQUENCE DESIGN

This paper presents a new method to optimize the phase sequence based on the time-space resource usage of intersections.

We should reduce the conflict time of the conflict area to improve the efficiency of the signalized intersection. First, we must find the conflict timing model between the conglomeration and the vehicles. As we know, the conflicting area between the conglomeration and the vehicles is on the crosswalk of the intersection. This is shown in Figure 5, while the area Q is the conflicting area. Based on the method of the suppositional grids, we can find the conflict timing model that is shown on the formula (1). After we calculate the conflict timing between the conglomeration and the vehicles, we can optimize the phase sequence from adjusting the starting timing of the conglomeration and the vehicles, and determine the optimal phase sequences.

$$t=L/V+x(Q/Y) \qquad (1)$$

Where T—conflict time, L—the length of the conflicting area, V—the reduced velocity of the conglomeration, X—the time interval of the consecutive conglomeration, Q—the length of the “suppositional grids” of the conglomeration occupying, and Y—the transverse amount of the “suppositional grids”.

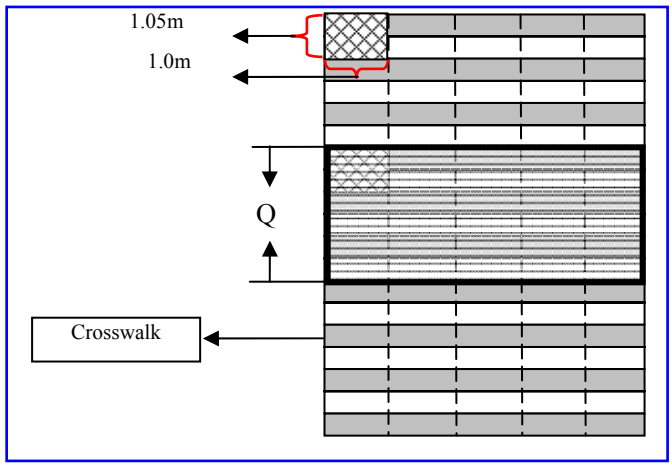

Figure 5. the conflicting area between the conglomeration and the vehicles

After determining the phase sequence through the method of the conflict timing model, we should choose a value to estimate the phase sequence. This paper chooses the time utilizing ratio of no-conflict to estimate the phase sequence. We can see that an intersection contains two kinds of resources:the space resource and the time resource. We found the model of the time utilizing ratio of no-conflict based on the time-space resource usage of the intersection.

The definition of the time utilizing ratio of no-conflict is a ratio between the no-conflict green timing and the whole green time in one signal cycle. It can estimate the intersection's efficiency, which is shown in the formula (2).

$$U = \frac{T - \sum_{i=1,j=1}^{n} (t_{(i,j)} - \bar{t}_{(i,j)})}{T} \qquad (2)$$

Where U—the time utilizing ratio of no conflicting, T—the whole green time of one cycle, n—the number of the conflicting area, $t_{(i,j)}$—the conflicting timing of the conflicting area, the letter "i" stands for the number of the vehicle flow, the letter "j" stands for the number of the crosswalk, and $\bar{t}_{(i,j)}$—the lead or lag time of the different phase sequences.

So from the model of the conflict timing we can determine the different phase sequences, and from the model of the time utilizing ratio of no-conflict we can estimate the phase sequences quantitatively. The optimization of the signal phase sequence is the first step to optimize the signal timing, and the time utilizing ratio of no-conflict is a very important estimation to optimize the signal timing following other values such as delay of the intersection, capacity of the interaction, and so on.

4. CASE STUDY

The application of this method is illustrated with the signalized intersection of Beijing Pingleyuan. The signalized intersection of Beijing Pingleyuan is a four-phase intersection. We chose the method of video analysis to investigate the intersection of

Beijing Pingleyuan. From the method of this paper, we calculated the conflicting time of the four import lanes with two directions applying the formula (1). The result is shown in Table 1.

Table. 1 the conflicting time of the intersection of Beijing Pingleyuan

Crosswalk	East		West		South		North	
Direction	N-S	S-N	N-S	S-N	E-W	W-E	E-W	W-E
Conflicting time（s）	5	6	6	7	3	4	3	5

If we want to reduce the conflicting time, we should adjust the signal phase sequence. From Table 1, we can see that, the scope of the adjustment of the east crosswalk and the west crosswalk is 5s-7s. The scope of the adjustment of the south crosswalk and the north crosswalk is 3s-5. We propose several strategies to adjust the signal phase sequence in Table 2, and we calculate the time utilizing ratio of no-conflict for every strategy to estimate the results by applying the formula (2). We used the simulation method to evaluate the strategies and determine the total delay of the intersection. From Table 2, we can see that the optimal signal phase sequence is number 4, and its time utilizing ratio of no-conflict is 1.0, but the total delay is 400.6s. This optimal strategy can produce a degree of order in the intersection, but the delay time could be better.

Table 2. four strategies and the time utilizing ratio of no conflicting

Design number	1		2		3		4	
Direction	N-S	S-N	N-S	S-N	E-W	W-E	E-W	W-E
Sequence adjust(s)	5	3	5	4	6	4	7	5
Time utilizing ratio of no-conflict	0.83		0.91		0.96		1.0	
Total delay(s)	509.2		328.0		366.6		400.6	

5. CONCLUSION

This paper presents a new method to analyze the phase sequence of signal controls based on the conglomeration of pedestrians and bicycles. We present a new definition of the conglomeration of pedestrians and bicycles after analysis of the signalized intersection. We present a new method to optimize the phase sequence based on the time-space resource usage of the intersection. The optimization of the signal phase sequence is a important step to optimize the signal timing. We will research the signal timing optimization of the intersection in the future study.

ABSTRACT

The effects of lane changing on the characteristics of traffic flow have not been investigated sufficiently. In this paper, we use a driving model based on finite-state-machine to investigate the effects of lane changing on macroscopic characteristics of traffic flow. In homogenous traffic, the effects of lane changing are not significant. However, in heterogeneous traffic composed of vehicles with different maximum speed, the flux in the low to middle density increase if lane changing is permitted. Furthermore, in heterogeneous traffic where vehicles only have difference in normal acceleration, lane changing can't increase the flux significantly. In conclusion, the effects of lane changing on traffic are tightly related to both the difference of vehicles and the density of traffic.

INTRODUCTION

Lane changing is one of the basic maneuvers in multi-lane traffic. However, the effects of lane changing on the characteristics of traffic flow have not been studied sufficiently. A few lane changing models have been proposed (Gipps 1986). Yang noted that there are two types of lane changing, named discretionary lane changing (DLC) and mandatory lane changing (MLC) (Yang 1998). Hidas pointed out the phenomenon of the forcing gap in lane changing (Hidas 2005). Kim found that the relationship of speed-flux in merging sections are different from that of the basic section because of the high frequency of lane changing (Kim, Son et al. 2002). Tanaka reported that there are high flux and low flux states if lane changing is permitted on two-lane roads (Tanaka, Nagatani et al. 2008). The effects of lane changing on the capacity of the highway are not clear. Coifman found that the capacity decreased because of lane changing (Coifman, Krishnamurthy et al. 2003). However, Jia found that the effects of lane changing are different in homogenous and heterogeneous traffic (Jia, Jiang et al. 2005; Jia, Li et al. 2006).

In this paper, we use a finite-state-machine (FSM) framework to model the driving behavior. Then we study the characteristics of homogenous and

heterogeneous traffic flow using microscopic simulation. Finally, the effects of lane changing are summarized.

FSM FRAMEWORK OF DRIVING

Driving is a complex process; it can be described with a finite state machine (FSM), as shown in Figure 1. The FSM has five states: staying in current lane (KCL), DLC intention, MLC intention, forcing gap (FG) and performing lane changing (PLC). At the beginning, we set the machine in the KCL state. MLC and DLC are different in the process of intention generating and disappearing. The MLC intention should persist till lane changing is finished. The DLC intention should only persist for certain duration and then disappear. If the vehicle is in the KCL state, and special conditions are satisfied, the machine switches into the state DLC Intention (DLCI) or MLC Intention (MLCI). In the MLCI state, once the safety condition is satisfied, the machine switches into the state PLC. If the safety condition has not been satisfied after a pre-determined length of time, the machine switches into the FG state. In the state DLCI, the driver checks the safety condition for a certain duration, if the condition is satisfied, the machine switches into PLC, otherwise the driver's intention of lane changing disappears and the machine switches into KCL. This model has been validated and can reproduce the characteristics of traffic flow.

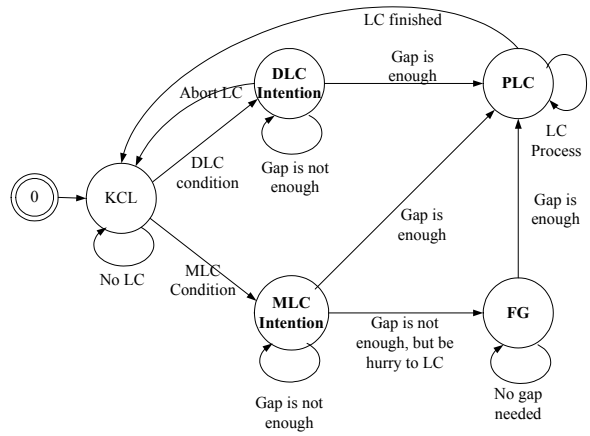

Figure 1. The Finite state machine of driving.

A decision tree is employed to model the longitudinal movement of vehicles (Zhang, Li et al. 2005). The traffic is classified into several states according to the lead gap and the difference of velocity between subject and its leader. Based on the traffic state, driver selects a basic maneuver from accelerating, decelerating or cruise. Once a basic maneuver is selected, the accelerate/decelerate rate will be calculated. The normal acceleration is smaller in high speed than in low speed

(Bham and Benekohal 2004), the two acceleration are a_1 and a_2.

EFFECTS OF LANE CHANGING IN HOMOGENOUS TRAFFIC

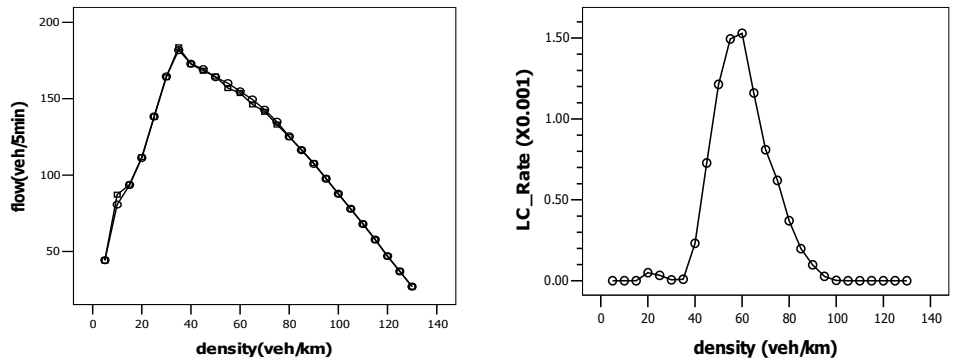
We investigate the effects of lane changing in homogenous traffic. Set the length of a two-lane road $L = 2000m$. There is only one type of vehicle on the road. Set $a_1 = 1.11, a_2 = 0.37$. In scenario LC, lane changing is permitted, $p = 0.5$. In scenario NLC, lane changing is not permitted, $p = 0$.

Initially, vehicles are located on the two lanes in a random manner. For density $5 < \rho < 130$ veh/km, with increment 5, we make 20 replications of simulation for each setting. In each test, we collect flux data and count the number of lane changes in steady state ($t \in [1000,1300)$). Then we calculate the mean of flux and lane changing rate in each density.

The relationship of flux-density in the two scenarios is depicted in Figure 2(a). The relationship of LC rate-density in scenario LC is shown in Figure 2(b). LC rate is defined as the ratio of number of lane changes in a unit time to the total number of vehicles. Counter intuitively, the flux-density curves have no significant difference in these two scenarios, though lane changes do occur in scenario LC.

The possible explanation is that flux reached its peak near the density $\rho = 40$. The gap between adjacent vehicles is large, there is almost no need to change lanes, as shown in Figure 2(b). Because lane changing seldom occurs at this density, the effect of lane changing is not significant. In density $40 \le \rho \le 80$, lane changing occurs frequently.

The gap between vehicles is small, lane changes do improve the speed of the subject vehicle, but at the same time, the followers in target lanes are hindered. The average speed does not increase, and the flux does not increase. Overall, flux does not increase even if lane changing is permitted in homogenous traffic.



(a) Flux-density in two scenarios (b) LC Rate-density in LC

Figure 2. Characteristics of homogenous traffic flow.

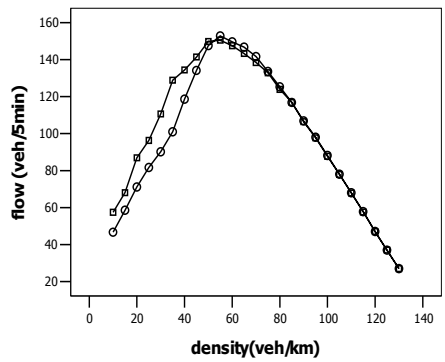
EFFECTS OF LANE CHANGING IN DUAL-SPEED MIXED TRAFFIC

Here we study the effects of lane changing in the mixed traffic where there are two vehicles, and the only different is maximum speed. The maximum speed of the fast vehicle is $v_{\max} = 30m/s$, and slow vehicle is $v_{\max} = 10m/s$. Set the mix ratio of slow vehicles $f = 0.05$.

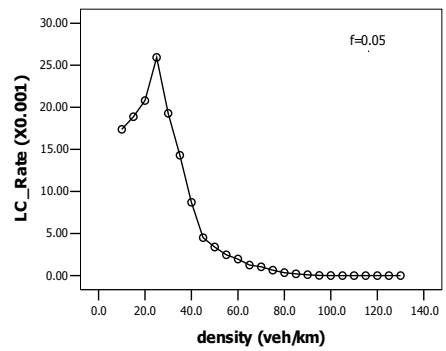
The flux-density relationship in two scenarios is depicted in Figure 3(a). The LC rate-density relationship in scenario LC is depicted in Figure 3(b). The flux in scenario LC is significant great than in scenario NLC when density is lower than the critical density. It implies that lane changing has effects if vehicles' max speeds are different, especially in the low and middle density.

The possible explanation is that in low density, the fast vehicle is hindered by the slow vehicle and generates intention to change lanes. The safety condition for lane changing is easily satisfied because the gap is large, so lane changing occurs frequently. After lane changing, the fast vehicle can increase its speed and slow vehicles are not affected.

The flux of mixed traffic increases because of lane changing in low density. In high density, the average speed is low, the fast vehicle and the slow vehicle have no distinction in their speed, lane changing seldom occurs, and the effect of lane changing is not obvious. These results imply that the difference of vehicle speed is important to the effects of lane changing.



(a) Flux-density in two scenarios



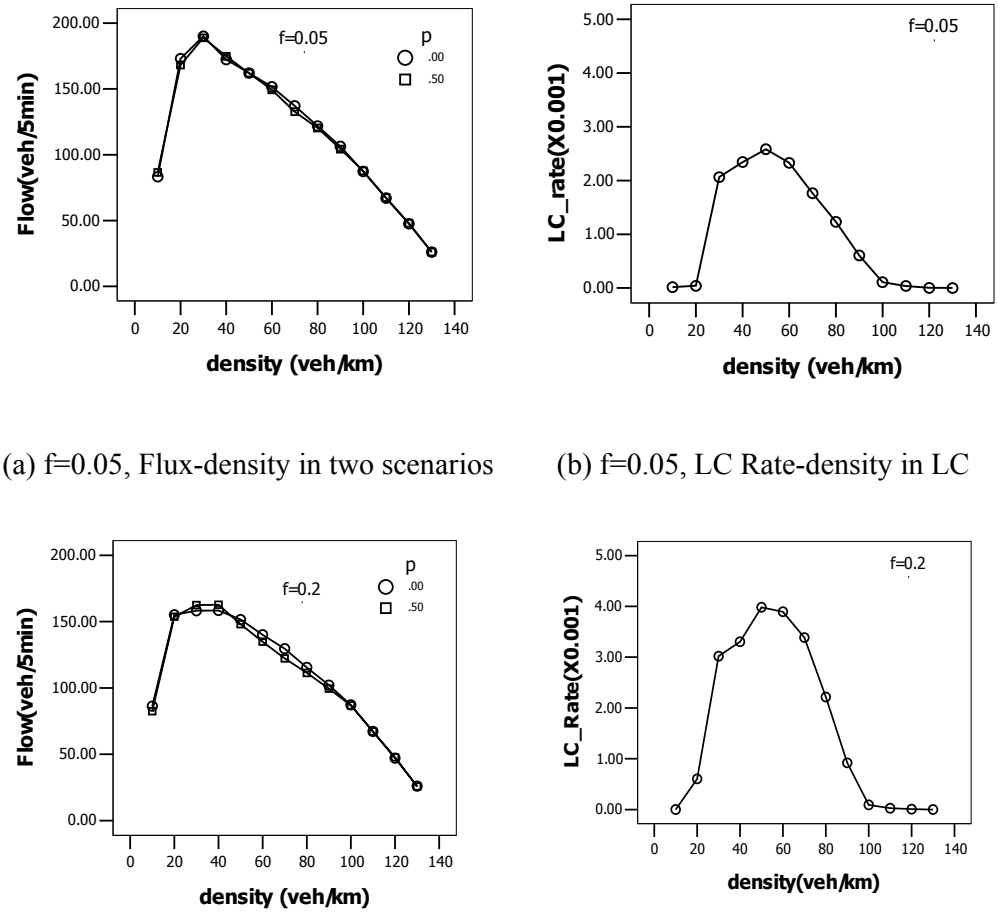
(b) LC Rate-density in LC

Figure 3. Characteristics of heterogeneous traffic with different max speed.

EFFECTS OF LANE CHANGING IN DUAL-ACCELERATION MIXED TRAFFIC

In this section we study the effects of lane changing in the mixed traffic where vehicles have different acceleration parameters. For type I, set

$a_1 = 1.3$, $a_2 = 1.0$, and type II $a_1 = 0.6$, $a_2 = 0.3$. The maximum speed of all vehicles is $v_{\max} = 30 m/s$. Set the mix ratio of type II vehicles $f = 0.05$ or 0.2 respectively. Initially all the vehicles are distributed on the two-lane road in a random manner. Make 20 replications for each density. Results are shown in Figure 4.



(a) f=0.05, Flux-density in two scenarios (b) f=0.05, LC Rate-density in LC

(c) f=0.2, Flux-density in two scenarios (d) f=0.2, LC Rate-density in scenario

Figure 4. Flux-density and LC rate-density in Dual-acceleration mixed traffic.

Figure 4(a) shows the flux-density curves when the mix ratio of low acceleration vehicles is small (f=0.05), and (b) is the LC rate-density curve in a scenario LC when f=0.05. Figure 4(c) and (d) are for mix ratio f=0.2. As shown in (a) and (c), lane changing has no obvious effect on the flux, even when the mix ratio of the low acceleration vehicle is 0.2. These results may be explained by the relationship of LC rate-density. The LC rate is very small, only several in a thousand, even though it will rise up when the mix ratio rises. These results indicate that lane changing has no significant effects on the characteristics of mixed traffic composed of vehicles with different acceleration rates.

CONCLUSION

The effects of lane changing on traffic have been unclear until now. In this paper we use a finite-state-machine to model driving on a multi-lane road. We investigate the effects of lane changing on the characteristics of traffic flow in several situations with microscopic simulation. In homogenous traffic, we find that lane changing behavior has no significant effects on flux. However, in the mixed traffic composed of fast vehicles and slow vehicles, the flux is greater than those in the scenario without lane changing. The effect is more obvious in low and middle density traffic than in high density.

Furthermore, in the mixed traffic composed of vehicles with differences in their normal acceleration, lane changing has no significant effects on flux. Based on these simulation results, the following conclusion may be made: the effects of lane changing on traffic are complicated, and closely relate to both the differences of the vehicles and the density range of traffic flow.

ABSTRACT

In general, two types of multi-fractality can be identified in time series. One type connects with a broad probability density function for the values of the time series, while the other connects with different long-range correlations of the small and large fluctuations. Recent analyses of traffic time series indicate that it exhibits multi-fractal properties. But which type of multi-fractality does it exhibit?

In this paper, multi-fractal detrended fluctuation analysis (MF-DFA) is used to study traffic speed fluctuations. Collected data shows that the speed time series, observed by microwave detector system on the outer side of the North Second Ring Road over a period of about 60 days, has strong multi-fractal properties. By comparing the fluctuation function of MF-DFA results for the original series to those for shuffled series, we find that the type of multi-fractality in traffic speed time series is consistent with long range correlations of the small and large fluctuations. In addition, by comparing the generalized Hurst exponent and multi-fractal spectrum of the original time series with those of the corresponding shuffled series, the results show that the multi-fractal properties of shuffled time series are stronger than those of the original time series, and both distribution multi-fractality and correlation multi-fractality are present in the speed time series.

INTRODUCTION

The investigation of the temporal fluctuations in traffic time series has recently revealed its potential for providing information related to prediction (Shang P., Li X., 2005; Safanov L.A. et al, 2002). In the study of seemingly complex phenomena such as traffic time series, fractal analysis techniques, developed to draw qualitative and quantitative information from the data, have been applied to the study of a variety of irregular non-stationary time series and have been found to be very useful for detecting deep dynamical features. These methods are mainly useful to detect the presence of long-range power law correlations that have been found to exist in a variety of systems (Shang P., Li X., 2005). Safanov et al (Safanov L.A. et al, 2002) showed that fractal behavior

in traffic time series could be due to delays in human reaction. Shang and Li (Shang P., Li X., 2005) showed that fractal and chaotic characteristics exist in the traffic system.

The traffic speed time series is studied using a fairly robust and powerful technique called multifractal detrended fluctuation analysis (MF-DFA) (Kantelhardt et al, 2002). This method provides a systematic means to identify and quantify the long-range correlation among data sets obtained from diverse settings (Kantelhardt J.W. et al, 2001; Yu C.X. et al, 2003; Seely A.J.E., Macklem P.T., 2004; Vjushin D. et al 2001; Ivanova K. and Ausloos M., 1999). One reason to employ the MF-DFA method is that it avoids spurious detection of correlations that are artifacts of non-stationarity in the time series.

The focus of this paper is on the intriguing multi-fractal properties of the traffic time series. In general, two different types of multi-fractality can be identified in time series: multi-fractlity due to a broad probability density function for the values of the time series and multi-fractality due to different long-range (time) correlation of the small and large fluctuations.

The paper is organized as follows. Section 2 describes the acquisition of traffic data. Section 3 provides the multi-fractal detrended fluctuation analysis of traffic time series. In Section 4, we show the comparison of the results of MF-DFA analysis for the original time series to the results for shuffled time series. We then detect the type of multi-fractality in the traffic time series. The conclusions are summarized in Section 5.

DATA DESCRIPTION

The basic data used in this paper was collected by microwave detector system in Beijing on the outer side of the North Second Ring Road over a period of about 60 days. The system provided data on volume and time occupancy of certain sections, so we indirectly obtained the average speed of the section during the collection period of two minutes through the vehicle length parameter set by the microwave detector.

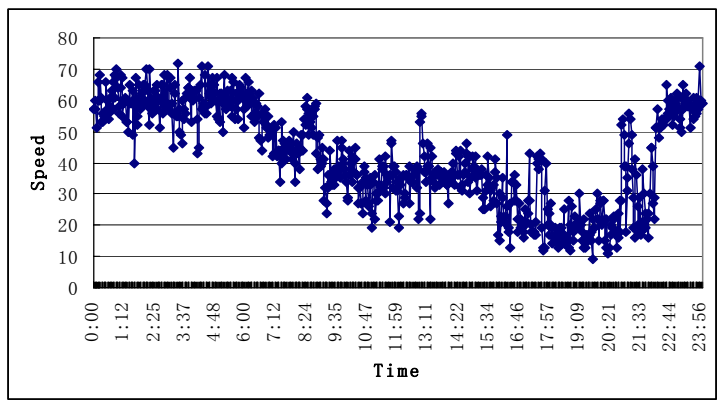

Figure 1. Time versus speed.

Figure 1 shows the time series plot of the speed data with the two-minute

sampling period, observed one day at one section on the outer side of the North Second Ring Road. A visual inspection of the speed series reveals significant variations in speed, but this is not enough to say anything regarding the existence of multi-fractality. Hence, additional tools are necessary to identify the possible presence multi-fractality.

MULTIFRACTAL DETRENDED FLUCTUATION ANALYSIS

Description of the Method. Traffic time series often present clear irregular dynamics, characterized by exchange of high frequency fluctuations that lend themselves to multi-fractal analysis evidencing the presence of different scaling behaviors for different intensities of fluctuations. Furthermore, the signal may appear non-stationary.

MF-DFA is a useful tool to characterize multi-fractality in non-stationary data. Traffic time series often exhibit non-stationary characters. So MF-DFA is used to analyze the multi-fractality of traffic time series. To illustrate the MF-DFA method, we consider the speed time series x_k, $k=1,2,...,N$.

First, estimate the signal profile:

$$Y(i)=\sum_{k=1}^{i}[x_k-\langle x\rangle],\quad i=1,...,N,\quad \text{here}\quad \langle x\rangle=\frac{1}{N}\sum_{k=1}^{N}x_k$$

Next, divide the profile $Y(i)$ into N_s=int(N/s) disjoint segments of equal length s. For each segment v, $v=1,2,...,N_s$ the local trend is to be calculated by least-squares fitting the polynomial of order m, to the data, and then obtain the qth-order fluctuation function:

$$F_q(s)\equiv\left\{\frac{1}{2N_s}\sum_{v=1}^{2N_S}\left[F^2(s,v)\right]^{q/2}\right\}^{1/q}$$

We are interested in how the generalized q dependent fluctuation functions $F_q(s)$ depend on the time scale s for different values of q. Determine the scaling behavior of the fluctuation function by analyzing log-log plots $F_q(s)$ versus for each value of q. If the time series x_k are long-range power-law correlated, $F_q(s)$ increases, for large value of s, as power-law:

$$F_q(s)\sim s^{h(q)}\quad (h(q)\text{ is the generalized Hurst exponent})$$

By knowing the spectrum of the generalized Hurst exponent, we can calculate the multi-fractal scaling exponent $\tau(q)$ using the following relation:

$$\tau(q)=q\,\tau(q)-1.$$

For various purposes, such as the description of the structure of the traffic time series over a certain period or the short-term prediction, it is helpful to be able to know the relationship between $f(\alpha)$ and $\tau(q)$. It can be easily obtained from a Legendre transformation (Peitgen H.O., Jurgens H., Saupe D., 1992).

Analysis of Multifractality. The MF-DFA fluctuation functions $F_q(s)$

are shown versus s in log-log plots in Figure 2. The different symbols correspond to the different values of the exponent q in the generalized averaging procedure q=-4.0,-2.0,-0.2,0.2,2.0,4.0. On a large scale, we observe the power-law scaling behavior.

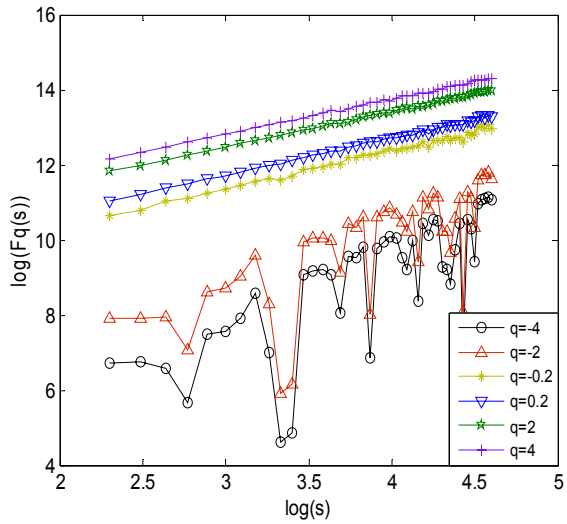

Figure 2. Graph of log(Fq(s)) versus log(s).

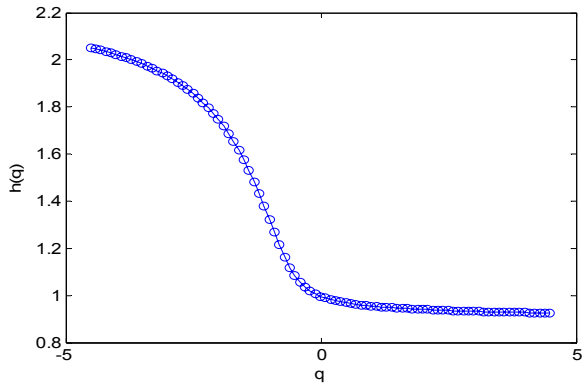

Figure 3. Graph of h(q) versus q.

Figure 3 shows the q dependence of the generalized Hurst exponent h(q) determined by fits in the regime 10<s<200, as shown for MF-DFA1. It can be seen that the exponent h(q) depends on q, and that h(q) decreases with increasing q.

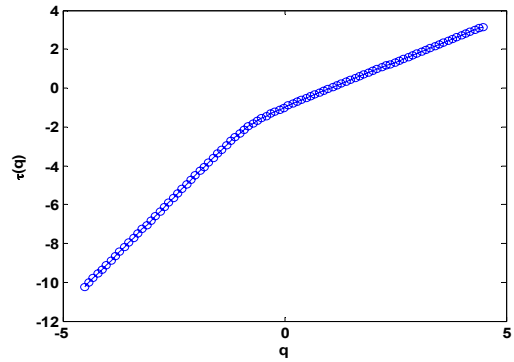

Figure 4. Graph of τ(q) versus q.

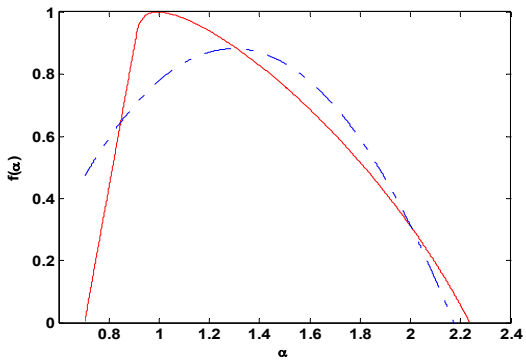

Figure 5. Graph of f(α) versus α.

Figures 4 and 5 show the corresponding exponents $\tau(q)=q\,\tau(q)-1$ and the corresponding $f(\alpha)$ singularity spectrum calculated from $h(q)$. We can see that the $\tau(q)$ curve clearly departs from a straight line (i.e. the q dependence of $\tau(q)$ is nonlinear). Furthermore, the spectrum $f(\alpha)$ displays the commonly observed bell shape. Thus, we conclude the speed time series has a behavior of multi-fractality.

The same method is used to analyze the shuffled time series. The results show that the $\tau_{shuf}(q)$ curve clearly departs from a straight line. The multi-fractal behavior of the speed time series cannot be removed by shuffling the original series. Comparing the spectrum for original series to those for shuffled series, it indicates that the shuffled series show stronger multi-fracrality than the original series.

Distinguishing the Two Types of Multifractality. As mentioned in the introduction, two different types of multi-fractality are prevalent in time series. The easy way to distinguish between them is to analyze the corresponding randomly shuffled series.

The shuffled series from correlation multi-fractals will exhibit simple random behavior. For distribution multi-fractals, on the contrary, the original $h(q)$ dependence is not changed. In order to directly determine the magnitude of the distribution multi-fractality, which is due to the broad probability density function, we compare the fluctuation function for the original series, $F_q(s)$, with

the corresponding shuffled series, $F_q^{shuf}(s)$. We consider the ratio $F_q(s)/F_q^{shuf}(s)$.

The scaling behavior of the ratio is:

$$F_q(s)\Big/F_q^{shuf}(s) \sim s^{h(q)-h_{shuf}(q)} = s^{h_{cor}(q)}.$$

If only distribution multi-fractality is present, $h(q)=h_{shuf}(q)$ depends on q. Deviation of $h_{cor}(q)=h(q)-h_{shuf}(q)$ from zero indicate the presence of correlations, and q dependence of $h_{cor}(q)$ indicates correlation multi-fractality. If only correlation multi-fractality is present, $h_{shuf}(q)$=0.5. If both distribution multi-fractality and correlation multifractality are present, both $h_{shuf}(q)$ and $h_{cor}(q)$ depend on q.

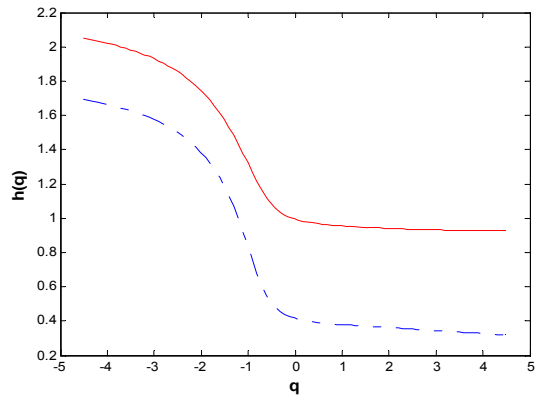

Figure 6. Graphs of h(q) versus q.

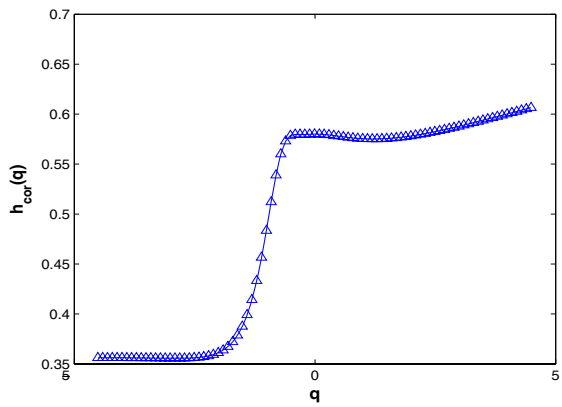

Figure 7. Graph of hcor(q) versus q.

The dependence of and $h(q)$ $h_{shuf}(q)$ are shown in Fig. 6. The solid line is the graph of $h(q)$ versus q and the dotted line is $h_{shuf}(q)$ versus q. The value of $h_{shuf}(q)$ decreases with increasing q. This suggests that the multi-fractality of speed time series is due to a broad probability distribution. Fig. 7 shows the q dependence on the slopes $h_{cor}(q)$. We can see that deviations of $h_{cor}(q)$ from zero indicate the presence of correlations, and q dependence of $h_{cor}(q)$ indicates correlation multi-fractality. From the data in Figures 6 and 7, we can conclude that both distribution multi-fractality and correlation multi-fractality are present in the speed time series.

CONCLUSION

The analysis presented in this paper shows that the MF-DFA method can reliably determine the multi-fractal scaling behavior of speed time series. In comparing the MF-DFA results for original series to those for shuffled series, we determine that the multi-fractality of the speed time series is mainly due to a broad probability density function, and that the multi-fractality of the shuffled series is stronger than that of the original series. These results may aid the application of multi-fractality in traffic flow theory. They also have signifigance for traffic time series theoretical modeling, short forecasting and the creation of control strategic plans.

ABSTRACT

In floating car data collection, the link average speed of floating cars is exported as link average speed of traffic flow. This results in low quality traffic information being shared with the public. This paper investigates the quantitative relationship between link average speed of floating cars and link average speed of traffic flow considering the traffic conditions, and verifies the research with simulated data based on a part road network in Changchun. The results show that the link average speed of floating cars can not be used instead of the link average speed of traffic flow, and that the link average speed of traffic flow can be estimated accurately using the method described in this paper.

INTRODUCTION

Link average speed is regarded as an effective traffic parameter for measuring the degree of traffic congestion. Floating car data collection has become one of the main means for collecting link average speed (Jiang G., 2004).

In typical case, a single vehicle type (taxi, bus, logistics vehicle etc.) is selected as the floating car in order to reduce system costs (Turner S.M., 1998). However, the structure of vehicle type in traffic flow is very complex, and the running characteristics of different types on road are distinctive. Therefore, the Link Average Speed of Floating Cars (LASFC) cannot usually be substituted for the Link Average Speed of Traffic Flow (LASTF).

Currently, research on floating car-based traffic information collection technology focuses on traffic data estimation methods based on individual floating car, and the average traffic data of floating cars is directly exported to users (Quiroga, C.A., 1997, Young-Ji, B., 2005 and Dong, J., 2006). The relationship between traffic data for floating cars and traffic flow is infrequently discussed.

In this paper, we present a method, verified with simulated data, for estimating the LASTF based on floating car data, through analyzing the relationship between LASFC and LASTF.

MEAN VALUE OF LASTF ESTIMATION

Generally, the characteristics of the traffic environment (road facilities, regulation measures, driving behaviors etc.) are consistent in a given area. Therefore, the mean value of LASTF can be expressed as a function of the mean value of LASFC.

Road grade is one of the main factors affecting the functional relationship between the mean value of LASTF and LASFC. In addition, the functional relationships are affected by the traffic conditions. For instance, the gap between the mean value of LASTF and LASFC is very small in that vehicles run with no interference among each other when the link is clear. The gap is very small, too, during congestion, when vehicles run in a queue. However, the gap is relatively large and vehicles run without order when the link's traffic condition is neither clear nor fully congested.

In this paper, the LASFC is used as the evaluation index for identifying link traffic conditions. The LASTF can be expressed as follows:

$$V_T = \begin{cases} f_1(V_F) & V_F \le V_1 \\ f_2(V_F) & V_1 < V_F \le V_2 \\ \vdots & \vdots \\ f_n(V_F) & V_{n-1} \le V_F \end{cases}$$

Where V_T is the LASTF, V_F is the LASFC, f_i is the function between the mean value of LASTF and LASFC for speed interval i, n is the quantity of speed intervals and V_i is the upper boundary for speed interval i.

INTERVAL OF LASTF ESTIMATION

The interval of LASTF cannot be calculated by this equation. The transmission error and fitting error of function are the main factors involved in estimating the interval of LASTF from LASFC (Fei Y., 2005).

The transmission of error from LASFC to LASTF by the pervious equation originates from the transmission of standard deviation from LASFC to LASTF on the basis of error theories (Sha D., 2003). The standard deviation of LASTF can be expressed as follows:

$$SV_T = \left| \frac{\partial f(V_F)}{\partial V_F} \right| \cdot SV_F$$

Where SV_T is the standard deviation of LASTF, SV_F is the standard deviation of LASFC and f is the function between the mean value of LASTF and LASFC.

The statistic of t-distribution structured by the sample mean value and standard deviation of LASTF can be expressed as follows:

$$\frac{V_T - \lambda}{SV_T/\sqrt{N}} \sim t(N-1)$$

Where λ is the population mean value of LASTF and N is the sample size of floating car.

The fitting error of function approximately obeys normal distribution. If α is the given confidence level and ε is the limit of fitting error with α for sample data, the interval of LASTF can be expressed as follows:

$$\left[V_T - \frac{SV_T}{\sqrt{N}} t_{\alpha/2}(N-1) - \varepsilon,\ V_T + \frac{SV_T}{\sqrt{N}} t_{\alpha/2}(N-1) + \varepsilon\right]$$

VALIDATIONS AND ANALYSIS

Traffic volume, travel time and signal timing parameters were collected by the authors at South Lake Street in Changchun, China, on Aug 18, 2008. Figure 1 shows the surveying route and sections.

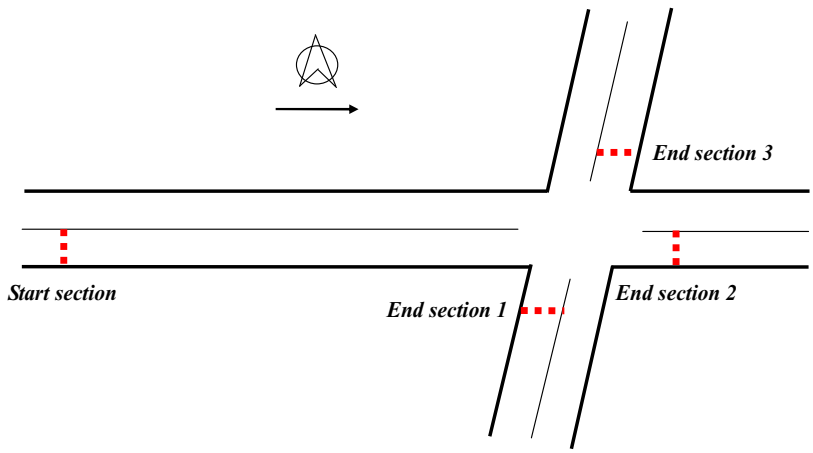

Figure 1. Route and sections of data collection.

The mean value of the average speed (LASFC and LASTF) was calculated at five-minute intervals from 04:00:00 to 08:00:00 a.m. for five successive working days. Measurements were taken using VISSIM 4.20 calibrated by measured data. In addition, two setting plans of control signals were designed. First, control signals were working full-time from 04:00:00 to 08:00:00 (designated the complete control plan). Second, control signals were working from 04:00:00 to 05:00:00 and closed from 05:00:00 to 08:00:00 (called the partial control plan).

Figures 2 and 3 show the fitting effects between the mean value of LASFC and LASTF for the complete control plan and partial control plan, respectively.

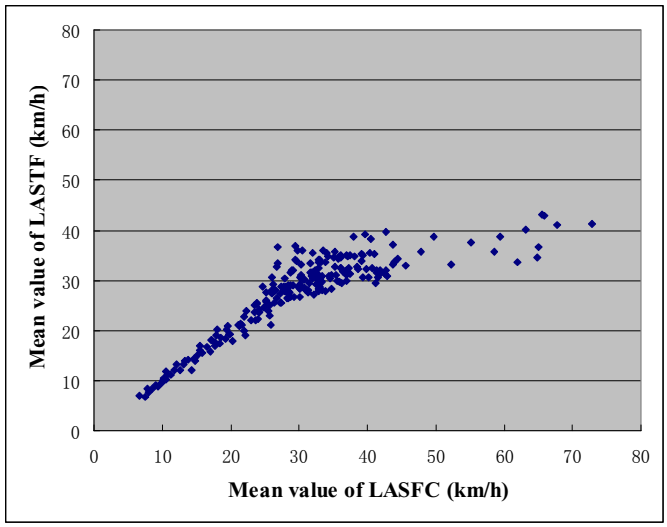

Figure 2. Fitting effect between the mean value of LASFC and LASTF for complete control plan.

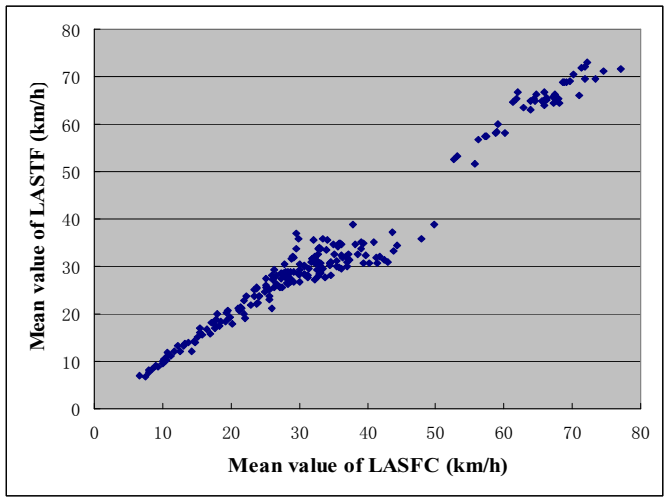

Figure 3. Fitting effect between the mean value of LASFC and LASTF for partial control plan.

Figures 2 and 3 show that the mean value of LASFC can be divided into three speed intervals: ≤25km/h, 25-50km/h and ≥50km/h. Tables 1 and 2 show the fitting results between the mean value of LASFC and LASTF for the complete control plan and partial control plan, respectively.

Table 1. Fitting results between the mean value of LASFC and LASTF for complete control plan.

Speed intervals	Functions	Correlation coefficients	Mean values of fitting error	Standard deviations of fitting error
≤25 km/h	y = 1.001x - 0.025	0.9789	0.8065	0.7756
25-50 km/h	y = 0.377x + 18.48	0.6052	2.1425	1.6000
≥50 km/h	y = 0.374x + 14.72	0.6033	2.3434	1.3195

Table 2. Fitting results between the mean value of LASFC and LASTF for partial control plan.

Speed intervals	Functions	Correlation coefficients	Mean values of fitting error	Standard deviations of fitting error
≤25 km/h	y = 0.982x + 0.225	0.9817	0.7876	0.6970
25-50 km/h	y = 0.432x + 16.26	0.6842	1.8460	1.5245
≥50 km/h	y = 0.853x + 8.884	0.9288	1.4942	1.1367

CONCLISION

In most cases, the LASFC cannot be equal to LASTF because sample sizes are much smaller than the total numbers of vehicles. The quantitative relationships between LASTF and LASFC are mainly affected by traffic conditions and setting plans of control signals. Consequently, the LASTF can be estimated from LASFC through the functions determined in advance.

RECOMMENDATIONS FOR FUTURE RESEARCH

The influencing factors on the quantitative relationship between LASTF and LASFC should be researched continuously using measured data, so that the functions determined are more accurate.

ABSTRACT

Mobile storage techniques have gained rapid development together alongside 3D technology, thus making mobile terminal integrated vision navigation possible. A vision vehicle navigation system can be a useful component of intelligent transportation systems, helping people to quickly find their destinations through realistic visual navigation guidance. In this paper, we propose a "reality vision" navigation system based upon a sequence geo-referenced image database. First, a sequence geo-referenced image collection technique with a land-based mobile mapping system is described. The sequence image database and index algorithm with spatial grid is designed to obtain fast query response with an image selection algorithm. Second, the road link model with sequence image database and a related navigation mode is presented as a way to realize reality vision navigation. Finally, we describe a prototype that is supported by Windows Mobile and can run with PDA、PND. The prototype can support an image database of a whole Wuhan city with data volume above 2GB and still achieve reality vision navigation.

INTRODUCTION

Due to the increasing public demand for spatial information services and location-based services, more and more navigation and LBS systems are being built. Navigation is a complex human activity (Burnett, Smith & May 2001) that has become a very popular research area. Researchers are especially interested in developing transportation systems that help drivers find their way in real or electronic worlds. The use of car navigation systems and personal navigation devices (PNDs) has spread rapidly, and all kinds of navigation systems come standard with new vehicles.. Many navigation systems use 2D maps to represent real-world objects, but they are unable to provide users with significant information

about the objects, such as their colors, shapes or materials. Features and navigational landmarks are not easily available in these systems, even though they can be very useful navigational tools. According to Coors et. al (2004), people recognize landmarks and find routes in the cities easier by using 3D vision models than using a symbolic 2D map which makes 3D visualization more relevant for navigation. Furthermore, the high visual correspondence between objects on a 3D map and real world objects increases the 3D map's navigational value.(Coors et. al., 2006). Thus the 3D vision personal or vehicle navigation systems have become a hotspot both in research fields and in practical areas.

Different applications involving 3D representations of real or virtual environments have been developed with the purpose of improving user navigation. Fukatsu S. et. al.(1998) introduced the simultaneous overlaying of global bird's-eye views as well as local views of the world. To aid the user in finding landmarks Elvins T. et. al.(1998) created miniature virtual worlds called Worldlets that act as 3D thumbnails. Sharkawi et. al (2008) proposed a 3D navigation system for virtual reality based on the 3D game engine for indoor or outdoor environment navigation applications. LI Yuan et. al (2008) presented a 3D indoor navigation framework of combining BIM with 3D GIS to provide 3D indoor navigation service for the emergency response. C. S. Wang et. al (2008) also successfully developed a 3D virtual navigation system for campuses, museums or art galleries. Chen (2008) discusses a multi-sensor-based 3D mobile navigation system and its application on telecommunication and social networking services. Although the 3D navigation has seen much development and various applications, it still some limitations. First of all, the 3D model represents a virtual scene which is very different from the real environment. The visual correspondence between 3D models and real-world objects still exists. Secondly, to generate the 3D map from satellite images and other 3D maps is time-consuming. Three-dimensional navigation cannot be widely used for the construction of another 3D map. Finally, the 3D map has demanding system memory and storage requirements.

In the following pages, we propose a reality vision navigation system based on a sequence geo-referenced image database. The geo-referenced images are taken as a 3D map, which produces a realistic representation of the scene. Thus, the images reduce the difference between the map and real world, helping people locate the landmark. The related data production and organization technique are discussed. An image navigation algorithm is presented to realize reality vision navigation. A reality image navigation prototype supported by windows mobile is developed.

RELATED WORKS

Image-based methods are a new approach to solving navigation problems. Instead of building a metric, or 3D, model of the environment, these methods work

directly within the sensor space, or image. The environment is represented as a topological graph, in which each node contains an image taken at some spot in the workspace. Typical image navigation techniques are adopted for Simultaneous Localization and Mapping, or SLAM. Visual SLAM systems using both monocular and stereo imaging to reconstruct 3D models of the environment have been studied in depth (A. J. Davison et. al, 2007). D. G. Lowe et. al (2004) and J. Tardif et. al (2008) present systems that use monocular vision and structure from motion techniques in order to provide a real-time estimate of the trajectory followed by a robot. Another typical image navigation application is that of unmanned aerial vehicles (UAVs). Researchers conduct image matching between a real-time imaging system and the image database for UAV navigation (Bruno Sinopoli et. al, 2001). Fiala (2005) provided an initial framework for immersive environments, in which the environment could be defined by a set of panoramas captured by catadioptric cameras, and the panoramas were defined as cubes. Sampling the plenoptic function from a single point and storing it in a cubic format is an idea used often in computer graphics. Fiala chose this idea for his framework because it would allow for the creation of new interpolated panoramas for 4 of the 6 sides used the image warping results of Seitz and Dyer (1996). Derek Bradley et. al (2008) presented an image navigation system based on real environments and using panoramas. This process has achieved actual applications for personal indoor navigation.

The current image navigation techniques focus on computer vision applications such as the SLAM and UAV systems. Images like monocular images or the panoramas have many advantages over 2D or 3D maps when seeking to achieve realistic representation. They can obviously be used for the vehicle navigation and personal navigation. Below we discuss the possibility of image navigation techniques vehicles and for personal navigation applications. These can be useful components of intelligent transportation systems, helping people to quickly locate their destinations through realistic visual guidance.

DATA COLLECTION OF IMAGE NAVIGATION

The land-based mobile mapping system integrates geodetic quality GPS, digital stereo cameras and inertial navigation system (INS) or dead reckon system (DR) that are mounted on a vehicle (Li D R et al, 2007). The system records highly accurate dual frequency GPS data and captures sequence images along the road in motion. Eight cameras are used in the mobile mapping system to form stereo images. GPS/INS/DR provides the orientation parameters for the stereo image models. It proves to be the most rapid, convenient, accurate and economic tool for collecting and updating geo-information data when used with sequence geo-referenced images, which can be used as the data source of image navigation (see Figure 1).

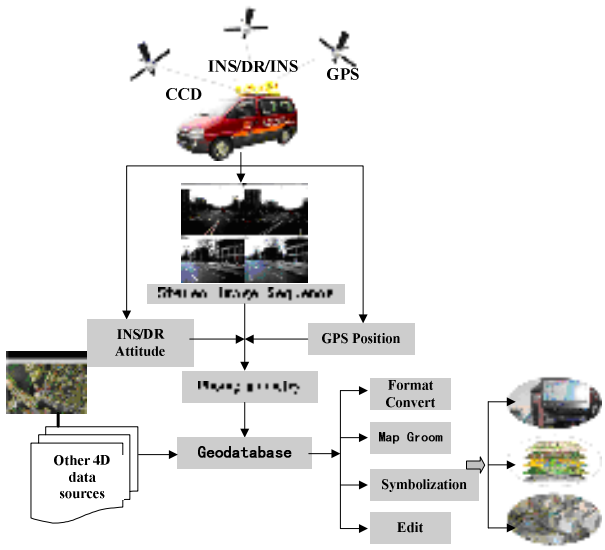

Figure 1 A land-based mobile mapping system for data collection

A land-based mobile mapping system is a close range photogrammetry system of direct geo referenced images. It closely simulates the perspective of human eyes and can collect a 360° sequence of street-view stereo image pairs at speeds over 100km/h. It can export vector maps, attribute data, and place digital measurable images in sequence. With the orientation data from DGPS/INS/DR, it can realize absolute position accuracy up to 0.5m and achieve a relative measurement at the centimeter level. The sequence geo-referenced image also records environmental information, such as transportation restrictions, POIs, and road networks to such a realistic degree that it can be used for navigation (see Figure 2).

Figure 2 Geo-referenced image databases for navigation

Geo-referenced images from a land-based mobile mapping system can overcome the probe error with manual labor, and it can reduce the time required to generate 3D maps. Consider, for example, street views of the real world. Compared to virtual 3D maps 2D maps, geo-referenced images can help people more easily

recognize a scene to locate an address or route. With a land-based mobile mapping system, we can obtain image navigation database directly from field work, thus making realistic 3D navigation possible.

IMAGE NAVIGATION MODEL

The geo-referenced images should integrate with 2D maps in order to support the path finding algorithm. Figure 3 represents the architecture of the image navigation system.

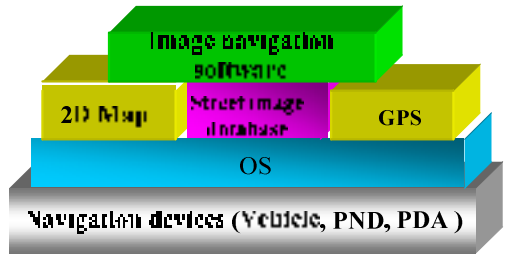

Figure 3 Architecture of the image navigation system

Street images are taken as a new data source combined with a 2D map. GPS matching with 2D map with the route can query the nearest reality image from the database to guide the user. The image navigation system should be run on common navigation devices such as a vehicle navigator, PND, PDA or smart phone. Thus the organization of the geo-referenced images becomes a key technique for the navigation system. Another question is the large volume of the image database. Usually, four to eight CCD sensors are installed on the land-based mobile mapping system. The data collection of street images can be defined as distance trigger of 8～20 meter or time trigger of 0.5～1. 0 second. One image has a volume size of 1.4 ～2. 0MB. A city about 200km^2 is about 1 TB volume and there are about 1,000,000 image files. The unique GPS time target is adopted to index the geo-referenced images (see Figure 4).

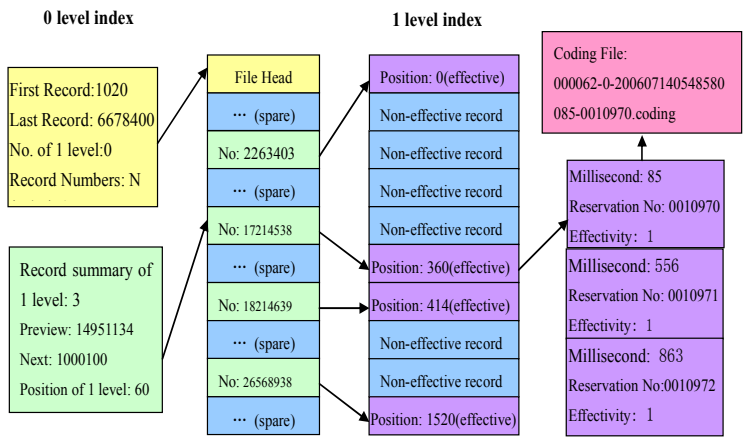

Figure 4 Geo-referenced image index model

For the street image index model, a position index of GPS time is built into the orientation. Then a time coding of each image is generated with two level indexes. 0 level records year to second. 1 level records milliseconds of each 0 level index item and its reservation information, such as the sensor ID. Each image will generate a one time coding file once it is captured. With the spatial position, it can query the image exposure time from the spatial index file. Then it can restore image files with image time stamp and find the image with the coding file.

Another key technique of the geo-referenced image database is the large data volume and number of files, especially for the navigator devices such as PND or PDA. Firstly, an image section algorithm is designed to reduce the data volume of geo-referenced images. The images are selected based on the road network, and POIs for the user will take care of the POIs. Only road intersections need detailed information. Images along the road link will be sampled at an interval of about every 50 meters (see Figure 5). Then a batch image compression process is used convert the image resolution from 1600×1200 to 256×256--a normal image size used to reduce data volume in portable screen devices.

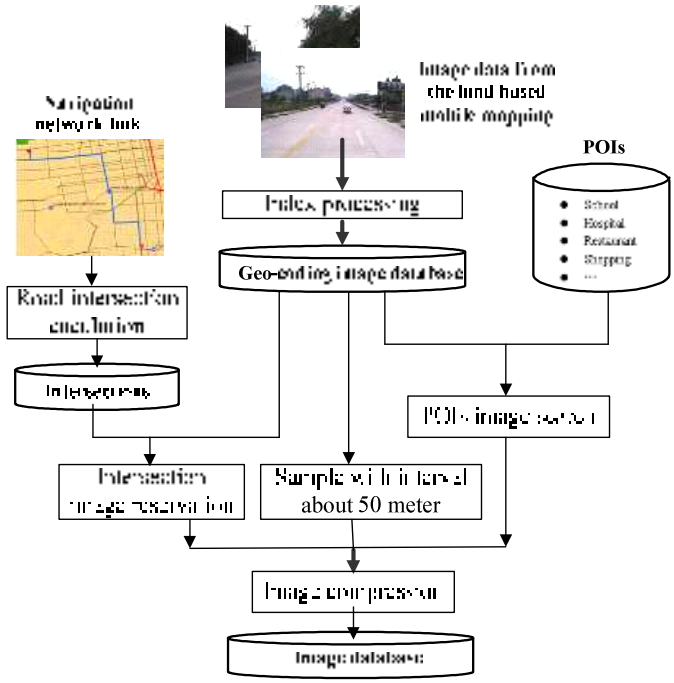

Figure 5 Image section algorithms for image navigation system

After the image selection, the image data volume of the 200km^2 city will be reduced from 2TB to 2GB, thus allowing it to be stored on the PND or PDA. 2GB images still have more than 100,000 files. In order to manage, query and store so many image files on the portable devices, a big image file is designed to store all the images in one file. Then the image file is connected with an image index target and

position as well as a network link ID. Each query therefore assigns each location or address an image index target. The index target will find the address of the image data in the big file. Comparing the query from the image folder with multiple image files, the big image file can avoid the search response time of operation systems, especially in a real-time application environment.

IMAGE NAVIGATION MODE

Geo-referenced images base navigation emphasis the reality experience for users during navigation. Geo-referenced images are taken as the main guide in navigation software. The 2D map serves as the eagle-eye for finding location addresses and routes. We designed two image navigation modes in the image navigation software. The first image navigation mode is the single image guidance mode (see Figure 6).

Figure 6 Single image navigation mode

Single image navigation mode uses the image as guidance, and the GPS position can be addressed on the geo-referenced image. The user can browse the left and right image of the current position. With the geo-referenced images and real scene, the user can still locate the address in case the GPS fails. The single image navigation mode is part of the personal navigation application. is suite of the personal navigation.

Another image navigation mode is the composite mode with images and a 2D map. This mode has the advantages of both 2D map navigation and single image navigation. The 2D map can show the current the GPS position alongside the planned path, allowing directions to be shown during navigation. The geo-referenced image can make it easier for the driver to locate the destination or landmark. (see Figure 7).

Figure 7 Composite navigation mode with image and 2D Map

Users can switch between composite navigation mode and single image navigation mode while *en route*. The routing plan can be done with the composite navigation mode. Before reaching the destination, the user can use the composite mode to obtain the general effect of the whole route plan. When nearing the destination, the single image navigation mode can be useful for finding the exact location of the destination. By comparison, GPS has a position error about 20 meters, especially in densely developed environments.

REALITY IMAGE NAVIGATION PROTYPE

We designed a reality vision navigation prototype of Wuhan city in order to verify the image navigation technique. With 3 sets of land-based mobile mapping systems, it only takes 2 months to collect the image navigation database with more than 3TB and 300,000 POIs. After creation of the image index and image selection, only about 3GB remain in the database for the final navigation system. We developed an image navigation mode in Windows Mobile 5.0 that can run with PDA、PND, allowing the image query response of the whole city to remain at less than 0.2s (Dopod , Windows mobile 5.0, 128M memory, 8G flash disk).

Table 1. Image query response of Wuhan city

	Data volume (GB)	Image number	Query response (s)
Hankou district	1.25	135058	0.13
Hanyang district	0.92	92325	0.08
Wuchang district	1.13	121347	0.11
Total city	3.30	348730	0.17

As Table 1 shows, the prototype can support the image database of a whole Wuhan city with data volume above 3GB and still reach reality vision navigation. The query response of the image based navigation averages about 0.17s. Figure 6 and Figure 7 show the navigation prototype of Wuhan city.

CONCLUSIONS

3D navigation is the future trend of vehicle navigation and personal navigation technologies. Sequence images captured along the road best resemble the habit of human vision and memory. It is unique in its ability to represent the real world. Geo-referenced images bypass the symbol representation errors occurring in map systems, and they incorporate more spatial semantics and non-spatial semantics than 2D maps and virtual 3D maps. Land-based mobile mapping systems provide a speedy tool for collecting and updating the image database necessary for the image-based navigation. With the spatial grid index algorithms of large volume geo-referenced images, portable devices can obtain fast access to the image database and destination addresses. This will be a new approach in 3D environment navigation. With the development of wireless communication, web service techniques, and intelligent vision, geo-referenced image navigation will become a new trend in the navigation systems. It will push the navigation system applications used in intelligent transportation and emergency response application. Some further research work will focus on supporting seamless access to geo-referenced images of different cities.

ACKNOWLEDGEMENTS

Signal Timing and Coordination –An Art of Engineer ing

Z. Tian[1]

Abstract

The scientific and engineering aspect of signal timing and coordination is reflected by sophisticated optimization algorithms, computer software, and roadway infrastructure to support servicing traffic flows. On the other hand, implementing a coordinated signal timing plan in the field often involves fine tuning of a plan in order to achieve the best performance. Such a field implementation and fine tune task provides a stage for the traffic engineers to demonstrate their intellectual and artistic skills of manipulating signal timing using the advanced traffic signal controller features. Therefore, traffic engineers often describe signal timing as a form of engineering art. This paper addresses such an artistic aspect of signal timing by illustrating various signal timing tricks applied on different cases. Specifically, the cases to be discussed include: left-turn phasing sequence, pedestrian handling, dealing with long arterials, and strategies for controlling closely-spaced signals. Applying the tricks and tips illustrated in this paper can provide quick fixes to some common operational problems without the need of significant capital investment. Finally, the paper also touches some basic issues related to traffic flow and roadway characteristics in China, and how the signal timing principles may be adapted to China's urban arterials.

Keywords: Signal Timing, Coordination, Art of Engineering, Traffic Flow

Introduction

Technology advancement over the last decade has significantly changed how modern traffic signal control systems operate. As one of the major components of Intelligent Transportation Systems (ITS), traffic signal control systems have adopted many such advanced technologies. Advancements of vehicle detection technology include development of video-detection systems to replace traditional inductive loops (Bonneson 1998; Tian et al. 2002; Tian and Abbas 2007). Advancements of detection technology also involve development of more efficient lane-by-lane detection schemes (Smaglik et al. 2005; Tian and Urbanik 2006; Wu and Tian 2007). Improvements in communication technologies allow fast signal timing exchange between a central computer and local controllers. Advanced computing technologies result in significant enhancements on signal controller features and functions, including more powerful processors and more sophisticated signal control algorithms for better handling of special service requests, such as bus priority, emergency vehicle preemption and transition.

Traffic engineers and scholars often describe traffic signal coordination as a form of art, resembling watching a ballet while observing traffic flows with well synchronized traffic lights. Because many factors cannot be explicitly considered and modeled, implementing the

[1] Zong Z. Tian, Associate Professor, Dept. of Civil and Environmental Engineering, University of Nevada, Reno, MS 258, Reno, NV 89557; zongt@unr.edu

best signal timing plan often involves fine tuning in the field, reflecting an engineer's artistic judgment and skillful mind trained by many years of experience and education. Such a field implementation and fine tune task provides a stage for the traffic engineers to demonstrate their intellectual and artistic skills of manipulating signal timing using advanced traffic signal controller features.

The primary objective of this paper is to address the artistic aspect of signal timing by illustrating various signal timing tricks applied in different case studies. The illustrated cases well reflect the author's many years of experience working in both the academic and practical fields. While the strategies proved to be effective in further improving signal timing solutions from traditional optimization models, they are not yet been explicitly modeled due to the nature and complexity of modeling them in scientific manners. However, with the advance of integrated approach to addressing engineering and scientific issues, these problems could be better modeled in the future. It is the author's intention to raise wide awareness of the signal timing field and to attract more scholars into this fascinating interdisciplinary field.

The Art of Signal Timing

Left-turn Phasing Sequence

One of the critical elements for signal coordination is the left-turn phasing sequence. It has been well recognized that the lead-lag phasing sequence can significantly improve progression bandwidth. In a recent study by Tian et al. (2008), the effectiveness of lead-lag phasing was given quantitative evaluations by developing a computer program that was able to randomly generate many network cases and to provide maximal bandwidth solutions. One of the major findings from the research (see Figure 1) was that lead-lag phasing can significantly benefit maximizing bandwidth over other phasing sequences, e.g., more than 70% of the cases.

While phasing sequence has generally been given more attention when dealing with coordination, it also affects operations at individual intersections. One of the phenomenons is the short-lane issue (Tian and Wu 2007; Zhang and Tong 2008). For example, a left-turn pocket is a commonly seen short-lane case, where queue blockage to the pocket section can reduce capacity and affect signal coordination. Depending on the proportion of left-turn and through traffic volumes, the sequence of leading or lagging the left-turn phase can make a significant difference in traffic operations. As can be seen in Figure 2, the figure on the left side shows the left-turn pocket is blocked by a through vehicle (typical when through traffic volume is higher than the left-turn traffic), while the figure on the right side shows the left-turn pocket is blocked by a left-turn vehicle (typical when the left-turn volume is higher than the through traffic). For the case shown in the left-side figure, lagging the left-turn phase is more effective because it would allow the left-turn vehicles getting to the stop line before the left-turn phase turns on. For the case shown in the right-side of the figure, leading the left-turn phase is then more effective because it would allow the through vehicles getting to the stop line before the through phase turns on. Signal-timing software generally does not take such short-lane case into consideration; however, some recent studies have attempted to address the short-lane issue using probability theories (Tian and Wu, 2006; Zhang and Tong 2008).

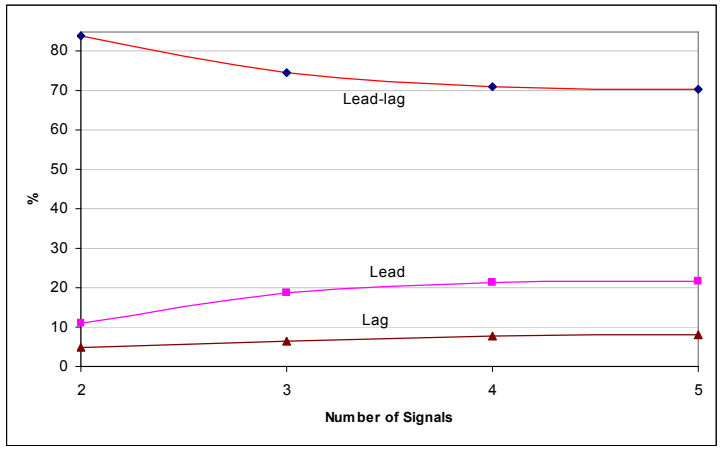

Figure 1 Percentage of Cases of Using Different Phasing Sequence for Maximizing Progression Bandwidth

Figure 2 Effect of Short Left-turn Lane and Phasing Sequence

Pedestrian Issues

As a major non-vehicular traffic mode, pedestrian crossing can affect signal operations and coordination in several ways. For signal operations and coordination, pedestrian timing needs to be programmed in traffic signal controllers, where the effect varies depending on the selection of pedestrian timing alternatives. Although practicing traffic engineers realize the importance of considering pedestrian timing, most signal timing optimization methodologies either completely ignore or give little consideration to pedestrian timing. Signal timing solutions derived from optimization methodologies without consideration of pedestrian timing generally cannot be implemented directly into traffic signal controllers. Because conflicting objectives generally exist between serving pedestrians and vehicular traffic, strategies for minimizing pedestrian impacts have been sought. Pedestrian crossing impact is best illustrated by the case of pedestrians crossing an arterial, where the time needed for pedestrians to cross is usually much longer than the time needed for vehicular traffic. The discussions next illustrate two common cases dealing with pedestrian handling in signal timing and coordination.

Pedestrian Timing Under Split Phasing

When split phasing is used for the cross street due to geometry and traffic flow patterns, pedestrian crossing has the most significant impact due to accommodation of two pedestrian splits for crossing both sides of the street. In a study by Tian et al. (2001), strategies were developed to provide a dynamic protected-permitted display, where a protected display is used when there is no pedestrian crossing in a cycle, while a permitted display is used when there are pedestrian crossings in a cycle. Such strategies are aimed at minimizing the pedestrian impact when split phasing is used. Figure 3 shows the phasing diagram for the side street under various pedestrian crossing scenarios. Using such a phasing scheme, only one pedestrian time split is needed for the side street, thus significant time savings could be

achieved compared to conventional ways of handling pedestrian timing.

Coordination Issues

In a study by Tian et al. (2000), two alternative treatments on pedestrian timings were addressed: timing based on pedestrian minimums where the required pedestrian crossing times were accommodated in the signal phase splits, and timing based on vehicle minimums where the phase splits were determined only based on vehicle demand. Various effects of the two pedestrian treatment alternatives were demonstrated through a case study. Various timing strategies were identified to minimize the negative effect while timing based on pedestrian minimums. These timing strategies included the appropriate setting of offsets, the effective use of side-street phasing, and the use of maximum recall. It was found that although timing based on vehicle minimums can generally result in a shorter system cycle length, timing based on pedestrian minimums can normally achieve the same operational efficiency. The most significant advantage of timing based on pedestrian minimums was that the signal system will always remain in coordination. The only drawback of timing based on pedestrian minimums is the likely use of longer cycle length. It was recommended that timing based on pedestrian minimum technique should be applied when longer cycle length was required for the system, and medium to high level pedestrian crossing activities exist.

Figure 4 illustrates how stops can be reduced by using the maximum recall feature in the signal controllers. The figure on the left shows that a max recall was applied at intersection #1, while the figure on the right shows no max recall was applied. Both cases resulted in the same vehicle delay, but by using max recall, the number of stops was reduced.

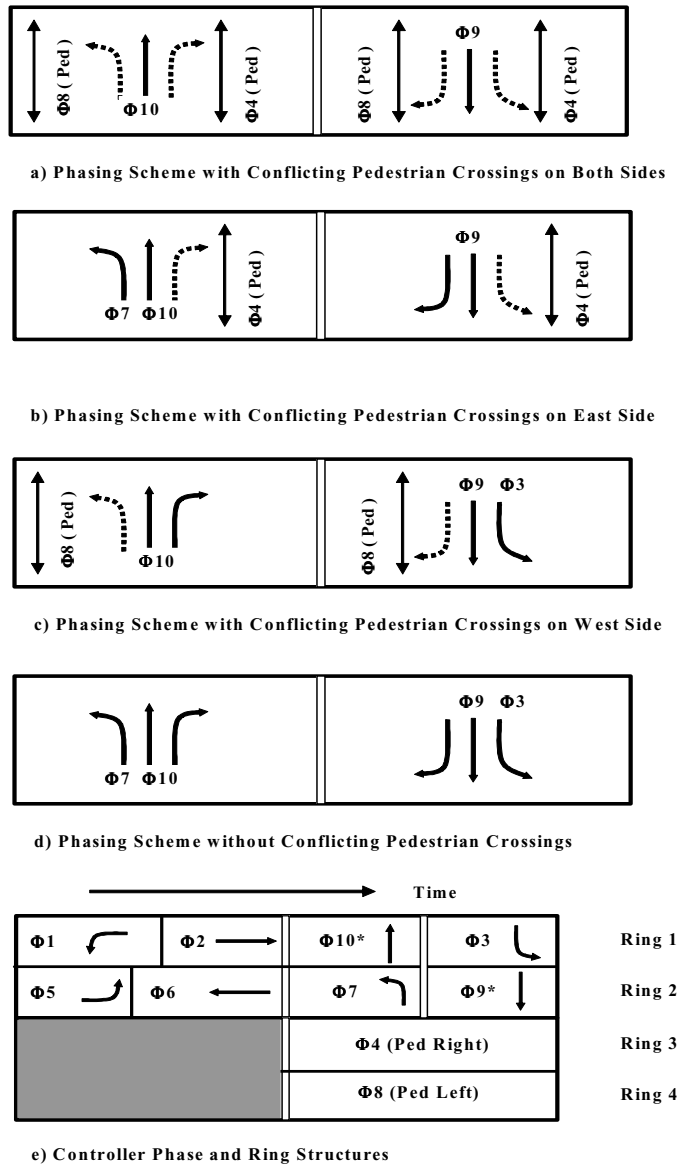

Figure 3 Strategies for Minimizing Pedestrian Impacts Under Split Phasing

Long Arterials

When a signal system has a large number signals (e.g., more than 10 signals), it is often difficult to achieve a good system bandwidth by using general signal-timing software packages, such as PASSER II, TRANSYT 7-F, and Synchro. In fact, attempting to achieve a total system progression band having low bandwidth efficiency may not be an efficient approach to developing signal-timing plans. In a study by Tian et al. (2007), a new approach to application of bandwidth-oriented signal timing was proposed based on a system partition technique. The proposed approach was to divide a large arterial signal system into sub-systems with 3 to 5 signals in each subsystem. Each subsystem was optimized to achieve the maximum bandwidth efficiency. A one-directional system progression bandwidth, normally the peak-flow direction was then formed by appropriately adjusting the offsets between each subsystem. Figure 5 illustrates a signal timing timing solution using the system partition technique. Such a signal timing solution would provide maximum progression for the peak

direction while still maintaining partial progression for the off-peak direction, where vehicles can at least go through each subsystem without having to stop.

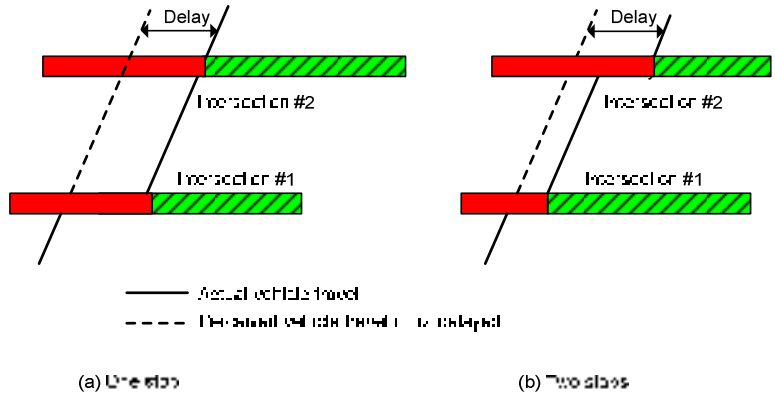

Figure 4 Use of Max Recall to Minimize Stops

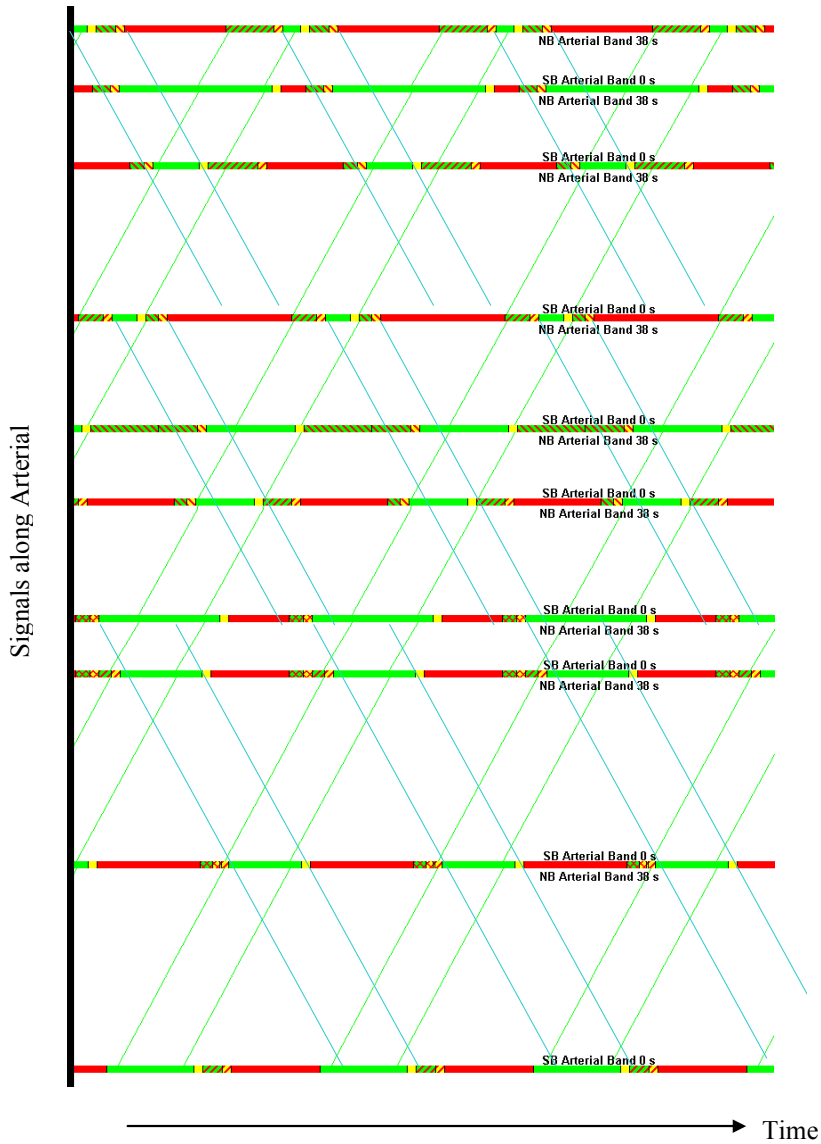

Figure 5 Partition Technique for Long Arterials

Concluding Remarks

This paper provided discussions on the artistic aspect of traffic signal timing and coordination. Through demonstration of various tricks for operating traffic signals, it indicated that many such cases have not been addressed by scientific and engineering models and algorithms. Rather, these signal timing techniques are mainly representations of the special skills of experienced traffic engineers, which reflect many years of field experience and manipulation of advanced traffic signal controller features. However, it is the author's intention to use such cases to draw interests from a broad range of scholars into addressing signal timing issues. Finally, the cases illustrated were mainly based on U.S. practice and traffic flow characteristics. The traffic conditions in China are quite different; therefore, adapting such strategies into China's urban arterials must take into consideration of its special traffic flow and signal system characteristics. For example, the pedestrian volume in

China is much higher than the U.S. Most urban arterials in China have low access control, where vehicles do not generally maintain a good platoon structure. The typical long peak period with high traffic demand also tend to make the actuated operation less effective.

ABSTRACT

This paper investigates the method of collecting real-time traffic information using the cell dwell time (CDT) theory. In this novel technique, mobile phones are used as a tools to collect traffic information. The mobile phone network has extensive probes and can acquire exact information in any condition. Research suggests CDT is associated with traffic condition: high CDT values usually indicate high traffic congestion, low CDT indicates good traffic conditions. This paper illuminates the theory of using CDT to collect traffic information, and presents the traffic parameters estimate model. The vehicle routes between two cells can be confirmed by map matching technique. Based on the relationship of vehicle velocity, density and traffic volume, the traffic volume can be estimated. Using CDT theory, the researchers were able to obtain the average velocity of vehicles on the road. The results showed encouraging performance in traffic condition estimation and traffic parameters estimation.

INTRODUCTION

In general, there are two alternatives for collecting traffic information: fixed sensors or mobile sensors. The loop detectors, an example of fixed sensors, tend to be installed on major roads. They have significant maintenance requirements. Although fixed sensors allow the use of video and camera for collecting traffic parameters, those instruments do not work well in adverse weather. Using mobile phones as a traffic probe is a novel technique in collecting traffic information. The network of mobile phones presents extensive probes that can acquire exact information in any condition. The advantages of mobile phones as traffic probes include:

1) There is an abundance of probes to collect information. Every vehicle with a mobile phone can be a probe.
2) Using mobile phones as traffic probes makes it possible to monitor the whole road network over all time periods without additional equipment.

Using mobile phones as a traffic probe basically relies on two technologies: the network and the handset. The handset technology relies on additional technology in the handset, such as a GPS receiver. The network

method uses data already being used in the mobile phone system. Approaches that rely on additional technology in the handset have the potential to produce more accurate data. However, the trade-off is additional communication costs. The network solution is less accurate and more cost effective than the handset-based method.

In 1995, the US Federal Communications Commission launched enhanced 911 (e911) emergency services. It proposed that the operators must be able to locate the phones within 50 m 67% of the time, and/or 150 m 95% of the time by using the handset based solution. In addition, the network-based method has to provide the location within 100 m 67% of the time and/or 300 m 95% of the time[1].

Using cell dwell time (CDT) for traffic information collection and estimation, as presented in this paper, is one of the network-based technologies. The CDT was proposed by Wasan and Ratchata. In Bangkok's field experiment, they used the software installed in the handset to analyze traffic conditions. Their results showed that the CDT method is a relatively accurate and real-time solution to collecting traffic congestion information.

The mobile phone network is composed of a myriad of base stations. A mobile phone will chose the closest base station to transfer signals, so it switches from one cell to another cell as the user moves. The time that the phone remains registered in one cell is called cell dwell time (CDT). Research determined that CDT was associated with the traffic condition: high CDT values usually indicate high traffic congestion, and low CDT means good traffic condition, indicating free-flowing traffic.

TRAFFIC PARAMETERS ESTIMATION

Data collection

In the described method, every vehicle with a mobile phone becomes a traffic probe. The cellular network used by mobile phones is composed of myriad cells, with a base station at the center of each cell. When a mobile phone moves into a cell, it obtains a cord or ID to distinguish it from others. As the mobile phone moves to the edge of the cell, the signal diminishes until the phone transfers to the nearest cell with stronger signal. These ID cords are recorded by the network operator as the mobile phone is switched on. The transfer information of a phone between cells can then be collected anonymously and easily, and can be obtained from the original record of the network operator.

The collected CDT data should be classified first. There might be some noise data, which should be wiped off by the classification method. According to the coverage size of the cell, the range of CDT is established, as shown in Table 1. A CDT is treated as a noise data if it is larger than the maximum value in the Table.

Table 1. The range of CDT.

Cell size (meters)	CDTs (seconds)
0~300	0~500
300~500	0~700
>500	0~900

In the case of traffic congestion, the CDTs might overrun the normal data. The first step of data processing is smoothing the data via table 1. The next step involves calculating the average value of CDT. The average value *($\bar{c}$)* is calculated from the averaging of the sample n values:

$$\bar{c} = \frac{\sum_{i=1}^{i=n} c_i}{n}$$

Traffic parameters estimation

Consider a highway between towns that is covered by several mobile phone cellular base stations. Neglecting the influence of pedestrians for simplicity, let *i=1,2,3,,M* be the set of M cells. Let r^i denote the road stretch that is covered under cell *i*. Moreover, assume the following:

a) l_i the length of the stretch r^i

b) m^i the number of vehicles in r^i

c) n^i the number of mobile phones in r^i

d) c_p^i the CDT of the mobile phone *p* in r^i

e) $\overline{v_c^i}$ the average velocity of vehicles in r^i

f) v_p^i the velocity of mobile phone *p* in r^i

Assume that all recorded CDTs denote the cell dwell times of mobile phones in vehicles. Then:

$$v_p^i = \frac{l_i}{c_p^i}$$

according to the definition of space mean speed,

$$\overline{v_c^i} = \frac{1}{\frac{1}{n^i}\sum_{p=1}^{p=n^i}\frac{1}{v_p^i}}$$

In cases where there may be more than one phone in a specific vehicle, some

researchers decided to choose one phone, disregarding the others. In the paper, let λ represent the average number of mobile phones in a vehicle. λ is variable in different areas and can be confirmed by traffic surveys. The total number of mobile phones can be detected, so the number of vehicles can be calculated by:

$$m^i = n^i \times \lambda$$

Next, estimate the density and the flow of vehicles in r^i. Let k^i and q^i be the density and traffic volume, respectively. These values are defined as:

$$k^i = \frac{m^i}{l_i}$$

$$q^i = \overline{v_c^i} \times k^i$$

The traffic volume q^i is computed indirectly based on the traffic engineering theory.

SIMULATION AND RESULTS

For the sake of simplicity, the experiment was implemented in the following conditions:

1） The road is a highway between cities, with no bicycles or pedestrians.

2） It was covered by 11 cells. The coverage size of each cell was 500 meters.

The experiment was executed by vissim. Vissim is a microscopic, behavior-based multi-purpose traffic simulation program. The CDT data were noted by several time detecting buttons. The record data were analyzed by using the formula.

Figure 1 shows the measured velocity and true velocity. The velocity relative error is shown in Figure 2. The estimated traffic volume is shown in Figure 3. Figure 4 shows the relative error of detected traffic volume.

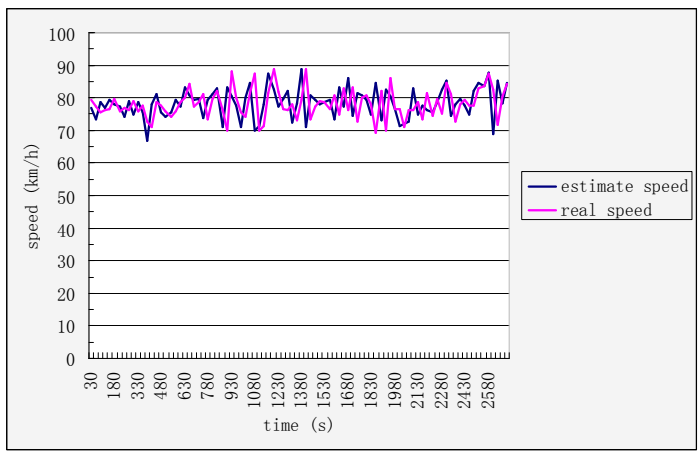

Figure 1. Estimated velocity vs. true velocity.

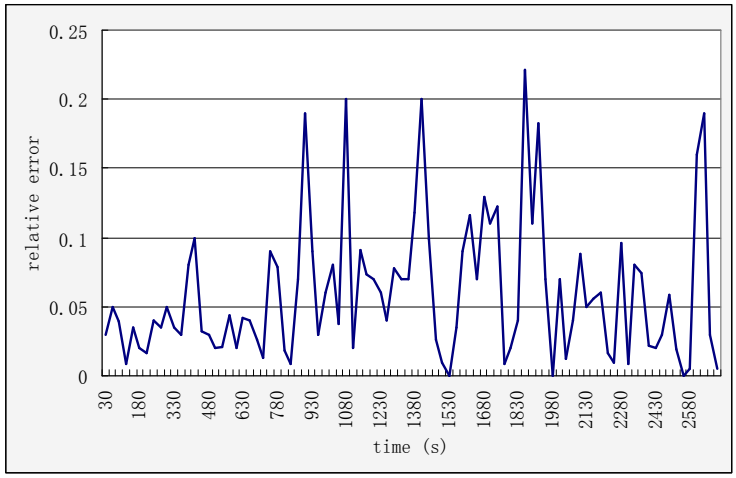

Figure 2. Relative error of estimated velocity.

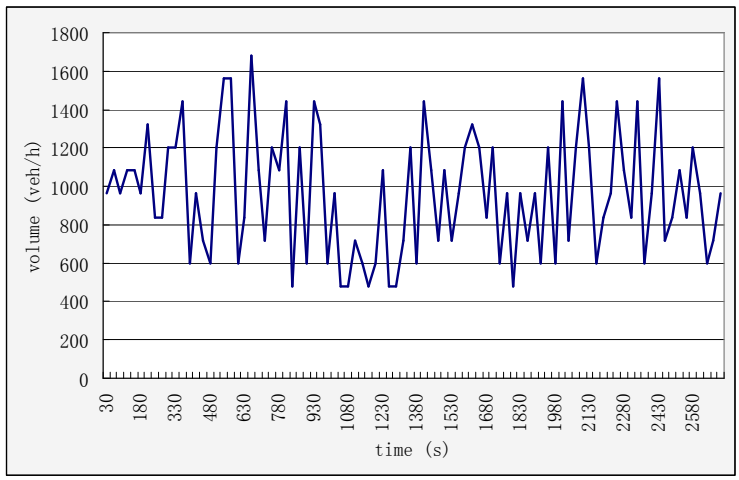

Figure 3. Estimated traffic volume.

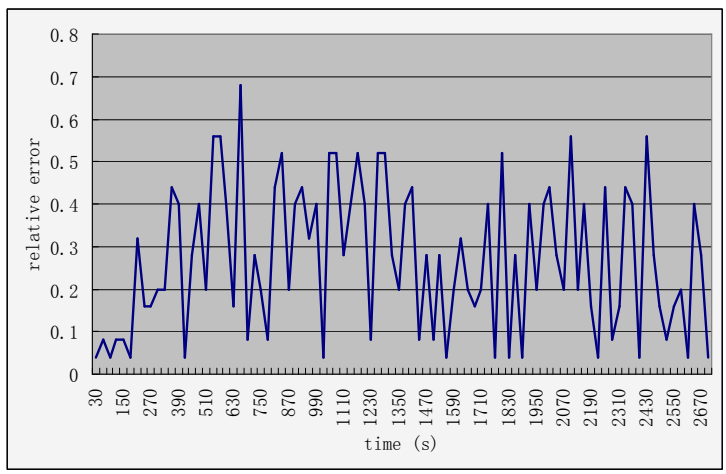

Figure 4. Relative error of detected traffic volume.

The experiment results show that the maximum relative error between the true vehicle speed and the estimated speed is about 22%, and over 90% relative error was below 10%. So the estimation of velocity is quite good. But

the detected traffic volume is not as satisfactory. Some relative error exceeds 65%. About 65% of the estimate volume error is below 30%. We ascribe the error to unpredictable driving behavior and complicated road conditions. In actuality, the volume we estimated is the traffic flow rate, which can be higher or lower than the actual traffic volume.

CONCLUSION

This paper investigates the collection of traffic information and estimation of traffic parameters using CDT. The experiment results show that using mobile phones to collect traffic information and estimate traffic parameters is a potentially useful method. The estimation of traffic parameters by using the information collected shows that adequate data is available. This technique may become another traffic probe application in the future.

Further research work will focus on the following:

1) Improving the parameter estimate modals.
2) Considering the impact of mobile phones that are not on the vehicles.
3) Investigating the road networks in the city. Junctions and traffic signal control systems will make estimation much more complicated.
4) Improving the experiment method and the simulation model.

ABSTRACT

Intelligent Transportation Systems—Public Transport (ITS—PT) make use of advanced techniques to obtain real-time public transport information to dispatch buses. ITS—PT is a new style of public transport dispatching, and it is an important step toward the realization of moderation management. This paper discusses the two dimensions of optimization of public transport networks, also called initial network optimization and real-time network optimization, and establishes the mathematical models to advance the optimization algorithm. The results achieve the goal of managing an urban public transportation system scientifically and modernly.

INTRODUCTION

With society's development, advanced science and technology are being applied to all trades and professions, offering a strong means of quick transmission, making information available for sharing and improving management. The public transport intelligent real-time dispatching system is intended integrate advanced techniques such as information technology, date communication, electron control, global positioning system information (GPS) and computer networks into the system (Moazzem et al.2000). It is wide ranging, real-time, accurate and highly efficient. This paper discusses the design of an intelligent real-time dispatching system for public transport networks, and studies the real-time dispatching control models and their solutions. The main purposes of real-time dispatching are the elimination of buses' actual running status from the schedule, selecting and assigning buses in real-time, use of other dispatching modes (vehicle frequency, etc.), and design for systems of Public Transport Network Optimization (PTNO) and Advanced Traveler Information Service (ATIS) at the same time.

In PTNO, the model is built using multi-objective programming (called initial network optimization). The model is built with the main target being the shortest pathway, so that the passenger flow obtains operating routes to arrive at destinations on time using real-time dispatching (called real-time network optimization).

In ATIS, the share of the data is furnished on Intelligent Cards (IC) and GPS, on Geographic Information System (GIS) and GPS, and on urban traffic management systems and public transport management systems. The

information can be provided to trip makers at home, work, wayside stops or on-board vehicles. With links to automatic vehicle location, traveler information systems specifically for transit are beginning to provide real-time information such as arrival times, departure times and delays. Travelers can access a variety of information, including transit routes, schedules, park-and-ride lot locations, weather and other information. The passenger flow en-route can obtain the public transport information by variable information plates and "Bus Route Guidance System (BRGS)" terminals oat the bus stops in the same time. Finally, it is proven that the real-time network optimization is rational, that the real-time dispatching system is advanced, and the information service system is timely and accurate. The application of the system also proves that it can offer a benefit for passengers and can attract more travelers to use public transit vehicles.

FOREWORD

Foreign research in public transport network optimization design starts very early. L. Bailiang et al established non-linear 0-1 plan model (Adamsli et al.1998), which considers passenger flow travel time and network fund investment as the expense objective functions. Y. Xinmiao, W. Wei et al proposed a fuzzy neural network forecasting model for public transport line passenger flow (Eberlin X.J et al.1998), etc. These models ushered in a brand-new research mentality for public transport network optimization in our country.

This paper proposes an optimization network model for public transport networks and basic ideas for network optimization, and it will be the foundation of future intelligent dispatching. According to the characteristics of modern urban development and urban transport development, the paper creatively proposes a new non-linear double-deck optimization model.

BASIC IDEA FOR AN IMPROVED PSO

The improved PSO algorithm uses a double-deck model implementing line network optimization. It first considers maximizing through passengers on the shortest path, and next considers minimizing the total travel time of through passengers in maximal through passenger volume groups (B.L.Lin et al.1999; Yang XinMiao 2000).

The model seeks the shortest path for a nonstop passenger volume group. It searches the shortest path in each pair of start and end points. Note the optimal path is not always a line between each pair of points, because line must not only satisfy the objective function of the model but must also satisfy all constraint conditions. Its searching process is as follows: First, it searches for the shortest path of a pair of points, then locates the second shortest path of this pair, the third shortest path, and so on. But the searching process is not unlimited; otherwise the result will be too large. Another constraint condition must be added, sorting according to the through passenger volume from in large to small consequence.

Second level of the model minimizes the average travel time of through passengers. Here “through passenger” refers to the maximal through passenger volume group found in the first level. Formula (1) Calculates the average shipping time of the line, which has the maximal through passenger volume. If it

is the minimal volume compared with other groups, it becomes the resulting line for this pair of start and end points. If it is greater than the average shipping time of through passengers in the shortest path, then it gets rid of it and continues searching. Formula (2): checking the second maximal through passenger volume, if the average shipping time is less than the shipping time in the shortest path, then it will be used. Otherwise, the result will be the through passenger volume of the shortest path.

Initial network optimization. The public transport network is adjusted and optimized so as to adopt real-time network optimization and real-time dispatching control (Adamsli et al.1998). This paper presents the algorithm for one-by-one searching and optimization.

Idea of solving problems. Formula (1) Decides the first route numbers with shortest pathways between a pair of nodes. It finishes the passenger flows OD matrix, defines numbers of OD nodes for traffic networks that can support buses, and runs the program that looks for the shortest pathway. Formula (2): To deduce traffic zones, the passengers are distributed over every node (on the basis of the averaging principle) in the same traffic zone. Formula (3) determines the second route numbers, which are, according to the OD matrix during investing passenger flows, traffic zones of OD nodes. OD passengers of all traffic zones are ordered from large to small until all routes have been arranged. Formula (4) searches surplus sections of many passenger flows to add third route numbers. In search for min $(D_{ij}+A)/Q_{ij}$, D_{ij} is the distance from node i to node j, Q_{ij} is the passenger flow from i to j, A is coefficient.

Mathematical model. The object functions the minimum of passengers' average distances, nonstop rate and daily average maximum full-loaded rate:

$$\min(L) = \frac{\sum_{i=1}^{n}\sum_{j=1}^{n} L_{ij} Q_{ij}}{\sum_{i=1}^{m}\sum_{j=1}^{m} D_{ij}} \qquad (1)$$

$$\max(\beta) = \frac{\sum_{i=1}^{n}\sum_{j=1}^{n} K_{ij}\delta_{ij}}{\sum_{i=1}^{m}\sum_{j=1}^{m} D_{ij}} \qquad (2)$$

$$\max(\gamma) = \frac{\sum_{k=1}^{N}\sum_{i=1}^{n}\sum_{j=1}^{n} q_{ijk} L_{ijk}}{\sum_{k=1}^{B}\sum_{i=1}^{n}\sum_{j=1}^{n} q_{oijk} L_{ijk}} \qquad (3)$$

The constraints are as follows:

$\delta_{ij}=1(i\neq j)$ or $\delta_{ij}=0$ (i=j), $R_{ij}\leqslant 1.41$, $O_{ij}\leqslant 1.3$, $T_{st}\leqslant 8.44$(min),

Where L is the average distance of passengers, N are the numbers of public transport routes, m are the numbers of traffic zones, n are node numbers of highway networks that can operate buses, K_{ij} are nonstop passengers from starting point i to destination j, L_{ij} are the distances from node i to node j, D_{ij} are

the OD from zone I to zone j, Q_{ij} are passenger numbers daily from node i to node j, δ_{ij} is the coefficient, R_{ij} is curve coefficient of the route, K_{ij} are various coefficients of the section of a highway, T_{ij} are the average walk times of the all passengers, q_{ijk} are actual passengers from node I to node j in k route, q_{oijk} are full loaded from node I to node j in k route. R_{ij} is the winding coefficient, O_{ij} is the variable coefficient, T_{st} are average walk times.

Algorithm application. Table 1 shows results before and after optimization in Tangshan City in China.

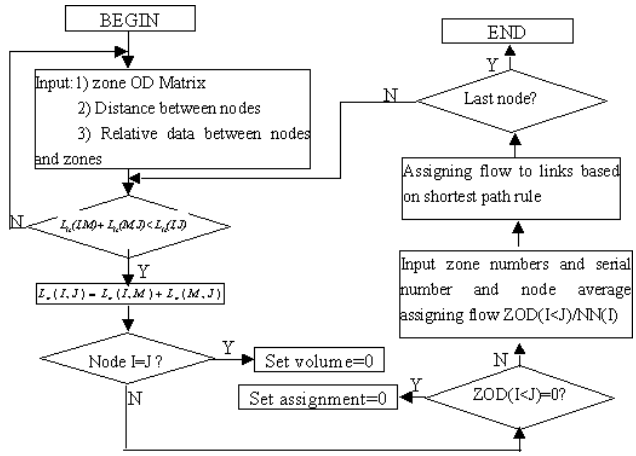

Figure 1. Diagram of flow distribution.

Table 1. Comparison of figures before and after public transit routine adjustment.

Plan	Before	Adjusted
Nonstop rate/%	40.84	43.62
Average walk time/min	7.68	6.58
Average distance/km	4.57	4.46
Average waiting time/min	9.3	6.2
Density of routine/km.km^{-2}	1.18	1.73
Routine multiplicity factor	2	1.48
Daily average full loaded rate/%	30.18	34.64
Mileage usage rate/%	98.05	98.90

Second level model. The objective function of the second level is to minimize the total riding time of all through passengers. The constraint condition is the same as with the first model; this model is proposed in domestic and foreign routes for the first time: distance between nodes is used to perform the modification:

$$\sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{s=i+1}^{j-1}\left[Q_{ij}(d_s+u_s)\alpha\right]$$

The equation represents the time expense on the stops, when passengers on the vehicle must wait for other passengers getting on or getting off the vehicle. Where Q_{ij}, D_{ij} is the same mean with above formula: V_{ij} is running speed from i to j (km/h); K_{ij} is the speed correctional factor from i *to* j (different speeds when passing school, shopping center and normal running speed). Normally the value is 1. The real speed correctional factor can use experiential value in different running environments according to real investigating results; d_s is the number of passengers who got off at stop S; u_s is the number of passengers who got on at the stop S.

$$\min f(x_{ijs}) = \frac{\sum_{i=1}^{n}\sum_{j=1}^{n} Q_{ij}\frac{D_{ij}}{V_{ij}K_{ij}} + \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{s=i+1}^{j-1} Q_{ij}(d_s + u_s)\alpha}{\sum_{i=1}^{n}\sum_{j=1}^{n} Q_{ij}} \tag{4}$$

All through passenger riding times are the sum of running time between nodes and dwell time on stops, because public transport vehicles must decelerate and accelerate when starting and stopping, which must consume time, here the speed correct factor is α factor (for several vehicle doors, each passenger's getting on or off time).

Steps for improving the PSO algorithm. First plans for the first public transport line are as follows: (1) Determine all the start points and end points, establish the distance matrix between nodes and through passenger matrix between nodes. If all constraints are satisfied, search for the shortest path between each pair of start end point and calculate through passenger capacity shipping on the shortest path. (2) Search the shortest path group. Search the second, third, fourth and fifth shortest path groups according to the condition that the path length is not more than 5% more than the shortest path length, and calculate the through passenger volume of the searched path. In the same way, later path searches must satisfy all the constraints. (3) Sort the shortest path groups according to passenger capacity in large to small consequence. Judge these five groups to determine whether there are groups whose passenger volumes are less than the shortest path's, if there are, get rid of them, and sort the groups again. In this kind of situation, through passenger volume of the shortest path could be possibly placed in any position. (4) Calculate the average passenger shipping time in the through passenger group. Seek the line whose through passenger volume is more than that of the shortest path, and average through passenger shipping time is less than that of the shortest path. If a line is found, then it is the result. Otherwise, continue until a line is found (maybe it is the shortest path in the shortest path group). (5) After determining a public transport line for each pair of start and end points, sort all these lines according to through passenger volume from large to small, then take the first 20 lines as the first candidate group of lines. Determine the first optimized public transport line in these 20 lines according sequence of artery, branch and temporary lines. Plan the second public transportation line. Because there is a public transport line in the public transport network, before planning the second line, get rid of through passenger capacity shipping through the first public transport line from the through passenger flow matrix. Then repeat the steps of planning the first line. Pay attention to the constraint of the line overlapping factor. Build other

public transportation lines in turn, until the next line is lower than the lowest line-building standard. According to this method of determining a public transport optimization network, each line moves towards basically conforming to the passenger origin direction, and can guarantee the least transfer time of the entire service area. Using the proposed public transport network optimization method, a brand-new public transportation network may be established; it is undoubtedly reasonable for a new city. For an existing city, which has a relative scale of public transport networks, it is unreasonable to ignore the existing system. Because it takes a long time for people to get familiar with the public transport line, large-scale changes in public transport lines c can bring great inconvenience to resident trips; it would be contrary to the goal of network optimization. To give a better solution to this problem, this article proposes adjusting the existing public transport network, combining the produced optimization network and existing network infrastructure. The adjustment principle is as follows: keep the reasonable lines in the existing network, perform lengthening, reduction and partial re-routing to the partial lines, discard the unreasonable lines, and propose additional lines.

EXAMPLE ANALYSIS

Changchun's public transport network layout has some difference with the resident trips requirement. Including: 1) 13% traveling passengers' walking time amounts to 8 ~ 14 minutes; 2) the urban public transport line overlapping factor reaches as high as 1.8, including 16 lines' non-overlap sections of 0 ~ 2km; 3) the passenger average travel time is very long: 60% are higher than 45 minutes, 48% are higher than 50 minutes, and transfer time is high. Through passenger volume in 30 lines amounts to 410,048, combined with Changchun's present road network, consisting of 36 arteries managed by Changchun's public transport corporation. We adjusted our planning result by adding, keeping, discarding and changing processing. In the new network, 40% of passengers need not transfer. Thus, Changchun's public transport network optimization process is totally completed.

CONCLUSION

This paper put forward a public transportation network optimization model based on the mathematical planning method. In particular, it proposed the second level model for the first time in the world, and I believe it will be a good reference for research in public transport network optimization. This paper improves the PSO algorithm and applies it in actual optimization, thus proving its practical application value. This paper proposed the idea of average allocation of passenger capacity in traffic plots to nodes based on the passenger flow volume investigation. Thus, network design and line arrangement will be more reasonable. The algorithm's reliability and computational precision will be very high because of allocating passenger flow volume in traffic plots to corresponding nodes and lines, and full constraint designing. Line overlapping factors in the optimized network have measured up to reasonable technology requirements. While keeping unchanged the public transport line's total length, discarding the excessively overlapping parts in routes and adding blank route resident trips that are needed urgently, the passenger through rate can achieve levels above 40%.

ABSTRACT

With the pace of social and economic development, the focus of public traffic scheduling is gradually changing from the previous pure emphasis on the economic benefits of public traffic enterprises to improving their service level. This paper presents an optimization scheduling model for a non-equivalent coordinated public transport network, which is based on the target of maximizing passenger benefit under the guidance of the basic idea while meeting the objective function, that of minimizing the total cost of passenger and public traffic operators. The research used an algorithm-hybrid of Genetic-simulated annealing (GA-SA) to optimize the frequency of public traffic scheduling, while using public traffic survey data of Shanghai to verify the model. The results indicate that the optimal model has strong practicability.

INTRODUCTION

As the society and economy rapidly develop, the policy of "people oriented public transport harmony" is advanced, and the government is focused on the level public transport service (Haghani et al. 2002). Little attention is paid to the public transport enterprise cost, however. Under the precondition of certain traffic route and vehicle choice, shortening passengers' trip time as much as possible is becoming one of the important criteria for evaluating the performance of a timetable plan (Huisman et.al 2006).

This paper studied a public transport network scheduling model based on non-equivalent real-time precedence coordinate optimization, which can be described as the target of minimizing passengers' transfer time, in a certain period and district, in coordination with the public transport lines (Cheng Li 2002).

PROBLEM DESCRIBED AND MODEL BUILT

In order to maximize social benefits, the objective function of the frequency optimization model is to minimize total cost of passengers and public traffic operators. The objective function is composed of four parts: (1) Passengers' total cost for waiting; (2) Passengers' total cost for riding; (3) Passengers' total cost for transfer; (4) public transport operator's total variable cost. Suppose that the general symbol: i, j is line (i, j =1, 2,...), s, t is station (s, t =1, 2,...) and u, v is vehicle (u, v =1, 2, ...).

Passengers' total cost for waiting. Passengers' total cost of waiting for

the bus is the accumulation of every passenger's waiting cost in the station; it can be expressed by the time and the value, which is the product of waiting time and unit waiting cost.

Suppose the arrival rate at which passengers arrive at station k is a constant. r_s is the arrival rate at which they randomly arrive at the station(person/minute), $d_{i,u}^s$ is the time at which bus u arrives at station s in line i, $d_{i,u-1}^s$ is the time when bus u-1 arrives at station s in line i. The number of waiting passengers is:

$$T_{w1}: T_{w1} = r_s(d_{i,u}^s - d_{i,u-1}^s) \quad (1)$$

Every passenger's average waiting time T_{w2} is:

$$T_{W2} = 0.5(d_{i,u}^s - d_{i,u-1}^s) \quad (2)$$

Passengers' waiting time in station s T_{wait} is:

$$T_{wait} = T_{w1}T_{w2} = 0.5r_s(d_{i,u}^s - d_{i,u-1}^s)(d_{i,u}^s - d_{i,u-1}^s) \quad (3)$$

Passengers' total cost for riding. Passengers' total cost for riding is composed of: (1) time it takes to carry passengers from station s-1 to s; (2) the waiting time for people who do not get off the bus.

(1) Suppose the number of passengers who were carried by bus u on line i from station s is $P_{i,u}^s$, and from station s-1 is $P_{i,u}^{s-1}$. The time that bus u is on line i from station s is $f_{i,u}^s$, from station s-1 is $f_{i,u}^{s-1}$. So the time it took to carry the passengers from s-1 to s is:

$$T_{i1} = (d_{i,u}^s - f_{i,u}^{s-1})P_{i,u}^{s-1} \quad (4)$$

(2) Suppose average time for a passenger unit to get on and off the bus is $\overline{ud}$ (minute/person, based on actual vehicle conditions). The rate that passengers get off the bus is q_s%. Because parts of the passenger unit get off the bus, every passenger who is on the bus must wait. Suppose the wait time is:

$$T_{\text{down}}: T_{down} = \overline{ud}P_{i,u}^{s-1}q_s \quad (5)$$

Because parts of passenger unit get on the bus, every passenger who is on the bus must wait. Suppose the wait time is:

$$T_{\text{up}}: \quad T_{\text{up}} = \overline{ud}r_s(d_{i,u}^s - f_{i,u-1}^s)P_{i,u}^{s-1}(1-q_s) \quad (6)$$

The waiting time for a passenger who does not get off the bus is T_{i2}:

$$T_{i2} = \begin{cases} T_{\text{up}} + T_{\text{down}} & \text{Suppose it is only one door to get on and off} \\ \max(T_{\text{up}}) \ T_{\text{down}} & \text{Supose there is one door to get on ,and the other to get off} \end{cases} \quad (7)$$

The time the passenger spends on the bus is T_{wait}:

$$T_{\text{wait}} = T_{i1} + T_{i2} \quad (8)$$

The cost passengers spend for transfer. The cost passengers spend for transfer is related to the transfer rate from line i to line j. Suppose the rate is $\omega_{i,j}^s$(%), $0 < \omega_{i,j}^s < q_s < 1$, $\delta_{i,j}^{s,t}$ where 0-1 is variable. "0" is representative, since it is impossible to transfer between two stations; otherwise, the result would be "1". So, the transfer time T_{transfer} is:

$$T_{transfer} = (f_{j,v}^{t} - d_{i,u}^{s}) P_{i,u}^{s-1} \omega_{i,j}^{s} \delta_{i,j}^{s,t} \quad (9)$$

Operator's cost. If we use time to denote operator's cost, it is the time $T_{\text{operation}}$ that the bus takes to run from the last station to this station:

$$T_{\text{operation}} = d_{i,u}^{s} - f_{i,u}^{s-1} \quad (10)$$

A public transport network optimization scheduling model. This model is based on non-equivalent real-time precedence coordination. Objective function:

Min

$$\left\{ \beta_1 \left[\frac{c_1}{2} \sum_i \sum_s \sum_u r_s (d_{i,u}^{s} - a_{i,u-1}^{s})^2 + c_2 \sum_i \sum_s \sum_u \{ (d_{i,u}^{s} - f_{i,u}^{s-1}) P_{i,u}^{s-1} + \overline{ud} T_{i2} \} + c_3 \sum_i \sum_j \sum_s \sum_t \sum_u \sum_v \delta_{i,j}^{s,t} (f_{j,v}^{t} - d_{i,u}^{s}) P_{i,u}^{s-1} \omega_{i,j}^{s} \right] \right.$$

$$\left. + \beta_2 \sum_i \sum_s \sum_u c_{i,u} (d_{i,u}^{s} - d_{i,u}^{s-1}) \right\} \quad (11)$$

Subject to:

$$s_i^{\min} \le f_{i,u}^{s} - d_{i,u}^{s} \le s_i^{\max} \qquad \forall i, s \quad (12)$$

$$s_j^{\min} \le f_{j,v}^{t} - d_{j,v}^{t} \le s_j^{\max} \qquad \forall j, t \quad (13)$$

$$f_{j,v}^{t} - d_{i,u}^{s} + M(1 - \delta_{i,j}^{s,t}) \ge 0 \qquad \forall i, j, s, t, u, v, j \ne i \quad (14)$$

$$\sum_t \delta_{i,j}^{s,t} = 1 \qquad \forall i, j, s, t, j \ne i \quad (15)$$

$$(f_{j.v}^{t} - d_{i,u}^{s}) \delta_{i,j}^{s,t} \le T \qquad \forall i, j, s, t, u, v, j \ne i \quad (16)$$

$$d_{i,u}^{s} - d_{i,u-1}^{s} \le h_i^{\max} \qquad \forall i, s, u \quad (17)$$

$$d_{j,v}^{t} - d_{j,v-1}^{t} \le h_j^{\max} \qquad \forall j, t, v \quad (18)$$

$$\frac{Q_{s.\max}}{N_s \times CAP} \le L_{\max} \quad (19)$$

$$\frac{Q_{s,\max}}{N_s \times CAP} \ge L_{\min} \quad (20)$$

β_1 is the weight factor of passengers' cost, according to passenger flow volume. β_2 is the weight factor of the public transport operator's cost. c_1 is the conversion factor that converts passengers' waiting time to trip cost (RMB /person minute): $c_1 = [1 + \alpha h_i] c_{\text{average}}$

As waiting time increases, c_1 increases. It is variable: α is passengers' complaint factor, $c_{average}$ is passengers' unit time value, c_2 is the conversion factor to convert passengers' riding time to trip cost (RMB / person minute). c_3 is the conversion factor that converts passengers' transfer time to trip cost (RMB /person minute). $c_{i,u}$ is the conversion factor that converts bus u running time on line i to operating cost (RMB/minute).

$h_{\text{i}}^{\max}$ and $h_{\text{j}}^{\max}$ are the maximum frequency on line i, j; $S_{\text{i}}^{\max}$ and $S_{\text{i}}^{\min}$ are the maximum and minimum stopping time on line i. $S_{\text{j}}^{\max}$ and $S_{\text{j}}^{\min}$ are the maximum and minimum stopping time on line j. t is the maximum transfer time (minutes), M is an arbitrarily large value, $L_{\max}$ and $L_{\min}$ are maximum load factors of lines i

and *j*.

From the model, we can see that the objective function is the frequency of every line in the network and 0-1 variable $\delta_{i,j}^{s,t}$ of the transfer station. $a_{i,u}^{s}$, $d_{i,u}^{s}$ and $\delta_{i,j}^{s,t}$ are variable, r_s, q, c_1, c_2, c_3, $c_{i,u}$ and $\overline{ud}$ can be obtained through research, and T and M are calibration factors.

OPTIMIZATION FREQUENCY BASED ON GA-SA ALGORITHM

Mixed GA-SA algorithm. GA-SA algorithm is an optimization algorithm that combines a genetic algorithm and simulated annealing algorithm. GA makes optimization come true through a group genetic operation, which is based on the idea of "survival of the fittest" (Kliewer et.al 2006). The local search ability of GA is poor. But it has the advantage in integral searches; SA has a strong ability in local searches, but it cannot make the search process go into a most hopeful area. We combine the two algorithms to optimize the search process and enhance search ability and efficiency under whole and part meaning. The model in this paper is a multiple objective nonlinear programming model. It is suitable for using the mixed GA-SA algorithm (Huisman et.al 2005).

Frequency optimization model on mixed GA-SA algorithm. Based on the mixed GA-SA algorithm, the steps of how to solve frequency are as follows:

Step 1: Input the number of lines in the public transport network and the number of 0-1 variables $\delta_{i,j}^{k,l}$ between every transfer station. At the same time, arrange every line and $\delta_{i,j}^{k,l}$ to ensure the arrangement of every variable in chromosome. Initialize parameters, including the range of frequency, population size N across probability R_c and mutating probability R_m, initial temperature S_0, genetic generation number i and threshold δ.

Step 2: Convert frequency to a binary string, and in accordance with population size and chromosome arrangement, produce N random chromosomes that are subject to frequency. They constitute the initial population. Every chromosome stands for a possible solution.

Step 3: Compute every chromosome's fit value $f(X_i)$ in number I generation, average fit value $\bar{f}_I$ and $|\bar{f}_I - \bar{f}_{I-1}|$, estimate if it is subject to $|\bar{f}_I - \bar{f}_{I-1}| < \delta$. If it is, go to Step 10. If it does not, go to Step 4.

Step 4: Compute every chromosome's chosen probability R_i, and accumulation probability λ_k.

Step 5: Get an evenly distributed random number ξ between 0 and 1. If $\xi \le \lambda_1$, choose the first chromosome to copy. If $\lambda_{k-1} < \xi \le \lambda_k$, choose the number ξ chromosome. Repeat this step N times and produce the next generation.

Step 6: Produce N evenly distributed random numbers ξ_1, ξ_2, …, ξ_k, …, ξ_N between 0 and 1 in turn. If $\xi_k < R_c$, let the chromosome X_k serve as the father chromosome and come into the crossing father chromosome population.

Step 7: Choose two chromosomes (p_1, p_2) randomly from the father population, choose a point randomly, and then cross two chromosomes. They produce son generation c_1, c_2. Compute fit value $f(c_i)$ of c_1, c_2. Start SA

algorithm. If $f(c_i) > f(p_i)$, let p_i stand for c_i. If not, accept c_i at the probability $\exp\{(f(c_i) - f(p_i))/T\}$. Leave the son chromosome and remove this father chromosome from the father population. Repeat this step until every father chromosome has been operated.

Step 8: Produce N evenly distributed random numbers ξ_1, ξ_2, …, ξ_k, …, ξ_N between 0 and 1 in turn. If $\xi_k < R_m$, let X_k mutate. Operation of SA is similar with Step (7).

Step 9: Lower temperature $T = T_0 \times a^K$, a is a constant between 0 and 1, K is the number of iterations.

Step 10: Let $I = I+1$, go back to Step 1.

Step 11: Stop computation. Output the son chromosomes that minimize the objective function.

EXAMPLE

Using the model above, passenger flow surveys and operating data of the No.59 and No.842 buses in Shanghai (the two lines cross in Wujiaochang), the average waiting, riding and transfer time value are respectively: the public transport passenger's unit time value is per-capital GDP per hour. It is 16095/(365×24)=1.84 RMB / hour·person =0.03 RMB / minute·person. The bus running speed is 20 km/h. The maximum transfer time is 15 minutes. Frequency change from 5 to 15, but it is a multiple of 0.5. The chosen optimization time period is 6:30 to 7:30. Passenger's average time of getting on and off is 4 seconds/ person; β_1=0.7, β_2=0.3. The Maximum number of iterations I=300. The threshold δ =1. Population size N=200. Initial temperature S_0=5000. Cross probability S_c=0.95. Mutation probability S_c=0.005.

The results are: the frequency of No.59 bus is 6.0 minutes, and No.842 bus is 7.0 minutes. The minimum objective function f^* = 6928.55 RMB. Passengers' total waiting cost is 754.36. Passengers' total riding cost is 3657.14 and total transfer cost is 1049.15 RMB, public transport enterprise's total variable cost is 1467.85 RMB. Through investigation and analysis of the basic related information for No.59, we can see passenger flow volume of the No.59 bus in a whole day. (Figure 1).

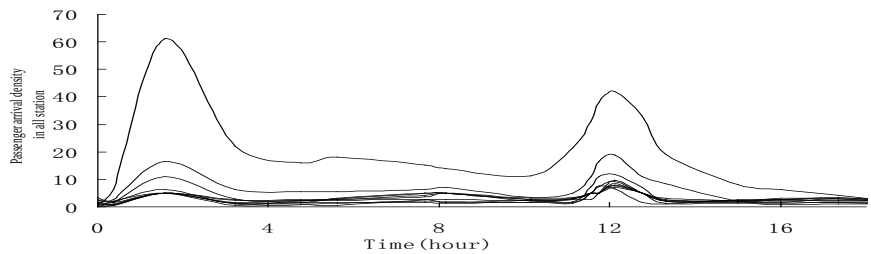

Figure 1. Passenger flow volume of No. 59 bus in one whole day.

The frequency distribution of No.59 bus in a whole day comes from the GA-SA Algorithm. (See Figure 2)

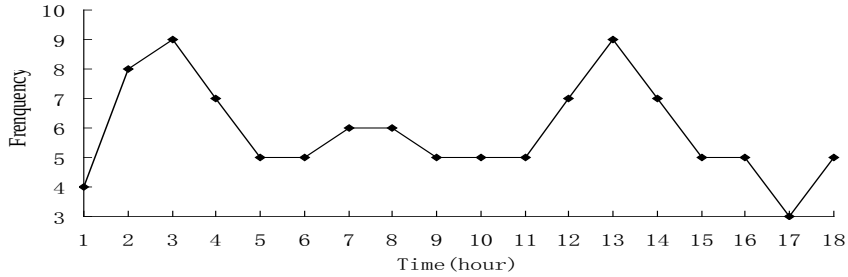

Figure 2. Frequency in a whole day by mixed GA.

From Figure 2, we can see that the result from the GA-SA algorithm conforms to the actual passenger flow distribution (Figure 1). Frequency also gets two rush hours. It corresponds with the morning and night rush hours. The result reflects passengers' benefit and shows that the model reflects fact. At the same time, it proves the GA-SA algorithm has a higher efficiency. It is feasible. The No.842 bus gets the same result.

CONCLUSION

The quality of public transport operation can directly affect enterprise's appearance and economic benefit. Improving operation has been a constant theme. This paper builds an optimization scheduling model of a non-equivalent coordinated public transport network which is focused on improving the public transport service level. This model, which has been verified with actual data, can support the decision-making in improving public transport operating management.

ABSTRACT

At present, traffic micro-simulation studies are mostly based on the following model and lane changing model, which are the fundamental models. What make them distinct are their different forms and parameters. Although these methods can simulate the foreign traffic system fairly well, they can not precisely simulate the mixed traffic of Chinese urban branch roads. This study, which focuses on the unique situation of Chinese motorized vehicles and non-motorized vehicles advancing in a mixed way on the urban branch roads, puts forward a new model that can be applied to motorized and non-motorized vehicles. It is an advanced model for mixed traffic on urban branch roads.

Take motorized vehicles for example; it will no longer be limited to fundamental forms, such as free driving, following driving or lane changing driving and so on, but will always be in an advanced state. There is no rigid lane dividing principle when the vehicle is advancing. Its lateral location, speed and other factors depend on the comprehensive traffic circumstance around it. In theory, there are numberless possibilities and choices.

The principles of the non-motorized vehicles model resemble the motorized vehicles model. When the model was built, we used the crossing bridge of north Jianshe street in Shijiazhuang for testing and verification. It turned out that this method can make an accurate micro-simulation of mixed traffic on Chinese urban branch roads. In this way, it filled the blank left by the imported software.

INTRODUCTION

At present, the microscopic traffic simulation technology developed abroad is more sophisticated, but it is mainly based on the two basic models: car following and lane changing. Chinese microscopic traffic simulation software is mainly imported from abroad, and the related study has been carried out at Harbin Institute of Technology, Tongji University and Beijing Jiaotong University.

But there is no good solution to the microscopic simulation problem of mixed traffic. The phenomenon of the mixed traffic on urban branch roads in China is studied in this paper, breaking traditional ideas based on the car following and lane changing model and putting forward an advanced model applied to the mixed traffic of urban branch roads in China whose lanes are not divided. The results of research can simulate and analyze the phenomenon of mixed traffic on urban branch roads in China, and the theoretical and practical value is important.

RESEARCH AND ANALYSIS AT HOME AND ABROAD

The research on microscopic traffic simulation software started earlier abroad, and the technology has become more sophisticated, but the operation of the software is mainly based on the car following and the lane changing models (Hoogendoorn et al., 2001). The car following model can generally be divided into the following categories: stimulus- response model, safe spacing model, physiological-psychological model, fuzzy reasoning model and cellular automaton model. The lane changing model mainly includes the model based on demand generation and the model based on behavior threshold. In recent years, many scholars, such as Willmann, Kumamoto et al (Wardrop J.G et al., 1994) devoted themselves heart and soul to the related research.

The microscopic traffic simulation software used in China are mainly imported from abroad, and the related study has been carried out at Harbin Institute of Technology, Tongji University, Beijing Jiaotong University. For example, study includes the advanced car following model based on dynamic, which is put forward by HanZhi, the car following propounded by RongJian based on variable following time and stochastic factors, and XuLunhai's nonlinear model based on lagging time. However, this research is all about the improvement of the car following model and the lane changing model, not involving the problem of mixed traffic on urban branch roads in China whose driveways are not divided.

MAIN RESEARCH CONTENTS

This paper aims at the special urban phenomenon of mixed traffic in China, and it is based on the safe distance model of the car following model. The speed and angle of the vehicle is controlled by timely estimating the speed of the non-motorized vehicles ahead, and also the size and location of the interstitial provided for overtaking. Thus, the phenomenon of motor vehicles interfering with non-motorized vehicles can be achieved on the condition that there is no driveway division. In this case there is no specific concept of driveway. Vehicles keep on searching for n interstitial, which can be used to accelerate in the non-motorized vehicles, and the speed and angle is controlled according to the interstitials. The traditional car following and lane changing models are no longer observed by the vehicles' running, which observe the improved running model based on the characteristics of the two models. The

research mainly contains the following basic contents.

θ numerical is introduced in the safe distance model of the car following model. After a great deal of actual investigation and study, θ is the angle between the direction of the vehicle' speed and the direction of the path. The following speed and angle of the vehicle are expressed by the changing of the angle. Motor vehicles adjust their speed and angle according to the movement of all the non-motorized vehicles ahead (the speed of each vehicle, whether there is space or not, the angle between the gap and current vehicle, etc) when the distance between the non-motorized vehicles ahead and the vehicles behind is longer than the safety distance of collision criticality. The model is the mould model with a safe distance if θ numerical is 0 degrees; the maximum of θ numerical is 45 degrees when considering actual traffic and the behavior of the driver. The characteristics of the vehicle are described objectively and accurately as θ numerical and change back and forth from 0 degrees to its maximum.

The improved model is based on the safe distance model by analyzing the behavior of the driver under the mixed traffic conditions of China. Its formula is:

$$v_n(t+T)=\min\left\{\begin{array}{l}\dfrac{v_n(t)}{\cos\theta}+2.5\dfrac{a_nT}{1-\sin\theta}\left[1-\dfrac{v_n(t)}{V_n}\right]\left[0.025+\dfrac{v_n(t)}{V_n}\right], \\ b_n\cos\theta+\sqrt{\left[b_n^2\cos^2\theta T^2-2b_n\cos\theta\left[x_{n-1}(t)-S_{n-1}-x_n(t)-v_n(t)\right]-b_n\cos\theta v_{n-1}^2(t)/\hat{b}\right]}\end{array}\right\} \quad (1)$$

The mean is following:

a_n is the maximum acceleration that the driver of vehicle N will make.

b_n is the maximum deceleration that the driver of vehicle N will make.

S_{n-1} is the utility of vehicles N-1, equal to body length and parking space.

$\hat{b}$ is the maximum reducing speed that is perceived by the driver of vehicle N and which takes the driver of vehicle N-1.

θ is the angle between the direction of vehicle speed and the direction of the path, which ranges from 0 degrees to 45 degrees.

There are two items in the right of this formula. The first item is composed of the expected speed limit, the angle and the acceleration. Traffic flow is under the free state if this item plays an important role in most of the vehicles. Vehicles are free or under the condition of car following when θ equals 0 degrees and the vehicles' running observes the improved mixed running model according to the characteristics of the two models, and if there exist changes of the angle. The second item is composed of the expected limit of the angle, and the distance and reduced speed. Traffic flow is under crowded conditions if this item plays an important role with most of the vehicles. Vehicles are under the condition of car following driving when θ equals 0 degree and the vehicles' running observes the improved mixed running model according to the characteristics of the two models when there exist changes of

the angle. The progress of the vehicle is a process of changing its speed and angle. These change constantly according to the circumstance ahead of the vehicle.

INSTANCE ANALYSIS

To compare the safety spacing original model and the advanced integration model, we used the 6m-wide one-way section of road near the overpass in the Jianshe north street in Shijiazhuang as an example. Through field observation, a vehicle weaves its way through the flow of non-motorized generally at the speed of about 40km/h. We simulate the situation separately, using the traditional safety spacing model and the integrated forward model proposed in this paper, and the data of the result is shown in Figures 1, 2 and Table 1. According to the analysis of running time of vehicles and the trajectory, the result indicates that the situation of mixed traffic in which the driveway is not divided, existing in the urban branch roads in China, can not be simulated by the original and classic models based on car following and lane changing, and illustrates the applicability to the situation of the model presented in this paper.

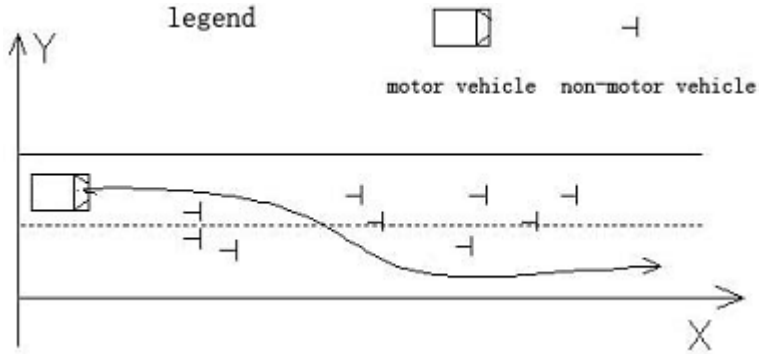

Figure 1. Trajectory by original model.

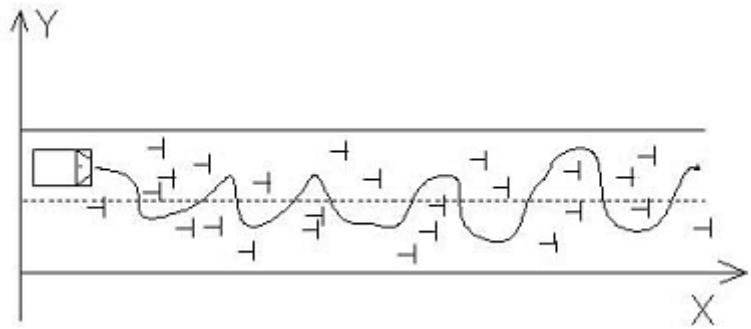

Figure 2. Trajectory by advanced model.

Coordinate values of the running trajectory from 1 to 10s is shown in table 1:

Table 1. Coordinate values of the running and trajectory (unit: m).

time（unit：s）	x in original	y in original	x in advanced	y in advanced
1	0	4.2	0	4.2
2	11.1	3.8	11.1	4.0
3	22.2	3.5	22.2	2.9
4	39.6	2.9	38.9	3.0
5	55	2.4	42.7	2.9
6	66.1	1.9	62.1	2.5
7	77.2	1.5	74.3	3.2
8	88.3	1.4	83.8	5.2
9	99.4	1.8	97.7	2.4
10	110.5	2.2	109.6	4.8

CONCLUSION

Targeting the situation of mixed traffic in Chinese urban roads whose driveways are not definitely divided, the motorized vehicle integration forward model is put forward in this research. It is based on the original and classic models of car following and lane changing. In the condition that the vehicle has no clear state of car following and lane changing, the forward speed and angle change in real time with the change of the front non-motorized vehicle speed, the gap between the vehicle and the angle of the current vehicle. Using the data from the vicinity of the overpass in the Jianshe north street in Shijiazhuang to demonstrate it, the study indicates that the situation can not be simulated by the microscopic traffic simulation software (such as Vissim, Synchro, etc). We have developed a separate simulation system based on the car following and lane changing models and the integrated forward model, and found that there is serious distortion in the simulation of the mixed traffic in the Chinese urban road whose driveway is not divided when using the classic microscopic traffic simulation models. The situation can be simulated precisely by the model put forward in this paper, however.

ABSTRACT

Traffic accident parameter determination is one of the most important topics in the traffic engineering domain. As a rule, parameter determination methods are all based on the brake marks, thrown objects etc. The results are often inaccurate due to the uncertainties of the road surface friction coefficient, the collision model and the geometric center of vehicles. In 2008, this study team proposed relying on large-scale construction of video surveillance equipment in China. A Gaussian mixture model is adopted to carry on background extraction and parameters such as vehicle movement path, real-time speed etc. were extracted from the video with Kalman Filter and obtained good results. Based on the research in 2008, this paper proposes that the background method of difference be used to replace the Gauss mixed model in the background extraction, and that a Kalman filtering track algorithm based on the fuzzy match be used to replace the traditional Kalman filtering track algorithm in the path track aspect. Through the theory, the example and the analysis, the newly proposed method is more effective.

INTRODUCTION

As a rule, parameter determination methods are all based on the brake marks, thrown objects etc. The results are often inaccurate due to the uncertainties of the road surface friction coefficient, the collision model and the geometric center of the vehicles. In 2008, this study team proposed relying on the recent large-scale deployment of video surveillance equipment in China. The Gaussian mixture model is adopted to carry out background extraction. Extracting parameters such as vehicle movement path, real-time speed etc. from the video fwas conducted using Kalman Filter, and it obtained good results. Based on the research in 2008, this paper proposes that the background method of difference be used to replace the Gauss mixed model in background extraction and that a Kalman filtering track algorithm based on the fuzzy match be used to replace the traditional Kalman filtering track algorithm in the path

track aspect. Through the theory, the example and the analysis, the newly proposed method is more effective.

ACTUALITY RESEARCH

Researchers have used processing by video technology in road traffic since the 1970s (M.Onoe, 1976). After the '90s, numerous countries invested massive funds to support research in this field. Massive work in lining up examination, transportation condition monitors, accident examination and other aspects has been done by numerous scholars on behalf of Hoose, Wan, Mieha, Poulos, Lu et al (P.G. Miehalo Poulos, 1993) (P.G. Michalo Poulos, 1992) (L. CyPers, 1990). For example, the Singapore EMAS system's vehicle examination system and the automatic accident examination system are all based on video detection technology. Mainland China started late in traffic flow research by use of video.

In 1998, The first domestic "video automatic observation system of vehicles running red lights" was developed by Beijing Zhonglian Tongda Technological Progress Limited Company. Soon after, massive work was done by Tan Tieniu, Liu Zhonghua, Liu Bo, Chen Zhaoxue and other scholars in the video examination of vehicles. In 2008, the Shijiazhuang Railway Institute proposed that traffic accident vehicles' paths could be extracted from the video footage, quantifying the parameter extracted from the video as the authority for judicature cognizance; it obtained good results. While the traditional Gauss mixed model and the Kalman filtering model are used in the study, its precision waits for further improvements.

THE MAIN RESEARCH

The goal of this study is to extract a car's track in a traffic accident, focusing on the precise trajectory caused by the specific target vehicle (people). This study contains basic elements as follows:

Background separation. For a specific traffic accident, the effective area should be separated from the vehicles and pedestrians in the video. The present paper uses the selective background renewal model. Its formula is as follows:

$$B_{i,j}^{t+1} = \begin{cases} (1-a)B_{i,j}^{t} + aI_{i,j}^{t}, if DB_{i,j} = 0 \\ B_{i,j}^{t}, otherwise \end{cases}, 0 \le a \le 1 \quad (1)$$

Where, $B_{i,j}^{t}$ is the pixel value of i line ,j row of background images at time t, $I_{i,j}^{t}$ is the pixel value of i line ,j row of input images at time t, a is the turnover rate.

Vehicle track identification. As shown in Figure 1, the vehicle track is detected in conventional traffic video detection technology, usually using black and white image analysis. The difference between the various parts of moving objects can not be carried out in this method. So it can't be ensured that the moving objects would be tracked precisely under different circumstances such as vehicles turning or sideslipping. As shown in Figure 2, if feature points as shown are selected to logo vehicle trajectory, the method of this paper ensures that the moving objects would be tracked precisely under several circumstances such as vehicles turning or sideslipping. In object tracking, the Kalman Filter model is proposed to deal with the vehicles turning, sideslipping, etc in this study. The method used in this paper is tailing after special point by improved Kalman Filter.

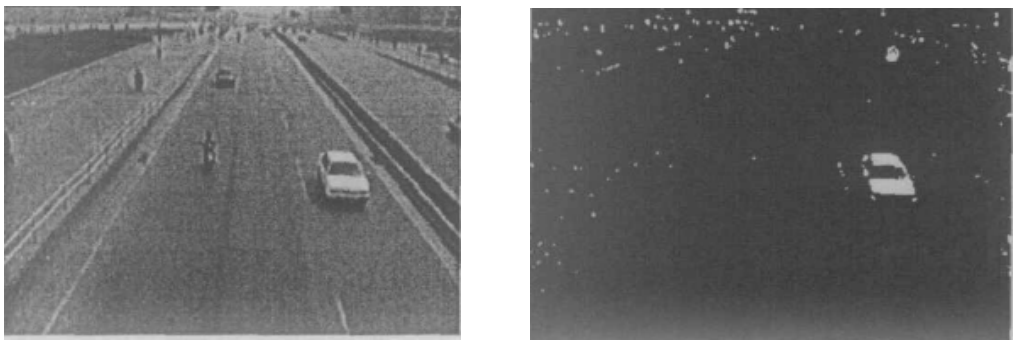

Figure 1. Classical video method of vehicle track determination.

Figure 2. Proposed method of vehicle track determination.

In the Kalman filter, the system model may be used to forecast the goal. When it carries on the forecast track of the object, we first need to establish a system mode model that suits the movement of the object track. Considering the vehicle path changes a lot in a traffic accident, and the space of time is small between the neighboring frames in a video sequence, we make following improvement to the Kalman filtering model:

$$p_t = \begin{bmatrix} p_x(t-1) + \left(p_x(t-1) - p_x(t-2)\right) \\ p_y(t-1) + \left(p_y(t-1) - p_y(t-2)\right) \end{bmatrix} = \begin{bmatrix} 2p_x(t-1) - p_x(t-2) \\ 2p_y(t-1) - p_y(t-2) \end{bmatrix} \quad (2)$$

Where, p_t is the center of mass position of movement object at time t, p_x is the x axis position component of the movement object center, p_y is the y axis position component of the movement object center.

Coordinate change. The coordinate changes between image plane and road plan. The vehicle's trajectory, which the video observed, will be restored to the road track of the vehicle. First, the corresponding equation is established relying on the correspondence relationship between the two-plane and the three-dimensional in photography space. After calibrating out the equation parameter, according to each image plane coordinate, we can determine its ground coordinates. The principle is shown in Figure 3. In Figure 3, S is the center of photography, A is any point on the ground, a is the projection point of A on the image plane. X, Y, Z are the three-dimensional coordinates. X, Y can be calculated by Equation (3).

$$\left.\begin{aligned} X &= \frac{a_1 x + a_2 y + a_3}{a_4 x + a_5 y + 1} \\ Y &= \frac{a_6 x + a_7 y + a_8}{a_4 x + a_5 y + 1} \end{aligned}\right\} \tag{3}$$

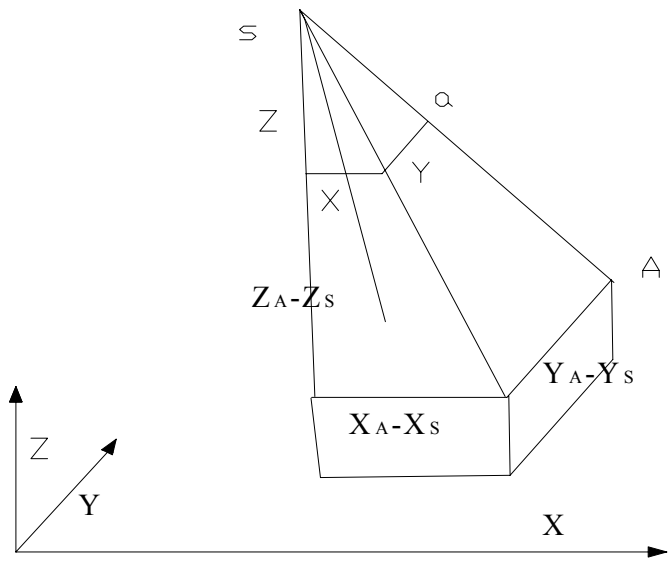

Figure 3. Three-dimensional coordinates.

CASE ANALYSIS

In this program, accident data is treated as a reference. The course of the accident is shown in Figure 2. The comparison result has been shown in Table 1. As shown in Table 1, this article's resulting algorithm examination is best in practice.

Table 1. Method comparison for traffic accident parameter identification.

Identification parameter	Brake marks method	Traditional video method	Proposed examination method	This article result algorithm examination
Velocity in collision (km/h)	42.3~63.4	43.7	45.6-47.8	46.2-26.9
Track length (m)	2.8	4.3	5.6	5.6
Efficiency of track length identification (%)	100	78	95	98

CONCLUSION

Compared with the traditional video detection of tire marks and thrown objects, the video examination data originates more directly, and as a result is more reliable. In 2008, this group proposed the vehicle's path parameter could be extracted from a traffic accident video. We have made improvement through nearly half a year of research into the background renewal algorithm and the vehicle path track algorithm. Looking from the example analysis result, the precision is further enhanced.

ABSTRACT

According to the characters of marine navigation, this paper extends the concept of the velocity obstacle and develops a reactive approach to collision avoidance among multiple ship agents. By selecting a reasonable velocity within free parts of its maneuvering space that aren't covered by the union of velocity obstacles of all other ship agents, a ship agent can navigate safely without collision. Simulation experiments show that our approach is able to navigate multiple ship agents with smooth and natural paths to avoid collision, and can be applied to multi-agent based marine traffic simulation systems.

INTRODUCTION

A simulation-based marine traffic flow analysis is widely used for safety assessment and maritime construction planning such as channel traffic control, port design, and water lane establishment. Simulation models are continuously upgraded with the advent of new computer technologies. The modeling of multi-agent and group behavior to simulate complex marine traffic flow has been gaining increasing attention (Inaishi, 2006). In this area, the motion planning of ship agents is a central problem. In previous works，we have studied how ship agents autonomously make their navigation plans, select routes and avoid collision with static obstacles in the environment (Pan, 2008). This paper further focuses on the collision avoidance among multiple moving ship agents and proposes a velocity obstacle-based approach.

The velocity obstacle concept (Fiorini, 1998) is a generally applicable, well-defined and simple technique that has been widely used for safe navigation among moving obstacles in robotics and virtual environments. This paper extends the concept to deal with encounters among multiple ships and develops a reactive collision avoidance model that agrees with marine navigation conventions to the outmost extent. In our approach, all ships navigate independently without explicit communication with each other. This is a simple and natural formulation that is applicable and easy to implement.

SHIP COLLISION AVOIDANCE

DCPA (Distance at Closest Point of Approach) and TCPA (Time to Closest Point of Approach) are two important concepts for ship collision avoidance, and they can be calculated easily according to the velocity triangle (see Figure 1).

$$DCPA = \sqrt{|V_{AB}|^2 - \left(\frac{V_{AB} \cdot (V_A - V_B)}{|V_A - V_B|}\right)^2} \qquad (1)$$

$$TCPA = \frac{V_{AB} \cdot (V_A - V_B)}{|V_A - V_B|^2} \qquad (2)$$

Many assessment models based on DCPA and TCPA have been proposed for evaluating the degree of collision risk and deciding appropriate avoidance action times (Imazu, 1983; Hasegawa, 1987). The collision avoidance action is generally decided based on the encounter situation between two ships according to the international convention for preventing ship collisions at sea (Zhao, 1994). For example, a collision avoidance pattern can be defined as follows (see Figure 2). If the target ship comes from (a) area, a right turn maneuver is needed; if the target ship comes from (b) area, a left turn plus speed reduction is safer than a sharp right turn; if the target ship comes from (c) and (d) areas, the ship maintains its route.

However, the international convention and the above collision avoidance pattern only solve the problem of an encounter between two ships. In a traditional marine traffic simulation system, encounter between more than two ships have to be divided into a series of encounters between two ships, with the most urgent encounter treated first. Obviously, the simple integration of encounters between two ships is difficult to reach from the complex interactions among all ships with a natural and realistic result.

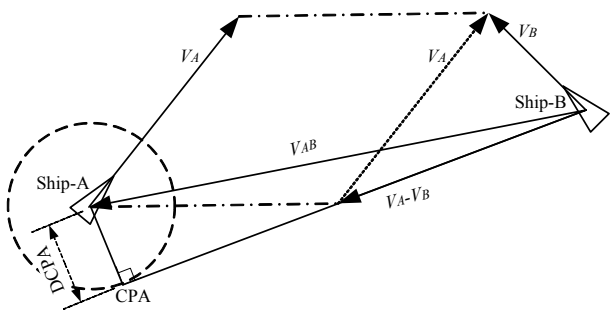

Figure 1. Velocity triangle.

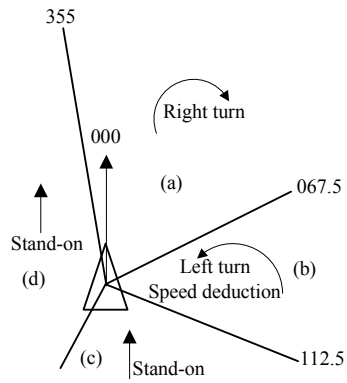

Figure 2. Collision avoidance action.

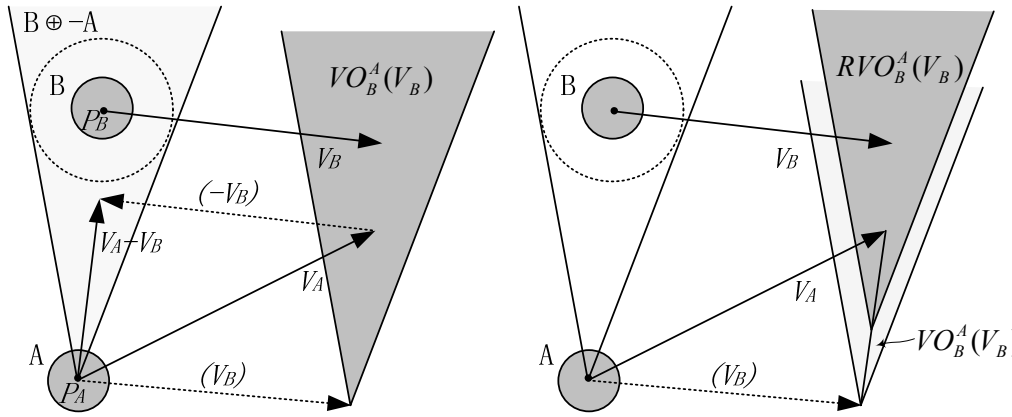

(a) Velocity obstacle **(b) Reciprocal velocity obstacle**

Figure 3. Velocity obstacle and reciprocal velocity obstacle (Jur, 2008).

VELOCITY OBSTACLE

Velocity obstacle is a simple and applicable approach for addressing motion planning in dynamic environments such as robot manipulators avoiding moving obstacles. The velocity obstacle can be geometrically defined as follows (see Figure 3(a) (Fiorini, 1998; Jur, 2008). Let $\lambda(P,V)$ denote the ray starting at P and heading in the direction of V, $-A$ denote the object A reflected in its reference point. If the ray starting at P_A and heading in the direction of the relative velocity of A and B (which is $V_A - V_B$) intersects the Minkowski sum of B and $-A$ (which is $B \oplus -A$) centered at P_B, velocity V_A is in the velocity obstacle of B.

Hence, the velocity obstacle of B to A is defined as follows:

$$VO_B^A(V_B) = \{V_A \mid \lambda(P_A, V_A - V_B) \cap B \oplus -A \neq 0\}. \quad (3)$$

As Figure 3(a) shows, the velocity obstacle is a cone with its apex at V_B. If $V_A \in VO_A^B(V_B)$, A and B will collide at some point in time. If V_A is outside the velocity obstacle of B, the objects will remain clear of each other. By choosing a velocity that lies outside any of the velocity obstacles induced by the moving obstacles and is most directed toward the destination, the robot (or other agent) will safely navigate among moving obstacles toward its destination.

Reciprocal velocity obstacle is an extension of velocity obstacle (Jur, 2008). In order to overcome the undesirable oscillatory motion that could be caused by the original concept of velocity obstacle, the reciprocal velocity obstacle translates its apex to $(V_A + V_B)/2$ instead of V_B (see Figure 3(b)). By preventing an old velocity from being re-chosen immediately in next planning cycle and requiring the choice of the closest velocity outside the other agent's reciprocal velocity obstacle, this guarantees oscillation-free navigation.

COLLISION AVOIDANCE AMONG MULTIPLE SHIP AGENTS

Velocity obstacle for ships. In the original concept of velocity obstacle, $B \oplus -A$ is the critical space that prevents object A from colliding with B (if

the ray of $V_A - V_B$ is tangent with $B \oplus -A$, object A will pass B with the minimal safe distance, radius of A). This definition of minimal safe passing distance is feasible and works well in the robot world. However, it is unsuitable for ships, which need larger and anisotropic passing distances to avoid collisions, due to their poor maneuverability and longilineal shape.

For navigating ships, ship domain is an important concept for assessing the avoidance of collisions. It is a buffer area around the ship that mariners want to keep clean and shut all other objects out of. Figure 4 shows a commonly used definition of ship domain and its frontier model. Obviously, using ship domain instead of the Minkowski sum of two objects to define the velocity obstacle is more feasible for marine navigation. So, this paper extends the velocity obstacle for ship collision avoidance (denoted by SVO) as follows (see Figure 5):

To simplify computation, the elliptical boundary of ship domain is replaced by its bounding box. Let D_A and D_B denote the ship domain of ship A and ship B, $-D_A$ denote ship domain of ship A reflected in its reference point, and the $conv(D_B \cup (-D))$ denote the convex hull of the union of D_B and $-D_A$. Then, the velocity obstacle of ship-B to ship-A is defined as follows:

$$SVO_B^A(V_B) = \{V_A \mid \lambda(P_A, V_A - V_B) \cap conv(D_B \cup (-D_A)) \neq 0\} \quad (4)$$

According to the navigation convention, for a pair of encountering ships, there is one obligation ship and one stand-on ship. The obligation ship has a duty to take collision avoidance maneuvers, and the stand-on ship has right to maintain its direction. So in order to enable unilateral action that guarantees both ships can keep each other out of their own ship domains, $conv(D_B \cup (-D_A))$ instead of $-D_A$ is used to define $SVO_B^A(V_B)$. Furthermore, the extension of reciprocal velocity obstacle proposed to overcome the undesirable oscillatory motion fails for such a case because it requires both objects to take avoidance action. In fact, because the stand-on ship maintains its velocity, the apex of $SVO_B^A(V_B)$ stays at the same position in next cycle which is also the reason why reciprocal velocity obstacle can protect against oscillatory motion. For example, Ship B is the obligation ship

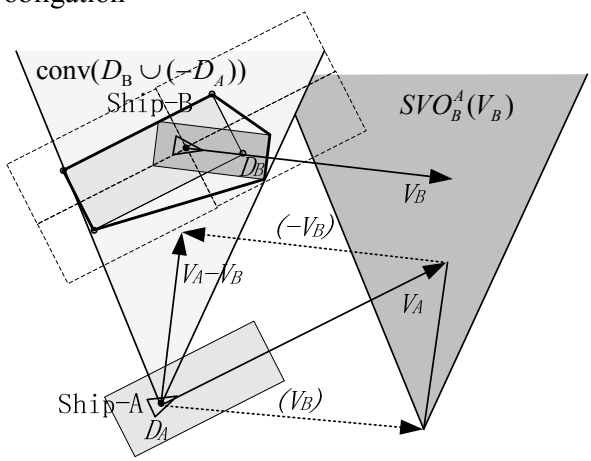

Figure 4. Ship domain.

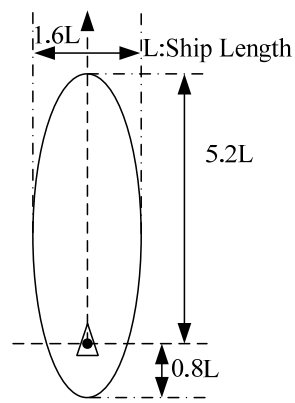

Figure 5. Velocity obstacle for ships.

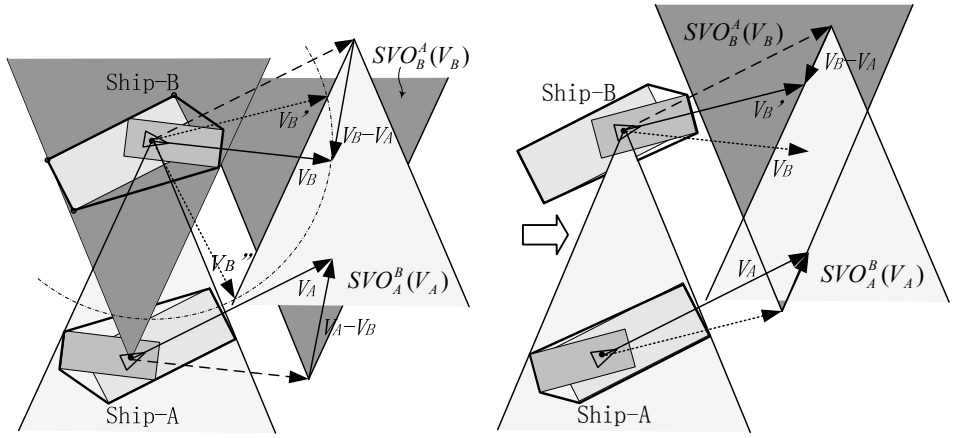


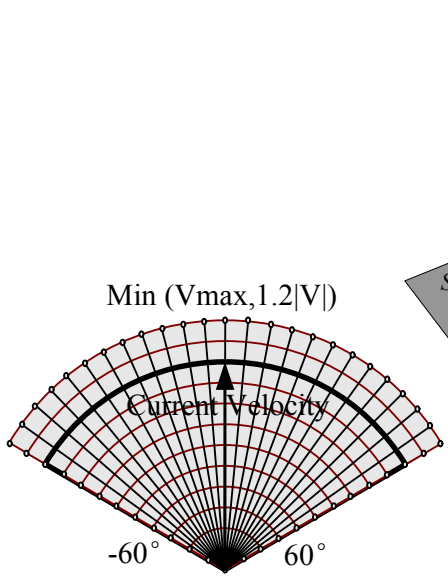
(a) Ship B should take a left turn. **(b) After Ship B takes left turn.**

Figure 6. Collision avoidance between a pair of ships.

and alters its velocity to V_B' so that it is outside the $SVO_B^A(V_A)$ and avoids collision with Ship A (see Figure 6 (a)). In the new situation, as the old velocity V_B is still inside the new $SVO_B^A(V_A)$ (see Figure 6 (b)), it cannot be chosen again as the new velocity for next cycle. Thus, oscillation between two velocities of V_B and V_B' can naturally be prevented. Although, due to the directional characteristics of ship domain, the $conv(D_B \cup (-D_A)$ is unable to always keep the same shape as $B \oplus -A$. If the new velocity V_B' is chosen close to $SVO_B^A(V_B)$, the old velocity V_B is still unable to escape out of the new $SVO_B^A(V_B)$. Figure 6(a) also shows why a left turn (V_B') is more feasible than a right turn (V_B'') when the target ship is coming from area (b) described in Figure 2.

Navigation of Multiple Ship Agents. Although the *SVO* is defined based on collision avoidance between two ships, its advantage lies in its ability to simply solve the problem of collision avoidance among multiple ships. It has been utilized to make decisions for ship agents to avoid collision with other moving ships in our multi-agent based marine traffic simulation system.

In the simulation system, ship agents are modeled to repeat a sense-decide-act cycle, perceiving the surrounding environment through a sensor to identify obstacles, making decisions to produce a steering order in the form of a velocity vector and executing the steering order by an effecter constructed according to TK model and PD controller of the ship (Pan, 2008). As subjected to these maneuverability and dynamic constraints, the admissible new velocities given the current velocity of a ship agent are restricted in limited set, called maneuver space. According to marine navigation conventions, the maneuver space can be defined as follows (Nagasawa, 1992). In geometry, it is a sector with apex at ship agent's center (see Figure 7).



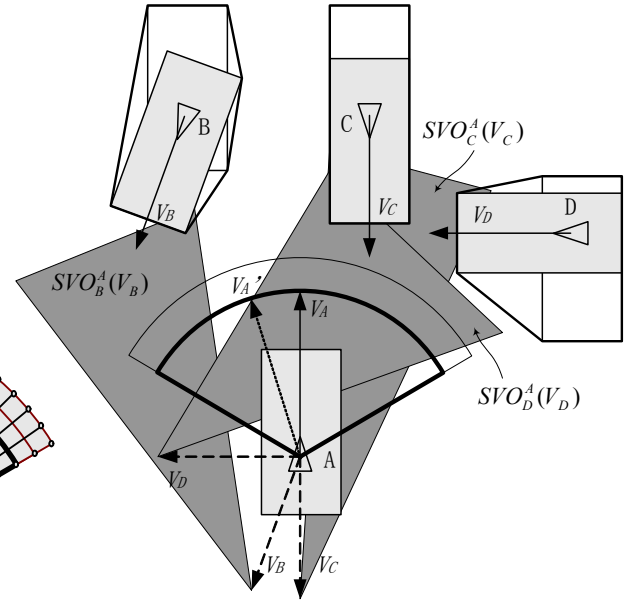


Figure 7. Maneuver space. **Figure 8. Collision avoidance among ship agents.**

$$MSpace(V) = \{V' | \frac{V' \cdot V}{|V||V'|} < \cos 60^o, |V'| < Min(V_{\max}, 1.2|V|)\} \quad (5)$$

When other ship agents appear in the sensing region of a ship agent, the union of all SVOs generated by the other ship agents is computed. To navigate without colliding with the others, the ship agent should choose a velocity within the free parts of its maneuver space that aren't covered by the union of SVOs (see Figure 8). In order to simplify the velocity selection computation, the maneuver space is quickly scanned to find a prefect new velocity that lies outside all the unions of SVOs and is closest to the current velocity. Differences between current velocity and the velocities within the left side of the maneuver space are multiplied by a factor of 1.5 to ensure the customary avoidance action of a right turn.

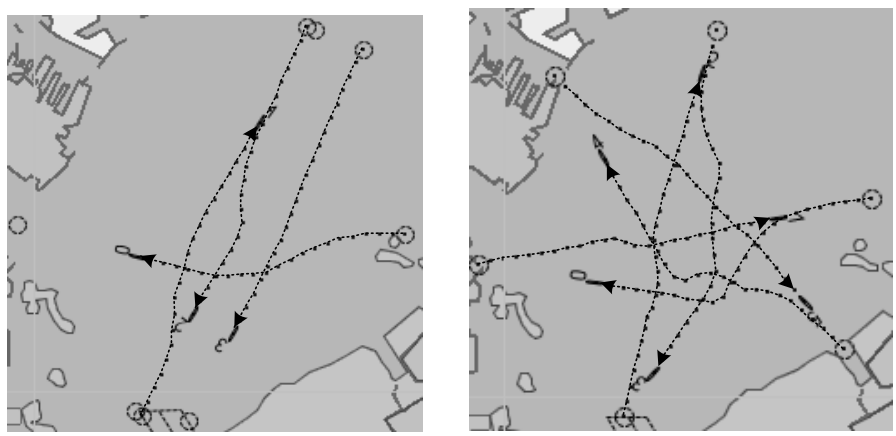

Figure 9. Example of simulation result (screenshots).

EXPERIMENT

Simulations have been conducted to investigate the effectiveness of the collision avoidance model. Figure 9 shows two example scenarios of complex encounters. All ship agents are modeled with equal size and maneuverability. The results show that the collision avoidance model navigated all ship agents safely without collisions and generated smooth and reasonable courses for the ship agents.

CONCLUSION

In this paper, we have extended the concept of velocity obstacle based on the characteristics of marine navigation and developed a reactive collision avoidance model that deals with collision avoidance among multiple ships. The model has been applied in a multi-agent based marine traffic simulation system and was shown to compute smooth and natural paths for ship agents in a dynamic environment. Because all ships navigate independently without explicit communication with each other, the model is a simple and natural formulation that is relevant and easy to implement.

ABSTRACT

Traffic signals on urban arterials operate in coordinated systems to provide smooth progression of major traffic movements. In recent decades, continued efforts have been made to research and develop coordinated traffic signal control strategies. As a result, many models, either off-line or on-line, have been developed. Despite the availability of customary models, all of them have been designed by coordinating all intersections at the same time, and there are many problems. For example, the individual intersection spacing may not be ideal, eventually leading to poor coordination.

An improved method is put forward in this paper to replace the classical method: the method of main intersection control strategies. The intersections on urban arterials that need to be coordinated are divided into two levels: the main intersection and the participation intersection. First, the intersections that are more important and appropriate to coordinate are selected as the main intersections. Then, the basic computing can be performed on the main intersections. The effect of coordination is better than the results from calculating all intersections directly. The rest of the intersections can be brought into the coordinated system through many other ways so as to minimize the impact on the system. Compared with the classic method, this method of main intersection control strategies optimizes the effectiveness of coordination, reduces the traffic delay and deals with the intersections step-by-step. In practical engineering, compared with the classical method, it has been proven that the new method can reduce the delay by about 10-20 percent. It has great value in practical application.

INTRODUCTION

Traffic signals on urban arterials operate in coordinated systems to provide for smooth progression of major traffic movements. In recent decades, continued efforts have been made to research and develop coordinated traffic signal control strategies. Despite the availability of customary models, all of them have been designed by coordinating all intersections at the same time. This causes many problems. For example, the individual intersection spacing may not be ideal, eventually leading to poor coordination. This paper presents an improved method to replace the classical method: the method of main intersection control strategies. Compared with the classical method, this method optimizes the effectiveness of coordination and reduces the traffic delay by dealing with the intersections step-by-step. In practical engineering, compared with the classical method, it has been proven that the new method can reduce traffic delays by about 10-20 percent or so and that it has great value in practical application.

ACTUALITY RESEARCH

Many experts have made in-depth studies about the timing design of traffic control systems by the numeric method. In China, Yang Peikun (L. Bohang, 2007) expounded the mechanism for the theory model of the ideal equidistant intersection in "Traffic Management and Control." Lu Huapu (J. Liye, 1996) brought forward the theory model, which was oriented toward the minimum delay of vehicles in two-way arterial travel. Yet his theory is based on the vehicles arriving at a uniform speed. Zou Chengwei and Li Zhihai conducted traffic control design at Harbin Hongqi Street. Abroad, national standards in America and Germany are all based on the numeric method. Some scholars (Van Aerde, Mohamadreza Farzaneh and Hesham Rakha) researched how to demarcate the classic models more accurately (Hesham Rakha, 2005). Despite the availability of customary models, all of them have been designed by coordinating intersections all at once, leading to many problems.

THEORY OF THE COMPOSITE NUMERIC METHOD

The composite numeric method has broken the basic pattern, of parallel computation with all intersections, of the traditional numeric method. Intersections are divided into two types: the main intersections and the participation intersections. First, according to different volumes or locations, select the more important and appropriate coordinating intersections to be the main intersections. Because of selection, most often, the coordination effects would be better than those that were calculated directly by the numeric method. Next, bring the rest into the traffic control system. We could adopt various ways to optimize the intersections brought in before, such as half-cycle, phase order, etc.

As shown in Figure 1, one should select four intersections, which are marked with yellow, to be the main intersections, then make fundamental calculations on these chosen ones by the numeric method. Then one would bring other intersections, which are marked with blue into the coordination with the main intersections and adopt methods of traffic signal optimization. Of course, this solution is the most applicable for the cases of alternating big and small intersections on urban arterials.

SELECTION OF MAIN INTERSECTIONS

The composite numeric method is used for the coordination of controlling main roads; the first problem deals with selecting the intersections that are the main intersections. We can take the selection through the following steps:

Determine the number of main intersections. Calculate the cycle C_i separately for each intersection and determine the total cycle C. Determine the ideal spacing L_{per} according to C and system speed V. Based on the basic concept that the ideal spacing is fluctuating in the vicinity of $VC/2$, calculate to the ideal spacing fluctuation range of main intersections, which equals $L_{per}\pm100$ meters in general. According to the system total length L and ideal spacing fluctuation range, determine the largest and smallest number of main intersections:

$$n_{\max} = l \Big/ (l_{per} - 100) + 1 \quad (1)$$

$$n_{\min} = l \Big/ (l_{per} + 100) + 1 \quad (2)$$

Where: $n_{\max}$ - Largest possible number of main intersections

$n_{\min}$ - Smallest possible number of main intersections

L- System total length

L_{per} -Ideal spacing fluctuation range

Determine the groups of main intersections. Set the number of all the intersections that need coordination as m, select n of them as the main intersections. There are C_m^n cases, and all the possible cases are:

$$k = \sum_{i=n_{\min}}^{n_{\max}} c_m^n \quad (3)$$

Where, k = Total number of possible options for main intersections;

i = Number of possible main intersections;

C_m^i = Total number of possible options for main intersections when the number of main intersections i is determined; and,

$n_{\min}$ and $n_{\max}$ are the same meaning with (1) (2) in 4.1.

Determine the specific main intersection groups. For each group, the total distance between the actual intersections and the ideal intersection will be calculated:

$$l_z = \sum_{i=1}^{m} l_i \qquad (l_i = \left| D_i - d_j \right|) \quad (4)$$

Where l_i is the distance between the number i actual intersection with the number i ideal intersection.

We use the traffic evaluation index W to ultimately determine the options for main intersection groups. The formula for W is:

$$W = 0.37Q - 0.63L \quad (5)$$

Where, W = Index of traffic evaluation;
Q = Traffic volume through main control intersection;
L = Distance between the actual intersection and the ideal intersection.

We can select the smallest values W of a group as the main intersections. That is, select the group as far as possible that has larger traffic volume and the smallest distance between the actual intersections and the ideal intersection.

INCORPORATE THE PARTICIPANT INTERSECTIONS

After the selection of main intersections, we face the problem of how to coordinate main intersections with the rest of the intersections. Other optimal methods in traffic control can be used, such as semi-cycle, phase adjustments, and so on:

Semi-cycle method. For some intersections with smaller traffic volume, the practical need for cycle time is close to half of the system cycle time. Therefore, we can set half of the system cycle time as signal cycle time for these intersections. That is the semi-cycle method.

Adjustment of the phase order method. In other words, two straight traffic volumes of the urban arterials are on different phases. This method can significantly reduce the loss of time, making the traffic operation achieve the best effect.

Set up hardware facilities. Hardware set up on the participant intersections can be taken into consideration. Essentially, this reduces the impact of pedestrians and vehicles from branch roads to vehicles on the urban arterials.

Figure 1. The main intersection and the participation intersection.

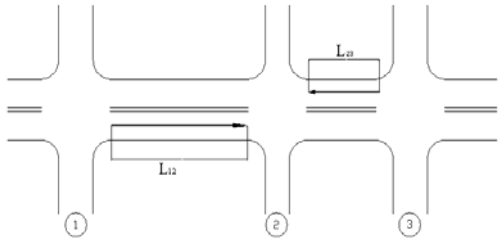

Figure 2. The distance between main intersection and the participation intersection.

CASE ANALYSIS

On November 18, 2007, we tested ten intersections along Yuhua Road in Shijiazhuang. As shown in Table 1, after the using the numeric method, the result of calculation for offset is very good. As shown in Table 2, the classic numeric method made the control system delay drop from 61.3V/S to 40.2V/S, while the composite numeric method made it reduce to 25.3 V/S, an obvious optimal effect.

Table 1. Calculated offset of main intersections.

Intersection	A	B	C	D
Ideal signal No	①	②	③	④
Signal location	right	left	left	left
Proportion of green time λ(%)	31.8	47.2	56.3	39.6
Loss of green time (%)	4.1	4.1	2.3	0.25
Proportion of green time of efficiency (%)	27.7	43.1	54	39.35
Difference of green time (%)	84.1	26.4	71.85	30.2
Relative green time (s)	135	42	115	48

Table 2. Data of delay of simulation in three conditions.

Instance	Delay of investigation	Delay of classical algorithm	Delay of of main intersections control strategies
Number	61.3	40.2	25.3

CONCLUSIONS

The numeric method is the basic method for urban arterial traffic control, and is also the most widely used method at present. We improved on the numeric method, on the premise of not increasing input parameters to the system. The example verified that the method can reduce traffic delays on urban arterials, and has more obvious effects on coordination.

ABSTRACT

Floating car data (FCD) are characterized by high dimensions and large data size with complex spatiotemporal relationships. This paper proposes a time interval-varying scheme for FCD dimensional reduction for clustering analysis, which can capture the main fluctuation closer to the original data. A self-organizing map is used as the clustering algorithm. Some interesting and hidden relationships between links can be found in the clustering results. The method proposed in this paper proved acceptable for FCD clustering, which is useful for road correlation analysis of the urban road network.

INTRODUCTION

A floating car equipped with a Global Position System (GPS) unit can be considered a moving geo-sensor with the ability to collect vehicle speed data. The data acquired by floating car is often used to indicate the traffic conditions of corresponding links. In order to understand road network traffic conditions, clustering is an often-used method that reveals the hidden spatiotemporal relationships that are of great value for many applications, such as traffic prediction. However, floating car data (FCD) are characterized by high dimensions and large data size with complex spatiotemporal relationships.

Focusing on the fluctuation of link average speed at different time intervals on a road network, this paper proposes a novel approach for road link traffic clustering based on a Self-Organizing Map (SOM) using a varying interval scheme for FCD dimension reduction.

RELATED WORKS

The most widely used clustering algorithms are K-means, c-means (CM) and fuzzy c-means (FCM) (Lee et al., 2006; Guo and Jiang, 2007). K-means clustering is sensitive to the initialization of clusters and data noises or outliers. CM and FCM algorithm may converge to create local solutions that are significantly inferior to the desirable global optimum (Selim and Ismail, 1984; Pollard, 1982). In order to find the global optimum, clustering methods using Genetic Algorithms (GA) have been proposed (Murthy and Chowdhury, 1996; Jones and Beltramo, 1991), which are usually computationally expensive. These methods are not feasible for large amounts of FCD with non-exhaustive enumeration and high dimensionality. SOM with excellent data mining capability and easy visualization is a potentially powerful clustering tool to solute these problems. It has been adopted in many fields, such as pattern recognition, data classification and image analysis (Oja and Kaski, 1999). In the field of traffic data analysis, there are some studies that aim to group the traffic flow time series from loop detectors and use equal-width schemes to prepare the input components of the SOM (Cheng et al., 2006a, 2006b, 2008).

If it can be considered a dimension in different time space, a floating car record attached to a link can be regarded as a point with high-dimension during a certain epoch (for example, 1440-dimention of a day at one-minute intervals). Thus, dimension reduction of FCD is critical and significant before conducting clustering. Major dimension-reduction methods include: Principal Component Analysis (PCA) (Cheng et al., 2006), Discrete Fourier Transformation (DFT) and wavelet decomposition (Qiao et al., 2003; Liu et al., 2008). A simple but rather useful technique for data dimension reduction is aggregation approximation (Keogh and Pazzani, 2000). Traditional traffic data aggregation schemes are based on equal-width methods, typically with 5 or 15-minute intervals, which may not be optimal for traffic changes that vary significantly throughout a day (Zheng and McDonald, 2006, 2007; Turner et al., 2000).

PROPOSED METHODOLOGY

The determination of the varying intervals is a Dynamic Programming (DP) problem. Using Sum Squared Error (SSE) as the error metric and given a sequence of source traffic data X of length N, finding the optimal aggregation intervals $\{[s_1,e_1],[s_2,e_2],\ldots,[s_M,e_M]\}$, $1 \leqslant i \leqslant M$, essentially minimizes the total: $SSE = \sum_{i=1}^{M}\sum_{j=si}^{ei}(x_j - y_i)^2$, where $y_i = \frac{1}{ei - si + 1}\sum_{j=si}^{ei} x_j$, $SSE(si, ei) = \sum_{j=si}^{ei}(x_j - y_i)^2$ is the i^{th} interval error, M is the number of aggregation intervals. The minimum total SSE indicates the least loss of traffic original information.

There exists an efficient algorithm to solve this kind of optimization problem. The algorithm based on DP with quality guarantees has been implemented in these studies (Jagadish et al., 1998, 2001). The crucial equation underlying the DP is:

$$SSE^*(i,k) = \min_{1 \le j < i}\{SSE^*(j,k-1) + SSE([j+1,i])\}$$

Where SSE*(i, k) is the minimum SSE for the data sub-vector X[1, i] aggregated at most k intervals and SSE([j+1, i])=SSE(j+1, i) is the SSE for the data sub-vector X[j+1, i] aggregated to one interval with the average of AVG([j+1, i]). Using iterative calculation, the solution for k intervals can then be reduced to the case of k-1 intervals by considering all possible left boundaries of the rightmost k^{th} intervals. Starting from SSE*(1,1), which is known, SSE*(N, M) can be found by calculating SSE*(i, k) for all $1 \le i \le N$ and $1 \le k \le M$ in increasing order of k, and for any fixed k, in increasing order of i.

An example of error comparison of the FCD aggregation scheme generated using the DP algorithm and equal-width scheme is shown in Figure 1. The error metric is Root Mean Square Errors (RMSE), which here is defined by:

$$RMSE = \sqrt{\frac{SSE}{N}}$$

As SSE is minimized in the optimal scheme, the RMSE is also the smallest. It is obvious that the varying aggregation intervals can catch the primary changes of the traffic feature, rather than reducing the dimension only.

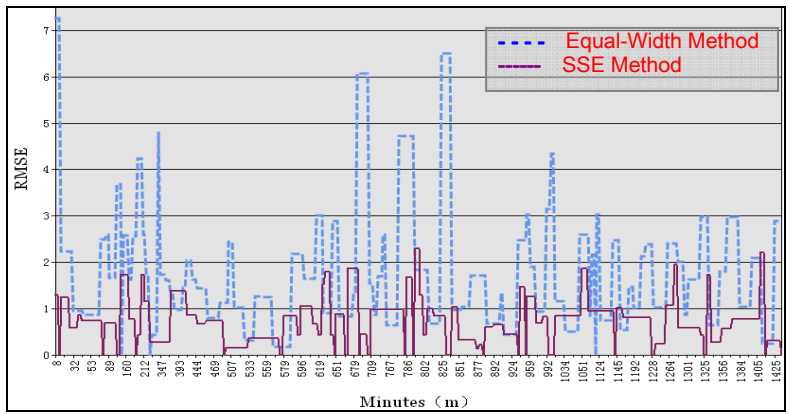

Figure 1. The RMSE of the equal-width method and the SSE method for the average link speed measurement.

SOM is a well-developed non-supervised neural network technique for data clustering with easy visualization. Details of SOM can refer to Oja et al. (1999). The size of the map usually reflects the number of clusters, depending on the amount of input samples. According to the empirical value, [10, 9] is used in this study. In order to interpret the results and find the clusters easily and exactly, a labeled map is used. Each link is considered a single label. During the training of the map, it can automatically assign labels to the nodes of a trained SOM. The closer labels are assigned to a particular cluster, and the farther ones are assigned to a different cluster. Moreover, several visualization methods of SOM are used in order to make the clusters or sub-clusters easily understood and interpreted.

CASE STUDY

The study used the FCD acquired from over 1000 of Nanchang's taxis

from July 14 to July 20 2008, including longitude, latitude, point speed and direction angle. The data were low-frequency and continuously transmitted. The study area included 77 links in the city central, as shown in Figure 2.

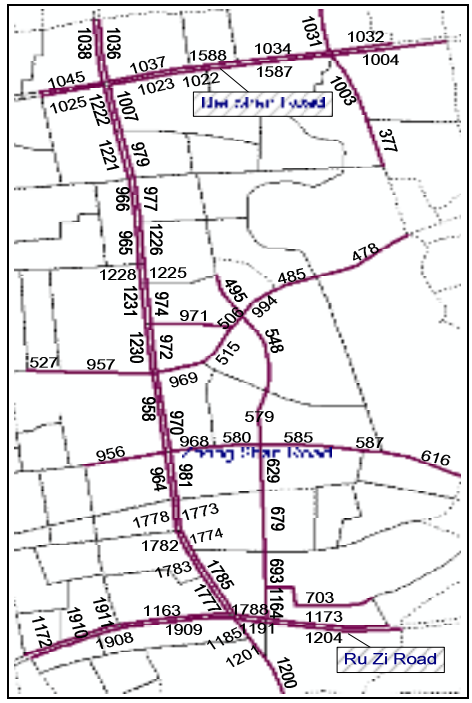

Figure 2. The study road links.

Using the proposed method, the FCD on the road links were divided into 96 optimal varying intervals for each day. The data that fell in the same interval were averaged as the link speed of that interval. Thus, the whole week average speed of each selected link was a vector with 672 dimensions. Thus, attributes of the studied links for a whole week were structured with a 77*672 matrix, which is the input of the SOM. The rows indicated the main links and the columns indicated the varying intervals that were the components of the samples. The resulting labeled map and the better visualization methods allowed us to better distinguish several obvious clusters and some sub-clusters.

The clustering results are shown in Figure 3. Some links are clustered in one group but some groups only have one link; these groups are the sub-clusters. Every lattice can be considered as one sub-cluster, and the sub-clusters can define the clusters according to the cluster boundaries' segmentation (see Figure 3(a) Clusters A, B, C for examples).

By comparing the clusters and the physical road network, some interesting relations between links in the same group can be easily found. For example, the links in the same sub-clusters are usually spatially close to each other or in the parallel direction, like Group 3 and link 1587 and link 1588 in group 4, or adjacent to intersections along the same street, like Group 1, or intersect at intersections, like Group 2. Table 1 illustrates some typical sub-clusters, and the positions of these links in the network can be shown obviously in Figure 2. The super-clusters can expose some hidden relationships between the links that are not connected with each other spatially. For example, link 1204 and link 1173 in Ru

Zi Road and link 1034 and link 1587 in Die Shan Road are far from each other (Figure 2), but they are in the same super-cluster A with similar speed levels (Figure 3(b)).

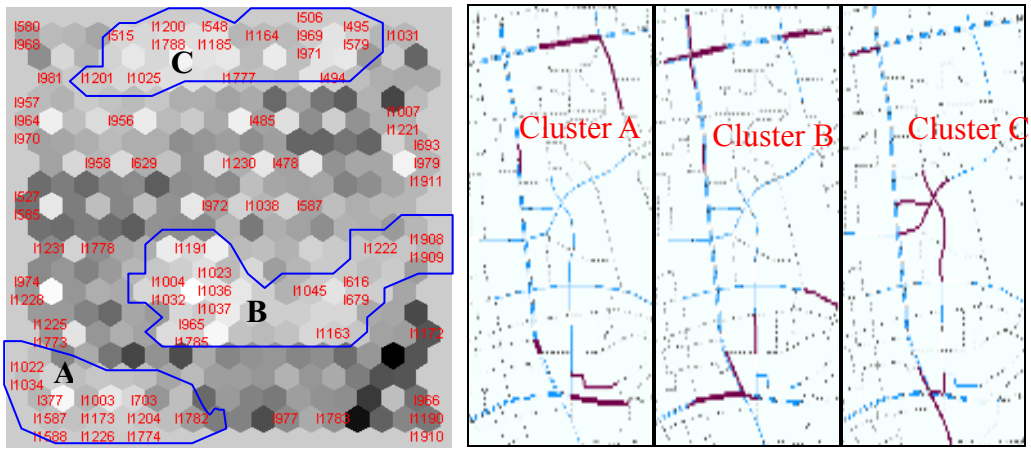

Figure 3. (a) is the clustering results, (b) Cluster A, B, C for an example.

Table 1. Some sub-clusters.

Sub-cluster	Link	Sub-cluster	Link
Group 1	l1908, l1909	Group 3	l1004, l1032
Group 2	l1023, l1036, l1037	Group 4	L377, l1587, l1588

CONCLUSION AND THE FURTHER RESEARCH

The method proposed in this paper proved acceptable for FCD clustering, which is useful for analyzing the fluctuation and the hidden relationships of FCD in the road network. Specifically, the varying aggregation level scheme fits for the dimensional reduction and feature extraction of the high-dimensional and large-size traffic data. The favorable features of SOM make it a potentially powerful tool for traffic data.

However, in order to indicate spatial distribution of the link traffic state (average speed) in the urban road network, the spatial attribute of road links (geometric shape, location, topological attributes etc.) should not be ignored. Therefore, our further research will consider these issues and use larger volume FCD.

ABSTRACT

Interconnection desirability testing between adjacent intersections is critical to analyzing traffic conditions and deciding whether the two isolated traffic signals should be interconnected. This paper reports the development of a route-based Interconnection Desirability Index model to evaluate the need to interconnect signalized intersections. In the first part, the shortcomings of existing traditional Interconnection desirability index model (link-based model) were analyzed. In the second part, a route-based model was built, considering not only the distance between intersections but also the signal phase plan and route volume composition. Finally, a case study, including two real intersections, is presented. The performance of traditional link-based models and the proposed route-based model were compared. Synchro and VISSIM were used to optimize and evaluate the isolated and coordinated signal timings. The results show that the proposed route-based model has the ability to describe the real relationship of adjacent intersections and find the most critical route for signal coordination. Moreover, the route-based model is more sensitive than link-based models under high interconnection desirability conditions.

INTRODUCTION

Modern traffic signal control strategy to reduce vehicle delay and fuel consumption has been enhanced by readjusting signal timing plans, installing control equipment and providing interconnection (Cohen. S. L, 1983; Wagner, 1980; Suhbier and Byrne, 1979). Even though few publications exist addressing when to interconnect a series of isolated signalized intersection, interconnection has been recognized as a viable traffic control improvement alternative. (Wagner, 1980; Yagoda, 1973; E. Chang, 1985) Many other researchers have found that a number of factors are important in determining the need for interconnection including geographic relationship, volume levels and traffic flow characteristics.

One of popular model used and indexed by the Traffic Control System Handbook (2005) was the coordination desirability index model developed by

Chang and Messer. It is described as (we call it the link-based model):

$$I = \left(\frac{0.5}{1+t}\right) * \left(\frac{q_{\max}}{q_T}\right) - (N-2) \quad (1)$$

Where t is link travel time in minutes, $q_{\max}$ is straight-through flow from upstream intersection (VPH), q_T is the sum of traffic flow at the downstream approach from the right turn, left turn, and through movements of the upstream signals, divided by the number of arrival links at the upstream intersection. N is the number of arrival lanes feeding into the entering link of the downstream intersection.

The inputting flow characteristics of a total link are considered in the model. However, one of the critical issues of signal coordination is that the route flow characteristics, rather than link flow characteristics, decide the benefit of interconnection of two isolated intersections. Moreover, the impact of a signal phase plan was not considered in the link-based model. Hence, this research will focus on fulfilling the following the two critical tasks.

ROUTE-BASED MODEL

Intersections should be interconnected only if the arrival flow rates of any movement downstream can be guided into compact platoons through an effective traffic signal timing plan. In order to capture the real desirability of interconnection, route volume characteristics and signal plan were considered in the proposed model (route-based model).

MODEL ASSUMPTIONS

To yield a tractable solution for the proposed formulations with realistic constraints, this study has employed the following assumptions:

Assumption 1: Data of every route.

The turn ratio at the downstream intersection of a movement of upstream intersection is needed in the model.

Assumption 2: signal phase plan

The signal phase design of intersections is input of the proposed model. Only the phase schema, including phase sequence and phase number, is needed.

NOTATION

To facilitate the presentation, all definitions and notations used hereafter are summarized:

- $\delta_{m,p}^{i}$ is the turn ratio of movement m at phase p of intersection *i*. $\delta_{m,p}^{i}$ = 1 if the movement m is not permitted at phase p.
- q_m^i is total volume of movement m at intersection *i.*
- p_i is the index of signal phase at intersection *i*.
- P_I is the number of phases of intersection *i.*
- A^N is the total number of lanes of downstream approach.

- $\lambda_{m,n}^{i,i+1}$ is the flow ratio of movement m of intersection *i* to movement n of intersection *i*+1.
- $R_{m,n}^{i,i+1}$ is the route composed by movement m of intersection *i* and movement n of intersection *i*+1.
- M_i is the number of movement of intersection *i*.
- The intersection i+1 represents the nearest neighbor to intersection *i*.

MODEL FORMULATION

The volume of movement in phase *p* of intersection *i* feeding movement *n* of intersection *i*+1, $q_{p,n}^{i,i+1}$:

$$q_{p_i,n}^{i,i+1} = \sum_{m=1}^{M_i} q_m^i \delta_{m,p}^i \lambda_{m,n}^{i,i+1} \qquad \forall i, m, p_i \qquad (2)$$

Maximum phase flow from intersection *i* to intersection *i*+1 feeding movement n of intersection *i*+1, $q_{\max,n}^{i,i+1}$:

$$q_{\max,n}^{i,i+1} = \max(q_{p_i,n}^{i,i+1}, \qquad \forall p = 1,2.....P_i) \quad (3)$$

The degree of arrival flow imbalance of movement *n* at downstream intersection *i*+1 ($IM_n^{i,i+1}$) is given by the ratio between the maximum phase traffic volume feeding from the upstream intersection *i* and the sum of traffic volume of all the phases coming from the upstream intersection. It can be stated as:

$$IM_n^{i,i+1} = \frac{q_{\max,n}^{i,i+1}}{\sum_{p_i=1}^{P_I} {}_{p,n}^{i,i+1} / P_I} \qquad \forall i, p_i \qquad (4)$$

$IM_n^{i,i+1}$ is the maximum degree of arrival flow imbalance of movement *n* of intersection *i*+1. Equation (5) indicates that the route composed by the movement corresponding to $q_{\max,n}^{i,i+1}$ of intersection *i* and movement n of intersection *i*+1 is one of the critical routes between the two intersections.

The interconnection desirability of the route decided by Equations (4) and (5) can be calculated by the Equation (6) based on the structure link-based mode:

$$IR_n^{i,i+1} = \left(\frac{0.5}{1+t}\right) * \left(IM_n^{i,i+1}\right) - (N-2) \qquad \forall i, n \qquad (5)$$

The maximum interconnection desirability of routes is adopted as the interconnection desirability of the intersections:

$$I_{keyRoute}^{ij} = \max(IR_n^{i,i+1}) \qquad \forall i, n \qquad (6)$$

The interconnection desirability of two intersections is equal to the largest index interconnection desirability of routes between two intersections.

SIMULATION AND EVALUATION

Comparing link-based and route-based index

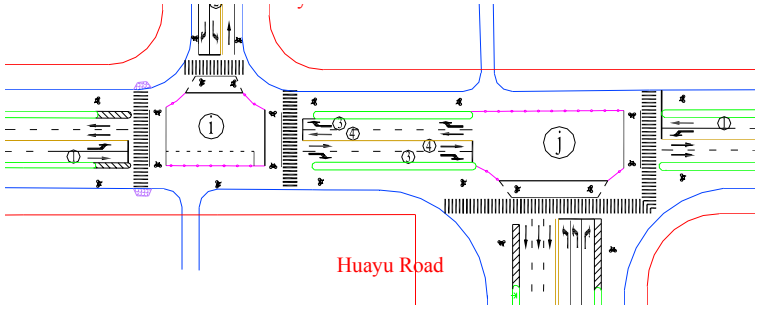

Figure 1. The geometry of the two intersections.

The two adjacent intersections in Ma'anshan City shown in Figure 1 were selected as a case to analyze the proposed model. The net distance between the two "T" type intersections is 50 meters (intersection *i* and intersection *j*). The traffic volume and turn ratio of related movements were calculated based on traffic survey data and shown in Table 1.

Table 1. Traffic volume of the two intersections

		i-j		j-i	
		Through (1)	Left (2)	Through (1)	Left (2)
Traffic volume		552	342	590	268
Turn ratio	Through	0.89	0.30	0.71	0.37
	Right	0.11	0.70	0.27	0.63

Let $R(im\text{-}jn)$ represent the interconnection desirability index of routes composed by movement m of intersection i and movement n of intersection j calculated by the proposed route-based model. Let $L(i\text{-}j)$ represent the interconnection desirability index from intersection i to intersection j calculated by link-based model. Based on the traffic survey data, the difference of route-based model and link-based model are shown in Figure 2.

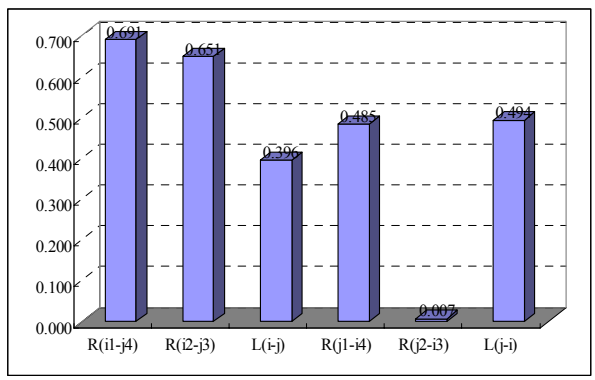

Figure 2. Differences of link-based model and route-based model.

Different routes have different interconnection desirability indices, and the index may larger or smaller than the results of the link-based model. this means that the link-based model does not reflect the real desirability of movements between the two intersections because the signal coordination should be

calculated based on routes. Moreover, the link-based model cannot identify the critical route that should be considered first in signal coordination. The critical route is *R*(i1-j4) based on the model (5) according to Figure 2. VISSIM was used to evaluate the efficiency of different signal plans and the results are shown in Figure 3.

Figure 3 indicates that signal coordination can create benefits for the given two intersections compared with no coordination scenario. The average delay of the intersection is various with the coordinated routes. The coordinated signal plan for route *R*(i1-j4) with the highest interconnection desirability index gets more benefit than other routes. The relationship between delay and interconnection desirability index with the change of difference of cycle arrivals under isolated conditions is show in Figure 4.

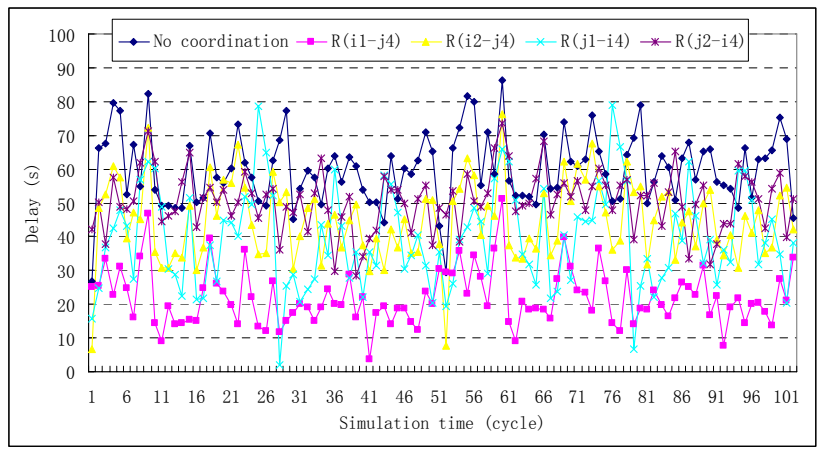

Figure 3. Impacts of different route on signal plans.

Figure 4 describes the relationship between average vehicle delay and interconnection desirability index under isolated condition. The average vehicle delay increases with the increase of the interconnection desirability index calculated by both link-based and route-based models. The gap of interconnection desirability index calculated by the models also increases with the increase of the interconnection desirability index. This means that the route-based model is more sensitive than the link-based model under high interconnection desirability.

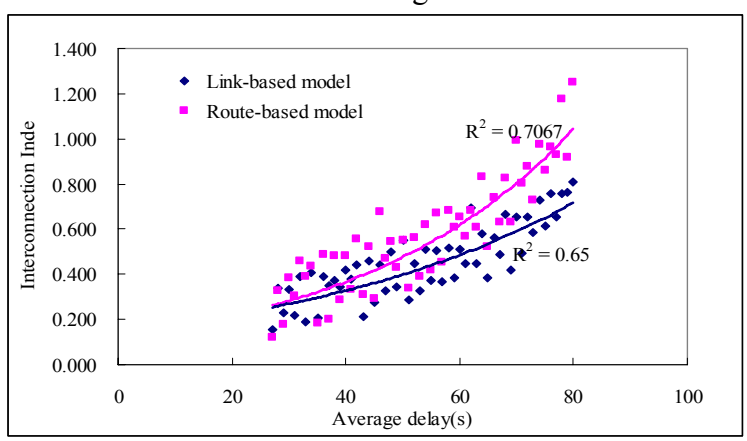

Figure 4. Relationship between delay and Interconnection desirability index.

CONCLUSION

This paper illustrates a route-based interconnection desirability index model that evaluates the need to interconnect signalized intersections. The proposed route-based model is capable of capturing the impact of signal phase plans and route volume characteristics, and produces detailed output information including the interconnection desirability index of every route and critical route between two intersections. The results of VISSIM simulation show that the proposed route-based model has the ability to describe the real relationship of adjunct intersections and find the most critical route for signal coordination. Moreover, the route-based model is more sensitive than the link-based model under high interconnection desirability.

Note that this paper has presented preliminary evaluation and sensitivity analysis results for the proposed model through a case study. More extensive tests or evaluations will be essential to assess the effectiveness of the proposed model under various traffic flow patterns and intersections.

ABSTRACT

This paper defines what VMS was and what the VMS's future range was, and points out the deficiency of the VMS's future range in China. The paper focuses on three themes: the VMS information reading, decision making and operating, main parameters that could affect the threshold scope of the VMS's future range and were reasonably analyzed in turn by the author. An optimal model for the VMS's future range is presented here, and some optimal quantitative methods to every concrete parameter are also introduced and constructed. Finally, some inherent relations between the characteristics of the vehicles' driving speed and the threshold scope of VMS's future range are studied through a discussion of the upper and the lower limit range of VMS's future range, and we discuss some important and useful conclusions to guide the VMS's project in the future.

INTRODUCTION

VMS is not only an information issue method, but also a kind of transportation control strategy. In the 1990s, with ITS technology development, there were more and more applications and some related research into VMS's use for highway or city expressway management (Li, X. 2008).

VMS's future range is the distances between VMS and the main road diversion points, or between VMS and alternative interchanges. Its establishment, whether it is reasonable or not, will relate to the VMS's effect (Abbas, M.M., et al., 1999). This article has taken VMS as a study object, thoroughly discussing the upper and lower threshold scope of VMS's future range, and elaborating on the intrinsic relations between the VMS's future range and the variation characteristics of vehicle speed in the road.

THE ESTABLISHMENT OF THE VMS'S FUTURE RANGE OPTIMAL MODEL

The driver's memory has a certain time limit for retaining VMS information. If the VMS's future range is too long, the VMS information will become fuzzy in his memory, so the driver can't judge how to change driving behavior. This can also produce a sense of distrust of VMS's information. If the VMS's future range is too short, the VMS is no better than the dummy (Jeffrey M. Henderson., 2004). Therefore, there is great significance for constructing a scientific and reasonable optimal model to calculate and study.

THE MAJOR INFLUENCING FACTORS AND ESTABLISHING CORRESPONDING MODEL FOR VMS'S FUTURE RANGE

The reaction of the driver to VMS information may divide into three stages: reading VSM information, judging and making a decision, and operation. The effect process of the VMS to the driver's behavior influence is as shown in Figure 1 (Che, G., et al 2006):

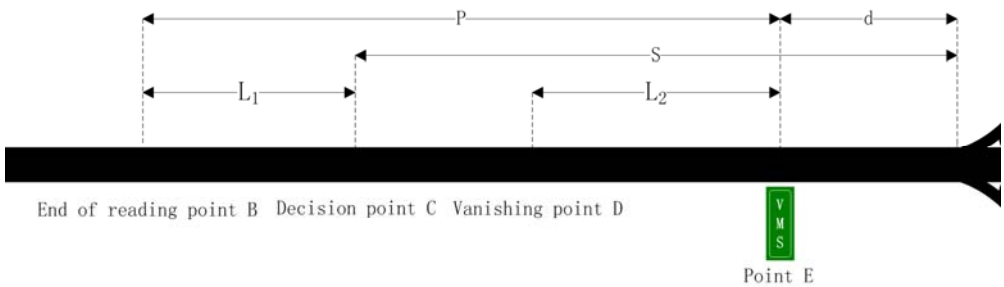

Figure 1. The influence of VMS on the driver's behavior decisions.

From Figure 1, we can determine an inequality:

$$d \geq S + L_1 - L_2$$

According to the memory material, people divide time, which maintains in the human brain, into three parts: the instantaneous memory, which does not surpass 1 or 2 seconds, the short-term memory, which does not surpass 1 or 2 minutes, and the long-term memory which surpasses 1 or 2 minutes (Zhidao Baidu, 2007). After the driver passes over Point D, VMS information rests on the driver's mind in the short-term memory. In the short-term memory, the driver should be able to arrive or pass over the road diversion point; otherwise, the VMS information will become fuzzy in his mind. Therefore, the distance L, which the driver has passed in the driver's short-term memory distance, should be less than the sum of VMS's future range d and disappeared distance L_2, so we can get the upper limit range of

d: $d + L_2 \leq L$

In summary, the value range of VMS's future range is defined as:

$$S + L_1 - L_2 \leq d \leq L - L_2$$

CALCULATING PARAMETERS OF THE VMS'S FUTURE RANGE OPTIMAL MODEL

From the above passage, the threshold value of VMS's future range d closely relates with four model parameters, which are L, L_1, L_2 and S. Its calculating formula is:

$$L = \frac{V_2 \times t}{3.6}$$

In this formula: V_2 is defined as a running speed (km/h), t is defined as the short-term memory time (s).

The decision distance L_1 is the distance that the vehicle passes in the time from when the driver will judge and decide to operate until the brake has an effect. Truly, it starts when the driver reads over the VMS information. The driver needs at least 0.4s conscious reaction time before he begins to brake, and 0.3s time to

produce the brake effect (Wei Wang, W., Guo, X. 2000). The total time comes to t_1=0.7s. The distance covered by the vehicle in this time is:

$$L_1 = \frac{V_1 \times t_1}{3.6}$$

In this formula: t_1 is defined as the total time(s) of sensory and braking reaction; V_1 is defined as a normal speed (km/h) on the road.

The disappeared distance L_2 (as shown in Figure 2) relates to four model parameters: H, b, e and ∂.

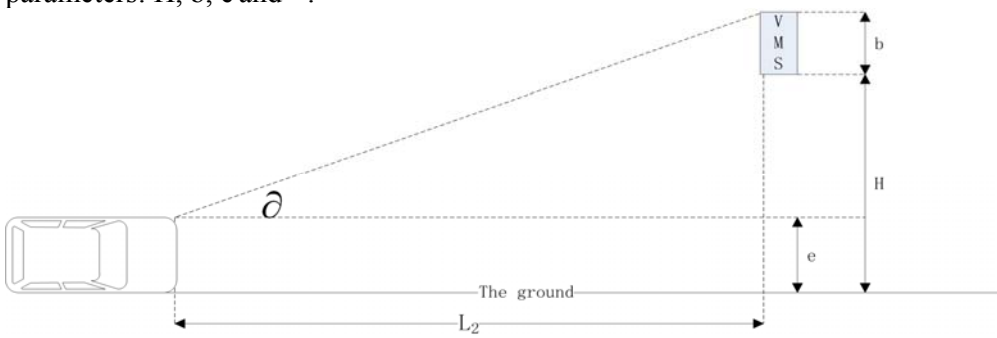

Figure 2. Calculating disappeared distance L_2.

Therefore, the disappeared distance L_2 can be calculated as follows:

$$L_2 = \frac{H + b - e}{\tan \partial}.$$

In this formula: e is defined as the driver's eye height (m), H is defined as the height from the VMS's bottom to the ground (m), b is defined as the VMS's width (m), ∂ is defined as the angle between the sight disappearing point and the VMS.

In the action distance S, the driver must be able to complete the total behavior according to the VMS information (i.e. change lanes, make deceleration, and change direction). The braking quality of the automobile mainly manifests on the braking distance. The braking distance's formula is (Yang, S. 2004):

$$S_1 = \frac{V_1^2 - V_2^2}{254\ (f + i + \phi)}.$$

In this formula: V_1 is defined as the speed（km/h) when the driver just read over VMS information, φ is defined as a road adhesion coefficient, i is defined as road longitudinal slope, f is defined as rolling resistance coefficient.

The process of changing traffic lanes is more complex, and it relates with the traffic flow density and running speed as well as the road condition (Chiu, Y. 2001). When calculating the braking distance, we should analyze it from the worst situation: in the changing traffic lane, the longest distance should occur when the automobile passes the vehicle in an adjacent lane and moves into that lane. The process in which the automobile overtakes another one as shown in Figure 3:

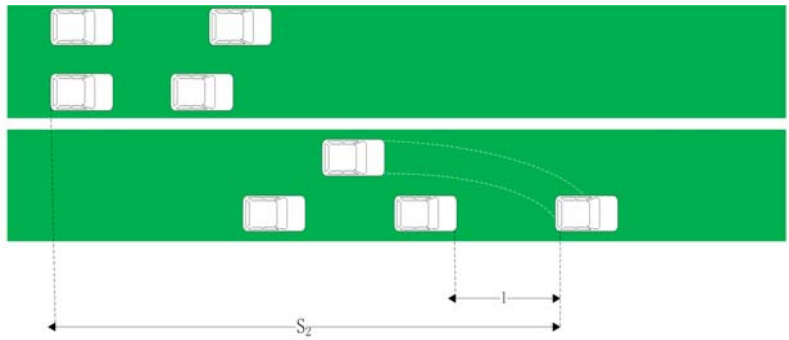

Figure 3. The process in which the automobile overtakes another one.

$$S_2 = \frac{V_1 \times l}{V_1 - V_3}$$

In this formula: S_2 is defined as passing distance (m), V_3 is defined as the speed of the passed automobile (km/h), l is defined as the minimum safe driving distance (m).

$$S = S_1 + S_2$$

In summary, the calculating formula for the value range of the VMS's future range d is as follows:

$$\frac{V_1 \times l}{V_1 - V_3} + \frac{V_1^2 - V_2^2}{254\ (f + i + \phi)} + \frac{V_1 \times t_1}{3.6} - \frac{b + 4.3}{\tan \partial} \le d \le \frac{V_2 \times t}{3.6} - \frac{b + 4.3}{\tan \partial}$$

EXAMPLE CALCULATION AND ANALYSIS

This article takes the most common overhang VMS as an example and calculates the threshold value scope of the VMS's future range. In the condition of traffic flow patency, the running speed V_2 is 0.5 the running speed V_1 after the driver adopts deceleration and changes lane when he reads over VMS information in front of him (Zhu, S. 2007). Because the velocity difference between the speed of the overtaking vehicle and the speed of the overtaken vehicle is generally in 20~30 km/h on the road (Erkin., 2004),

$$V_3 = V_1 - 25\,(\text{km/h})$$

Practice states that the driving safety distance is roughly equal to the driving speed. When the driving speed is 100km/h, the driving safety distance is about 100 meters (Admin., 2008). Deducting from this, the driving safety distance is approximately equal to the value of V_1. f relates to road surface type, tire structure and driving velocity etc. It is generally determined by experiments (Yang, S. 2004). f is 0.015 in this example. Φ mainly depends on roughness, moisture, muddiness of the road surface, the tire's pattern and pressure, driving speed and load etc. (Yang, S. 2004). In this passage, Φ is 0.6. The width b of the overhang VMS in the road is 1.94m. α is 7^o for the overhang VMS. e= 1.2m; H=5.5(m); i=3%; t=120s.

Leading the parameter value into the formula, we can obtain the overhanging VMS's future range d in the road:

$$\frac{V_1^2}{25} + \frac{V_1^2 - 0.25 V_1^2}{254 \times 0.645} + \frac{V_1 \times 0.7}{3.6} - \frac{1.94 + 4.3}{\tan 7^o} \le d \le \frac{0.5 V_1 \times 120}{3.6} - \frac{1.94 + 4.3}{\tan 7^o}$$

That is： $0.045 V_1^2 + 0.194 V_1 - 50.82 \le d \le 16.67 V_1 - 50.82$

From this calculation, we may conclude some variations between the threshold value scope of VMS's future range d and driving speed as follows:

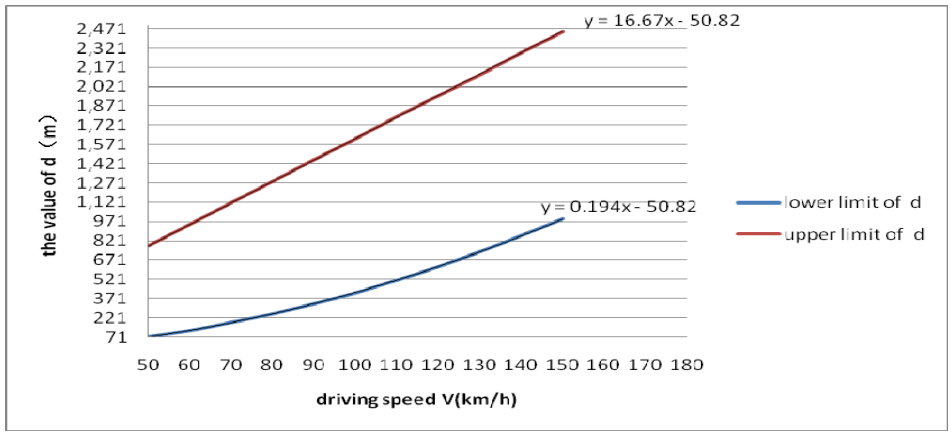

Figure 4. The variation between the threshold scope of d and driving speed.

From Figure 4, we can see that the variation characteristics of the driving speed are important aspects reflecting the traffic flows' characteristics. From these, we may reach the following conclusions:

The upper limit value tendency of VMS's future range d increases quickly, and the lower limit value tendency increases a little slower. When the driving speed is approximately 183 km/h, the upper and lower limit value tendencies increase equally. Along with the speed increasing, the increasing tendency of the lower limit value will surpass the increasing tendency of the lower limit value.

On the different kinds of roads (expressway, first class highway, the second class highway, the third class highway etc.) speed decreases gradually. Therefore, the threshold value choice scope of d also gets smaller and smaller, and the value of d is correspondingly shrinks.

CONCLUSIONS

From the above study, we can draw some useful conclusions:

When the other conditions are the same and the traffic flow density doesn't surpass the critical density, the average driving speed reduces along with the traffic flow density increase (He, H., Guan, W. 2006). For a much bigger traffic flow density, VMS's future range d is slightly smaller.

When there are many kinds of vehicles mixed (e.g. automobiles, buses and trucks mixed), the mutual interference leads the average driving speed to decrease, so VMS's future range d should select the smaller option.

On some roads that have good conditions, the average driving speed is much higher, the threshold value choice scope of VMS's future range d is a little bigger and the value of d is correspondingly a little bigger.

In summary, the setting of VMS's future range, whether it is reasonable or not, will affect the efficacy of the VMS. This article has conducted research into the threshold value scope of VMS's future range on the road, and elaborated some inherent relationships between VMS's future range and the driving speed, so this research has certain reference values.

ABSTRACT

Using traffic data collected by floating car is a feasible way to determine road network traffic conditions. But conventional travel speed estimation from high sampling floating car data (FCD) is not applicable in practice. In this paper we propose a method for estimating road travel speed from low sampling FCD based on a trajectory-based approach, which also takes intersections into consideration. The experiment demonstrates that this approach can achieve a trade-off between low sampling FCD and higher estimation accuracy, and can be further used for traffic state analysis and short-term prediction.

INTRODUCTION

Traffic parameter estimation is important for real-time traffic management, short-term prediction and long-term transport planning. Using floating cars (taxis or buses), equipped with GPS to collect traffic data and extract traffic information is a feasible way to reflect traffic conditions of the whole road network, a system that has been widely used in recent years (Kerner et al., 2005; Chen et al., 2007; Weng et al.,2007). Conventional travel speed estimation methods based on high sampling floating car data (FCD) are not applicable in practice, however. The aim of our study is to propose a trajectory-based road travel speed estimation method using low sampling FCD.

In this paper, we chose an urban road as our study area. The rest of this paper is organized as follows: Section 2 reviews some related work. Section 3 describes our proposed road travel speed estimation method. Section 4 illustrates a case study and experimental result. The final section concludes with discussions on future directions.

RELATED WORK

Ideally, if there are enough floating cars running in the road network and data are transmitted under high frequency (sample interval <10s), the average of their instantaneous velocities can be used to represent the approximate road travel speed (Weng et al., 2007). However, more advanced methods have been used to get higher accuracy, such as statistic theory, which can describe the relationship among road travel speed, time period and other related factors (such as lanes and road class) by analyzing GPS instantaneous velocity over a certain time period (Rohini, 2002; Quiroga and Bullock, 1998; Zhang, H.S. et al., 2007). Another solution is to calculate average speed of two consecutive GPS signals and use the average speed as road travel speed (Kerner et al., 2005; Chen et al., 2007).

By far, most studies are based on high sampling FCD. But in practice, many FCD collection systems use low frequency sample technology (interval >30s). Chen et al. (2007) attempted to estimate traffic states using fewer GPS signals; however, other vehicle trajectory information is used in their study. Moreover, these works are essentially constrained to freeways, and do not consider the effect of intersections.

ROAD TRAVEL SPEED ESTIMATION METHOD FROM LOW SAMPLING FCD

This section describes precise map-matching and extraction of vehicle trajectory. The detailed method can refer to Brakatsoulas et al. (2005) and Zhang et al. (2007). In this section, we describe the proposed road travel speed estimation method based on the identified trajectory.

Related definition. The Digital Road Map (DRM) has many short links that do not cross any intersection, and their travel speeds are smoother than those of long links with intersections. Previous studies (Lao et al., 2007) have found that intersections could affect road travel speed. Therefore, in this study we artificially divide a road link into two parts: Smooth Part (SP) and Intersection Part (IP) (see Figure 1).

Here, DRM links between signalized intersections or primary zebra crossing are treated as SP. The length of IP is determined by a threshold, which is determined by road class and historical queue length. We also define two adjacent road links as Road A and Road B, represented as R_A and R_B. Meanwhile, two consecutive GPS signals are defined as G_j (x_j, y_j, T_j) and G_{j+1} (x_{j+1}, y_{j+1}, T_{j+1}), respectively, where (x, y) is the matched GPS coordinate and T is the corresponding time stamp.

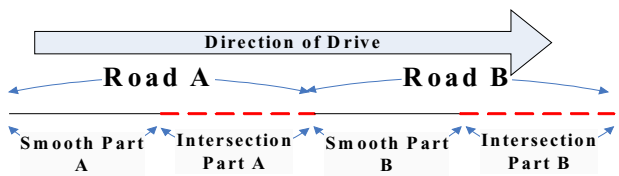

Figure 1. Road model.

The situation of low sampling FCD may cause two consecutive GPS signals that are not located in the same part of road, so we identify the distribution of two consecutive GPS signals as six types, based on their relation with R_A, R_B , SP and IP (see Figure 2).

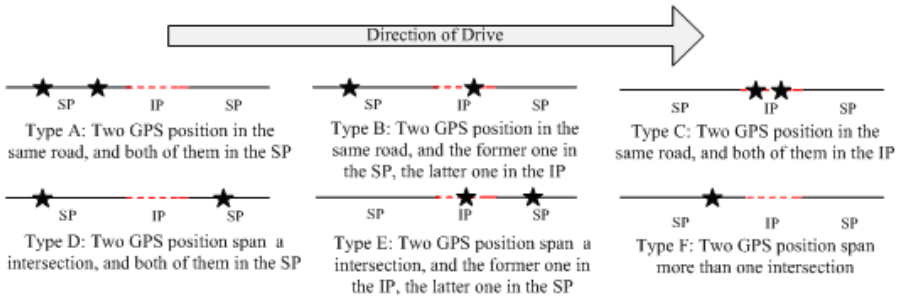

Figure 2. Distribution of Two Consecutive GPS Signals.

Proposed road travel speed estimation method from low sampling FCD. Since types B, C and F are less meaningful in terms of intersection travel speed estimation, only type A, D and E are discussed in this study. The proposed method is described as follows:

Step 1: Extract all trajectories passing through R_A or R_B, and identify useful GPS signal pairs according to Figure 2.

Step 2: Calculate SP's travel speed of R_A and R_B. First, GPS signal pairs belonging to type A are selected, and their average speed can be used as road travel speed:

$$V_{ave}^{A} = \frac{\Delta d}{\Delta T} = \frac{d_{j+1} - d_j}{T_{j+1} - T_j}$$

Where V_{ave}^{A} is the average speed from G_j to G_{j+1}, d_j and d_{j+1} are distance from the start point of R_A to G_j and G_{j+1}, separately, Δd is the distance from G_j to G_{j+1} and ΔT is the time interval from G_j to G_{j+1}.

SP's travel speed can then be calculated as a proportion of the distance from G_j to G_{j+1} and road length, which is described as:

$$TS_{SP}^{A} = (\sum_{i=1}^{n} V_A^i \times \alpha_A^i) / \sum_{i=1}^{n} \alpha_A^i$$

Where TS_{SP}^{A} is travel speed of R_A's SP, V_A^i is the distributed velocity contribution of R_A given by GPS signal pair i and α_A^i is the proportion of distance from G_j to G_{j+1} and road length.

Travel speed of R_B's SP can also be calculated as above, set as TS_{SP}^{B}. If there is no type A in some period, then use the average of instantaneous velocities in the SP as the approximate travel speed of SP.

Step 3: Calculate travel speed of R_A's IP, which will use TS_{SP}^{A} and TS_{SP}^{B}. First, GPS signal pairs belonging to Type D or Type E are selected. A GPS signal pair belonging to Type D can be used to calculate travel speed as:

$$\frac{L_A}{V_{\text{intersection}}} + \frac{L_B}{TS_B} = T_{j+1} - T_j$$

Where $V_{\text{intersection}}$ is the travel speed of R_A's IP from a GPS signal pair, L_A is the distance from G_j to the end point of R_A, and L_B is the distance from the start point of R_B to G_{j+1}.

A GPS signal pair belonging to type E can be used to calculate travel speed as:

$$\frac{L_A}{TS_A} + \frac{L_{\text{intersection}}}{V_{\text{intersection}}} + \frac{L_B}{TS_B} = T_{j+1} - T_j$$

Travel speed of R_A's IP can be calculated by the average of $V_{\text{intersection}}$, set as $TS_{\text{intersection}}^{A}$.

After the above three steps, travel speed of R_A can be calculated as:

$$TS_A = \frac{L_{TotalA}}{\frac{L_{\text{intersection}}}{TS_{\text{intersection}}^{A}} + \frac{L_{TotalA} - L_{\text{intersection}}}{TS_{SP}^{A}}}$$

Where L_{TotalA} is the length of R_A.

CASE STUDY

In this study, an arterial road between Square intersection and DingGong intersection in downtown area of Nanchang, a medium-sized Chinese city, was selected as our study road (Figure3.) The study road consists of 4 DRM links, and the length is about 867.4m.

Experiment data was obtained from a calling-taxi service system from 14th June, 2008 to 20th, June, 2008. On-board GPS are equipped on 1,245 taxis, which cover about 90% roads of this city. Each GPS signal includes vehicle information about unique ID, position, time stamp, heading direction and instantaneous velocity.

According to our statistics, a taxi returns 1200 to 2400 GPS signals every day (about a return of GPS signal during 50s). Figure 4 shows a vehicle's trajectory during 24 hours after map-matching and trajectory identification.

Three periods (6:00-7:00 (non-peak), 8:00-9:00 (morning peak), and 18:00-19:00 (evening peak)) were selected as our experiment periods, and the time interval was set at five minutes. In order to evaluate our proposed method, two other methods were selected for comparison purpose: (1) use the average of GPS instantaneous velocity as road travel speed; (2) calculate road travel speed based on trajectory, but do not consider the impact of intersections.

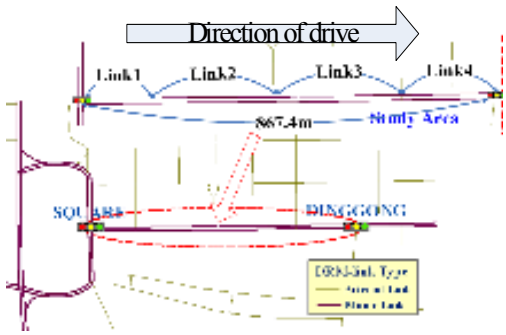

Figure 3. Study Area.

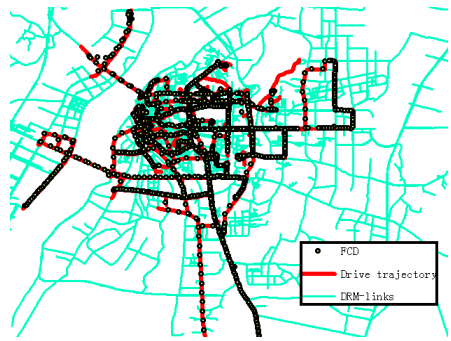

Figure 4. A Vehicle's trajectory during 24 hours.

Experiment results show that Method (1) depends on sample size, and that the accuracy of estimation cannot be reliable when sample size is low. Comparing this with Method (2), our method has no obvious superiority in smooth periods: both of them have a similar and better accuracy. But in congested periods, our method (Method (3)) decreases the impact of intersections and can achieve a better accuracy all the same, as illustrated in Figure 5. Table 1 shows the estimation accuracy in detail.

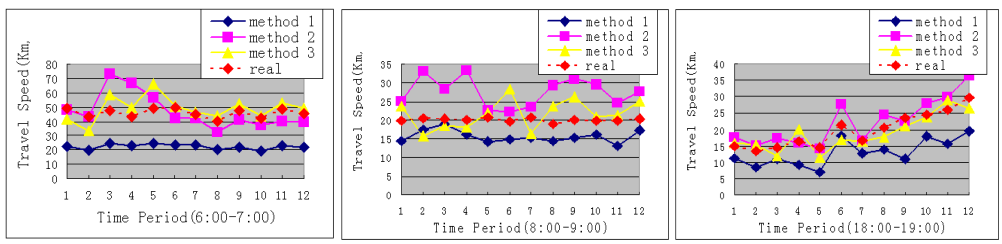

Figure 5. Experiment results.

Table1. Accuracy comparison (ARE=Average Relative Error (%); MRE= Maximum Relative Error (%); SE=Standard Error (km/h)).

	Time period								
	6:00-7:00			8:00-9:00			18:00-19:00		
Method	ARE	MRE	SE	ARE	MRE	SE	ARE	MRE	SE
(1)	23.9	27.0	25.1	4.4	6.6	4.9	6.7	12.6	7.6
(2)	8.5	25.5	11.9	7.4	13.3	8.7	2.8	6.8	3.6
(3)	6.1	16.9	7.9	3.8	8.7	4.6	2.4	4.6	2.9

CONCLUSION

This paper proposes a novel method for estimating road travel speed based on low sampling FCD and considering the impact of intersections. The method can serve as the basis for traffic state analysis and short-term traffic prediction. The experiment demonstrates that this approach can provide the basis for traffic state analysis and short-term prediction research.

For further work, we will improve the speed of map-matching and trajectory identification methods, extend this method to road networks and further develop the method to satisfy real-time requirements.

ABSTRACT

Driver fatigue is one of the main causes of fatal accidents. The development of countermeasures against driver fatigue has been an urgent issue. This paper focuses on in experiments that, in the virtual driving environment, based on the formation mechanism of driver fatigue, caught the driver fatigue state of subjects, used sound as an environmental stimulus to intervene, and applied experimental data to analyze effects of different types of sound stimuli on driver fatigue. Four factors and three levels of orthogonal design were carried out in the experiment, according to eye movement and physiological indicators before and after different types of sound stimuli to identify the extent of driver fatigue. We then selected the most effective sound combination to combat fatigue. The result showed that sonic intensity and stimulation time were the most significant factors to fighting driver fatigue, and frequency and stimulating interval were weak factors.

INTRODUCTION

Driver fatigue is a behavior in which psychological and physiological functions decline. Efficiency and performance are impaired by long and monotonous continuous driving. (Lingcong, Z., Zhengguo, W., 2003). According to China's Ministry of Transportation and Communications, road accidents caused by driver fatigue both in absolute numbers and proportion is the highest, and is believed to account for 10–25% of all vehicle accidents. It can be seen that driver fatigue is a significant cause of traffic accidents. In response to this serious problem, it is very necessary to monitor fatigue and take effective countermeasures against driver fatigue to prevent road accidents.

To date, many countries have begun sound ergonomics research, and

have indicted that sound stimulus can reduce fatigue (Landstrom, U., Englund, K., 1999). Yukie Hirata found that when fatigue emerged, drivers stimulated with music could improve alertness, and avoid drowsiness (2001). However, very little evidence exists on how the sound affects driver fatigue. Research has generally suggested the possibility of using sound stimulus as a countermeasure against driver fatigue, but no further study has been done on the effect of the different factors of sound. The research described in this paper used orthogonal experimental methodology, conducted a driving simulation experiment, collected physiological data of drivers to analyze the different types of sound on the effects of reducing diver fatigue, then identified the most effective sound stimulus to use as a countermeasure against driver fatigue. This could play an important role in reducing driver fatigue and improving road safety.

EXPERIMENTAL SYSTEM

The driver physiological information collection experiment was carried out in a car driving simulator. The experiment used a virtual driving scene and real car cockpit, as in Fig. 1. P80 (Dinges and Grace, 1998) was used to monitor the state of fatigue. At the same time, 16 channel electroencephalogram (EEG) data was recorded.

Figure 1. Virtue driving scene.

Environment. In order to reach fatigue state as soon as possible, the road scene is monotonous, straight two-lane two-way road, without any indicatory signs. The driver was asked to drive at the right side of the center line, and followed the front car with stable speed of 50 km/h. The laboratory temperature was 20-23℃ and soft lighting was set at 5 Lux.

Participants: To exclude individual differences, all participants were males, aged around 25 years old, with more than two years' driving experience, good health and normal hearing and without any sleep–related disease. Before the experiment, all participants were requested to have adequate rest and do nothing provocative for 72 hours prior to the measurements.

Variables. In the recent years researchers have investigated different types of fatigue monitor indicators. However, PERCLOS (Wierwille, Ellsworth, Wreggit, Fairbanks, and Kim, 1994) and EEG (Eoh, Chung, and Kim, 2005; Lal, 2003) were found to be superior compared to other detection techniques and were both promising neurophysiologic indicators of driver fatigue. During this study we could obtain P70 (the proportion of time within one-minute blocks that the

eyelid covers 70% of the pupil) and P80 from the eye tracker. Four frequency components could be obtained from EEG recordings: delta (δ) (±0 to 4 Hz), theta (θ) (4–8 Hz), alpha (α) (8–13 Hz) and beta (β) (13–20 Hz).

METHOD

Orthogonal experimental design is an experimental design method used to examine many levels of many factors; this method is an efficient, rapid and economic method of experimental design (Xue, L., 2005). The main purpose was to balance the different types of sound stimuli, collect various physiological indicators and analyze effects of each factor on reducing driver fatigue.

Validation of factors and levels. By actual measurement, the noise of vehicle simulator was at 60 dB or so. This experiment simulated the actual driving state, and given that the long period of time driving above 85 dB in the noise environment would lead to hearing impairment, 60 dB, 70 dB, 80 dB were selected as the levels of sonic intensity; Research has shown that alert sounds should meet the requirement of high-frequency, so 1050 Hz，5800 Hz, 10750 Hz were selected as levels of sonic frequency. Three different stimulating times weretested in this study, and were between 3-7s; stimulating intervals varied between 10-60s. Table 1 shows the different factors and levels of sound.

Table 1. factor-level table.

	factors			
levels	A（dB）	B（Hz）	C（s）	D（s）
1	60	1050	3	10
2	70	5800	5	30
3	80	10750	7	60

A= sonic intensity; B= sonic frequency; C= Stimulating time; D=Stimulating interval

Design of test scheme. From the analysis above we can conclude that this was a four-factor and three-level experiment, so the orthogonal table $L_9（3^4）$ was the most appropriate.

Procedure.

Step 1: Before the experiment, subjects were ensured to be in full understanding of the experimental process, and randomly sampled the sequence of sound stimuli.

Step 2: The subject entered the laboratory, and experimental personnel placed EEG electrodes and adjusted eye-movement equipment, which required around 30 minutes per subject.

Step 3: The subject entered the driving simulator, and experimental personnel adjusted the relative position of each section of the virtual instrument and connected the feedback machine to the subject.

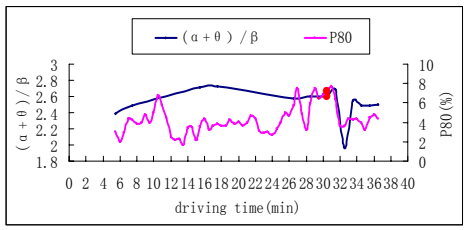
Step 4: We recorded physiological signals of subject in the natural, quiet state for five minutes.

Step 5: Testing began. Experimental personnel operated the data acquisition software, stimulated the subject with relevant types of sound when

the driving time was up to 30 minutes, then finished experiment after 10 minutes of sound stimulus.

Validation of fatigue indicators. Current studies both at home and abroad found that P80 provided a good indication of fatigue, which could truly represent fatigue and be the best way to evaluate fatigue (Kang Huawu, 2008). By combing the method of subjective evaluation and external evaluation during the driving, we found that P80 showed an increasing slope as the driver became fatigued. Hence, the paper took P80 as one of the fatigue indicators.

EEG is the golden standard for driving fatigue. The current study investigated EEG activity in separate frequency bands: delta, theta, alpha and beta, and four different algorithms: (i) (θ + α)/β, algorithm, (ii) α/β, algorithm, (iii) (θ+ α)/ (α + β), and algorithm (iv) θ/β. A greater increase of ratios was found for algorithm (i) (θ+ α)/ β at the end of the monotonous driving session, compared to the separate frequency bands and other three algorithms (Budi, Thomas, Jap, and Sara, 2007; Lal, 2007). By fitting the curve of P80 and the curve of absolute and relative EEG indicators, this paper obtained the same conclusion with the aforementioned research that algorithm (θ+ α)/ β showed regular change and had the same trend with P80.



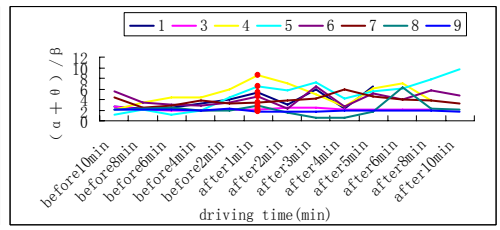


Figure 2. Trend graph of indicators. **Figure 3. changing law of（α+θ）/β.**

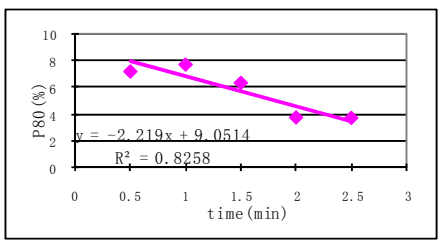
Figure. 2 and 3 showed that P80 and（α+θ）/β increased with the driving time. After the sound stimulus decreased with different degrees, this demonstrated that sound stimulus can reduce driver fatigue, but after a period of driving this downward trend was not obvious.

RESULT ANALYSIS

Identification of orthogonal experiment indicators. The EEG data of each sample after stimuli of nine types of sound were divided into one section every other minute. Eye movement signals were divided into one section every 30 seconds, then the average calculated regressing P80 and (α+θ)/β from the first point to the first minimum point after stimulus with the least square method.



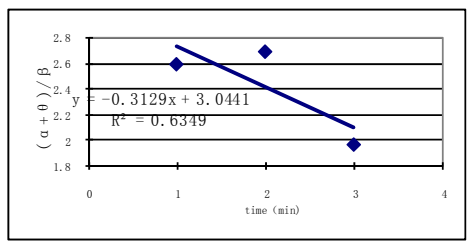


Figure 4. linear regression.

Figure 4 shows the example of regression processing of one type of sound stimulus; others were the same. The slope of regression equation demonstrated the recovery extent of driver fatigue. The slope of the regression equation was chosen as an indicator of the orthogonal experiment, and it was a "larger the better" experiment: the greater the slope was, the lower driving fatigue would be.

Variance analysis. SPSS generated $L_9(3^4)$orthogonal table by parameter settings. The slope of the linear regression equation was added to the table to set up data sets. The results of variance analysis are shown in Tables 2-5.

Table 2 shows that factors A ($p<0.05$), C ($p<0.05$) and D ($p<0.05$) had significant influence on experimental results, while factor B ($p>0.05$) had no significant influence. The important order of the factors that affected the P80 was A, C, D and B in turn.

	2	-.21	.362	-1.028	.609
	3	-.32	.362	-1.141	.495

Variance Analysis concluded the important order of factors of sound stimulus on driver fatigue indicators:

P80: A>C>D>B

(α＋θ)/β: C>A>B>D

Combined with p value size of variance analysis, we comprehensively considered P80 as a primary indicator that should gave first priority. We finally ascertained the important order of four factors: A>C>B>D. By comprehensive balance analyzing，the optimum sound stimulus conditions are: $A_2 B_1 C_1 D_1$, that is, sonic intensity was 70 dB, sonic frequency was 1050 Hz, stimulating time was 3s, and stimulating interval was 10s.

CONCLUSIONS

The paper is based on variations of P80 and (α +θ)/β. By orthogonal experimental design, statistically analyzed experiment data, we concluded the best combination of sound stimulus to ease fatigue. This will provide new thoughts on reducing driver fatigue and lay a foundation for driver fatigue countermeasures based on audio, optical and vibration signals. However, because of limitations of time and experimental equipment, the paper only made a preliminary investigation into sound countermeasures, so a set of systematic theoretical systems has not formatted.

Future studies will focus on recordings from distinct groups of drivers rather than individuals, simultaneously integrate psychology, physiology, behavioral science and other disciplines to optimize the experiment program, and develop a comprehensive set of sound countermeasure systems.

ACKNOWLEDGEMENTS

The research was supported by the 2008 Scientific and Technological Innovation Platform-Study on Driving Error Mechanism and Countermeasures (JJ 004011200803). We would like to thank the drivers and laboratory technician for their participation.

The Evaluation of Level of Service for Expressway in Operating Stage

Li Hong-ping[1] and Pei Yu-long[1]

[1] School of Transportation Science and Engineering, Harbin Institute of Technology, P.O. Box 2525, 202 Haihe Road, Nangang District, Harbin, 150090, China; PH (86) 451- 86282117; FAX (86) 451-86282832; email: lihongping1995@gmail.com

ABSTRACT

Because expressway construction has recently progressed rapidly in China, traffic management needs more efficiency. So we urgently need to study the expressway system's level of service (LOS) evaluation methods. In the planning, design, and operating stages, our aims in evaluating LOS and the data to be used were different, and we have accordingly adopted different evaluation methods for each stage. This paper investigates the LOS evaluation method in the operating stage, evolving a model to estimate travel speed based on the dual loop detectors that were developed, to verify the precision of the model. We have proved that it is feasible to replace the data of the section with that of lane 2 for analysis. Taking the travel speed index as a service measure, we developed a quantitative method for evaluating expressway LOS, and we developed procedures for operating quality analysis. We also successfully applied this method to an example.

INTRODUCTION

Constructing an expressway system is one of the most effective methods for optimizing a road network to alleviate traffic congestion in big cities. And expressway systems are playing a very important role in metropolitan transportation. The expressway system in Peking, for example, includes 4 ring roads and 15 radial roads. Its total length is about 380 kilometers, which is about 8% of the total length of the road network, but it will be taking on 50% of the vehicle traffic volume in the future. When more and more expressway systems are completed and put into use, the traffic management on expressways will have to become more efficient. The level of service is an important index to measure the operating quality of the road transportation system. Presently, the same method is applied to evaluate the level of service (LOS) of each kind of facility in the planning, design and operating stages in the widely used Highway Capacity Manual (HCM) (TRB,2000). LOS procedures in HCM vary little with the data in different stages. For an expressway, the goal and the data for an LOS evaluation in the operating stage are quite different from that of the planning and design stages, and different evaluation methods shall be developed for each respective stage in the process.

MODEL OF ESTIMATING TRAVEL SPEED BASED ON DUAL LOOP DETECTORS

Travel speed (TS) numerically equals to the ratio of mileage to travel time (TT). So travel speed forecasting and travel time forecasting are the same in essence, and the difference lies in the application. Whereas managers tend to use travel speed, users prefer travel time (Christopher, 2006). Travel speed or travel time forecasting is one of the key problems in ITS researches, and both present difficulties. According to the data used, forecasting methods can be divided into two types: those based on moving detectors (in-vehicle instruments), and those based on fixed detectors (such as loop detectors). Those methods based on fixed detectors have no recognized solutions (Jiang, 2004).

Spot speed obtained from dual loop detectors on an expressway mainline can be adopted to forecast travel speed. In the model shown on Figure1, l_i is the distance between detector *i* and the upstream detector, between the start detector and the start profile, or between the end detector and the end profile, km; L_i is the length of the forecasting section using the average spot speed obtained from detector *i*, km; L is the length of the whole section, km; $\bar{v}_{ti}$ is the average spot speed at detector *i*, km/h.

Equations (1) to (6) have been developed to estimate travel speed:

$$\bar{v}_{si} = \bar{v}_{ti} - \sigma_{ti}^2 / \bar{v}_{ti} \tag{1}$$

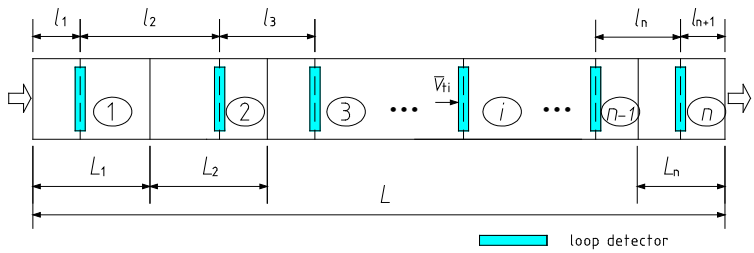

Figure 1. Travel speed forecasting model based on dual loop detectors.

$$L_i = \begin{cases} l_1 + l_2 \ / 2, & i = 1 \\ (l_i + l_{i+1}) / 2, & i = 2,3,\cdots \mathrm{n}-1 \\ l_n / 2 + l_{n+1}, & i = n \end{cases} \tag{2}$$

$$L = \sum_{i=1}^{n} L_i \tag{3}$$

$$TT = \sum_{i=1}^{n} t_i \tag{4}$$

$$t_i = L_i / \bar{v}_{si} \tag{5}$$

$$TS = L / TT \tag{6}$$

where $\bar{v}_{si}$ is the average space speed in section *i*, km/h; σ_{ti}^2 is variance of

average spot speed; *TT* is travel time, h; *TS* is travel speed, km/h.

LOS EVALUATION METHOD BASED ON TRAVEL SPEED INDEX

Expressway LOS Criteria Based on Travel Speed Index

Free flow travel speed (FFTS) is the travel speed of vehicles passing through a section in a free flow state. It is defined as the weighted mean value of the theoretical free flow speed of the components of the section, which includes a basic segment of the expressway, a diverging area, a merging area and a weaving area. The weight is the ratio of the length of each component to that of the section.

The expressway is divided into three components: the expressway's basic segment; its diverge and merge areas; and its weaving area (TRB, 2000).

(1) The diverge area is the distance extending from the physical diverge point to 450 m upstream, and merge area is the distance extending from the physical merge point to 450 m downstream.

(2) The weaving area is from a point at the merge gore where the right edge of the freeway shoulder lane and the left edge of the merging lane(s) are 0.6 m apart to a point at the diverge gore where the two edges are 3.7 m apart.

(3) The basic segment is outside the influence area of diverging, merging and weaving movements.

The theoretical free flow speed can be drawn from a fitted Greenshield model because of the direct correlation between the theoretical and measured free flow speeds (Sasaki, 1994; Li, 2007). The travel speed index (TSI) is defined as the ratio of actual travel speed to free flow travel speed. As a service measure, TSI indicates the extent the expected speed (FFTS) achieved. The expressway LOS criteria has been developed according to widely adopted 5-level categories (Su, 2000). They are: excellent, good, medium, bad, and worst . (Table 1). The traffic state in the 5 levels can be described respectively as free, smooth, steady, crowded and congested.

Table 1. Expressway LOS Criteria.

LOS	Ⅰ	Ⅱ	Ⅲ	Ⅳ	Ⅴ
TSI	≥0.90	[0.8,0.9)	[0.7,0.8)	[0.5,0.7)	＜0.5
Traffic state	free	smooth	steady	crowded	congested

Expressway LOS Procedures for Operating Analysis

Supposing the analysis period is divided into *i* intervals (usually 5 minutes), and the expressway LOS procedure is as follows:

(1) Calculating FFTS;

(2) Calculating TS in each interval, and labeled as TS_1、$TS_2 \cdots TS_i$;

(3) Calculating TSI in each interval and determining LOS, which is labeled as $SLOS_1$、$SLOS_2 \cdots SLOS_i$;

(4) Processing the evaluating result according to the users to facilitate understanding and communication.

MODEL VERIFICATION AND CASE STUDIES

Data Sets and Outcomes

The data includes two parts. The traffic flow data for developing the model is obtained from dual loop detectors on a section of the Yanan elevated expressway in Shanghai (Figure 2). And the measured travel speed for verifying the model is investigated by a car-following method (see Table 2). The travel time during a peak hour and a nonpeak hour is 530s and 372s respectively and the corresponding travel speed is 47.7km/h and 67.9km/h (the analysis process is omitted).

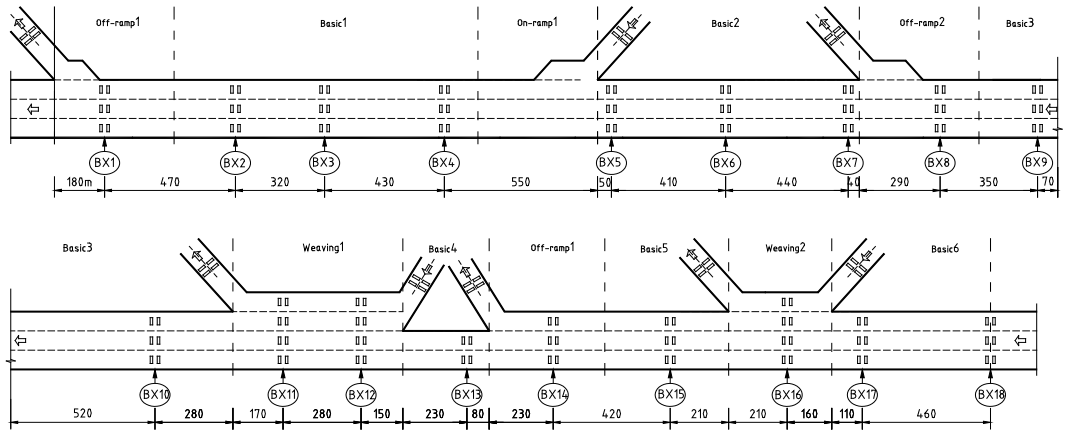

Figure 2. Road conditions and sites of loop detectors for travel speed analysis.

Table 2. Investigated Data of Travel Speed.

Period of Time	Time to Enter	Time to Leave	*TT*/s	*TS*/ (km·h^{-1})
Peak hour	8:03:28	8:11:43	495	51.1
Nonpeak hour	22:04:06	22:10:36	390	64.8

Note: L=7.02km.

Error of Travel Speed Forecasting.

The forecasted value of travel speed during a peak hour is less than that in a nonpeak hour (see Table 3), which mainly results from the instability of the traffic flow, and this instability cannot be reflected in the spot speed drawn from the detectors. The relative error in a peak hour forecast is -6.7%, greater than that in that of a nonpeak hour, but it meets our need for an operating analysis.

Table 3. Error Analysis for Travel Speed Forecasting.

Data	Profile Average		Lane 2	
Time Period	Peak Hour	Nonpeak Hour	Peak Hour	Nonpeak Hour
Measured TS / ($km \cdot h^{-1}$)	51.1	64.8	51.1	64.8
Forecasted TS /	47.7	67.9	45.5	68.2
Absolute Error/	-3.4	3.1	-5.6	3.4
Relative Error /%	-6.7	4.8	-11.0	5.2

Feasibility of Replacing Data of the Whole Profile by That of Lane 2.

In equation (5), the average spot speed can be the average of all lanes or one lane. Generally speaking, the margin of error would be lessened if the average of all lanes is included, but doing so also greatly increases the amount of data processing necessary, especially for real time analysis and information release. Therefore, we have used the average spot speed of one lane to estimate space mean speed. The lane is the one in which traffic flow characteristics are closest to that of the whole profile, and for a 3-lane profile, this turns out to be lane 2, the middle lane. (Li, 2007).

Space mean speed is estimated based on the average spot speed of the profile and lane 2 respectively (see Table 4). Relative errors are less than 10% except for 4 values in which they can be as much as 24.8%. As a whole, the relative errors in a peak hour are greater than those in a nonpeak hour.

Table 4. Space Mean Speed of the Profile Compared with That of the Lane2.

Detector No.	Section Type	Peak Hour				Nonpeak Hour			
		Profile $\bar{v}_{si}$ / ($km \cdot h^{-1}$)	Lane 2 $\bar{v}_{si}$ / ($km \cdot h^{-1}$)	Absolute Error/ ($km \cdot h^{-1}$)	Relative Error/%	Profile $\bar{v}_{si}$ / ($km \cdot h^{-1}$)	Lane 2 $\bar{v}_{si}$ / ($km \cdot h^{-1}$)	Absolute Error/ ($km \cdot h^{-1}$)	Relative Error/%

Note: Conversion equations in the table: ③=①-②; ④=｜③｜/①; ⑦=⑤-⑥; ⑧=｜⑦｜/⑤.

The travel speed estimate is based on the data of the profile as a whole and lane 2 respectively (see Table 3). The errors using the data from lane 2 are greater but not as much as those using the data of the whole profile. It is feasible to replace the data of the whole profile by that of lane 2 for LOS analysis, for which the data processing work can be greatly cut down in the Advanced Traveler Information System (ATIS) application.

LOS Analysis.

The level of services on the expressway from the respective time periods of 8:00 to 9:00 and 22:00 to 23:00 have been analyzed. The Greenshield model of each profile has been developed to calculate theoretical free flow speed, on which free flow travel speed is rendered as 82.5km/h (with the calculating process omitted). The values of service measure in each interval and the results of our LOS evaluation are listed in Table 5.

Table 5. Example of System LOS Analysis at Operating Stage.

	Peak Hour					Nonpeak Hour			
End Time	*TT*/h	*TS*/ (km·h^{-1})	*TSI*	*SLOS*	End Time	*TT*/h	*TS*/ (km·h^{-1})	*TSI*	*SLOS*
8:05	0.151	46.4	0.562	IV	22:05	0.102	69.0	0.836	II
8:10	0.148	47.6	0.577	IV	22:10	0.102	68.7	0.833	II

	SLOS= IV*n*V(10-*n*)= IV6V4*						*SLOS*=II		

Note: The number of the intervals (*i*) is converted into 10 here, that is n and (10-n) are the proportions of the intervals with LOS IV and LOSV to the total intervals.

CONCLUSIONS

A real-time analysis and release of LOS is becoming indispensable in

expressway system management as managers cry for more effective evaluation methods. The expressway LOS procedures developed in this paper are based both on the user's perception of LOS levels and on the current situation of traffic management facilities which can directly bring it into effect. It should be pointed out that for a 2-lane or 4-lane expressway, this information must be analyzed using the method proposed in the paper to determine which lane's data can most closely represent that of the overall profile.

ABSTRACT

This paper proposes a novel method for the detection and segmentation of vehicles from video traffic surveillance. A Bayesian decision rule is derived for background and foreground classification based on the statistics of a principle feature. The kernel density function is used to represent feature statistics. Considering that background pixel variation has strong spatial and temporal correlations, the pixels of the video's background have been divided into two types of static or dynamic pixels which are described by different principal features. Foreground objects are extracted by fusing the detection results from both stationary and motional points. Gradual and sudden background changes, are addressed with different learning strategies proposed in this paper. Our experiments on traffic surveillance have shown promising results in extracting vehicles from their complex backgrounds.
